The diagnosis of cervical carcinoma is made by pathologic examination of a tissue specimen. A biopsy sample taken from the periphery of a tumor is more likely to contain morphologically intact neoplastic cells that are best able to represent the tumor pathologically. A biopsy specimen taken from the center of a tumor mass may include necrotic tumor debris; the result of hypoxia induced by the tumor's outgrowing its blood supply. Therefore, to rely on these dead and distorted cells is to compromise the accuracy of the histologic interpretation.

The endocervix should be curetted if no lesion is visible or if the cervix is enlarged, nodular, or hard. Older patients with adenocarcinoma require an endometrial biopsy. It may be difficult to distinguish an endocervical primary tumor from an endometrial primary tumor involving the lower uterine segment.

Patients with an abnormal Pap smear and no visible lesion require colposcopy and biopsy. The tissue specimen may be a simple colposcopy-directed biopsy specimen, an endocervical specimen obtained with a curette, or a conization specimen.

It is the current recommendation of FIGO to classify as stage IA any invasive cancer that can be identified only with a microscope. All gross lesions, even with superficial invasion, are at least stage IB cancers. Vascular space involvement, either venous or lymphatic, should not alter staging. Many clinicians prefer to use the term microinvasion and use criteria recommended by the Society of Gynecologic Oncologists instead of using the FIGO staging system. Microinvasion is invasion limited to 3 mm in depth, is measured from the base of the squamous or glandular epithelium of origin, and does not encompass lymphatic or vascular space involvement. A simple punch biopsy is inadequate for making the diagnosis

of microinvasion: a conization specimen, containing the entire neoplastic process, is necessary. Additional tissue is required from patients with positive cone margins because an occult, frankly invasive carcinoma may lie adjacent to a positive margin.

Evaluation and staging

Successful therapy planning requires detailed evaluation of the patient's general medical condition and the size and extent of the carcinoma. Medical illness must be stabilized and anemia must be corrected before treatment commences. Patients with anemia, which has been extensively studied, have a higher local relapse rate than patients with a normal hemoglobin (Table 2).^{96, 97} The patient's surgical history is important, and operative notes may describe the status of the abdominal organs as well as report abdominal and pelvic operations. Diagnoses of importance to therapy planning include ulcerative bowel disease, diverticulitis, and pelvic inflammatory disease. Such inflammatory conditions induce adhesions and fix loops of the intestines to each other, the adjacent organs, and the peritoneal surfaces.

Table 2 Relapse rates for patients with stage IIB or III cervical cancer

Hemoglobin (gm/dL) Patients (number)		Relapse rate (%)		
		Local	Distant	Total
<10	29	46	18	49
10–11.9	319	29	24	47
12–13.9	578	20	16	33
≥14	129	20	18	33

Relapse rates for patients with stage IIB or III cancer of the cervix according to average hemoglobin level during radiation therapy. *p* Values: *p* = 0.002 (local), *p* = 0.1 (distant), *p* = 0.0007 (total).

Patients with small stage I carcinomas should undergo chest radiography, a complete blood count, urinalysis, and blood chemistry analysis before treatment. Patients with advanced carcinomas require cystoscopy and proctoscopy. It is important to apply the FIGO rules for clinical staging (Table 3).⁹⁸ It is clearly stated in the FIGO guidelines that for staging purposes, the following examinations are permitted: cystoscopy, inspection, colposcopy, ECC, hysteroscopy, proctoscopy, intravenous pyelography, chest radiography, and skeletal radiography.⁹⁹ Findings from examinations such as lymphangiography, laparotomy, laparoscopy, computed tomography (CT), magnetic resonance imaging (MRI), and other examinations unnamed by FIGO should not be the basis for changing the clinical stage, despite the fact that such examinations or procedures can provide valuable information for planning therapy. The tumor-nodes-metastasis (TNM) staging categories have also been accepted by FIGO.¹⁰⁰ Lymph node status is not addressed in the FIGO staging system for carcinoma of the cervix, but three radiologic imaging techniques are available to evaluate lymph node status: CT, MRI, and fluorodeoxyglucose-positron emission tomography (FDG-PET) detect abnormal lymph nodes more lymphangiography.

Table 3 Modified FIGO staging

Stage	Description
I	The carcinoma is strictly confined to the cervix (extension to the corpus should be disregarded)
IA	Invasive cancer identified only microscopically. All gross lesions, even with superficial invasion, are stage IB cancers. Invasion is limited to measured stromal invasion with a maximum depth of 5 mm and a width no >7 mm
IA1	Measured invasion of stroma ≤3 mm in depth and ≤7 mm in width
IA2	Measured invasion of stroma >3 and ≤5 mm in depth and ≤7 mm in width
IB	Clinical lesions confined to the cervix or preclinical lesions larger than stage IA
IB1	Clinical lesions ≤4 cm
IB2	Clinical lesions >4 cm
II	The carcinoma extends beyond the uterus but has not extended onto the pelvic wall or to the lower third of vagina
IIA	Involvement of up to the upper 2/3 of the vagina. No obvious parametrial involvement
IIA1	Clinical visible lesion ≤4 cm
IIA2	Clinical visible lesion >4 cm
IIB	Obvious parametrial involvement
III	The carcinoma has extended onto the pelvic wall. On rectal examination, there is no cancer-free space between the tumor and the pelvic wall. The tumor involves the lower third of the vagina. All cases with hydronephrosis or a nonfunctioning kidney should be included unless they are known to result from another cause
IIIA	No extension onto the pelvic wall but involvement of the lower third of the vagina
IIIB	Extension onto the pelvic wall or hydronephrosis or nonfunctioning kidney
IV	The carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum
IVA	Spread to adjacent organs
IVB	Spread to distant organs

The best radiologic imaging technique for detecting lymph node metastases is unclear. CT and MRI are good in identifying enlarged nodes; however, the accuracy of these techniques in the detection of positive nodes is compromised by their failure to detect small metastases, and many enlarged nodes are not due to metastases, but inflammation associated with advanced disease. The accuracy of MRI in the detection of lymph node metastases (72–93%) is similar to that of CT; however, when compared with surgical findings, MRI is superior to CT, clinical examination, and sonography in the evaluation of tumor location, tumor size, depth of stromal invasion, vaginal extension, and parametrial extension of cervical cancer.^{101–104} Furthermore, studies suggest that MRI is a cost-effective method of evaluating cervical cancers.¹⁰⁴

[Figure 13](#) shows an MRI of a patient with a cervical tumor.

Figure 13 Magnetic resonance image of a patient with cervical tumor.

PET or PET/CT is the rapidly expanding modality in oncologic imaging ([Figure 14](#)). In a study of 101 patients with carcinoma of the cervix, Grigsby and colleagues reported that CT demonstrated enlarged pelvic lymph nodes in 20% and enlarged para-aortic lymph nodes in 7%, while PET demonstrated abnormal FDG uptake in pelvic lymph nodes in 67%, abnormal FDG uptake in para-aortic lymph nodes in 21%, and abnormal FDG uptake in supraclavicular lymph nodes in 8%.¹⁰⁵ The 2-year progression-free survival rate (PFS), based solely on para-aortic lymph node status, was 64% in CT-normal and PET-normal patients, 18% in CT-normal and PET-abnormal patients, and 14% in CT-abnormal and PET-abnormal patients. The authors concluded that often CT and that the findings on PET are a better predictor of survival than those on CT in patients with carcinoma of the cervix. Further studies are needed to confirm these results and determine if PET imaging is better than surgical staging particularly for determining if patients have positive para-aortic nodes.

Figure 14 Positron emission tomography scan of a patient with cervical tumor showing positive nodes.

In some patients, surgical examination of the lymph nodes is warranted. The risk of occult para-aortic metastases is highest in patients with grossly involved pelvic nodes, and these patients may be the best candidates for operative exploration. These patients also may benefit from removal of the grossly enlarged nodes, which may be difficult to control with radiation alone.¹⁰⁶ When lymph node metastases are sought surgically, the extraperitoneal approach is currently the preferred technique.¹⁰⁷ It is preferred because high complication rates resulted from using a transperitoneal approach followed by radiation therapy.¹⁰⁸ Lymph node exploration and dissection may also be performed using a laparoscopic approach, which is associated with a shorter postoperative recovery time and probably less late radiation morbidity than open transperitoneal staging.¹⁰⁹

Prognostic factors

FIGO stage correlates with survival and control of pelvic disease in patients with cervical cancer; however, prognosis is also influenced by other factors, including tumor characteristics and patient characteristics that are not included in the FIGO staging system.

Tumor size and local extent

Tumor size is one of the most important predictors of local recurrence and death in patients with cervical cancer treated with surgery or radiation therapy ([Figure 15](#)). The FIGO staging classification for stage I disease was recently modified to include tumor diameter (i.e., ≤4 cm, stage IB1; >4 cm, stage IB2).⁹⁸ For patients with more advanced disease, other estimates of tumor bulk that correlate with prognosis include presence of medial versus lateral parametrial involvement in FIGO stage IIB disease and unilateral versus bilateral pelvic wall involvement in FIGO stage IIIB disease.^{111, 112}

Figure 15 Disease-specific survival (DSS) is indicated for patients grouped according to size of cervix (NL, cervix of normal size; ENL, enlarged cervix, 4–4.9 cm).

Source: Lai et al. 1999.¹¹⁰ Reproduced with permission of Wolters Kluwer Health.

In patients who have had a radical hysterectomy, histologic evidence of extracervical spread (≥ 10 mm) and deep stromal invasion ($>70\%$ invasion) are associated with a poorer prognosis, as is parametrial extension, which is associated with higher rates of lymph node involvement, local recurrence, and death from cancer.^{91, 113, 114, 115} Uterine body involvement is associated with an increased rate of distant metastases in patients treated with radiation or surgery.¹¹⁶

Lymph node involvement

Lymph node metastasis is another important prognostic factor for survival that is not part of the FIGO staging system. In several surgical series, after a radical hysterectomy, patients with positive pelvic lymph nodes had a 35–40% lower 5-year survival rate than patients with negative nodes.^{89, 91} However, recent studies suggest that post-operative chemoradiation improves these results.¹¹⁷ Several authors have reported a correlation between size of the largest node involved or higher number of nodes involved and decreased survival rates. Patients with positive para-aortic nodes have a survival rate that is about half that of patients with similar-stage disease and negative para-aortic nodes.^{89, 91, 114, 118, 119} With extended-field radiation therapy, patients with early-stage disease and positive para-aortic nodes have a cure rate of approximately 40–50%.

There is a strong correlation between positive lymph nodes in patients with cervical neoplasms and positive lymph-vascular space invasion (LVSI) in the tumor specimen. However, LVSI may be an independent predictor of prognosis, as a number of large series of patients treated with radical hysterectomy have demonstrated.^{113, 114, 120, 121} Roman and colleagues reported a correlation between the percentage of histopathologic sections containing LVSI and the incidence of lymph node metastasis.¹²² In patients with adenocarcinoma of the cervix, there is a strong correlation between LVSI and outcome.^{123, 124}

Histologic type

There is controversy regarding whether adenocarcinomas of the cervix are associated with outcome similar to that seen with squamous carcinomas of the cervix. In several retrospective studies, investigators found that patients with adenocarcinomas of the cervix had outcome similar to that of patients with squamous carcinoma of the cervix treated with radiation therapy.^{125, 126} However, other investigators have come to an opposite conclusion. Among patients treated surgically, they found that patients with adenocarcinoma had unusually high relapse rates compared with the rates in patients with squamous cell carcinoma and among patients treated with surgery or irradiation, they found that patients with adenocarcinoma had poorer survival rates than the rates seen in patients with squamous cell carcinoma.^{110, 127, 128} Eifel et al.,¹²⁷ in an analysis of 1767 patients treated with radiation for FIGO stage IB disease, reported that patients with adenocarcinoma had a significantly higher risk of recurrence and death from disease. This finding was independent of age, tumor size, and tumor morphology. There was no difference in the rate of pelvic recurrence between patients with bulky adenocarcinoma (≥ 4 cm) and patients with squamous cell carcinoma; however, the rate of distant metastasis was almost twice as high in patients with adenocarcinoma as in patients with squamous cell carcinoma. Although the prognostic significance of histologic grade for squamous carcinomas has been disputed, there is a clear correlation between the degree of differentiation and the clinical behavior of adenocarcinomas.^{123, 124, 129}

Other tumor factors

Pretreatment SCCAg levels have been shown to correlate with tumor bulk, stage, histology, grade, type of tumor (i.e., exophytic vs infiltrative), microscopic depth of invasion, and risk of lymph node metastases in

patients with early-stage disease.^{130–132} The most important property of the pretreatment SCCAg level, however, is its ability to predict clinical outcome. Several authors have reported significantly lower survival rates in patients with very elevated values compared with patients with normal baseline levels, independent of stage.^{132–135} Monitoring of tumor response using SCCAg needs further investigation, especially studies designed to determine how often SCCAg measurement should be done, the level of SCCAg that is significant, which patients would benefit from this monitoring and the cost-effectiveness of using SCCAg as a tool for monitoring patients after treatment.¹³⁶

Several authors have reported a correlation between HPV subtype and prognosis.^{137–139} In two studies of patients with histologically negative lymph nodes, investigators reported higher rates of disease recurrence when findings on PCR assay of the lymph nodes were strongly positive for HPV DNA.^{140, 141}

Other molecular markers that have recently been evaluated for predictive power in cervical carcinoma are EGFR and cyclooxygenase-2.¹⁴² Studies have small populations and are presently too difficult to interpret. Other biologic features that have been investigated for their predictive power, with variable results, include inflammatory response in cervical stroma, peritoneal cytology, tumor vascularity, and DNA ploidy or S-phase fraction.^{143, 144}

Patient factors

Several investigators have reported correlations between low hemoglobin level before or during treatment and poor prognosis.^{111, 145} It has been speculated that the poor prognosis of anemic patients is cause in part by hypoxia-induced radiation resistance. Other patient-related factors that have been shown to correlate with prognosis include age, platelet count, socioeconomic status, and smoking.^{93, 146, 147, 148, 149, 150} Kucera et al.¹⁴⁹ reported that smokers with cervical cancer had a poorer 5-year survival rate than nonsmokers, and this relationship was statistically significant in patients with stage III disease (5-year survival rate 20.3% vs 33.9%, $p < 0.01$).

Surgical treatment options

Sentinel lymph nodes

A biopsy of sentinel lymph node was originally a process meant to simplify the surgical procedure and decrease morbidity by removing just one or a few nodes instead of systematic lymphadenectomy. However, the concept may have other advantages including a more reliable detection of key nodes in atypical localizations, detection of small metastasis, and intraoperative triage of patients, thanks to identification of key nodes for pathologic evaluation. The first large, multicenter study on sentinel lymph nodes for cervical cancer was published in 2008 and found a sensitivity of only 77%, which was a major setback for this procedure in cervical cancer.¹⁵¹ However, there were multiple problems with this study including the size of tumors included, lack of surgeon proficiency assessment, and pathologic ultrastaging. Subsequent studies have shown a very high sensitivity in women with small tumors undergoing lymphatic mapping including a recent large French SENTICOL study that has reported a sensitivity of 92% and a negative predictive value of 98%.¹⁵² Presently, sentinel lymph node biopsies is a useful intraoperative triage for patients with small tumors where the false-negative rate is lower.

Cervical conization and LEEP

Cervical conization is a procedure that removes or destroys the transformation zone and can be diagnostic, therapeutic, or both. A conization specimen is conical, as the name implies, and its size varies

according to the area in question. The cone is shallow when an exocervical lesion is removed. The cone is deeper when the endocervix is being investigated. Patients requiring conization usually have one of the following: normal colposcopy findings and an abnormal Pap smear or positive ECC specimens; abnormal colposcopy findings in the form of failure to visualize the entire squamocolumnar junction or failure to define the extent of the lesion; microinvasive carcinoma in a biopsy specimen; adenocarcinoma *in situ* in a biopsy or ECC specimen; or a lack of correlation between cytologic (Pap smear), colposcopic, and histologic interpretations.

Cone biopsy is designed to completely remove the squamocolumnar junction and the lower portion of the endocervical canal in women with very small cervical cancers. The surgical specimen should include the entire lesion, as this permits measurement of both depth of invasion and extent of lateral spread.

Another surgical technique that can be used for conization is LEEP. In LEEP, a thin wire loop electrode is used to excise the lesion in patients with HGSIL. LEEP is an outpatient procedure. Although destructive techniques (such as laser ablation and cryotherapy) can provide effective treatment of suspicious lesions; the preferred technique is one that provides an appropriate histologic specimen, such as cervical cold knife conization (CKC) LEEP, or laser conization. Recently, Linares and colleagues compared CKC, laser conization, and LEEP and found that LEEP was associated with fewer complications and a shorter operating time than the other two procedures.¹⁵³ The only drawback of the LEEP procedure was a slightly shorter cone depth and a slightly higher risk of lesion recurrence.¹⁵³

Patient selection

Conization as sole treatment of early cervical cancers is a relatively recent concept. For women who have very limited risk of lymph node spread and who have a strong desire to maintain fertility, conization may be an option.^{154, 155} MD Anderson Cancer Center recommends that conization be considered only for patients with squamous cell lesions that invade <3 mm, have no LVSI, and have uninvolved resection margins.¹⁵⁶ There is very little information on which to base a recommendation regarding the use of conization as therapy for women with nonsquamous cervical cancer.¹⁵⁷

Complications of CKC include hemorrhage, pelvic cellulitis, cervical stenosis, and incompetent cervix.¹⁵⁸ In addition, because this procedure requires general anesthesia, there is the additional burden of possible complications and cost of anesthesia.

Complications of LEEP are similar to but not the same as those of CKC: Infection, bleeding, burns to the vagina, cervical stenosis, cervical incompetence, and recurrence of dysplasia. With LEEP, however, stenosis is rare (occurring in 1% of patients) and is seen primarily in nulliparous, perimenopausal, or postmenopausal patients. Cervical incompetence is usually only a complication of multiple procedures. The other advantage of LEEP is that it does not require general anesthesia. As mentioned earlier, when three conization techniques (CKC, laser conization, and LEEP) were compared, LEEP was associated with fewer complication as well as decreased operative time.¹⁵³

Radical trachelectomy

Recently, for early stage disease, several groups have tried to preserve the uterus and child-bearing capability by treating patients with a radical vaginal trachelectomy. This technique involves a laparoscopic pelvic lymphadenectomy followed by vaginal resection of the cervix, the upper 1–2 cm of the vaginal cuff, and the medial portions of the cardinal and uterosacral ligaments. The cervix is transected at the lower uterine segment, and a prophylactic cerclage is placed at the time of surgery. Several investigators recommend that this procedure be limited to patients with a tumor not exceeding 2

Extrafascial hysterectomy

The extrafascial technique permits removal of the intact uterine fundus and cervix, leaving the parametrial soft tissues and a portion of the upper vagina. Extrafascial hysterectomy can be accomplished through an abdominal incision, transvaginally, or using a combination of laparoscopic and transvaginal techniques.

Simple extrafascial hysterectomy is the standard definitive treatment option for women with stage IA1 cervical cancers and is sometimes performed following radiation therapy for bulky endocervical carcinomas. For patients with stage IA2 disease, there is some controversy regarding the most appropriate surgical procedure. These patients have 3–5% incidence of lymph node metastases and a higher rate of vaginal recurrence than patients with IA1 disease. So, although some data suggest that these IA2 lesions can be effectively resected with extrafascial hysterectomy, many American gynecologic oncologists limit this operation to women with IA1 tumors.^{161, 162} There is uniform consensus that conization-only therapy should not be offered to women with stage IA2 disease.

Radical hysterectomy

Radical hysterectomy involves the en bloc removal of the uterus, cervix, parametrial tissues, and upper vagina. In the early twentieth century, Wertheim of Vienna described the radical hysterectomy for the treatment of cervical cancer. In the 1940s, Meigs of the United States championed the procedure, to which he added a pelvic lymphadenectomy. Today, radical hysterectomy with pelvic lymphadenectomy is the standard treatment in the management of stage IA2-IIA tumors.

The type II (modified radical) hysterectomy is a less extensive version of the type III (radical) hysterectomy. The primary indication for type II hysterectomy is early invasive carcinoma, tumors <2 cm diameter. The type II operation ensures an adequate paracervical specimen and a vaginal cuff of 2–3 cm. In the type II operation, the medial half of the parametrium and upper one-third of the vagina are included in the surgical specimen. This is accomplished by exposing the ureters and taking the medial half of the cardinal and uterosacral ligaments instead of taking these ligaments where they attach to the pelvic wall and pelvic floor. The posterior approach is the surgeon's choice. The incidence of bladder and ureteral complications is lower with the type II operation than with a type III procedure. The type II hysterectomy can be performed with a modified or complete pelvic lymphadenectomy.

The type III (radical) hysterectomy is the classic Wertheim-Meigs radical hysterectomy. This operation is reserved for patients with stage IB and selected stage IIA carcinomas. The vaginal extension for stage IIA patients should be limited to no more than 1 cm. The parametrium, cardinal, and uterosacral ligaments are severed at the pelvic wall, and half of the vagina is removed. The uterine vessels are taken at their origin from the internal iliac vessels. The ureters are taken out of their tunnel and reflected laterally. This dissection of the distal ureters sacrifices the blood supply from the uterine and superior vesicle arteries. Reflection of the ureters clears the way for applying instruments across the parametrium along the pelvic wall. Complete removal of the cardinal ligaments and the rectal pillars and uterosacral ligaments at their base results in a greater risk of bladder atony, and loss of the distal-ureter blood supply results in a greater risk of fistulae. This operation produces an excellent cure rate in properly selected patients. In young patients, the ovaries are spared.

Intraoperative and immediate postoperative complications of radical hysterectomy include blood loss (average, 0.8 L), ureterovaginal fistula (occurring in 1–2% of patients), vesicovaginal fistula (<1%), pulmonary embolus (1–2%), small bowel obstruction (1–2%), and postoperative fever secondary to deep

vein thrombosis, pulmonary infection, pelvic cellulitis, urinary tract infection, or wound infection (25–50%).¹⁶³ Subacute complications include lymphocyst formation and lower extremity edema, the risk of which is related to the extent of the node dissection. Lymphocysts may obstruct a ureter, but hydronephrosis usually improves with drainage of the lymphocyst.¹⁶⁴ The risk of complications may be increased in patients who undergo preoperative or postoperative irradiation.

Although most patients have transient decreased bladder sensation after radical hysterectomy, with appropriate management severe long-term bladder complications are infrequent. However, chronic bladder hypotonia or atony occurs in approximately 3–5% of patients despite careful postoperative bladder drainage.¹⁶⁵ Bladder atony probably results from damage to the bladder's innervation and may be related to the extent of the parametrial and paravaginal dissection.¹⁶⁶ Radical hysterectomy may be complicated by stress incontinence, but reported incidences vary widely and may be influenced by the addition of postoperative radiation therapy.¹⁶⁷ Patients may also experience constipation and, rarely, chronic obstipation after radical hysterectomy.

Criteria for selecting patients who are appropriate candidates for radical hysterectomy include factors affecting the patient's suitability for major surgery as well as tumor characteristics, including tumor volume and lymphatic involvement. Patient factors play a very important role in the selection of primary radical surgery versus primary radiation therapy in patients with early-stage disease. The ability to preserve ovarian function as well as a more pliable vagina is important to young women facing this decision. Just as important, for women with significant medical problems, including obesity, primary radiation therapy may be the better treatment option.

In patients with early-stage (IA-IB1) disease, tumor characteristics play a very important role in treatment selection. Patients with high-risk factors may benefit from up-front definitive radiation therapy plus possible chemotherapy. Multiple studies have found that morbidity increases in patients who receive both radical surgery and radiation therapy.¹⁶⁸ High-risk tumor characteristics include large tumor size, which is associated with lymph node spread, increased chance of recurrence, and decreased survival rates. Eifel et al.¹⁶⁴ found that DSS decreased significantly in patients with stage IB carcinoma if the tumor diameter was >5 cm (88% vs 69%, $p < 0.0001$). Other high-risk factors include lymph node metastases, parametrial involvement, and positive surgical margins.

Outcomes after surgical treatment

Reported 5-year survival rates for women with stage IB cervical cancer treated with radical hysterectomy and pelvic lymphadenectomy are approximately 80–90% ([Table 4](#)).^{89, 90, 91, 168, 169, 170, 171, 172, 173, 174, 175, 176} Patients with positive surgical margins or positive lymph nodes are at the highest risk of recurrence and poor outcome. Delgado et al.,⁹¹ in a large prospective study, reported 3-year DSS rates of 85.6% in patients with negative nodes and 50–74% in patients with positive nodes. In the group with positive nodes, increasing number of positive nodes and involvement of common iliac nodes correlated with decreased survival. A randomized study showed that postoperative chemoradiation improved survival in patients with positive lymph nodes, positive surgical margins, or tumor present in the parametrium.¹¹⁷

Radiation therapy

The management of invasive carcinoma of the cervix with primary radiation therapy involves a combination of external beam radiation therapy (EBRT) plus either low dose rate (LDR) or high dose rate (HDR) intracavitary irradiation. The goal of treatment is to balance these two elements in a way that optimizes the ratio of tumor control to treatment complications. The required dose varies according to the tumor burden in the cervix, paracervical sites, and regional nodes. Factors that influence the tolerable dose of radiation include the patient's vaginal and uterine anatomy, the degree of tumor-related tissue destruction and infection, and patient characteristics (e.g., body habitus, comorbid illnesses, and smoking habits).

Treatment options EBRT

EBRT is used as initial treatment in patients with bulky tumors. The usual plan is to give 40–45 Gy to the whole pelvis. This gives a homogeneous distribution to the central mass plus the regional lymph nodes. Such treatment reduces the primary tumor and any regional lymph nodes harboring disease, and it destroys microscopic foci in lymph-vascular spaces adjacent to the tumor. The shrinkage of the primary tumor allows better dose distribution from intracavitary irradiation.

High-energy photons (15–18 MV) are usually preferred for pelvic treatment because they spare superficial tissues that are unlikely to be involved with tumor. Simulation films, as well as CT, MRI, PET scan, and lymphangiography, guide the radiation oncologist in selecting boundaries for the portals. Typical radiation therapy fields are shown in [Figure 16](#). A standard course of radiation therapy is 40 to 45 Gy given with external beam radiation therapy (EBRT). Patients with grossly positive pelvic nodes within the 40- to 45-Gy field require a boost with a small field (Figures 16 and 17). The dose to the boost area is 8–10 Gy. The total dose to the positive nodes, including a 1–2 cm margin, is 60–66 Gy, which includes the contributions from brachytherapy intracavitary systems. Intensity-modulated radiation therapy (IMRT) may be used to boost the dose to large pelvic nodes (up to approximately 66 Gy) in a very tightly defined volume.

Figure 16 Typical radiation fields for a patient with cervical cancer. (a) Anterior field; (b) lateral field.

There has been a recent interest in using IMRT in the treatment of cervical carcinoma. Unlike standard treatment, IMRT allows one to dose paint tissues in the area of treatment, that is, allowing higher doses to tumor, while giving less dose to normal tissues especially small bowel ([Figure 17](#)). Mundt et al.¹⁷⁷ have published reports showing a decrease in both acute and chronic¹⁷⁸ bowel toxicities in patients with endometrial or cervical carcinoma treated postoperatively to the pelvis with IMRT compared to standard treatment. However, the highly conformal dose distributions achieved by IMRT also increases the room of error. In particular, great attention needs to be given to internal organs motion (especially the bladder and the rectum) and tumor regression, and therefore at this time IMRT is still considered the investigation therapy, especially in the field of intact cervix. Several multi-institutional trials are underway evaluating the use of IMRT for cervical cancer.

Figure 17 Dose distribution of a typical intracavitary system; it is important to note how quickly the dose falls off the further one gets from the system. (a) Anterior view; (b) lateral view.

Intracavitary radiation therapy (ICRT)

The importance of ICRT (intracavitary radiation therapy) for cervical cancer should not be underestimated because, although EBRT plays a critical role in sterilizing pelvic wall disease and improving tumor geometry, too much reliance on external beam irradiation will compromise the chance for central disease control and increase the risk of complications.

Brachytherapy is usually delivered using afterloading applicators that are placed in the uterine cavity and vagina. Ideal placement of the intrauterine tandem and vaginal ovoids produces a pear-shaped radiation distribution, delivering a high radiation dose to the cervix and paracervical tissues and a reduced dose to the rectum and bladder. Several systems have been used throughout the world to determine dose rates and doses for cervical cancer. In the United States, the paracentral doses are most frequently expressed at a single point, point A, which is defined earlier. Point A bears no consistent relationship with the tumor or target volume but lies approximately at the crossing of the ureter and uterine artery. Other systems of dose specifications include the International Commission on Radiation Units and Measurements (ICRU) reference points based on ICRU Report 38 (1985) and the mg-h system. Whichever system of dose specification is used, emphasis should always be placed on optimizing the relationship between the intracavitary applicators and the cervical tumor and other pelvic tissues. Source, strength, and position should be carefully chosen to provide optimal tumor coverage with exceeding safe doses to normal tissue ([Figure 18](#)).

Figure 18 A patient with cervical cancer being treated with radiation therapy after a hysterectomy. The areas that need to be covered are the nodes and vagina. This is an IMRT plan that conforms to the area that needs to be covered while sparing the small bowel. Most of the small bowel receives <30 Gy.

In the past, clinicians regarded the radiobiological advantages of LDR intracavitary treatment (usually delivery of 40–60 cGy/h to point A) as a major factor contributing to the success of cervical cancer treatment. These LDRs permit repair of sublethal cellular injury, preferentially sparing normal tissues and optimizing the therapeutic ratio. During the past two decades, computer technology has made it possible

to deliver brachytherapy at very HDRs (<100 cGy/min) using a high-activity cobalt 60 or iridium 192 source and remote afterloading. HDR intracavitary therapy is now become the standard of care in most parts of the world. Clinicians have found this approach attractive because it does not require that patients be hospitalized and may be more convenient for the patient and the physician. Multiple randomized and nonrandomized studies have suggested that survival rates and complications rates with HDR treatment are similar to those with traditional LDR treatment.¹⁷⁹ In 2012,¹⁸⁰ the American Brachytherapy Society suggested guidelines for the use of HDR brachytherapy for carcinoma of the cervix. The group emphasized the importance of factors that were already considered critical to successful LDR treatment—optimized applicator position, balanced use of external beam therapy and brachytherapy, compact overall treatment duration, and delivery of an adequate dose to tumor while respecting normal tissue tolerance limits.

Image-based brachytherapy is becoming increasingly common, particularly in Europe. Institutions are using MRI-based treatment planning to plan their doses to tumor as well as doses to avoid structures such as the bladder and rectum; however, large prospective studies and careful analysis will be needed before this becoming standard of care.

Interstitial brachytherapy

Several groups have advocated the use of interstitial perineal template brachytherapy in patients with poor anatomy or parametrial or pelvic sidewall disease. These implants are usually placed transperineally, with placement guided by a Lucite template that encourages parallel placement of hollow needles that penetrate the cervix and paracervical spaces and are usually loaded with iridium 192. Advocates state that the advantages of this method are the ease of inserting implants in patients whose uterus is difficult to probe, the ability to place sources directly into the parametrium, and the relatively homogeneous dose. Recent updates report poor survival rates and higher rates of major complications for patients with stage IIB and IIIB disease.^{181, 182} Outside of an investigational setting, interstitial treatment of primary cervical cancers should probably be limited to patients who cannot accommodate intrauterine brachytherapy and patients with distal vaginal disease that requires a boost with interstitial brachytherapy.

Patient selection

For patients with IB1 tumors, the choice between surgery and radiation therapy is based primarily on patient preference, anesthetic and surgical risks, physician preference, and understanding of the nature and incidence of complications of radiation therapy and hysterectomy. In general, surgery is often chosen for younger patients in the hope of preserving ovarian function and hopefully reducing vaginal shortening, while radiation therapy is often selected for older postmenopausal women to avoid the morbidity of a major surgical procedure. Patients with stage IB2 disease can be treated with either surgery followed by radiation therapy or definitive radiation therapy. The biases are so large that the Gynecologic Oncology Group (GOG) could not complete trial randomizing patients with stage IB2 disease between surgery followed by chemoradiation therapy and definitive radiation therapy. Radiation therapy is the primary local therapy for most patients with stage IIB-IVA disease.

Outcomes

Stage IB-IIA disease

Radical radiation therapy achieves excellent survival and pelvic disease control rates in patients with

stage IB-IIA cervical cancer. Eifel et al.¹⁶⁴ reported 5-year DSS rates of 90%, 86%, and 67% in patients with stage IB tumors with cervical diameters of <4, 4–4.9, and >5 cm, respectively. The 5-year survival rates of patients with stage IIA disease range from 70% to 85% and, like survival rates in patients with stage IB disease, are strongly correlated with tumor size.^{112, 183, 184} Studies suggest that results for patients with bulky tumors may be improved further by concurrent administration of chemotherapy.^{185, 186}

Stage IIB-IVA disease

Five-year survival rates of 65–75%, 35–50%, and 15–20% have been reported in patients who received radiation therapy alone for stage IIB, IIIB, and IV tumors, respectively ([Table 5](#)).^{111, 112, 184, 187} The addition of cisplatin-containing regimens may further improve local control and survival.^{186, 188, 189}

Table 5 Pelvic disease control and survival rates^a

FIGO stage	Patients (n)	Control rate (%)	Survival rate (%)
I	229	93	89
IIA	315	88	85
IIB	314	80	62
IIIA	266	63	62
IIIB	216	57	50
IV	43	18	20

Complications

Acute side effects

Acute side effects of pelvic irradiation include symptoms related to the bowel, bladder, rectum, and vagina. Most patients experience mild fatigue and mild to moderate diarrhea that usually is controllable with antidiarrheal medication and dietary modifications. Less frequently, patients may complain of bladder or urethral irritation. These symptoms may be treated with Pyridium or antispasmodics after urinalysis and urine culture have ruled out a urinary tract infection. Patients treated with extended-field radiation may have nausea, gastric irritation, and mild depression of peripheral blood cell counts. Acute symptoms may be increased in patients receiving concurrent chemotherapy. Unless the ovaries have been transposed, all premenopausal patients who receive pelvic radiotherapy experience ovarian failure by the completion of treatment.

Fatal or life-threatening complications of ICRT are rare. Thromboembolic events, uterine perforation, fever, vaginal laceration, and the usual risk of anesthesia are other less serious complications associated with ICRT.¹⁹⁰

Problems after therapy

For patients with cervical cancer, overall estimates of the risk of major complications of radiation therapy usually range between 5% and 15%.^{191, 192} The risk of experiencing a late complication is

greatest within the first 3 years after treatment; however, major complications have been reported as late as 30 years or more after treatment. Most complications occurring after radiation involve the rectum, bladder, or small bowel. During the first 3 years after treatment, rectal complications are most common and include bleeding, stricture, ulceration, and fistula. The average onset of major urinary tract complications tends to be somewhat later than that of intestinal complication, with an actuarial risk of hematuria requiring transfusion of 2.6% at 5 years.¹⁹¹ The overall risk of developing a gastrointestinal or urinary tract fistula was 1.7% at 5 years with an increased risk of patients who underwent adjuvant hysterectomy or pretreatment transperitoneal lymphadenectomy. The risk of small bowel obstruction is strongly correlated with a number of patient characteristics and treatment factors including type of surgery, history of pelvic infection, history of smoking, and body habitus.^{150, 191, 192}

Patients who are treated with radiation for cervical cancer tend to have varying degrees of atrophy, telangiectasia, or scarring of the upper third of the vagina. However, more severe shortening can occur. Changes may be greater in patients with very extensive tumors and in patients who are elderly, sexually inactive, or hypoestrogenic.^{192, 193} Regular intercourse and use of vaginal dilators may help prevent vaginal shortening.

Current practice by disease stage

CIS and stage IA1 disease

Treatment of HGSILs is rapidly changing. LEEP is one effective therapy for HGSILs. Other techniques such as cryosurgery and laser ablation have also proven effective. Regardless of the technique used, HGSILs should be entirely visible by colposcopy, the entire transformation zone should be visualized, and the ECC specimen should be negative. Conization with a knife is preferred when the ECC specimen is positive. All margins must be clear of intraepithelial lesions.

Stage IA1 (microinvasive) squamous cell carcinomas that invade the stroma <3 mm and have no LVSI are usually not visible to the unaided eye, and cytology is abnormal. The diagnosis requires cone biopsy, which yields a specimen adequate for diagnostic purposes. Conization alone is also potentially a low-risk therapy for patients who wish to retain fertility and who have invasion <3 mm in depth with no LVSI. It is important to remember that the margins of a cone specimen must be negative. When the conization specimen has a positive margin, a second tissue specimen must be obtained because foci of frankly invasive carcinoma may lie adjacent to the positive margin. Patients should be informed that the conservative approach carries a small risk. There is very little current information on which to base a recommendation regarding the use of conization as therapy for women with nonsquamous cervical cancers.¹⁵⁵ Patients who elect conization therapy must be willing to be monitored closely for the development of residual or recurrent cervical neoplasia.

The most conventional treatment of stage IA1 disease is a type 1 (simple extrafascial) hysterectomy. If the patient is young, the ovaries are left in place. Patients can also be treated with radiation therapy alone, usually consisting of intracavitary therapy alone. The 10-year disease control rate with radiation therapy alone is 95–100%.¹⁹⁴

Stage IA2 disease

Small lesions that invade 3–5 mm have an average risk of lymph node metastasis of about 5%. The standard treatment of patients with this stage of disease is type II (modified radical) hysterectomy and

pelvic node dissection.

Recently, a number of studies have explored less radical surgical options for early-stage cervical cancer, including simple hysterectomy, simple trachelectomy, and cervical conization with or without sentinel lymph node biopsy and pelvic lymph node dissections especially in patients who wish to preserve fertility. Such options may be available for patients with low-risk early-stage cervical cancer including patients with any histology except neuroendocrine tumor, tumor size <2 cm, stromal invasion <10 mm, and no LVSI. Presently, three international trials are underway looking at this option for patients with early-stage disease.

If surgery is contraindicated, these patients can be treated with radiation alone, usually with pelvic radiation therapy plus brachytherapy. However, in special situations, brachytherapy alone may be sufficient in controlling disease.

Stage IB1 and small-stage IIA disease

Treatment of invasive carcinoma or carcinoma of FIGO stage IB or greater is determined on the basis of tumor size and the presence or absence of lymph node metastases ([Figure 5](#)).

Stage IB1 tumors, which are <4 cm in size, are considered small; however, they are associated with a significant risk of microscopic paracervical extension or lymph node metastasis. In a prospective study in patients treated with radical hysterectomy who had clinically estimated maximum tumor diameter <3 cm, the GOG reported that 16% of the patients (42 of 261) had lymph node metastases.¹⁹⁵ Landoni et al.¹⁶³ found a 25% incidence of positive nodes (28 of 114 patients) in patients treated with radical hysterectomy for stage IB-IIA tumors that measured 4 cm or less on initial clinical examination. Therefore, for patients with stage IB1 or small IIA (<4 cm diameter) disease, the treatment is either type III (radical) hysterectomy plus bilateral pelvic lymphadenectomy or radical radiation therapy. The goal of both of these treatment options is to destroy malignant cells in the cervix, paracervical tissues, and regional lymph nodes.

OS rates for patients with stage IB1 or small IIA disease treated with either surgery or radiation therapy are usually in the range 80–90%, suggesting that the two treatments are equally effective. However, only one prospective randomized trial has compared the two treatments directly.¹⁶³ There were no significant differences in the rates of relapse or survival between the two arms, but the overall rate of grade 2 and 3 complications was greater for patients treated with hysterectomy. Therefore, for patients with stage IB1, the choice of treatment is based on patient preference, anesthetic and surgical risks, physician preference, and an understanding of the nature and incidence of complication with radiation therapy and hysterectomy. The role of pelvic radiation therapy after radical hysterectomy is still being defined. The GOG, in a prospective trial, randomized patients with intermediate risk of recurrence after radical hysterectomy for stage IB carcinoma to pelvic irradiation or no further treatment.¹⁹⁶ The preliminary analysis showed a 47% reduction in the risk of recurrence when postoperative irradiation was given (15% vs 28%, $p = 0.008$). An update of this study published in 2006 showed a statistically reduction in the risk of recurrence and PFS however no statistical difference in OS with the addition of postoperative radiation therapy. The conclusion by the authors was that pelvic radiotherapy after radical surgery significantly reduced the risk of recurrence and prolongs PFS in women with stage IB cervical cancer, particularly in patients with adenocarcinoma or adenosquamous histologies.¹⁹⁷ The Southwest Oncology Group reported the results of a randomized trial of patients treated with radical hysterectomy followed by radiation therapy versus radiation therapy plus cisplatin-based chemotherapy in patients with high risk factors including pelvic lymph node metastases, parametrial involvement, and or positive margins. The authors

found that patients who received radiation therapy plus chemotherapy had a significant improvement in survival compared with the survival of patients treated with radiation alone.¹¹⁷

Stage IB2 disease

Patients with tumors >4 cm in diameter whose para-aortic lymph nodes are found to be free of disease have excellent survival rates when treated with whole-pelvis EBRT plus brachytherapy. However, these tumors appear on clinical examination to be technically resectable, and the ideal management of these tumors is a subject of considerable controversy. The approach to these tumors differs widely between centers, and the biases are so large that the GOG closed a trial early owing to a lack of accrual that compared surgery plus chemoradiation versus chemoradiation alone.

Although radiation therapy is effective for many patients with stage IB2 disease, central disease recurrences occur in at least 8–10% of patients with bulky endocervical cancers.^{167, 183, 184} The literature contains numerous reports on the use of an adjunctive hysterectomy for patients with bulky endocervical carcinomas treated with primary radiation therapy. However, in 1999, the GOG concluded from a study that evaluated adjunctive hysterectomy, that adjunctive hysterectomy did not improve local control or survival but did increase toxicity when added to chemoradiation therapy in patients with stage IB2 disease.¹⁸⁵

Several investigators recommend treating these tumors with initial surgery followed by postoperative radiation therapy or chemoradiation depending on the pathology findings. In a randomized trial by Landoni et al.,¹⁶³ patients with stage IB2 tumors were randomized to initial surgery versus definitive radiation therapy. In this trial, even though the survival was similar in both arms, 84% of the patients treated with initial surgery required postoperative radiation therapy, which contributed to a higher complication rate in that arm.

Several trials have been initiated to study the role of induction chemotherapy before surgical exploration in patients with bulky lesions who would otherwise be poor candidates for radical hysterectomy.^{198, 199} A meta-analysis²⁰⁰ collected individual patient data (IPD) from 21 randomized trials of neoadjuvant chemotherapy in locally advanced cervical cancer. This analysis included data from comparison of the benefits of neoadjuvant chemotherapy followed by radical radiotherapy versus radical radiotherapy alone (2074) and for comparison of neoadjuvant chemotherapy followed by surgery (\pm radiotherapy) versus radical radiotherapy alone (872 patients). They found that the group of trials using cycles lasting longer than 14 days showed a significant 25% increase in the relative risk of death with neoadjuvant chemotherapy, representing an absolute 8% reduction in 5-year survival compared to shorter chemotherapy cycle lengths, where there was a significant 17% decrease in the relative risk of death, representing an absolute improvement in 5-year survival of 7%. They also found a significant 35% increase in the risk of death for trials that used <25 mg/m² cisplatin per week, reducing absolute 5-year survival by 11%; however, the results for the higher dose-intensity group were less clear, with only a trend toward increased survival. The second comparison of patients treated with neoadjuvant chemotherapy and surgery versus radiation therapy only showed that patients treated with neoadjuvant chemotherapy had a highly significant 35% reduction in the risk of death ($p = 0.0004$) that translated into a 14% absolute increase in 5-year OS.²⁰¹ Unfortunately, this meta-analysis only included trials before 1999, when radiotherapy alone was still the standard treatment. Ultimately, however, this approach may need to be compared with optimized chemoradiation to determine the most effective, least toxic therapy for these patients. The EORTC (European Organisation for Research and Treatment of Cancer) completed a trial addressing this specific question. Patients with IB2 cancers are being randomized to neoadjuvant

chemotherapy followed by radiation or current chemotherapy and radiation.

Two prospective randomized trials^{185, 186} indicate that patients who are treated with radiation for bulky central disease benefit from concurrent administration of cisplatin-containing chemotherapy. A third study suggests that patients who require postoperative radiotherapy because of findings of lymph node metastasis or involved surgical margins also benefit from concurrent chemoradiation.¹¹⁷ These studies are discussed in more detail in the section titled “Concurrent Chemoradiation,” later in this chapter.

Stage IIB-IVA disease

Radiation therapy is the primary local treatment of most patients with locoregionally advanced (stages IIB-IVA) cervical carcinoma. The success of treatment depends on a careful balance between EBRT and brachytherapy that optimizes the dose to tumor and normal tissues and on the overall duration of treatment. In the French Cooperative Group study of 1875 patients treated with radiation therapy according to Fletcher guidelines, Barillot et al.¹¹² reported 5-year survival rates of 70%, 45%, and 10% for patients with stage IIB, IIB, and IVA tumors, respectively.

Local and distant disease recurrences continue to be a problem for patients with locally advanced disease. Neoadjuvant chemotherapy has produced excellent tumor responses; however, randomized trials have failed to demonstrate improvements in survival. Other approaches that have been used to try to improve outcome in these patients, including neutrons, hyperbaric oxygen, and hypoxic cell sensitizers, have also produced disappointing results.

Concurrent chemoradiation

In 1999, five prospective randomized trials, involving patients with locoregionally advanced cervical cancer,^{117, 185, 186, 188, 189} provided compelling evidence that the addition of concurrent cisplatin-containing chemotherapy to standard radiotherapy reduces the risk of disease recurrence by as much as 50% and thereby improves the rates of pelvic disease control and survival ([Table 6](#)).

Table 6 Prospective randomized trials: role of concurrent radiotherapy and cisplatin-containing chemotherapy^a

First author (references)	Eligibility	Patients (numbers)	CT: investigational arm	CT: control arm	Relative risk of recurrence (90% CI)	p Values

Abbreviations: CI, confidence interval; FU, follow-up; HU, hydroxyurea; PA, para-aortic; RT, radiotherapy.

Results from prospective randomized trials that investigate the role of concurrent radiotherapy and cisplatin-containing chemotherapy for

patients with locoregionally advanced cervical cancer.

^a Patients in control arm had prophylactic para-aortic irradiation.

^b All patients had extrafascial hysterectomy after radiotherapy.

^c Survival.

^d Chemotherapy was begun on day 1 and continued every 4 weeks throughout and after radiation therapy.

^e This study had four arms: arm 1, conventional radiation therapy (RT); arm 2, conventional RT with adjuvant chemotherapy consisting of 5-FU orally at 200 mg/day given for 3 courses of 4 weeks, with a 2-week rest every 6 weeks; arm 3, conventional RT with concurrent chemotherapy; and arm 4, conventional RT with concurrent and adjuvant chemotherapy. The addition of adjuvant therapy did not affect recurrence, but there was a significant difference in the recurrence rate between the conventional RT and the conventional RT plus concurrent chemotherapy arms.

In two studies,^{188, 189} the GOG randomly assigned patients with stages IIB-IVA disease to receive either hydroxyurea or cisplatin-containing chemotherapy during external beam irradiation. All three of the cisplatin-containing regimens in these trials produced local control and survival rates superior to those for the control (hydroxyurea and radiation). In a third study,¹⁸⁵ patients with stage IB tumors measuring at least 4 cm in diameter were randomly assigned to receive radiation alone or radiation plus weekly cisplatin before an extrafascial hysterectomy. Patients who received cisplatin were more likely to have a complete histologic response and were more likely to be disease free at the time of preliminary analysis. A fourth study,¹¹⁷ sponsored by the Southwest Oncology Group and the GOG, randomized patients after a radical hysterectomy pelvic radiation therapy or pelvic radiation therapy plus chemotherapy if they had high risk factors. The trial found improvement of survival of chemotherapy and radiation therapy compared to radiation therapy alone at 5 years; however, the benefit of the chemotherapy to the radiation therapy in a univariate analysis was less significant in tumors size <2 cm and patients with only one node positive.²⁰⁵ The absolute improvement in 5-year survival for adjuvant chemotherapy in patients with tumors ≤2 cm was only 5% (77% vs 82%), while for those with tumors >2 cm, it was 19% (58% vs 77%). Similarly, the absolute 5-year survival benefit was less evident among patients with one nodal metastasis (79% vs 83%) than when at least two nodes were positive (55% vs 75%).²⁰⁵

During the same interval, the Radiation Therapy Oncology Group (RTOG)¹⁸⁶ conducted a trial in which radiotherapy alone was compared with pelvic irradiation (including prophylactic para-aortic irradiation) plus concurrent cisplatin and 5-FU. This study demonstrated a significant improvement in outcome for patients with stages III or IV disease as well as for patients with stages IB2 or II cervical cancer with concurrent chemotherapy.¹⁹⁴ An update of this trial, with a median follow-up period of 6.6 years for the surviving patients,²⁰⁶ reported that the OS rate for patients treated with chemotherapy and radiation therapy compared to radiation therapy was still significantly better (67% vs 41% at 8 years, $p = < 0.0001$) and the conclusion by the authors was that chemotherapy with radiation therapy significantly improved the survival rate of women with locally advanced cervical cancer without increasing the rate of late treatment-related side effects.²⁰⁶ Only one large randomized trial has failed to demonstrate a significant advantage from concurrent cisplatin-based chemotherapy in cervical cancer patients. Pearcey et al.²⁰² published this trial in 2002. The authors suggest that difference in technique could explain the difference between their results and the results of the five earlier trials, although the survival rate in their control arm indicated that the margin for improvement was smaller than that in the earlier trials. This trial was also the smallest of the six trials.

Taken together, the randomized trials provide strong evidence that the addition of concurrent cisplatin-containing chemotherapy to pelvic radiotherapy benefits selected patients with locally advanced cervical cancer. It remains to be resolved whether or not 5-FU plays a significant role. The combination of

cisplatin plus FU was tested in four of the trials [RTOG 90-01, GOG 85, GOG 120, and Southwest Oncology Group (SWOG) 8797]. In GOG 120, the frequency of grade 3 and 4 leukopenia was significantly higher in the arm with cisplatin/5-FU and hydroxyurea compared to the arm with cisplatin and hydroxyurea alone, with equal effectiveness. Therefore, it was felt that cisplatin alone was equally effective as cisplatin-5-FU and less toxic, although there has been no adequately powered direct randomized comparison of these two regimens without hydroxyurea.

A meta-analysis of 18 trials²⁰⁷ with concurrent chemotherapy and radiation (4580 patients) in patients with cervical cancer concluded that concomitant chemotherapy and radiotherapy improved overall and PFS and reduced local and distant recurrence in selected patients with cervical cancer. Concomitant chemotherapy and radiation therapy produced a 12% absolute increase in survival with greater evidence of benefit in the trials using platinum-based chemotherapy than in those with nonplatinum-based chemotherapy.²⁰⁷ More recently, a systematic review and meta-analysis based on IPD²⁰⁸ has documented a 7% absolute improvement in 5-year survival. The benefits were similar in the trials using platinum and nonplatinum chemoradiotherapy.²⁰⁸ In this analysis, there is a suggestion that the magnitude of benefit with chemoradiotherapy varies according to stage, but not to other patients characteristics, suggesting a greater benefit in patients with early-stage disease compared to stage III and IV disease.²⁰⁸

In 2012, Duenas-Gonzales published a large phase III study that randomized patients with locally advanced cervical cancer to cisplatin plus radiation versus cisplatin plus gemcitabine and radiation therapy.²⁰⁹ Women assigned to treatment with the combination regimen also received additional systemic therapy after chemoradiation was complete. With a median follow-up of 3 years, women who received cisplatin plus gemcitabine had a 32% reduction in disease progression and a higher rate of PFS at 3 years compared with those treated with cisplatin alone (74% vs 65%, respectively). In addition, cisplatin plus gemcitabine resulted in a 32% survival advantage. However, there were methodological problems with follow-up in this study and a second publication by the authors purported no benefit in various subgroups.²¹⁰ Despite these results, there are reports from other investigators that the combination of cisplatin, gemcitabine, and pelvic irradiation results in unacceptable toxicity²¹¹ and presently is not commonly used in the United States.

These studies raise other interesting questions that will undoubtedly be the subjects of future studies. Although North American studies have emphasized cisplatin-containing regimens, investigators in Southeast Asia have reported improved outcome when radiation was combined with epirubicin²⁰³ or mitomycin and 5-FU.²⁰⁴ Other drugs that are being studied for their radiosensitizing effects in patients with advanced disease are paclitaxel,²¹² carboplatin,²¹³ nedaplatin,²¹⁴ topotecan,²¹⁵ and multiple biologic response modifiers. RTOG just published results of a phase II study evaluating the combination of bevacizumab with cisplatin in combination with radiation therapy and found results that were promising with 3-years OS, DFS, and LRF of 81.3%, 68.7%, and 23.3%, respectively, in 49 patients.²¹⁶ Another potential pathway is the inhibition of ribonucleotide reductase (RNR). Elevated RNR levels are associated with an increased risk of an incomplete response to chemoradiation and an increased risk of disease recurrence.²¹⁷ Therefore, targets that inhibit RNR may be of potential value in combination with RT. One such agent, 3-aminopyridine-2-carboxaldehyde thiosemicarbazone, has been evaluated in a single-institution phase 2 trial and with a median follow-up of 20 months; clinical responses were observed in 24 of 25 patients with suggested metabolic complete responses noted in 23 of 24 patients evaluated by PET/CT at 3 months.²¹⁸ These encouraging results have prompted a larger, multi-institutional, randomized phase II study as well as a possible phase III through NRG. Other potential targets/pathways that are being investigated include EGFR expression and inhibition of poly (adenosine

diphosphate-ribose) polymerase (PARP).

Para-aortic metastasis

Metastatic cancer in the para-aortic lymph nodes can be confirmed with fine-needle aspiration, laparoscopy, or extra-peritoneal laparotomy. Laparoscopy and laparotomy, using the extra-peritoneal approach, allows the removal of positive nodes and sampling of other para-aortic nodes, which may enhance control with radiation therapy and help design the treatment field.

The superior boundary of the extended EBRT portal provides a margin of 3 cm above the most cephalad of the positive nodes. The superior boundary limit is the T12 vertebra. Currently, patients with positive pelvic nodes or low common iliac nodes may have the field extended to the L1–L2 interspace.

Patients with para-aortic lymph node involvement can be treated effectively with extended-field irradiation. Five-year survival rates range from 25% to 50%.^{219, 220} The value of prophylactic extended-field irradiation was tested in two randomized trials and both trials found no advantage in the use of prophylactic para-aortic radiation.^{221, 222}

The role of concurrent chemotherapy with extended-field irradiation has been evaluated in several phase II studies.²²³ Although, side effects are greater when treatment fields are enlarged, combined therapy may be tolerable if careful consideration is given to the chemotherapy regimen, volume of tissue irradiated, and other factors that might increase the risk of serious toxicity. In conclusion, it is tempting to extrapolate from the results achieved with combinations of pelvic radiation and chemotherapy; however, patients need to be informed that the cost-benefit ratio of concurrent chemotherapy and extended-field irradiation has not been formally tested but this is where IMRT may be a benefit in reducing acute toxicity.

Unsuspected invasive cancer discovered after simple hysterectomy

Sometimes the pathologist discovers unsuspected invasive cervical carcinoma in the tissue specimen in patients who undergo hysterectomy for what is presumed to be a benign pelvic condition. Many factors can lead to such an event.²²⁴

Patients with unsuspected invasive cervical carcinoma detected after simple hysterectomy have been classified in five groups according to the amount of disease and presentation: (1) microinvasive cancer, (2) tumor confined to the cervix with negative surgical margins, (3) positive surgical margins but no gross residual tumor, (4) gross residual tumor by clinical examination documented by biopsy, and (5) patients referred for treatment more than 6 months after hysterectomy (usually for recurrent disease).²²⁵ The therapy plan is based on the amount of residual disease. Patients with minimal invasion and no residual disease require at most brachytherapy to the vaginal apex; patients with gross disease at the specimen margin require full-intensity therapy. Patients with minimal or no known gross residual disease (groups 1–3) have excellent 5-year survival rates (59–79%), whereas rates for patients with gross residual disease (groups 4 and 5) are poorer (in the range of only 41%).²²⁶

Recurrent disease

Prognostic factors

Various clinicopathologic features have been associated with adverse outcomes in patients with recurrent cervical carcinoma in the pelvis; however, the relatively small numbers of patients and the heterogeneity of clinical and treatment parameters in most series preclude detailed statistical analysis of these factors.

Two clinical factors commonly correlated with the probability of the success of salvage therapy are the location (central vs side wall involvement) and the size of the recurrent pelvic tumor.²²⁷ The presence of nodal disease in conjunction with pelvic relapse portends a dismal outcome; other unfavorable clinical variables include nonsquamous histologies (particularly adenocarcinomas) and a higher FIGO stage at the time of diagnosis of the primary tumor.²²⁸ Controversial factors include the interval between primary therapy and relapse and symptomatic versus asymptomatic pelvic failures.^{172, 228, 229}

Radical hysterectomy

In rare, carefully selected patients initially treated with primary radiation therapy, radical hysterectomy for salvage may be a feasible alternative to exenterative surgery. Coleman et al.²³⁰ reported 50 patients who underwent radical hysterectomy for persistent or recurrent disease after definitive radiation therapy. The 5- and 10-year survival rates were 72% and 60%, respectively. Severe complications were noted in 64% of patients, and 42% of patients had permanent complications. The authors concluded that radical hysterectomy was an alternative to exenteration in patients with small, centrally recurrent cervical cancer, but that it should be used only in carefully selected patients.²³⁰

Pelvic exenteration

Pelvic exenteration is a potentially curative procedure for patients who, following radiation therapy, have a central pelvic recurrence or a new primary tumor in the irradiated field.^{231–233} Advances in surgical technique, anesthesia, and postoperative care have decreased intraoperative and postoperative complications, and thus have greatly reduced operative mortality.^{224, 232, 233} Advances in ostomy appliances and care have given patients the opportunity to live a nearly normal life and to be able to meet their personal needs and responsibilities after surgery. The type of exenteration is determined by the anatomical site of the cancer ([Figure 19](#)).

Figure 19 Survival curves are shown to compare the three types of exenterations performed in an MD Anderson series (1955–1984). Although the curves are similar, it should be noted that posterior exenteration is performed more frequently than the other procedures for vulvar and anorectal cancer and is associated with more local cancer recurrences.

Source: Rutledge 1987.²³¹

Anterior exenteration

Anterior exenteration encompasses the removal of the uterus, adnexa, bladder, urethra, and vagina. Patients selected for this operation have cancers that are sufficiently anterior to allow clearance of the rectum and do not extend to involve the vaginal apex or the posterior vaginal wall. Vaginal reconstruction is performed as indicated.

Posterior exenteration

In posterior exenteration, the uterus, adnexa, anus, rectosigmoid colon, levator muscles, and vagina are removed. Many gynecologic oncologists leave a portion of the anterior vaginal wall to support the urethra, and this can lessen postoperative urinary incontinence. This procedure is performed in patients with lesions confined to the posterior vaginal wall and rectovaginal septum.

Total pelvic exenteration

In total pelvic exenteration, the uterus, adnexa, bladder and urethra, vagina, rectosigmoid colon, levatores, and anus are all removed. Patients treated with this procedure usually have lesions that are central or involve the upper half of the vagina. Contiguous extension to the base of the bladder and rectovaginal septum leaves no opportunity to perform a less extensive operation. Vaginal reconstruction is performed for functional purposes and to aid in the reconstruction of the pelvic floor. An omental pedicled graft is required to aid in reconstruction of the pelvic floor, and this technique for bringing in a new blood supply has been a major factor in reducing postoperative complications.²³⁴ In both anterior and total pelvic exenteration, a continent urinary conduit can be constructed.

Total pelvic exenteration is widely used, and 5-year survival rates of 40–50% can be expected. At MD Anderson, a total of 448 exenterations were done from 1955 to 1984 and reported by Rutledge.²³¹ The 5-year survival rates for patients treated with exenteration are shown in [Figure 19](#).

Radiation therapy

Patients who have an isolated pelvic recurrence after initially being treated with a radical hysterectomy should be treated with radical radiation therapy. A literature review by Lanciano found disease-free survival rates ranging from 20% to 50% following radiation therapy for locoregional failures. More favorable outcomes were reported in patients with small-volume disease and a central pelvic relapse location.²²⁷ In most patients, treatment consisted of EBRT with or without brachytherapy. Patients who have isolated central recurrences without pelvic wall fixation or regional metastasis can be cured in up to 60–70% of cases.²²⁹ The prognosis is much poorer when the pelvic wall is involved (usually 10–20% of patients survive 5 years after radiation therapy).

Treatment of stage IVB or recurrent disease

Chemotherapy

Single-agent chemotherapy

Using chemotherapy to treat metastatic or recurrent carcinoma of the cervix is relatively ineffective. Median survival ranges between 4 and 8 months. The most active single agents include cisplatin, paclitaxel, topotecan, vinorelbine, and ifosfamide. Cisplatin is regarded as the most active agent in cancer of the cervix. The response rate (RR) is 17–21%.^{235, 236} Doses used range from 50 to 100 mg/m². Bonomi and colleagues compared 50–100 mg/m² and noted that the higher dose was associated with a better partial RR (31% vs 21%) and a slightly better complete RR (13% vs 10%). Response duration, PFS, and survival measures failed to improve with the higher dose.²³⁶ Carboplatin given at 340–400 mg/m² every 28 days to 175 patients induced a complete response in 10 (5.7%).²³⁷ The total RR for carboplatin from a number of studies is 19%.

Paclitaxel has consistently demonstrated clinical activity, even in patients who received prior platinum therapy with RRs of 17–31% and median survival of about 7 months, including those patients with nonsquamous histology. The other three—topotecan, vinorelbine, and ifosfamide^{238–240}—have also shown substantial responses and are being used in combination therapy in phases II and III trials.

Combination chemotherapy

Nineteen single agents have activity against cervical cancer, defined as the ability to induce a 15% RR

when used as a single-agent ([Table 7](#)), but survival rates have not been improved by adding other drugs to cisplatin. Numerous reports describe a higher RR with combination therapies accompanied by an increase in toxicity. Ifosfamide has received the most interest until recently. Several small phase II studies evaluated treatment with combinations of ifosfamide and either cisplatin or carboplatin in patients who had not received radiotherapy. RRs for these combinations ranged between 50% and 62%.^{241–244}

Table 7 Single-agent chemotherapy for cervical cancer

Agent	Response (%)
Alkylating agents	
Cyclophosphamide	38/251 (15)
Chlorambucil	11/44 (25)
Melphalan	4/20 (20)
Ifosfamide	35/157 (22)
Mitolactol	16/55 (29)
Heavy metal complexes	
Cisplatin	190/815 (23)
Carboplatin	27/175 (15)
Antitumor antibiotics	
Doxorubicin	45/266 (17)
Bleomycin	19/176 (11)
Mitomycin	5/23 (22)
Antimetabolites	
Fluorouracil	29/142 (20)
Methotrexate	17/96 (18)
Hydroxyurea	0/14 (0)
Plant alkaloids	
Vincristine	10/55 (18)
Vinblastine	2/20 (10)
Etoposide	0/31 (0)
Miscellaneous agents	
Altretamine	12/64 (19)
Irinotecan (CPT-11)	36/192 (19)
Paclitaxel	14/74 (19)
Docetaxel	1/13 (8)
Topotecan	8/43 (19)
Hexamethylmelamine	12/64 (19)
Razoxane	5/28 (18)

Combinations of cisplatin and continuous infusion 5-FU,^{245–247} cisplatin and paclitaxel,^{248, 249} cisplatin and vinorelbine,²⁵⁰ and cisplatin and gemcitabine^{251, 252} also produce high response in previously untreated patients. The combination of carboplatin and liposomal doxorubicin has shown modest activity in this clinical setting.²⁵³ Again, RRs decrease significantly if patients have had previous irradiation.^{246, 252}

A GOG-randomized phase III trial reported that combining topotecan with cisplatin had a better RR than cisplatin alone.²⁵⁴ The RR was 13% in the cisplatin arm and 27% in the combination arm. There was also an improvement in median survival by 3 months as well as a slight improvement in quality of life as determined by the functional assessment of cancer therapy-cervical (FACT-CX). They found the previous radiosensitizing chemotherapy and interval from diagnosis predicted for response. Response was more frequent in nonirradiated sites (70% vs 23%). This has led the GOG to their next prospective trial for primary stage IVB or recurrent/persistent carcinoma of the cervix. In this trial, patients were randomized between four arms: arm 1, paclitaxel and cisplatin (PC); arm 2, vinorelbine and cisplatin (VC); arm 3, gemcitabine and cisplatin (GC); and arm 4, topotecan and cisplatin (TC). This study was closed early due to futility. However, in 513 patients, VC, GC, or TC was not superior to PC in terms of OS, but the trend in RR, PFS, and OS favored PC.²⁵⁵ In a separate report, health-related quality of life outcomes for this study showed no difference between the four arms except that PC had a higher rate of neuropathy, but the final conclusion was that PC should be the standard of care for recurrent or metastatic cervical cancer.²⁵⁶

Recently, however, a major step forward in the treatment of patients with recurrent or metastatic cervical cancer was achieved with the result of GOG 240, which randomly assigned patients to treatment with 1 of 2 chemotherapy regimens (cisplatin plus paclitaxel vs paclitaxel plus topotecan) and to bevacizumab versus no bevacizumab.²⁵⁷ There was no difference in outcomes noted between the chemotherapy regimens. However, when compared with chemotherapy alone, the addition of bevacizumab significantly improved OS (17 months vs 13.3 months), PFS (8.2 months vs 5.9 months), and RR (48% vs 36%) without a significant deterioration in health-related quality of life.²⁵⁸ Major treatment-related toxicities included fistula (3%), thromboembolism (8%), and easily managed hypertension (25%).²⁵⁸ Since this publication, cisplatin-paclitaxel-bevacizumab triplet has been listed as Category 2A in the National comprehensive Cancer Network (NCCN) Clinical Practice Guidelines for Cervical Cancer.²⁵⁹

Despite the result of GOG 240, the prognosis of patients with recurrent or metastatic cervical cancer remains poor and represents an urgent unmet need worldwide. Therefore, better alternatives need to be explored including determining prognostic factors, administration of novel agents that may improve the therapeutic index of definitive chemoradiation and various immunotherapeutic approaches. Moore et al.²⁶⁰ evaluated 428 patients enrolled in three GOG trials and determined 5 prognostic factors including race, performance status, pelvic disease, prior radiosensitizer, and time interval from diagnosis to the first recurrence <1 years, that may have utility in clinical practice to identify women who are not likely to respond to standard cisplatin-based regimens and that may benefit from investigational trials.

The rationale for immunotherapy in cervical cancer is based on the causative role of HPV infection in the disease. HPV infection invokes cellular immune response, and regulatory T cells appear to play a role in local immune suppression in HPV-associated tumors. New agents that interrupt the mechanisms involved in cancer immune evasion have soon promising results. Basu presented final results of a randomized phase II trial involving 110 women from India with recurrent/refractory cervical cancer who were randomized to receive live attenuated *Listeria monocytogenes* vaccine with or without cisplatin at the 2014 Annual Meeting of the American Society of Clinical Oncology.²⁶¹ The final 12-month OS was 36%

and 18 month OS was 28%.²⁶¹ The overall RR was 11% and included 6 complete responders and 6 partial responders.³²¹ The addition of cisplatin did not significantly improve OS or RR.²⁶¹ These promising results have led to a trial in the United States using the same live-attenuated vaccine under the auspices of the NRG (GOG 265/NCT01266460).

Other pathways including regulatory pathways that limit the immune response to cancer including the upregulation of cytotoxic T lymphocyte-associated molecule-4 (CTLA-4) and PD-1 are increasing being well characterized. In addition, the role of adoptive immunotherapy using tumor-infiltrating lymphocytes represents another potential useful approach for patients with advanced or metastatic disease. In this technology, the tumor is excised and enriched for tumor-infiltrating lymphocytes, which are expanded after selection and reinfused to patients after lymphodepletion. On the basis of the responses noted in tumors such as malignant melanoma, this approach is being evaluated in an ongoing trial at the NCI for patients with recurrent or refractory metastatic cervical cancer (NCT01266460).

Signaling pathways affected by HPV are also an area where novel targeted drugs may be a benefit in the fight against cervical cancer. Genomic data have documented KRAS and P13KCA mutations and are now awaiting proof of concept by demonstration that these pathways are both turned on and necessary for the cervical cancer success. Endpoints including showing purposeful activations of MEK/ERK and AKT proliferation, invasion and survival pathways would provide justification for testing active agents targeting these pathways. Potential new agents include cetuximab, gefitinib, erlotinib, and selumetinib. Irradiation is a major cause of DNA damage. Therefore, inhibition of PARP provides another potential target for the treatment of cervical cancer. Two trials currently are being conducted among patients with cervical cancer through NRG (GOG 127W/NCT0101266447 and GOG76HH/NCT01282852).

Summary

In patients with recurrent cervical cancer, it is important first to determine if the patient is a candidate for definitive surgery or radiation therapy. Five-year survival rates range from 20% to 50% if one of these therapies can be administered. Systemic chemotherapy can be used for treatment of both recurrent and metastatic disease, but careful attention should be paid to balancing benefit and toxicity. Further research is needed to determine the impact of chemotherapy on quality of life and the sensitivity to chemotherapy of patients who received prior chemotherapy as part of chemoradiation therapy as well as the importance of biological and immunotherapy agents. The key to success will be the transportation of success seen in the developing countries to success in areas of the world where advanced-stage invasive cervical cancer is most common.

Chapter 103

Endometrial cancer

Jamal Rahaman, MD ■ Karen Lu, MD ■ Carmel J. Cohen, MD

Overview

Endometrial carcinoma is the most frequent gynecologic cancer in the United States with over 50,000 new cases diagnosed per year. Over 80% have Type I cancers with the classic estrogen-dependent endometrioid histology and a favorable prognosis. Type II cancers have a different molecular profile associated with more virulent disease and diminished survival and include uterine serous papillary carcinomas (UPSC) and clear cell carcinomas. The Cancer Genome Atlas (TCGA) has recently defined four molecular subtypes of endometrial cancer based on somatic mutations, copy number alterations, and microsatellite instability status. Over 75% of patients are present with irregular or postmenopausal bleeding. Surgical staging includes a total hysterectomy, bilateral salpingo-oophorectomy, and pelvic and para-aortic lymph node sampling, which can be performed via a laparotomy, laparoscopy, or robotic surgery. Surgery, where possible, constitutes the definitive primary treatment for most patients with endometrial carcinoma. Primary radiation therapy and primary hormonal therapy are alternatives for inoperable patients. Adjuvant therapy for Stage I disease is determined by age, depth of myometrial invasion, lymphovascular space invasion, and tumor grade. For patients with advanced and recurrent disease, radiation therapy, chemotherapy, and hormonal therapy are utilized. Paclitaxel (T), carboplatin (C), cisplatin (P), and doxorubicin (A) are the most active single agents with TC and TAP being the most effective combination of chemotherapy regimens. Hormonal therapy includes oral progestins, the progesterone-containing intrauterine device, tamoxifen, gonadotropin-releasing hormone analogs, and aromatase inhibitors. Emerging biologic agents with activity include bevacizumab and mTOR inhibitors. Tumor molecular profiling, minimal invasive surgery, sentinel lymph node assessment, and integration of novel biologic therapies will likely play a greater role in the future.

Epidemiology

In 2015, approximately 54,870 new cases of uterine corpus cancer will be diagnosed in the United States and 10,170 women will die from this cancer.¹ Since 1991, the death rate from endometrial cancer in the United States has exceeded that of cervical cancer, although cervical cancer is the most prevalent gynecologic cancer in less developed countries, causing the most gynecologic cancer deaths worldwide.¹ After declining between the mid-1980s and 1990, the incidence rates for endometrial cancer increased by about 0.6% per year from 1988 to 1999. Norway, Czechoslovakia, and other northern European countries also reported significant increases in the incidence of endometrial cancer. Despite an increase in incidence, early stage disease has an excellent prognosis.² Results from FIGO show that 85% to 91% of Stage I patients are alive at 5 years, and patients in the SEER database with localized disease have 96% 5-year survival.^{2,3}

While black women have a lower incidence of endometrial carcinoma than white women, their mortality

is higher.^{1, 4} Hicks and colleagues observed that black women were diagnosed with less favorable histologies, more advanced stages of disease, and more poorly-differentiated tumors than were white women.⁴ Black women were treated surgically less frequently, and the surgically-treated patients with advanced-stage disease received adjuvant radiotherapy (RT) less often and chemotherapy more often than did white patients. Five-year survival was poorer for black women, even for those with stage I disease who were treated surgically.^{1, 4}

Risk factors

Risk factors include larger body size, obesity, diabetes, nulliparity, history of colon and/or breast carcinoma, ovulatory failure, increased endogenous estrogen exposure, and exposure to exogenous oral estrogens. Peripheral aromatization of estrogen precursors in body fat results in a higher level of circulating estrogen explaining, in part, the risk from obesity. Nulliparity, compared with multiparity of five or more births, menopause after age 53 years, and 50 pounds of excess weight are all important risk factors, increasing a woman's probability for endometrial cancer by 5–10 times compared with patients without these risk factors.

Pathologic conditions increasing the risk of endometrial cancer often include increased levels of endogenous estrogen or the requirements for exogenous estrogen supplementation.⁵ Gusberg and Kardon reviewed the endometrial histology from 115 patients with theca-granulosa cell ovarian tumors and found that 21% developed endometrial carcinoma and 43% had precancerous hyperplasia.⁵ Others have not found the same incidence of adenocarcinoma but have identified a high incidence of atypical hyperplasias.^{6, 7} Patients with polycystic ovary syndrome usually do not ovulate and, thus, are exposed to endogenous unopposed estrogen production. When endometrial carcinoma occurs in women younger than 45 years of age, it is often in patients with polycystic ovary syndrome^{8, 9} and is most frequently surrounded by atypical hyperplasia histologically. Finally, patients who are treated for ovarian dysgenesis by oophorectomy and unopposed estrogen replacement develop endometrial carcinoma in the residual uterus.¹⁰ This association of continuous unopposed exposure to endogenous estrogens or exogenous oral estrogens and endometrial carcinoma has been widely reported.^{11–19}

The Centers for Disease Control and Prevention reported that oral contraceptive use for at least 12 months diminished the risk of endometrial cancer by 50% compared with the risk for women who had never used oral contraception. Nulliparous women seemed to benefit most, and the protection lasted for a decade following the discontinuation of oral contraceptive use.²⁰ Brinton and Hoover's study observed that previous oral contraceptive use did not protect women from increased relative risk of endometrial cancer when they employed unopposed estrogen in postmenopausal hormone replacement therapy, suggesting that the role of the progestogen in the combination oral contraceptive pills is essential in protecting against endometrial carcinoma.¹²

For more than 20 years, tamoxifen has been used to treat breast cancer, following the observation that it causes regression of metastatic tumor, diminishes the incidence of cancer in the contralateral breast, delays time to recurrence, and improves survival in subsets of patients.²¹ Clinically, tamoxifen diminishes serum cholesterol, increases sex hormone-binding globulin,²² preserves bone density in the lumbar spine,²³ thickens the vaginal epithelium in some patients,^{23, 24} and is associated with the enlargement of uterine fibroids, the growth of endometrial polyps, and the development of endometrial neoplastic change. These are all estrogen-like functions. Paradoxically, the same drug is associated with the production of vaginal atrophy, the onset of vasomotor symptoms, and the development of clinical dyspareunia. These

are features of estrogen deprivation.

The action of tamoxifen may be organ specific, just as it is known to be species specific in its association with hepatic neoplasia in laboratory animals. When immortalized breast cancer and endometrial cancer cell lines were implanted in athymic mice, both cancers grew well in the same animal. When tamoxifen treatment was given, the breast cancers were inhibited and the endometrial cancers continued to grow.²⁵ Several investigators have described an increase in the incidence of endometrial cancers among patients with breast cancer who were treated with tamoxifen.^{26–31} Killackey and colleagues were the first to report endometrial carcinoma occurring in three breast cancer patients receiving antiestrogens.²⁸ The strongest initial data implicating tamoxifen use in the subsequent development of endometrial carcinoma were reported by Fornander and colleagues, who reviewed the frequency of new primary cancers in the Swedish Cancer Registry for a group of 1,846 postmenopausal women with early breast cancer.²⁶ There was a 6.4-fold increase in the relative risk of endometrial cancer in the 931 tamoxifen-treated (40 mg/day) patients compared with controls. The National Surgical Adjuvant Breast and Bowel Project (NSABP) described observations on 3,863 patients studied prospectively.²⁷ In the B-14 protocol, 2,843 patients with node-negative, ER-positive breast cancer received either tamoxifen (20 mg/day) or placebo. An additional 1,020 patients taking tamoxifen were registered in this project. The relative risk calculated for the tamoxifen-treated group compared with the placebo group was 7.5, with an annual hazard rate of 0.2 per 1,000 for the placebo group and 1.6 per 1,000 for the randomized tamoxifen-treated group. More recently, in the Breast Cancer Prevention Trial (P-1) of the NSABP, 13,388 women were randomly assigned to receive placebo (6,707) or 20 mg/day of tamoxifen (6,681) for 5 years.³² The rate of endometrial carcinoma was increased in the tamoxifen group (risk ratio = 2.53); this increase occurred primarily in women aged 50 years or older. All endometrial carcinomas in the tamoxifen group were stage I, and no endometrial cancer deaths have occurred in this group.

A prospective longitudinal study in Canada on 304 women with breast cancer receiving tamoxifen found that routine surveillance with ultrasonography was not useful in asymptomatic patients.³³ In another study, Barakat and colleagues evaluated 159 tamoxifen-treated patients by serial office endometrial biopsies obtained at the start of tamoxifen therapy and at 6-month intervals for 2 years, followed by three additional annual biopsies.³⁴ Although the procedure was feasible, significant pathology requiring hysterectomy was observed in only three patients, and the authors concluded that the utility of routine endometrial biopsy for screening in tamoxifen-treated women is limited. None of these studies provide strong support for screening with ultrasonography or endometrial biopsy.³⁵ Prompt evaluation of any vaginal bleeding is mandated. However, clinicians should not be reluctant to obtain endometrial biopsies or vaginal ultrasound in patients with multiple risk factors.

In 1980, Bokhman first proposed the concept of a Type II endometrial cancer as distinct from the classic Type I estrogen-dependent endometrioid endometrial cancer. ([Table 1](#)). These women have a distinct phenotype and now are recognized to also have a different molecular profile associated with more virulent disease and diminished survival.^{36, 37} Type I cancers are associated more frequently with tamoxifen therapy and unopposed estrogen use.

Table 1 Clinical and molecular features of endometrial carcinoma

Features	Type I	Type II
Clinical ³⁷		
Risk factors	Unopposed estrogen	Age
Race	White > black	White = black
Degree of differentiation	Well differentiated	Poorly differentiated
Histology	Endometrioid	Nonendometrioid
Stage	I/II	III/IV
Prognosis	Favorable	Unfavorable
Molecular		
K-ras overexpression	Yes	Yes
<i>HER2/neu overexpression</i>	No	Yes
<i>TP53 overexpression</i>	No	Yes
<i>PTEN mutations</i>	Yes	No
Microsatellite instability	Yes	No

Pathology

Endometrial hyperplasia

When Gusberg and colleagues introduced the term “adenomatous hyperplasia” to describe the pattern of hyperplastic glands noted in association with, and often prior to, the development of endometrial adenocarcinoma, they included all of the variants of precursor histology. These ranged from a mild arrangement of densely crowded glands with eosinophilic cytoplasm through the spectrum of more disordered arrangements, characterized by intraluminal tufting and an increase in mitosis, pseudopalisading, and bizarre nuclei.³⁸ Similarly, Hertig and Sommers studied preinvasive changes in the endometrium and described three intensities of abnormality which they called “adenomatous hyperplasia,” “atypical hyperplasia,” and “carcinoma in situ.”³⁹ Kurman and colleagues followed 170 patients with endometrial hyperplasia for a minimum of 1 year; the mean follow-up time was 13.4 years.⁴⁰ They established criteria for distinguishing lesions on the basis of architectural abnormalities and cytologic abnormalities. Only 1.6% of patients without cytologic atypia progressed to cancer compared with 23% of those with atypical cytology. Architectural abnormalities were not prognostically important. [Table 2](#) presents the details of Kurman and colleagues' classification and observations. Their classification of simple or complex hyperplasia, with or without atypia, is now accepted for describing these lesions.

Table 2 Comparison of follow-up of 170 patients with simple and complex hyperplasia and simple and complex atypical hyperplasia

	No of patients	Regressed <i>n</i> (%)	Persisted <i>n</i> (%)	Progressed to carcinoma <i>n</i> (%)
Simple hyperplasia	93	74 ⁴¹	18 ¹⁹	1 ¹
Complex hyperplasia	29	23 ⁴¹	5 ¹⁷	1 ³
Simple atypical hyperplasia	13	9 ⁴²	3 ²³	1 ⁸
Complex atypical hyperplasia	35	20 ⁴³	5 ¹⁴	10 ²⁹

Endometrioid adenocarcinoma

Endometrioid adenocarcinoma is the most common of the endometrial cancer histologies. It is characterized by the disappearance of stroma between abnormal glands that have infoldings of their linings into the lumens, disordered nuclear chromatin distribution, nuclear enlargement, and a variable degree of mitosis, necrosis, and hemorrhage. This classic variety accounts for 80–95% of the adenocarcinomas.

Adenosquamous carcinoma

Adenosquamous cancer has malignant elements from both its squamous component and its adenomatous component. It usually accounts for 7% or less of the adenocarcinomas of the endometrium. It is suggested that adenosquamous cancer will not behave differently from endometrioid adenocarcinomas of the same stage and grade.

Uterine papillary serous carcinoma

Described by Hendrickson and colleagues in 1982, uterine papillary serous carcinoma (UPSC) comprises 5 to 10% of stage I endometrial carcinomas and is characterized by expansive papillary architecture with a fibrovascular matrix, marked cytologic atypia, bizarre nuclei, and widespread nuclear pleomorphism (Figure 1).^{44, 45} The features are suggestive of papillary serous cystadenocarcinoma of the ovary. The lesion is highly virulent, usually found with deep myometrial penetration at the time of diagnosis, often extrauterine in location in patients with clinical early-stage disease, and almost always incurable when the disease has spread beyond the uterus.^{45–48}

Figure 1 Uterine papillary serous carcinoma. Broad stalks supporting papillary fronds, appearing like papillary ovarian carcinoma. Courtesy of Diane Deligdisch, MD, Mount Sinai School of Medicine. A four-color version of the figure is available on the CD-ROM. a Correlation of the Federation Internationale de Gynecologie d'Obstetrique (FIGO), Unio Internationale Contre Cancrum (UICC), and American Joint Committee on Cancer (AJCC) nomenclatures.

Endometrial papillary adenocarcinoma

Endometrial papillary adenocarcinomas must be distinguished from UPSC because of their different behavior. Histologically, they are characterized usually as being well-differentiated endometrioid

adenocarcinomas composed of very slender papillations, orderly neoplastic epithelial cells, few mitoses, and less cellular disorder than UPSC. The distinction between these two groups has been carefully detailed by Chen and colleagues.⁴⁹ The endometrial carcinomas with papillary features behave identically to the endometrioid adenocarcinomas.

Clear cell carcinoma

Kurman and Scully described clear cell cancers in detail.⁵⁰ Histologically, although there are a variety of patterns, a presentation of polygonal or flattened cells with clear cytoplasm accounts for more than half of the cells. This group constitutes approximately 6% of endometrial carcinomas and occurs more frequently in older women. The 5-year overall survival rate is approximately 40%,⁵¹ but this may be a result of the older age of the patients and the fact that clear cell carcinomas are generally found in patients with higher stages of cancer. Clear cells often appear in histologic mixtures when tumors are assigned to a different category on the basis of the prevalent cell type, and their presence usually confers a diminished prognosis.⁵²

Genomic alterations

The Cancer Genome Atlas (TCGA) has recently provided a comprehensive mapping of DNA, RNA and protein alterations in endometrioid and serous endometrial cancers.⁵³ In the decades leading up to the TCGA, individual genes and proteins had been implicated in the pathogenesis of endometrial cancer. Based on these molecular alterations, and clinical features, endometrial cancers have been classically divided into Type I and Type II ([Table 1](#)). Type I tumors include low to moderate grade endometrioid tumors and demonstrate high estrogen and progesterone receptor (PR) positivity and PTEN mutations. Type II tumors include high grade endometrioid and serous histologies and are characterized by a high mutational rate of TP53. This dual classification, while oversimplified, still holds some clinical utility.

The PI3K pathway is the most common dysregulated pathway in endometrial cancer, with mutations seen in multiple key members. Loss of PTEN (phosphate and tensin homolog deleted on chromosome 10) occurs in approximately 75–85% of tumors of the endometrioid histology⁵⁴ and results in unopposed activation of the PI3K pathway. Mutations account for the majority of PTEN loss, and may occur early in endometrial carcinogenesis. However, other mechanisms including gene methylation and destabilization of the protein may also contribute to PTEN loss. Mutations have also been found in other components of the PI3K pathway, including PIK3CA, PIK3R1 and AKT ().⁵⁵ A key downstream effector of the PI3K pathway is mTOR, which stimulates protein synthesis and entry into the G1 phase of the cell cycle. Therapies that target mTOR, AKT and PIK3CA are currently being tested in endometrial cancer patients with advanced and recurrent disease.

The Ras/Raf/MEK/ERK pathway is also frequently dysregulated in endometrial cancer. K-ras mutations occur in approximately 18–20% of endometrioid endometrial cancers. Mutations in the FGFR2 receptor tyrosine kinase occur in approximately 12% of endometrioid endometrial cancers, and do not co-occur with tumors that have K-ras mutations. Among early stage endometrioid endometrial cancer patients, K-ras mutations are associated with a more favorable prognosis and FGFR2 mutations are associated with a worse prognosis.⁵⁶ Therapies that target FGFR2 have shown limited efficacy.⁵⁷ Therapies that target the Ras/Raf/MEK/ERK pathway are currently being studied in combination with PI3K pathway inhibitors. ARID1A has been shown to be mutated in approximately 25% of low grade and 44% of high grade endometrioid cancers.⁵⁸ The WNT pathway is another important dysregulated pathway in endometrioid endometrial cancer, with beta-catenin or CTNNB1 mutations occurring in approximately 10–28% of

Microsatellite instability occurs in approximately 35% of endometrioid endometrial cancers.⁵⁶ The MSI phenotype results primarily from somatic silencing of MLH1 through promoter methylation. In a minority of cases, MSI results from germline mutations in the Lynch syndrome genes, including MLH1, MSH2, MSH6 or PMS2. MSI status has not been found to have prognostic significance in endometrioid endometrial cancer patients.

TP53 mutations occur in the majority of serous cancers. In addition to mutations, stabilization of the protein can also lead to p53 overexpression. Similar to high grade serous ovarian cancer, TP53 mutations occur early in the pathogenesis of uterine serous cancers. Other alterations that have been reported in uterine serous cancers include mutation in PPP2R1A, amplification and overexpression of ERBB2 or Her2/neu, mutations in FBXW7 and overexpression of cyclin E.^{43, 60–63}

Rather than through a single gene approach, the TCGA performed a large scale, integrated genomic analysis of both endometrioid and serous endometrial cancers.⁵³ Four molecular subtypes of endometrial cancer were defined, based on somatic mutations, copy number alterations, and microsatellite instability status. These four groups are: (1) POLE ultramutated; (2) hypermutated/microsatellite unstable; (3) copy number low/microsatellite stable, and (4) copy number high (serous-like). The first group, called POLE “ultramutated” tumors, includes the clinically most favorable tumors with endometrioid histology. POLE refers to DNA polymerase epsilon, which is involved in DNA replication and harbors numerous hotspot mutations in tumors in this category. There are few copy number abnormalities in tumors of the POLE subtype, but a very high number of mutations. Mutations in PTEN, PIK3R1, PIK3CA, and KRAS are common. The second group, called MSI “hypermutated” tumors, includes endometrioid tumors with microsatellite instability due to MLH1 promoter methylation, few copy number abnormalities, and mutation rates lower than the “ultramutated” POLE group but higher than the copy number low/MSS group. Mutations in KRAS and PTEN are frequent. The third group is the copy number low/MSS group which has PTEN and PIK3CA mutations, but is characterized by frequent beta catenin mutations. The fourth group is the copy number high (serous-like) tumors with extensive copy number abnormalities. In addition to most of the serous tumors, approximately one quarter of the grade 3 endometrioid patients fall in this category. Validation of these four subtypes is needed, as is defining its clinical utility. Another classification of endometrioid endometrial cancers has also been proposed, also based on TCGA gene expression data. In this classification, presence of beta catenin mutations in low grade endometrioid tumors was associated with a poor prognosis.⁶⁴ Our ultimate goal is to integrate known clinical and pathologic features with molecular data to develop a useful classification to better guide patient care.

Diagnosis

The median age for patients with adenocarcinoma of the endometrium is 61 years, with the highest prevalence during the sixth decade. Only 5% develop adenocarcinomas before the age of 40 years, and these are usually women with the abnormal syndromes discussed previously. Eighty percent of patients are post-menopausal. Irregular or postmenopausal bleeding is the presenting symptom in at least 75% of patients, and at the time of diagnosis, 75% of patients have disease confined to the uterus. Thus, it is obvious that irregular bleeding is a critical symptom, and by explaining it histologically, one has an opportunity to identify endometrial cancer when it is highly curable by relatively uncomplicated therapy.

The traditional technique for diagnosis has been fractional dilation and curettage of the uterus, with careful sampling of both the endometrial cavity and the endocervical canal. Once a procedure for the hospital operating room, this is now performed as an office procedure with greater than 95% accuracy.⁶⁵

⁶⁶ There will always be patients who require general anesthesia in a hospital setting, however, either because of very low pain thresholds, cervical stenosis, or other intercurrent ailments.

Hysteroscopy, either by direct observation or with video-camera amplification, allows direct assessment of the topography of the endometrial cavity with the possibility for more selective sampling and the assurance of not missing any occult lesions. Many reserve this procedure as an accompaniment to formal dilation and curettage under anesthesia. However, caution should be exercised because hysteroscopic dissemination of malignant cells has been described in the literature.^{67, 68}

Imaging

Noninvasive radiographic imaging techniques, such as magnetic resonance imaging⁶⁹ and ultrasonography,⁷⁰ are not cost-effective for screening. For diagnosis and documenting recurrence, these techniques and CT scan and PET scan can achieve an accuracy rate above 80%.^{42, 71–76}

Staging

Historically, endometrial cancer staging was a clinical exercise, based on physical examination, noninvasive radiographic testing, and measurement of the depth of the uterine cavity. In 1988, the International Federation of Gynecology and Obstetrics (FIGO) introduced the requirement for surgical staging of patients with endometrial carcinoma following the GOG 33 study that demonstrated that 9.6% of 843 patients in clinical stage I had lymph node metastasis on comprehensive surgical staging.^{77–80}

In 2009, FIGO updated the surgical staging classification for endometrial cancers as indicated in [Table 2](#).⁴¹ In addition, in 2009 uterine carcinosarcomas were to continue to be staged using the 2009 FIGO staging for endometrial cancer and new specific Staging Classifications were developed for leiomyosarcomas, endometrial stromal sarcomas and uterine adenosarcomas ([Table 3](#)).

Table 3 Staging—endometrial carcinoma

TNM categories	FIGO ^a stages	Definition
<i>Primary tumor (T)</i>		
TX		Primary tumor cannot be assessed
T0		No evidence of Primary Tumor
Tis ^b		Carcinoma in situ (preinvasive carcinoma)
T1	I	Tumor confined to the corpus uteri
T1a	IA	Tumor limited to the endometrium or invades less than one-half of the myometrium
T1b	IB	Tumor invades one-half or more of the myometrium
T2	II	Tumor invades stromal connective tissue of the cervix but does not extend beyond the uterus ^c
T3a	IIIA	Tumor involves serosa and/or adnexa (direct extension or metastasis) ^d
T3b	IIIB	Vaginal involvement (direct extension or metastasis) or parametrial involvement ^d
	IIIC	Metastasis to pelvic and/or para-aortic lymph nodes ^d
T4	IVA	Tumor invades bladder mucosa and/or bowel (bullous edema is not sufficient to classify a tumor as T4)
<i>Regional Lymph Nodes (N)</i>		
NX		Regional lymph nodes cannot be assessed
N0		No regional lymph node metastasis
N1	IIIC1	Regional lymph node metastasis to pelvic lymph nodes (positive pelvic nodes)
N2	IIIC2	Regional lymph node metastasis to para-aortic lymph nodes, with or without positive pelvic lymph nodes
<i>Distant Metastasis (M)</i>		
M0		No distant metastasis
M1	IVB	Distant metastasis (includes metastasis to inguinal lymph nodes, intra-peritoneal disease or lung, liver or bone. It excludes metastasis to para-aortic lymph nodes, vagina, pelvic serosa or adnexa)

^a Either G1, G2, or G3.

^b Note: FIGO no longer includes Stage 0 (Tis).

^c Endocervical glandular involvement only should be considered as Stage I and no longer as Stage II.

^d Positive cytology has to be reported separately without changing the stage.

Data from Pecorelli 2009⁴¹ and Edge 2010.⁸¹

Surgical staging requires the performance of total hysterectomy, bilateral salpingo-oophorectomy, and washings for cytologic examination. Lymph node sampling from the pelvic and para-aortic lymph nodes is

preferred for those patients whose cancers are other than well-differentiated with greater than minimal myometrial penetration. While the tradition has been to perform this surgery abdominally (typically through a vertical midline incision), minimally invasive techniques have increasingly been integrated into the forefront with conventional or robotic-assisted laparoscopy.⁸² There has been investigational assessment of the role of sentinel lymph node identification with colorimetric and fluorescent imaging to minimize the impact of extensive lymph node dissection.^{83, 84}

Initially, the adoption of a surgical staging system created controversy regarding what constitutes an adequate staging procedure, which patients should be surgically staged, and whether extensive staging or lymphadenectomy has therapeutic value.⁷⁹

Prognostic factors

Several factors have been identified in large prospective surgical-pathologic staging studies conducted by the GOG^{77, 80} that are predictive of extrauterine spread of disease at the time of initial diagnosis and ultimate survival. Surgical stage and age are highly-significant prognostic features that maintain their significance in each of the analyses performed in the various reports.

Histologic type

Whereas 80–95% of endometrial cancers are classic endometrioid adenocarcinomas, the remainder constitute a series of histologic types with a more unfavorable prognosis. These include serous papillary adenocarcinoma and clear cell, undifferentiated, and squamous cancers. These cell types confer an unfavorable prognosis independent of other known prognostic factors ([Table 1](#)).⁸⁵

Tumor grade

Within classic endometrioid adenocarcinomas, tumor grade is highly significant as an independent prognostic factor ([Table 4](#)). In addition, numerous studies have demonstrated that, in general, there is a greater tendency for the less differentiated tumors to be associated with other poor prognostic factors, including deep myometrial penetration, vascular space invasion, and increasing stage.^{80, 86, 87} Salvesen and colleagues showed that morphometric nuclear grade was a stronger prognostic factor than subjective histologic grade.⁸⁸

Table 4 Histopathology: degree of differentiation

G1:	5% or less of a nonsquamous or nonmorular solid growth pattern.
G2:	6% to 50% of a nonsquamous or nonmorular solid growth pattern.
G3:	More than 50% of a nonsquamous or non-morular solid growth pattern.

Myometrial invasion

The depth of myometrial penetration is a very important independent prognostic factor for outcome in stage I disease. Deeper penetration is associated with higher probabilities of tumor recurrence and death.^{80, 86, 89} Although increasing depth of invasion correlates with increasing grade of tumor, depth appears to be a more significant prognostic factor and predicts for the presence of extrauterine disease as detected at surgical staging procedures.⁷⁷ Regardless of grade, however, only 1% of patients with disease confined to the endometrium have extrauterine disease compared with patients with deep muscle invasion,

for which the incidence of pelvic node invasion rises to 25% and para-aortic nodal involvement rises to 17%.⁷⁷ DiSaia and colleagues found that patients with only endometrial involvement had an 8% recurrence rate compared with 12% if there was superficial or intermediate myometrial invasion versus 46% if there was involvement of the outer third of the myometrium.⁸⁹

Capillary lymphatic space invasion

Vascular space invasion is a significant risk factor for recurrence, but it is not as important as the grade and depth of myometrial penetration. Approximately 15% of endometrial adenocarcinomas have capillary-like space invasion and is associated with a five-fold increase rate of positive pelvic (27%) and para-aortic lymph (19%) node involvement.^{77, 90}

Positive peritoneal cytology

Positive peritoneal cytology as the sole upstaging factor was dropped in the 2009 FIGO staging revisions as a stage-defining characteristic.⁴¹ The presence of positive peritoneal cytology in washings is associated with an increased risk of relapse.⁸⁰ Approximately 15% of patients have positive peritoneal cytology⁸⁰ and this is often related to other poor prognostic factors, such as high grade or deep myometrial penetration. Thus, it is not surprising that it is also associated with an increased risk of metastases to pelvic (25%) and paraaortic (19%) lymph nodes. Opinions and data in the literature conflict with respect to interpreting the independent prognostic significance of peritoneal cytology. Approximately 5% of patients with positive peritoneal cytology have no evidence of extrauterine disease,⁷⁷ but approximately one-third of patients with extrauterine disease do have positive cytology. In a review of the literature, Wethington categorized patients into groups based on low-risk uterine features (grade 1–2, <50% depth of invasion, no lymphovascular space invasion) with positive peritoneal cytology. In this group, positive cytology occurred in 11% of cases and had a recurrence rate of 4%. Patients with higher-risk features plus positive cytology had a 32% risk of recurrence.⁹¹

Race

Liu and colleagues reviewed the treatment patterns, risk factors, and survival of 219 patients treated surgically for endometrial cancer between 1990 and 1993.⁹² In this study, black women, when compared with white women, had a higher incidence of unfavorable histology (38% vs 12%), advanced-stage disease (51% vs 19%), poor differentiation (49% vs 18%), and poor survival.

Hormone receptor status

The presence of cytoplasmic ER- and PR- binding proteins has been quantitatively associated with better histologic differentiation,⁹³ favorable histologic subtype, and response to therapy.^{94–96} Ligand binding to ER and PR was higher in well-differentiated lesions and was significantly lower in grade 3 lesions and the nonendometrioid carcinomas.⁹⁶ Alterations in receptor expression, receptor assembly and activation, response element recognition, and/or receptor degradation are among the possible explanations for loss of hormone binding. In addition, recent evidence suggests that promoter site hypermethylation might account in part for the loss of ER.⁹⁷ Likewise, differential expression of the PR-alpha (PRA) and PR-beta (PRB) have been reported.⁹⁸ PRA appears to down-regulate ER action and PRB is the primary activator of the progesterone responsive gene, and the loss of either would theoretically result in an unopposed estrogen effect. Clinically, reduced levels of ligand interaction with the ER, PR or both in endometrial cancer samples significantly ($p < .01$) correlate with recurrence and death from disease.^{95, 96}

Treatment of primary disease

Surgery

The initial surgical staging procedure, outlined earlier (see [Figure 2](#)), is the standard therapeutic procedure as well. When there is disease outside the uterus and in the retroperitoneal nodes, there is no reason to believe that aggressive cytoreductive efforts might not help in presenting a reduced tumor burden during adjunctive therapy, despite the absence of a clinical trial suggesting efficacy.

Figure 2 Surgical management of endometrial carcinoma.

There are occasions when, at the time of staging laparotomy, cervical or parametrial invasion is detected and a radical (Wertheim) hysterectomy with pelvic and aortic lymphadenectomy is performed to achieve clearance of all disease. However, the addition of tailored external beam RT following surgery has largely eliminated the routine performance of such procedures.⁹⁹

Surgery for recurrent disease is generally confined to those patients who have symptoms of intestinal or urinary tract obstruction, isolated regional recurrence, or isolated lung metastases that have not responded to cytotoxic or hormonal therapy. For such patients, surgery may be useful to correct functional deficits or to excise isolated recurrences or resistant metastatic deposits.

After several years of debate and discussion, minimally invasive techniques have been integrated into the management of endometrial cancer as a standard of care.¹⁰⁰ Techniques utilized in the initial treatment of endometrial cancer include laparoscopic assisted vaginal hysterectomy (LAVH),^{101–105} total laparoscopic hysterectomy (TLH),^{106–108} and robotic hysterectomy⁸² with pelvic and paraaortic nodal dissection to stage patients. Minimally invasive staging techniques include transperitoneal and extraperitoneal assessment of nodes, and may be done at the time of hysterectomy or at a later time to re-stage patients following incomplete surgical staging. Robotic surgery may represent the next step forward in minimally invasive surgery. Since FDA approval for hysterectomy and myomectomy procedures in 2005, there has been an increasing utilization of robotic surgery within gynecologic oncology.^{82, 109–113}

The role of Sentinel Lymph Node (SLN) mapping for endometrial cancer staging is currently being evaluated, however, there is no randomized trial reported yet. According to current NCCN guidelines, SLN may be considered (category 3) during surgical staging of apparent uterine confined cancer when there is no metastasis demonstrated by imaging studies and no obvious disease at exploration. The expertise of the surgeon and attention to technical detail is critical.^{83, 84, 114}

Radiation therapy (RT)

Although surgery, where possible, constitutes the definitive primary treatment for most patients with endometrial carcinoma, it is clear that RT is the second most effective modality in its management.

Definitive irradiation for inoperable patients

Modern surgical techniques and improved postoperative care have diminished the number of patients considered inoperable. Nevertheless, because endometrial cancer is frequently a disease of the elderly (over 65 years of age), who are often obese and sometimes diabetic with other co-morbidities, surgery is not always possible. Several relatively large series have demonstrated pelvic RT as effective definitive

management of endometrial cancer without initial surgery.^{115–119}

The proportion surviving depends on tumor grade, just as for patients treated surgically; those with grade 1 tumors have better survival rates than do those with grade 3.¹¹⁵ Significant numbers of patients die of causes unrelated to their primary carcinoma.¹¹⁹ Inoperable patients who did not die from comorbidities had a median 5-year survival rate that approached that of operable patients.¹¹⁹

Some patients with small uteri may be cured by intracavitary radiation only, but usually, definitive management consists of both external beam and intracavitary irradiation because of more favorable radiation dosimetry. Complication rates are acceptable (usually less than 10%). After definitive irradiation, the pattern of failure in contrast to that following surgery, consists mainly of central failure in the uterus. This observation is important for developing treatment strategies for patients with stage II disease. Removal of the uterus at some point in treatment provides better overall central control than that achieved by radiation alone. Three series indicate 5-year survival rates of approximately 50% for patients with Stage II disease who received RT as definitive therapy.^{99, 115, 120, 121}

Kucera and colleagues reported their experience with high-dose iridium-192 intracavitary brachytherapy without additional external beam radiation in 228 patients.¹²² At 5 years, the overall survival rate was 59.7%. In clinical stage IA disease, the survival rate was 88.6% at 5 years and 82.7% at 10 years—significantly different in comparison with 80.2% and 63.4%, respectively, in stage IB disease. Others have also reported high-dose-rate brachytherapy with or without external beam radiation,^{123, 124} and the American Brachytherapy Society published guidelines and recommendations.^{124, 125}

Adjuvant RT for stage I disease

The present recommendation to give postoperative RT in surgical stage I is dependent on prognosis as defined by the histologic features of the primary tumor within the endometrium. Extensive staging studies have identified that several of the aforementioned factors predict for the presence of clinically occult extrauterine disease.⁸⁰

Although patients considered to be at high risk of recurrence (e.g., those with grade 2 or 3 disease with penetration of the outer 50% of the myometrium) have generally been treated with postoperative adjuvant RT, there is only one randomized trial addressing the benefit of adjuvant RT in surgically staged patients (GOG-99).¹²⁶ There are three randomized clinical trials in patients who had incomplete surgical staging (Aalders,⁸⁶ Portec-1,¹²⁷ and Portec-2¹²⁸).

The GOG-99 study stratified risk and validated pelvic radiation therapy (RT) for improved recurrence free survival in the high intermediate risk (HIR) group. The HIR subgroup of patients was defined (as an increased recurrence rate of 25% at 5 years based on GOG 33) as those with¹ moderately to poorly differentiated tumor, the presence of lymphovascular invasion, and outer third myometrial invasion;² age 50 years or greater with any two of the risk factors listed above; or³ age of at least 70 years with any risk factor listed above. The treatment difference was particularly evident among the HIR subgroup (2-year cumulative incidence of recurrence in NAT vs RT: 26% vs 6%; RH = 0.42). Overall, radiation had a substantial impact on pelvic and vaginal recurrences (18 in NAT and 3 in RT),¹²⁶ but did not achieve a significant difference in overall survival.

Vault irradiation

On a theoretic basis, the patient who undergoes thorough staging, ideally with a bilateral pelvic and lower

para-aortic lymphadenectomy, might be at low risk of a pelvic side wall recurrence in the absence of lymph node metastasis. Other occult pelvic side wall disease not found at surgery, such as in the lymphatic channels in the parametrium or in parametrial lymph nodes, occurs infrequently and is an unlikely source of recurrence. The major site for possible recurrence within the pelvis for these patients would be the vaginal vault, which is amenable to brachytherapy with a lower morbidity.^{129, 130} There are several retrospective studies which have demonstrated rare pelvic recurrences in high-risk patients (stage IB, grade 3 and stage IC) who undergo therapeutic pelvic lymphadenectomy and either no RT^{131, 132} or vault brachytherapy¹³² alone in the absence of lymph node metastasis.^{130, 133–137} In addition the prospective data from PORTEC-2 supports this hypothesis for vaginal brachytherapy alone in unstaged patients with HIR features by the PORTEC definition (where intermediate risk factors were outer-half invasion, grade 3, or greater than 60 years of age, but excluded deeply invasive high-grade tumors, and where patients were deemed HIR with two of the three factors). At a median follow-up of 45 months, the estimated 5-year vaginal recurrence rates were 1.8% for brachytherapy alone and 1.6% for external irradiation. The nodal failure rate was significantly different at 3.8% for the brachytherapy-alone arm and 0.5% for external beam irradiation. Distant metastases, disease-free survival, and OS were similar in both arms.¹²⁸

Stage III

The 2009 FIGO surgical staging for endometrial cancer includes patients with metastases to pelvic and/or para-aortic lymph nodes as stage IIIC. The current staging classification covers a broad spectrum of prognostic groups that have diverse outcomes after standard surgery with or without adjuvant pelvic irradiation. Unfortunately, many of the published series include patients with microscopic extension to the adnexa (stage IIIA), those with malignant ascites (stage IIIA), and those with gross pelvic side wall disease (stage IIIA or IIIC) without distinction, resulting in widely variable survival data.

Treatment recommendations at this time for patients with stage III disease must be made on an individual basis. Those in whom appropriate surgical staging has been completed without evidence of disease beyond the ovaries should be considered for adjuvant postoperative pelvic irradiation, although the importance of microscopic adnexal invasion in patients without other risk factors is unclear. For those who have had surgical staging and who have pelvic but not para-aortic nodal involvement, it may be appropriate to offer postoperative adjuvant irradiation confined to the pelvis. Disease-free survival rates between 35% and 60% have been reported for patients receiving 45–50 Gy of external beam irradiation to the paraaortic nodes, usually with pelvic irradiation. In almost no case is macroscopic para-aortic nodal disease curable with RT without complete cytoreduction first.^{65, 70, 80, 138–148} Retrospective data from Johns Hopkins Hospital suggest that in patients with stage IIIC endometrial carcinoma, complete resection of macroscopic nodal disease and the administration of adjuvant chemotherapy, in addition to directed RT, are associated with improved survival ([Figure 3](#)).¹⁴⁹

Figure 3 Postoperative management of endometrial carcinoma. EFRT = extended field radiation therapy; PRT = pelvic radiation therapy; VBT = vaginal brachytherapy; WAR = whole abdominopelvic radiotherapy; LIR = low intermediate risk; HIR = high intermediate risk based on Gynecologic Oncology Group 99: age <50, 50–70, >70, LVSI = lymph–vascular space invasion, outer third invasion, grade 2 or 3 (see text).

Some subsets of Stage III endometrial cancer patients may be candidates for cytotoxic chemotherapy with or without RT and two Phase III trials are currently evaluating this concept (GOG 258 and Portec 3).

Adjuvant chemotherapy for high risk early stage disease

Stringer et al¹⁵⁰ studied 31 patients with high risk stage I endometrial cancer and 2 patients with occult stage II disease. Postoperatively, the patients were treated with cisplatin, 50 mg/m², doxorubicin, 50 mg/m², and cyclophosphamide, 500 mg/m², (CAP) every 4 weeks for six cycles. The 2-year progression-free interval rate was 79%, and the 2-year survival was 83%. The median survival time for patients was not reached at 45 months. These results were considered superior to those of historical controls from the same institution.

The GOG randomized patients with high risk clinical stage I and stage II disease to postoperative whole-pelvis irradiation with or without doxorubicin and found no difference in PFI and OS.¹⁵¹

The Japanese GOG was designed to address the relative efficacy of CAP chemotherapy versus WPRT in Stage IC to III. Although there was no difference in PFS or OS in the entire cohort, a subgroup analysis of 120 HIR patients reported improved PFR and OS.¹⁵²

GOG 249 is the phase III trial that examined vaginal cuff brachytherapy followed by three cycles of Paclitaxil / carboplatin (TC) chemotherapy versus external beam RT in patients with high risk uterine confined endometrial carcinoma. The preliminary results presented at SGO 2014 suggest no significant difference in survival outcomes between the groups.

In a study of 74 patients with Stage I UPSC, Kelly et al have demonstrated that all patients with residual disease (including disease confined to the endometrium) have improved PRI and OS with adjuvant platinum based chemotherapy. There were no vaginal recurrences in those receiving vaginal brachytherapy.^{45, 153} Because clear cell carcinoma behaves like UPSC, despite the absence of data they should be treated in a similar fashion with TC chemotherapy and vaginal brachytherapy.^{45, 52}

Treatment of recurrent disease

Radiotherapy

Patients who develop isolated vaginal recurrences without previous radiation can expect a salvage rate of 80% with RT.¹⁵⁴ Those who develop a component of extra pelvic recurrence will require systemic therapy.

In the patient who has had initial adjuvant postoperative pelvic irradiation, there may rarely be a role for interstitial therapy at relapse if there is isolated central pelvic failure. For some, systemic therapy may be applicable. For patients with other sites of disease or bony, cerebral, or nodal metastases, short courses of palliative irradiation may be useful in relieving the symptoms of disease. Similarly, palliative irradiation may be used for the uncommon patient (approximately 3% of those at presentation) who has stage IV disease.

Surgery

Unlike ovarian carcinoma, little is known regarding the role of secondary cytoreduction in recurrent endometrial carcinoma.¹⁵⁵ In a report from an Italian group, 20 women with recurrent endometrial adenocarcinoma were treated with maximal cytoreductive surgery.¹⁵⁶ Sixty-five percent of patients had complete resection of their tumor. Women with no residual tumor had a significantly increased progression-free and overall survival compared with women with residual tumor; however, there was a 10% perioperative death rate in this series. The role of pelvic exenteration was examined in a four-

institution retrospective review of 31 patients.¹⁵⁷ Twenty patients underwent exenteration with curative intent, all of whom had received pelvic irradiation previously. The 5-year disease-free survival rate was 45%.

Cytotoxic chemotherapy

Cytotoxic chemotherapy for patients with endometrial cancer was rarely administered before 1980. In his 1974 literature review, Donovan reported only 126 patients who had been treated with 16 different agents.¹⁵⁸ In 1977, Muggia and colleagues reported that doxorubicin (Adriamycin, 37.5 mg/m²) in combination with cyclophosphamide (500 mg/m²) intravenously (IV) every 21 days in 11 patients with recurrent endometrial cancer resulted in five objective responses.¹⁵⁹ The GOG studied single-agent doxorubicin at a dose rate of 60 mg/m² IV every 3 weeks and reported a 37% response rate in 43 patients.¹⁶⁰ Although the most frequent adverse effect was on the hematopoietic system, cardiac toxicity occurred in 12%, and there was one cardiotoxic death in a patient who had received more than 500 mg/m² of drug. This study was important because it clearly established the value of doxorubicin as a single agent in the chemotherapy of endometrial cancer. Studies by GOG and The Eastern Cooperative Oncology Group demonstrated no benefit from adding cyclophosphamide ([Table 6](#)).^{175, 176}

The GOG found no efficacy for cisplatin alone in heavily-pretreated patients¹⁷⁷; however, Trope observed four responses (36%) in 11 chemotherapy-naïve patients given cisplatin, 50 mg/m².¹⁷⁸

A combination of cisplatin and doxorubicin in advanced or recurrent endometrial cancer produced response rates of 33–80%, depending on the proportion of patients treated previously with either chemotherapy or radiation.^{146, 147}

If one selects only drugs that have achieved at least a 20% response rate in studies including at least 20 patients, the list is small ([Table 5](#)). Paclitaxel is an active drug in recurrent endometrial adenocarcinoma. The GOG studied paclitaxel in patients with advanced or recurrent adenocarcinoma of the endometrium.¹⁴⁴ Among 28 evaluable patients, four complete responses and six partial responses were observed, for an overall response rate of 35.7%. Similarly, Lissoni and colleagues evaluated paclitaxel in 19 patients with advanced endometrial adenocarcinoma previously treated with cisplatin, doxorubicin, and cyclophosphamide.¹⁴⁵ Two complete responses and five partial responses were achieved, for an overall response rate of 37%.

Table 5 Single-agent cytotoxic chemotherapy for endometrial cancer

Agent	Reference	N	Prior treatment	No CR + PR	(%)
Paclitaxel	144	28	No	4 + 6	36
Paclitaxel	145	19	Yes	2 + 5	37
Cisplatin	161, 162	75	No	3 + 18	28
Carboplatin	163–165	76	No	5 + 18	28
Doxorubicin	160, 166, 167	280	No	31 + 49	29
Epirubicin	168	27	No	2 + 5	26
Fluorouracil	169	34	NS	7	21
HMM	170	30	No	10	33
Docetaxel	171	35	No	3+4	21
Topotecan	172, 173	42	No	3+5	20

Note: Reported series with at least 20 patients with a response rate of at least 20%.

HMM = Hexamethylmelamine.

CR = complete response; PR = partial response. NS = Not stated.

Data from Muss,¹⁷⁴ Thigpen.¹⁶⁶

Our best information on combination chemotherapy comes from the randomized phase III trials listed in [Table 6](#). The randomized trials that have included hormonal therapy are listed in [Table 7](#).

Table 6 Randomized trials of combination chemotherapy regimens for endometrial cancer

Author	Year	Regimen	Number evaluable	RR %	Median PFS (months)	Median overall survival (months)
Thigpen ¹⁷⁶	1994	A	132	22	3.2	6.7
		AC	144	30	3.9	7.3
Thigpen ¹⁶⁶	2004	A	150	25	3.8	9.2
		AP	131	42*	5.7*	9.0
Aapro ¹⁶⁷	2003	A	87	17	7.0	7.0
		AP	90	43*	8.0	9.0*
Gallion ¹⁷⁹	2003	AP standard	169	46	6.5	11.2
		AP circadian	173	49	5.9	13.2
Fleming ¹⁸⁰	2004	AP	157	40	7.2	12.6
		AT	160	43	6.0	13.6
Fleming ¹⁸¹	2004	AP	129	34	5.3	12.3
		TAP	134	57*	8.3*	15.3*

PFS = Progression Free Survival;
 RR = response rate = complete response + partial response;
 C = cyclophosphamide;
 A = doxorubicin (Adriamycin); P = cisplatin; F = 5-fluorouracil.
 T = Paclitaxel * = Significant difference.

Table 7 Randomized trials of combination chemotherapy + hormonal therapy for endometrial cancer

Author	Year	Regimen	Number evaluable	RR %
Horton ¹⁸²	1982	CA + MA	55	27
		CAF + MA	56	16
Cohen ¹⁸³	1984	F- Mel + MA	126	38
		CAF + MA	131	36
Ayoub ¹⁸⁴	1988	CAF	20	15
		CAF + MPA/TAM	23	43*
Cornelison ¹⁸⁵	1995	APE + MA	50	54
		F-Mel + MPA	50	48

RR = response rate = complete response + partial response; C = cyclophosphamide;
 A = doxorubicin (Adriamycin); P = cisplatin; F = 5-fluorouracil; Mel = melphalan.
 MA = Megestrol acetate; MPA = Medroxyprogesterone acetate.
 TAM = Tamoxifen.
 * = Significant difference.

Table 6 lists the randomized trials that compared single agents with one or two different combinations. In the European Organisation for Research and Treatment of Cancer (EORTC) study reported by van Wijk and colleagues, a survival advantage was demonstrated with a response rate of 43% for the doxorubicin and cisplatin combination versus 17% for single-agent doxorubicin (p < 0.001).¹⁴⁸ The GOG found no difference when doxorubicin and cisplatin were administered in a circadian fashion compared with a standard fashion.¹⁷⁹

The GOG also conducted a phase III study of doxorubicin plus cisplatin versus doxorubicin plus 24-hour paclitaxel in primary stage III or IV or recurrent endometrial carcinoma. This study found no difference in response rate, progression-free survival, or overall survival.¹⁸⁰

The next phase III prospective randomized GOG study (Protocol 177) compared standard doxorubicin (60 mg/m2) and cisplatin (50 mg/m2), that is, AP against TAP (Taxol 160 mg/m2/3 h), doxorubicin (45 mg/m2), and cisplatin (50 mg/m2).¹⁸¹ Two hundred sixty-six patients were randomized, and the results indicated that TAP produced a significant improvement in response rate (57% vs 34%; p < 0.01), progression-free survival (median 8.3 vs 5.3 months; p < 0.01) and overall survival (median 15.3 vs 12.3 months; p = 0.037). Neurologic toxicity was worse for those receiving TAP, with 12% grade 3 and 27% grade 2 peripheral neuropathy.

The GOG followed up with GOG Protocol 209 which randomly assigned patients with advanced (stage IVB) or recurrent disease to either TAP or TC (paclitaxel and carboplatin). Trial data presented in 2012 demonstrated similar oncologic outcomes but the toxicity and tolerability profile favored TC.¹⁸⁶

In patients with surgical bulk reduction (to residual < 2 cm) for stage III to IVA disease, a randomized phase III trial, GOG Protocol 122, demonstrated that chemotherapy with doxorubicin (60 mg/m²) and cisplatin (50 mg/m²) had superior progression-free survival (0.71; 95% confidence interval [CI] = 0.55–0.91; $p < 0.01$) and overall survival (0.68; 95% CI = 0.52–0.89; $p < 0.01$)¹⁵⁰ compared with whole-abdomen radiation.¹⁸⁷

Hormone therapy

Kelly and Baker, in 1961, described six objective responses in 21 patients that lasted from 9 months to 4.5 years.¹⁸⁸ Since then, numerous reports described treatment with a variety of progestational drugs: most commonly 17-hydroxyprogesterone caproate, medroxyprogesterone acetate (MPA), and megestrol acetate (MA). Reifstein analyzed 992 patients treated with hydroxyprogesterone caproate by 113 investigators.¹⁸⁹ He studied the records of 314 patients in detail and found that there was little response before 7 weeks of treatment, that the longest remissions were achieved with a minimum of 12 weeks of initial therapy, and that there was no relationship between clinical response and patient age when correction was made for tumor differentiation. Kauppila reviewed 1,068 patients treated in 17 different trials with either MPA (Provera), MA, or hydroxyprogesterone caproate and found an overall response rate of 34%.¹⁹⁰ The duration of response was approximately 20 months and the average survival time was approximately 25 months.

The optimum dose for progestational treatment has not been determined and the doses employed in the most recent GOG studies were based on dose-seeking studies by Kohorn and Thigpen.^{191, 192} There is no evidence that lower doses are not equally effective and there is no advantage for the parenteral route¹⁹⁰; therefore, selecting lower doses in special circumstances may be permissible in order to avoid complications.

Ramirez and colleagues,¹⁹³ in reviewing the literature, found that the majority of patients with well-differentiated endometrial adenocarcinoma who undergo conservative treatment for primary uterine cancer (in lieu of hysterectomy) with a progestational agent respond to treatment (62 of 81 = 76%). When an initial response is not achieved or when disease recurs after an initial response (15 of 62 = 24%), carcinoma extending beyond the uterus is rare. In addition, Montz and colleagues¹⁹⁴ described the feasibility of using a progesterone-containing intrauterine device to treat presumed FIGO stage IA, grade 1 endometrioid cancer in women at high risk of perioperative complications.

In summary, the following generalizations can be made concerning progestational therapy:¹ the response rate for patients with advanced or recurrent endometrial carcinoma ranges from 10–30%, probably relating to the receptor level in the tumor;² well-differentiated cancers respond best;³ the PR level diminishes sharply as the grade of the tumor increases;⁴ clinical responses may not occur before 7–12 weeks of therapy;⁵ two-thirds of patients will not respond;⁶ there is no published evidence that progestational agents employed in an adjuvant mode offer any benefit;⁷ appropriate oral doses based on GOG studies are 160 mg/day of megestrol or 200 mg/day of MPA; however, lower doses can be individualized; and⁸ oral progestins and the progesterone-containing intrauterine device are alternatives to consider for primary treatment of selected cases of early-stage, low-grade endometrial cancer.

Tamoxifen

Hormonal therapy by agents other than progestogens has been studied by many researchers. Extrapolating from the experience with breast cancer, investigators employed tamoxifen in doses of 20–40 mg daily for

patients with advanced or recurrent endometrial carcinoma. In a review of eight published studies, Moore and colleagues¹⁹⁵ described an overall response rate of 22%. As one might predict, there is a wide spectrum of reported responses, ranging from 0–53%.¹⁹⁶ This variation may be explained by the report of Edmonson and colleagues,¹⁹⁷ who found a 21% response rate in patients naive to hormone therapy and no response in patients who had failed progesterone treatment. Not unlike the progestin experience, it would seem that tamoxifen is more likely to be effective in patients with low-grade tumors, receptor positivity, and either no previous hormone therapy or a previous response to progestin therapy.

Because progestins ultimately down-regulate PRs, and because tamoxifen induces these receptors in target tissues, the notion of the combined administration of these hormones has been examined by the GOG with two different strategies. In Whitney and colleagues' report, tamoxifen citrate 40 mg/day combined with alternating weekly cycles of MPA 200 mg/day in 58 patients with recurrent or measurable advanced endometrial carcinoma resulted in a 33% response rate (10.3% complete response and 23.4% partial response), with a median progression-free interval of 3 months and a median overall survival of 13 months.¹⁹⁸ In the Fiorica study, alternating 3-week courses of MA (160 mg/day) and tamoxifen citrate (40 mg/day) in 56 patients with recurrent or measurable advanced endometrial carcinoma produced a 27% response rate (21.4% complete response and 5.4% partial response), with a median progression-free interval of 2.7 months and a median overall survival of 14.0 months.¹⁹⁹

The combination of tamoxifen, progestin, and chemotherapy has also been tested. Ayoub and colleagues studied 46 patients with metastatic endometrial cancer, randomly assigning them to receive monthly cycles of cyclophosphamide, adriamycin (doxorubicin), and 5-fluorouracil (CAF) or CAF plus MPA, 200 mg daily for 3 weeks, followed cyclically by tamoxifen, 20 mg daily for 3 weeks.¹⁸⁴ Objective responses of 15% and 43% were seen, respectively, with CAF and CAF plus hormonal therapy ($p = 0.05$). Because progestational agents have not improved the response to chemotherapy in previously cited studies,²⁰⁰ it is reasonable to attribute this difference to the addition of tamoxifen. Pinelli and colleagues evaluated sequential cyclical hormone therapy (MA and tamoxifen citrate) plus the single agent carboplatin.²⁰¹ Of 13 evaluable patients, 4 patients had a complete response and 6 had partial responses, for an overall response rate of 77%. The median progression-free interval was 14 months for complete responders. The median survival was 11 months for all patients and 33 months for complete responders.

Other hormones

Gonadotropin-releasing hormone analogues have been tested in small phase II trials of patients with recurrent endometrial carcinoma, with response rates varying from 0% to 35%.^{202–204} Aromatase inhibitors have been tested in a limited fashion. The GOG phase II trial had a 9% response rate (2 partial responses of 23) with anastrozole,^{205–207} whereas the Canadian National Cancer Institute study reported a 9.4% response rate (2 partial responses of 28) with letrozole.²⁰⁸

Biologic therapies

New molecular and biologic therapies for recurrent or metastatic endometrial cancer are being evaluated in clinical trials. In a phase II trial of 52 evaluable patients (with up to two prior chemotherapy regimens), bevacizumab demonstrated a 13.5% response rate and an overall survival of 10.5 months.²⁰⁹ Preliminary results of a phase II trial of the mTOR inhibitor temsirolimus in chemo-naïve patients with recurrent or metastatic endometrial cancer were encouraging with 5 (27%) partial responses out of 19 evaluable patients.²¹⁰ A phase II trial of the mTOR inhibitor everolimus combined with an aromatase

inhibitor letrozole demonstrated a 32% response rate (n = 35; nine complete responses and two partial responses) in patients with recurrent endometrial cancer.²¹¹

The future

Efforts must continue to expand information about molecular characteristics to better define patient susceptibilities and therapeutic possibilities. From a surgical standpoint, laparoscopy and robotic surgery are now accepted as standard techniques, but the role of sentinel lymph node assessment is still incompletely defined. For patients with early disease and poor prognostic features, further randomized studies comparing RT with systemic therapy are required. For patients with advanced or recurrent disease, better systemic therapy including biologic agents must be identified. It is obvious that with a cure rate in the United States of approximately 80%, it will be essential that patients with poor prognostic features or recurrent or metastatic disease be entered into collaborative trials to maximize the opportunities for improving survival.

Chapter 104

Epithelial ovarian, fallopian tube, and peritoneal cancer

Jonathan S. Berek, MD, MMS, FASCO ■ Michael L. Friedlander, MD, MBChB, PhD ■ Robert C. Bast Jr. MD

Overview

Ovarian cancer is one of the most treatable solid tumors, as the majority will respond temporarily to surgery and cytotoxic agents. The disease, however, frequently persists and recurs in 70% of cases, having the highest fatality-to-case ratio of all the gynecologic cancers.^{1, 2} Ovarian cancer is neither a common nor a rare disease, with a lifetime risk of 1 in 70 and a prevalence in the postmenopausal population in the United States of 1 in 2500, which impact strategies for early detection and prevention. Germ line mutations of BRCA1 and BRCA2 are associated with 10–15% of ovarian cancers and increase the risk of ovarian cancer dramatically. Factors that contribute to persistent ovulation increase the risk in women with sporadic disease, whereas use of oral contraceptives decreases the risk of disease post menopause. While epithelial ovarian cancers have been thought to arise from the ovarian surface epithelium or in the lining of inclusion cysts beneath the ovarian surface, many high-grade serous “ovarian” carcinomas as well as peritoneal cancers are now believed to arise in the fimbriae of fallopian tube, rather than the ovary or peritoneum.^{3–10} Epithelial ovarian cancers can exhibit serous, endometrioid, mucinous, or clear cell histotypes. Low-grade type I ovarian cancers grow slowly, can evolve from tumors of low malignant potential, bear Ras mutations in a majority of cases, express wild type TP53, often are detected in early stage (I–II), and respond less frequently to platinum- and taxane-based therapy. High-grade type II ovarian cancers grow rapidly, arise from precursors with TP53 mutations, are driven by DNA copy number changes, are diagnosed in late stage (III–IV), and frequently respond to combination chemotherapy. Owing to a lack of specific symptoms or an effective screening strategy, more than 70% of ovarian cancers are diagnosed in an advanced stage (III–IV). Primary treatment of epithelial ovarian cancer involves cytoreductive surgery and 6–8 cycles of carboplatin and paclitaxel. For those women with small volumes of disease after surgery, intraperitoneal administration of chemotherapy improves survival. Recurrent disease cannot be cured with currently available agents, but survival can be prolonged with combinations of cytotoxic agents including retreatment with paclitaxel and carboplatin. Palliative agents include liposomal doxorubicin, gemcitabine, topotecan, bevacizumab, pemetrexed, and etoposide. Experimental therapy for low-grade cancers involves MEK inhibitors, whereas trials of PI3K pathway inhibitors and PARP inhibitors are underway in patients with high-grade epithelial ovarian cancers. Combinations of targeted agents will be required.

Incidence, etiology, and epidemiology

Incidence

Ovarian, fallopian tube, and peritoneal cancers are predominantly diseases of postmenopausal women, with only 10–15% of all cases diagnosed premenopause.^{1–3} The median age for diagnosis of epithelial

cancers from these three sites ranges between 60 and 65 years. Less than 1% of epithelial cancers are found in women younger than 30 years of age, and most ovarian malignancies in these younger patients are germ cell tumors (GCTs) (see **Chapter 105**).² The prevalence of ovarian cancer among postmenopausal women in the United States is 40 per 100,000 or 1 in 2500. The lifetime risk for a woman to develop ovarian cancer in the United States is approximately 1 in 70 (1.4%), compared to 1 in 8 or 9 for breast cancer. The prevalence of ovarian cancer in the general population impacts substantially on strategies for prevention and early detection. In the absence of better markers for increased risk, strategies for prevention must have few, if any, serious adverse effects and screening strategies must be highly specific. A strong hereditary component contributes to development of the disease in at least 10% of cases with inherited germ line mutations in *BRCA1* and *BRCA2* being the most common with only a small percentage of cases related to mutations in mismatch repair (MMR) genes or p53.

In 2015, in the United States, almost 22,000 new cases of ovarian cancer and more than 14,000 deaths are expected.¹ There is a trend toward improved survival for ovarian cancer.^{1, 2} On the basis of Surveillance, Epidemiology, and End Results (SEER) data in the United States, the 5-year survival for all stages combined increased from 33.6% in 1975 to 45.9% in 2003 to 2011.² Using statistical models for analysis, rates for new ovarian cancer cases have been falling on average 1% per year over the past 10 years. Death rates have been falling on average 1.6% per year over the same period. The death rate decreased 22% from 10 per 100,000 women per year in 1976 to 7.8 per 100,000 per women per year in 2010.² Ovarian cancer rates are highest in women aged 55–64 years (median age 63 years), and deaths are highest in people aged 75–84 years (median age 71 years).²

The incidence of ovarian cancer varies in different geographic locations throughout the world. Western countries, including the United States and the United Kingdom, have an incidence of ovarian cancer that is 3–7 times greater than in Japan, where epithelial ovarian tumors are considered rare.^{10, 11} In Asia, the incidence of GCTs of the ovary appears to be somewhat higher than in the West. Japanese immigrants to the United States, however, exhibit a significant increase in the incidence of epithelial ovarian cancer at a rate approaching that of white women from the United States. The incidence of epithelial tumors is about 1.5 times greater in whites than in blacks.

Etiology and epidemiology

In the past, most epithelial ovarian cancers were thought to arise from a single layer of epithelial cells that covers the ovarian surface or from the epithelial cells that line “inclusion cysts” immediately beneath the ovarian surface. Over the past decade, this view has been modified. Of all epithelial ovarian cancers, approximately 10–15% arise in women with germ line mutations of *BRCA1* and *BRCA2* and most of these are high-grade serous neoplasms. Up to 80% of these high-grade serous “ovarian cancers” associated with *BRCA1/2* mutations are derived from the fimbriae of the fallopian tube, accounting for at least 10% of all epithelial ovarian cancers. Some 20% of high-grade serous cancers coat the ovary rather than grow from it and have been termed “primary peritoneal carcinomas.” Most of these high-grade serous primary peritoneal cancers are likely to arise from fimbriae of the fallopian tube, although some may be derived from developmental remnants of the secondary Müllerian system.¹² Primary peritoneal carcinoma explains how “ovarian cancer” can arise in a patient whose ovaries, but not fallopian tubes, were surgically removed many years earlier.^{13–15} Thus, at least a third, and possibly a majority of high-grade serous cancers arise from the fallopian tube, although the remainder are still of ovarian origin. High-grade serous cancers of the ovary, fallopian tube carcinomas, and peritoneal carcinomas should be regarded as a single disease entity and managed with a common approach. In this regard, fallopian tube cancer is now included in the same FIGO (International Federation of Gynecology and Obstetrics) staging

system with ovarian cancer, as discussed in the following paragraph.⁴

The causes of ovarian cancer are not well understood.^{16, 17} Cigarette smoking has been linked to mucinous ovarian cancers but not to the more common serous carcinomas.¹⁷ Case–control studies have also pointed to an association of white race, high-fat diet, and galactose consumption with a higher incidence of the disease.^{16, 18} Prior reproductive history and the number of ovulatory cycles are associated with development of the disease, with low parity, infertility, early menarche, and late menopause increasing the risk.^{16, 19, 20} Fertility-enhancing drugs, such as clomiphene citrate, and gonadotropins used for ovulation induction have been thought to increase the risk of ovarian cancer (ROC), but the data have not been consistent and have not adequately distinguished the influence of infertility per se from the use of fertility-stimulating agents.^{21–24} A pooled analysis of eight case–control studies that included 5207 cases and 7705 controls found an association of fertility-stimulating drugs with serous borderline tumors but not with invasive ovarian cancers.²⁴ Many case–control and cohort studies have failed to link hormone replacement therapy to an increased risk of epithelial ovarian cancer.²⁵ A large cohort study had reopened controversy regarding this issue.²⁶ Among 44,241 postmenopausal women in the Breast Cancer Detection Demonstration Project, 329 developed ovarian cancer. Women who had received estrogen replacement therapy only for more than 10 years without progestin were at increased risk of developing ovarian cancer. By 20 years, the relative risk (RR) was 3.2-fold. This is supported by a recent meta-analysis, which included individual data from just over 12,000 postmenopausal women, 55% of whom had used hormone therapy, who developed ovarian cancer. Among women last recorded as current users, risk was increased even with <5 years of use (RR 10.43, 95% confidence interval [CI] 10.31–10.56; $p < 00.0001$). Combining current-or-recent use resulted in a RR of 10.37 (95% CI 10.29–10.46; $p < 00.0001$); this risk was similar in European and American prospective studies and for estrogen-only and estrogen–progestagen preparations but differed across the four main histological subtypes, being definitely increased only for the two most common types, serous (RR 10.53, 95% CI 10.40–10.66; $p < 00.0001$) and endometrioid (10.42, 10.20–10.67; $p < 00.0001$). The authors concluded that the increased risk may be causal and that women who use hormone therapy for 5 years from around age 50 years have about one extra ovarian cancer per 1000 users.²⁷

Prevention

As parity is inversely related to the ROC, having at least one child reduces the RR by 30–40% and use of oral contraceptives for 5 or more years reduces the risk by 50%.²¹ Women who have had two children and have used oral contraceptives for 5 or more years have as much as 70% reduction in risk. To date, oral contraceptive medication is the only documented method of chemoprevention for ovarian cancer, and it can be recommended to women for this purpose. When counseling patients regarding birth control options, this important benefit of oral contraceptive use should be emphasized. This is also important for women with a strong family history of ovarian cancer in the absence of BRCA1 or BRCA2 mutation.²⁸ Surgical prevention is important, but its use depends critically on identifying women at sufficient risk to justify prophylactic salpingo-oophorectomy with or without total abdominal hysterectomy.

Genetic predisposition

Hereditary ovarian cancer

The ROC is significantly higher than that of the general population in women with a family history of

breast or ovarian cancer as well as in families with Lynch syndrome.^{29–45} Although most epithelial ovarian cancer is sporadic, at least 10–13% of patients with epithelial ovarian cancer have a germ line mutation in either *BRCA1* or *BRCA2*.⁴²

BRCA1 and BRCA2

Most hereditary ovarian cancer results from mutations in the *BRCA1* gene, which is located on chromosome 17, with a smaller fraction of familial ovarian cancers associated with mutations in *BRCA2*, which is located on chromosome 13. Both genes mediate DNA repair. *BRCA1*-associated ovarian cancers generally occur in women approximately 10 years earlier than those with nonhereditary tumors.^{36, 42} As the median age of epithelial ovarian cancer is 62–63 years, a woman with a first- or second-degree relative who had early onset ovarian cancer may have a higher probability of having a *BRCA1* or *BRCA2* mutation. There is, however, no significant family history in 44% (95% CI, 35.8–52.2%) of mutation-positive women, which underscores the importance of offering mutation testing to all women with high-grade serous ovarian cancer diagnosed under the age of 70 irrespective of family history, and this is reflected in current guidelines.⁴⁴

There is a higher carrier rate of *BRCA1* and *BRCA2* mutations in women of Ashkenazi Jewish descent, Icelandic women, and in other ethnic groups.^{35, 36} There are three specific founder mutations that are carried by the Ashkenazi population: 185delAG and 5382insC on *BRCA1*, and 6174delT on *BRCA2*. The carrier rate of at least one of these mutations for a patient of Ashkenazi Jewish descent is 1 in 40 or 2.5%, which is considerably higher than the general Caucasian population. The increased risk is a result of the *founder effect*—that is, a higher rate of mutations that have occurred within a specific population group that was geographically or culturally isolated in the past in which one or more of the ancestors carried the mutant gene.

A combined analysis of 22 studies unselected for family history has found that women who have a germ line mutation in the *BRCA1* gene have a lifetime ROC of 39% (18–54%), and the risk has been calculated to be 11% (2.4–19%) in women with a *BRCA2* mutation.⁴⁵ Women with a *BRCA1* or *BRCA2* mutation have a risk of breast cancer as high as 65% and 45%, respectively. The breast cancers typically occur at a young age and may be bilateral. There is a higher incidence of triple-negative (ER-, PR-, HER2-) breast cancers in women with *BRCA1* mutations. A large consortium found genetic risk modifiers on 4q32.2 and 17q21.31 that significantly increased the risk of developing ovarian cancer in *BRCA1*-mutation carriers, which may explain the variable risks that have been reported.⁴⁶

Lynch syndrome

There are other less common genetic causes of ovarian cancer. Lynch syndrome, which is also known as the *hereditary nonpolyposis colorectal cancer (HNPCC) syndrome*, confers increased risk for colorectal cancer and a wide range of other malignancies (e.g., endometrial, ovarian, and gastric cancer) as a result of a germ line MMR genetic mutation.³⁹ The mutations that have been associated with this syndrome are *MSH2*, *MSH6*, *MLH1*, *PMS1*, and *PMS2*. The risk of endometrial cancer equals or exceeds that of colorectal cancer in women with Lynch Syndrome. The diagnosis of gynecologic cancer precedes that of colorectal cancer in over half the cases, making gynecologic cancer a “sentinel cancer” for Lynch syndrome. The lifetime ROC in women with Lynch Syndrome has been estimated at approximately 6–12%. The mean age at diagnosis is 42.7–49.5 years. There is a higher risk of endometrioid and clear cell subtypes, and the majority of cases are diagnosed in stage I or II.

The management of women at high risk for ovarian cancer

The management of a woman with a strong family history of epithelial ovarian cancer must be individualized and will depend on her age, reproductive plans, and the estimated level of risk. A thorough pedigree analysis is important. A geneticist should evaluate the family pedigree for at least three generations. Decisions about management are best made after careful study of the pedigree and, whenever possible, verification of the histologic diagnosis of the family members' ovarian cancer as well as the age of onset and other tumors in the family. Although recommended by the National Institutes of Health Consensus Conference on Ovarian Cancer⁴⁷, the value of screening with transvaginal ultrasonography and CA125 has not been established in women at high risk. The findings of two prospective studies of annual transvaginal ultrasonography and CA125 screening suggest a very limited benefit, if any, of screening high-risk women.^{48, 49}

Data derived from a multi-institutional consortium of genetic screening centers has suggested that the use of oral contraceptives is associated with a lower ROC in women who have a *BRCA1* or *BRCA2* mutation,⁵⁰ but this has not been confirmed.⁵¹ Tubal ligation may also decrease the ROC in patients with a *BRCA1* but not *BRCA2* mutation, but the protective effect is not nearly as strong as risk-reducing bilateral salpingo-oophorectomy (BSO).⁵²

The value of prophylactic risk-reducing BSO in these patients has been well documented.^{53–58} Occult ovarian/fallopian tube cancers detected at the time of risk-reducing BSO have been reported in many studies with wide variability in reported prevalence ranging from 2.3% to 23%. The performance of a prophylactic salpingo-oophorectomy reduces the risk of BRCA-related gynecologic cancer by 96%.⁵⁶ There remains a small risk of subsequently developing a peritoneal carcinoma. The risk of developing peritoneal carcinoma was 0.8% and 1%, respectively, in two series.^{54, 55} As discussed earlier, many so-called ovarian cancers arise from the fallopian tube, and it is essential that women having prophylactic surgery have their fallopian tubes removed as well and that these are carefully assessed by the pathologist as it is easy to miss small cancers or precursor lesions, particularly in the fimbrial end of the fallopian tube.⁶ Prophylactic salpingo-oophorectomy in premenopausal women also reduced the risk of developing subsequent breast cancer by 50–80%.^{54, 55}

Grann et al.⁵⁹ reported the application of Markov modeling—that is, quality-adjusted survival estimate analysis—in a simulated cohort of 30-year-old women who tested positive for *BRCA1* or *BRCA2* mutations. The analysis predicted that a 30-year-old woman could prolong her survival beyond that associated with surveillance alone by 1.8 years with *tamoxifen*, 2.6 years with prophylactic salpingo-oophorectomy, 4.6 years with both *tamoxifen* and prophylactic salpingo-oophorectomy, 3.5 years with prophylactic mastectomy, and 4.9 years with both prophylactic surgeries. Quality-adjusted life expectancy was estimated to be prolonged by 2.8 years for *tamoxifen*, 4.4 years with prophylactic salpingo-oophorectomy, 6.3 years for *tamoxifen* and prophylactic salpingo-oophorectomy, 2.6 years with mastectomy, and 2.6 years with both operations. This has been supported by a study of women with *BRCA1* and *BRCA2* mutations which found that risk-reducing mastectomy was associated with a lower risk of breast cancer, risk-reducing BSO was associated with a lower ROC, and that there was an improvement in all-cause mortality, breast cancer-specific mortality as well as ovarian cancer-specific mortality.⁶⁰

The survival of women who have a *BRCA1* or *BRCA2* mutation and develop ovarian cancer is longer than that for those who do not have a mutation. In one study, the median survival for mutation carriers was 53.4 months compared with 37.8 months for those with sporadic ovarian cancer from the same institution.⁶¹

These findings have recently been confirmed in a population-based study from Israel in which Chetrit et al.⁶² reported that among Ashkenazi women with ovarian cancer those with *BRCA1* and *BRCA2* mutations had an improved long-term survival (38% vs 24% at 5 years). This may result from intrinsic growth properties or from a better response to chemotherapy.

Recommendations

Current recommendations are that all women under the age of 70 with a nonmucinous epithelial ovarian, fallopian tube, or peritoneal cancer should undergo testing for *BRCA1* to *BRCA2* mutations.⁶³ The recommendations for management of women at high risk for ovarian cancers are summarized as follows^{40, 41, 47, 51–59, 64} :

1. Women who appear to be at high risk for ovarian and or breast cancer should undergo genetic counseling; if there is a probability of 10% or greater of having a *BRCA* mutation, they should be offered genetic testing for *BRCA1* and *BRCA2*.
2. Women who wish to preserve their reproductive capability or delay prophylactic surgery should undergo periodic screening by transvaginal ultrasonography and CA125 every 6 months, although the efficacy of this approach has not been established and is not based on evidence that this reduces mortality.
3. Oral contraceptives should be recommended to young women at increased risk.
4. Women who do not wish to maintain their fertility or who have completed their family should undergo PBSO. In women who have a strong family history of breast or ovarian cancer, annual mammographic and magnetic resonance imaging (MRI) breast screening should be performed commencing at age 30 years, or younger if there are family members with documented very early onset breast cancer.
5. Women with a documented Lynch syndrome should be counseled about prophylactic hysterectomy and oophorectomy after childbearing, in view of the risk of both endometrial and ovarian cancer. Although there are no definitive studies to support screening, endometrial sampling and transvaginal ultrasound of the ovaries may be considered from ages 30 to 35. Colonoscopy is recommended every 1–2 years starting from ages 20 to 25 or 10 years younger than the youngest person diagnosed in the family.^{39, 65, 66}

Molecular, cellular, and clinical biology

Similar to most epithelial cancers, more than 90% of epithelial ovarian cancers arise from the progeny of a single cell, that is, ovarian cancer is generally a clonal disease.⁶⁷ Despite origin from a single cell, ovarian cancers are markedly heterogeneous at a molecular, cellular, and clinical level. A number of genetic abnormalities are observed in ovarian cancers ([Table 1](#))⁶⁸ that activate or inactivate different genes. The function of several tumor suppressor genes has been lost ([Table 2](#))⁶⁸ by deletion, loss of heterozygosity, inactivating mutation (*BRCA1*, *BRCA2*, and *TP53*), promoter methylation (*ARHI*), histone modification, or loss of processed miRNAs. Abnormalities in miRNA processing with decreases in Dicer and Drosha have been found in 60% and 51% of ovarian cancer associated with a poor outcome.⁶⁹ Oncogenes have been amplified, transcriptionally overexpressed and/or mutationally activated ([Table 3](#)).⁶⁸ At a cellular level, the fraction of proliferating cells can vary from 1% to 90%.⁷⁰ Ovarian

cancers vary in histotype exhibiting the serous, endometriod, mucinous and clear cell variants described in the following paragraphs, related at least in part to the aberrant expression of HOX genes associated with normal gynecologic development.⁷¹

Table 1 Genetic and epigenetic abnormalities in epithelial ovarian cancer

Activating events	
Amplification by CGH	1q22 (RAB25), 3q26 (PKCιota, EVI1, PIK3CA), 5q31 (FGF-1), 8q24 (MYC), 19q (PI3Kp85, AKT2), 20p, 20q13.2 (BTAK)
Mutation ^a	<i>K-Ras, BRAF, CTNNB1, CDKN2A, PIK3CA, KIT, MADH</i>
Hypomethylation	<i>BORIS, CLDN-4, IGF2, MCI, SAT2, SNCG</i>
Histone modification	<i>cyclin B1, GATA4, GATA6, p21/WAF1</i>
miRNA	<i>BAP1, DLK1, MSX2, PTEN, SIP1, VEGFA, ZEB1/2</i>
Inactivating events	
Deletion by CGH	4q, 5q, 16q, 17p, 17q; Xp, Xq
LOH	(>50 %): 17p13, 17q21 (>30 %): 1p, 3p, 5q, 5q, 6q, 7q, 8q, 9p,10q,11p, 13q, 18q, 19p, 20; Xp
Mutation	<i>ARID1A, TP53, Rb1α, APC, BRCA1, BRCA2, CDK12, NF1, PTEN, PP2R1A</i>
Promoter methylation	<i>APC, ARHI, ANGPTL, ARLTS1, BRCA1, DAPK, FBX032, H-CADHERIN, hMLH1, HOXA10, HOXA11, Hsulf-1, ICAM-1, LOT-1, MCJ, MUC2, MYO188, OPCML, PACE-4, PALP-B, PAR-4, PEG3, p16, p21, RASSF1, SOCS1, SOCS2, SPARC, TMS/ASC, TUBB3, 14-3-3σ</i>
Histone modification	Adam 19, GATA4, GATA6, RASSF1
miRNA	BCL2, FGF2, MMP13, PAR8, c-SRK, VEGFA
Inhibition of growth by chromosome transfer	2, 3, 7, and 22

Table 2 Putative tumor suppressor genes in epithelial ovarian cancer

Gene	Chromosome	Downregulated or inactivated	Mechanisms of downregulation	Function
<i>ARHI</i> (<i>DIRAS3</i>)	1p31	60% of all histotypes	Imprinting; LOH; promoter methylation; transcription downregulated by E2F1 and	26 kDa GTPase; inhibits proliferation and motility; induces autophagy and dormancy; upregulates p21; inhibits Cyclin D1, PI3K, Ras-MAP, Stat3

			E2F4	
<i>ARID1A</i>	1p35.5	49% of clear cell and 30% of endometrioid histotypes	Mutation	Chromatin remodeling
<i>RASSF1A</i>	3p21	—	Hypermethylation	Inhibits proliferation and tumorigenicity in many different cancers. Interacts with Ras inhibiting downregulating cyclin D and signaling through JNK, stabilizes microtubules, and regulates spindle checkpoint and fas- and TNF-induced apoptosis
<i>DLEC1</i>	3p22.3	73%	Promoter hypermethylation and histone hypoacetylation	166 kDa cytoplasmic protein that inhibits anchorage-dependent growth
<i>SPARC</i>	5q31	70–90% decreased expression; 9% lost	Transcription, hypermethylation	32 kDa Ca ⁺⁺ binding protein; prevents adhesion
<i>DAB-2</i> (<i>DOC2</i>)	5q13	58–85% lost	Transcription	105 kDa protein binds GRB2 preventing Ras/MAP activation, prevents c-fos induction and decreases ILK activity, contributing to anoikis and inhibiting proliferation and anchorage-independent growth and tumorigenicity
<i>LOT-1</i> (<i>ZAC1</i>)	6q25	39%	Imprinting; hypermethylation LOH; transcription downregulated by EGF, TPA	55 kDa nuclear zinc finger protein inhibits proliferation and tumorigenicity
<i>RPS6KA2</i>	6q27	64%	Monoallelic expression in ovary; LOH	90-kDa ribosomal S6 serine threonine kinase that inhibits growth, induces apoptosis, decreases pERK and cyclin D1, and increases p21 and p27
<i>PTEN</i> (<i>MMAC-1</i>)	10q23	3–8% mutated; expression lost in 27%, particularly in endometrioid and clear cell histotypes	Promoter methylation; LOH; mutation	PI3 phosphatase; decreases proliferation, migration, and survival; decreases cyclin D and increases p27
<i>OPCML</i>	11q25	56–83%	Promoter	GPI-anchored IgLON family member;

			methylation; LOH; mutation	induces aggregation; inhibits proliferation and tumorigenicity
<i>BRCA2</i>	13q12-13	3–6%	Mutation; LOH	Binds RAD51 in repair of DNA double-strand breaks (DSBs)
<i>ARLTS1</i>	13q14	62%	Promoter methylation	ADP ribosylation factor induces apoptosis
<i>WWOX</i>	16q23	30–49%, particularly in mucinous and clear cell histotypes	LOH; mutation	Decreases anchorage-independent growth and tumorigenicity; mouse homolog required for apoptosis
<i>TP53</i>	17p13.1	50–70% overall; 96% of high-grade serous histotype	Mutation	53-kDa nuclear protein induces p21 with cell cycle arrest promoting DNA stability; induces apoptosis
<i>OVCA1</i>	17p13.3	37%	LOH	50 kDa protein; decreases proliferation and clonogenicity; decreased Cyclin D1
<i>BRCA1</i>	17q21	6–8%	Mutation; LOH; promoter methylation	E3 ubiquitin ligase that participates directly in repair of DNA DSBs through homologous recombination; regulates c-Abl; induces <i>TP53</i> , androgen receptor, estrogen receptor and c-Myc
<i>PEG3</i>	19q13	75%	Imprinting; LOH; promoter methylation; transcription	Induces <i>TP53</i> -dependent apoptosis
<i>PPP2R1A</i>	19q13.44	7% of clear cell histotype	Mutation	Protein phosphatase 2 regulatory subunit inhibits proliferation

Candidate tumor suppressor genes with preliminary reports in the literature also include *APC*, *BRMS1*, *CTGF*, *EPB41L3*, *MAP2K4*, *MKK4*, *RNF43*, *RP36RA7*, *PINX1*, *SFRP4*, *SLIT2*, *SOX11*, *TUSC3*, and *53BP1*.

Table 3 Oncogenes associated with epithelial ovarian cancer

Oncogenes	Chromosome	Amplified (%)	Overexpressed (%)	Mutated (%)	Function
Rab25	1q22	54	80–89	—	Cytoplasmic GTPase/apical vessel trafficking
Evi-1	3q26	—	—	—	Transcription factor
eIF-5A2	3q26	—	—	—	Elongation factor
PKCi	3q26	44	78	—	Cytoplasmic serine-threonine kinase
PIK3CA (PI3K p110α)	3q26	9–80	32	8–12	Cytoplasmic lipid kinase
FGF-1	5q31	—	51	—	Growth factor for cancer and angiogenesis
Myc	8q24	20	41–66	—	Transcription factor
EGFR	7p12	11–20	9–28	<1	Tyrosine kinase growth factor receptor
Notch-3	9p13	20–21	62	—	Cell surface growth factor receptor
K-Ras	12p11-12	5–53	30–52	2–24	Cytoplasmic GTPase
HER-2	17q12-21	6–11	4–12	—	Tyrosine kinase growth factor receptor
p85 PI3K	19q	—	—	—	Cytoplasmic lipid kinase
Cyclin E	19q12	12–53	42–63	—	Cyclin
AKT2	19q13.2	12–27	12		Cytoplasmic serine-threonine Kinase
BTAK/Aurora A	20q13	10–15	48	—	Nuclear serine-threonine kinase/activates telomerase

Additional targetable genes with low or high gain of copy number in >20% of high-grade serous ovarian cancers include *AKT1*, *AKT3*, *CDK2*, *IL8RB*, *EPCAM*, *ERBB3*, *FGFR2*, *HDAC4*, *HSP90AB1*, *HSP90B1*, *IGF1*, *IGFR1*, *LPAR3*, *MAP3K6*, *MAPK15*, *MAPKAPK2*, *MAPKAPK5*, *MECOM*, *MSTN*, *MTOR*, *NCAM1*, *NOS1*, *NOS3*, *PIK3CD*, *POLB*, *POLE*, *RHEB*, *RICTOR*, *PPS6KC1*, *RAPTOR*, *SKI1*, *STAT1*, *STAT4*, *TERT*, *TGFB1*, *TGFB2*, *TGFBR3*, *TNFRSF9*, and *VEGFA*.

Biologically and clinically, there is a major distinction between low-grade (type I) and high-grade (type II) epithelial ovarian cancers.⁷² Low-grade serous cancers (comprising <10% of ovarian epithelial malignancies) are thought to develop from borderline tumors, to present in early stage (I–II) and to depend on mutations of Ras (>50%), PIK3CA (30%), and PTEN (10%), as well as upon expression of the insulin-like growth factor receptor (IGFR), which responds to IGF produced by the tumor stroma. High-grade serous cancers (comprising 60% of all ovarian epithelial malignancies) are thought to develop from histologically normal ovarian and fallopian tube epithelial cells, to present in late stage (III–IV), and to depend on amplification of multiple wild-type oncogenes and the functional loss of tumor suppressor genes. While *TP53* is rarely mutated in low-grade type I cancers, it is mutated in nearly all high-grade serous type II cancers. When germ line and somatic mutations of *BRCA1/2* are associated with

epithelial ovarian cancer, the cancers are generally high grade. Defects in homologous recombination DNA repair deficiency (BRCAness) are associated with up to half of high-grade cancers, but few, if any, low grade cancers, possibly accounting for the fact that high-grade cancers are more sensitive to platinum-based chemotherapy than low-grade cancers. Current strategies are being developed to exploit this deficiency using PARP inhibitors in the presence and absence of BRCA1/2 mutations. The PI3-kinase pathway is a potential target in both type I and type II cancers and is activated in at least half of high-grade cancers.⁷³

The Tumor Cancer Genome Atlas (TCGA) project has sequenced DNA from more than 300 high-grade serous ovarian cancers and aside from *TP53* (98%) and *BRCA1/2* (15–20%) only a few genes are mutated more than 1% of the time (*NF1*, *RB1*, *CSMD3*, and *CDK12*).⁷⁴ Consequently, low-grade cancers are driven by mutations and high-grade cancers by DNA copy number abnormalities.

Clear cell ovarian cancers have mutations of *ARID1A* (49%),⁷⁵ a chromatin-processing enzyme and *PP2R1A* (6%), a phosphatase. Endometrioid ovarian cancers also have mutations of *ARID1A* (30%). Among the nonepithelial ovarian cancers, 97% of granulosa cell tumors (see the following discussion) exhibit a characteristic mutation, 402C → G (C134W) in *FOXL2*, a gene encoding a transcription factor known to be critical for granulosa-cell development.⁷⁶

Ascites formation results from increased leakage of proteinaceous fluid from capillaries under the influence of vascular endothelial growth factor/vascular permeability factor (VEGF/VPF) produced by ovarian cancers and from inhibition of fluid outflow through diaphragmatic lymphatics that have been blocked by metastatic disease.⁷⁷ Studies of the immunobiology of the peritoneal cavity suggest that it may function as an immunoprivileged site, with elevated levels of suppressive molecules and growth factors. Angiogenesis in ovarian cancer has been shown to depend on multiple factors including VEGF and IL-8. The presence of multiple angiogenic factors can explain, in part, development of resistance to bevacizumab therapy. Autophagy and tumor dormancy are regulated by *ARHI* (*DIRAS3*) an imprinted tumor suppressor gene that is downregulated in 60% of ovarian cancers of low and high grade.^{78, 79} The upregulation of *ARHI* and high prevalence of autophagy in dormant, drug-resistant cancer cells in positive second look specimens after primary surgery and chemotherapy, suggest that autophagy could be a target in ovarian cancer.⁸⁰

Upregulation and aberrant glycosylation of extracellular mucins have provided markers for monitoring disease. *MUC-1* is a mucin expressed by more than 80% of ovarian cancers.⁸¹ In transformed cells, aberrant glycosylation exposes peptide determinants recognized by murine monoclonal antibodies that have been used for serotherapy. CA125 is also a mucin (*MUC16*) associated with cells that line the coelomic cavity during embryonic development. CA125 is shed from 80% of epithelial ovarian cancers^{82, 83} and can be measured using the murine monoclonal antibody OC125. Regression and progression of disease tend to correlate well with falling or rising CA125 levels. The precise function of the glycoprotein is unknown,^{84–86} but knockout of murine *MUC16* does not affect the development or fertility of mice.⁸⁷ In cancer cells, CA125 expression is upregulated transcriptionally and 80% of the CA125 is cleaved and shed. Interaction of CA125 is with mesothelin at the peritoneal surface and is likely to be the first point of contact for ovarian cancer cells metastasizing within the peritoneal cavity.

Classification and pathology

Primary ovarian cancers are classified according to the structures of the ovary from which they are derived.⁸⁸ As noted above, most have thought to be derived from the epithelial cells that cover the

ovarian surface or that line inclusion cysts, although, as described earlier, this concept has recently been challenged by recognition that many high-grade serous cancers arise from the fimbriae of fallopian tubes. These cells are ultimately derived from the coelomic epithelium of mesodermal origin and share cytologic markers with mesothelium. Germ cell malignancies constitute the next most common group and the least common tumors are derived from ovarian stromal cells (see [Chapter 105](#)). Granulosa-Theca tumors are derived from the specialized connective tissue of the ovary and are the least common (see [Chapter 105](#)).

Epithelial malignancies account for 85–90% of ovarian cancers. The majority of epithelial lesions are seen in patients who are 40 years of age or older. Under the age of 40 years, epithelial malignancies are uncommon, and most malignancies seen in women under the age of 30 years are of germ cell origin. The histologic types of the epithelial tumors are listed in [Table 4](#). The majority of lesions, about 75%, are of the serous type, followed by the mucinous, endometrioid, clear cell, mixed, Brenner, and undifferentiated histologies.¹¹

Table 4 Epithelial ovarian tumors

Histologic type	Cellular type
1. Serous (a) Benign (b) Borderline (c) Malignant	Endosalpingeal
2. Mucinous (a) Benign (b) Borderline (c) Malignant	Endocervical
3. Endometrioid (a) Benign (b) Borderline (c) Malignant	Endometrial
4. Clear cell “mesonephroid” (a) Benign (b) Borderline (c) Malignant	Müllerian
5. Brenner (a) Benign (b) Borderline (proliferating) (c) Malignant	Transitional
6. Mixed epithelial (a) Benign (b) Borderline (c) Malignant	Mixed
7. Undifferentiated (a) Anaplastic	
8. Unclassified (a) Mesothelioma (b) Other	

Invasive histotypes

Serous carcinomas may have a complex admixture of cystic and solid areas with extensive papillations,

or they may contain a predominantly solid mass with areas of necrosis and hemorrhage ([Figure 1](#)). The poorly differentiated tumors may have some areas with a papillary pattern, but other portions may be indistinguishable from the other histologic patterns described in the following paragraphs ([Figure 2](#)). Stage I or II lesions are most frequently unilateral, with about 10–20% involving both ovaries. Conversely, about 50–70% of stage III serous carcinomas are bilateral.¹¹

Figure 1 Serous cystadenocarcinoma gross with omentum.

Figure 2 Poorly differentiated serous carcinoma of ovary.

Mucinous tumors tend to be large, with many masses over 20 cm in diameter ([Figure 3](#)). The histologic pattern resembles uterine endocervical glands. The lesions frequently contain areas of hemorrhage, necrosis, and various quantities of mucin. These tumors are bilateral in 10–20% of cases. Occasionally, mucin is secreted into the peritoneal cavity and produces a condition known as pseudomyxoma or myxoma peritonei. A mucocele of the appendix may also be seen in conjunction with this tumor.

Figure 3 Mucinous cystadenocarcinoma.

Endometrioid carcinomas of the ovary resemble typical carcinomas of the endometrium. These tumors may be seen with synchronous endometrial carcinoma, and when they are, both lesions may be of low stage. Rarely, endometrioid carcinomas may arise in conjunction with pelvic endometriosis, resulting from malignant transformation of a benign process ([Figure 4](#)).¹¹ Similar to previous endometrial cancers, endometrioid ovarian cancers are associated with inactivating mutations of *PTEN* with consequent activation of PI3 kinase signaling. Bilaterality is seen in 10–15% of stage I and II disease and in about 30% of stage III.

Figure 4 Endometrioid carcinoma.

Ovarian clear cell carcinomas have abundant intracellular glycogen that is removed during histopathologic processing. About one-fourth of clear cell tumors are associated with endometriosis. Clear cell tumors are only rarely bilateral.¹¹

Brenner tumors are uncommon, representing less than 1% of all epithelial malignancies. Mixed epithelial tumors may contain small areas of Brenner tumor histology, which have a histologic pattern similar to that of transitional cell. Malignant Brenner tumors are unilateral.¹¹

Borderline tumors

Borderline tumors, or those of low malignant potential, are important to differentiate from those that are frankly invasive. The treatment and prognosis for borderline lesions are considerably different from those for invasive malignancies. Borderline tumors tend to remain confined to a single ovary at the time of diagnosis and also tend to occur in younger, premenopausal women ([Figure 5](#)). They may be confused with a well-differentiated invasive ovarian cancer, and the treatment for the two may be different. Thus, in a young patient who has a lesion confined to the ovary, which is suspected of being an epithelial ovarian

cystadenocarcinoma, a borderline tumor must be excluded because bilateral oophorectomy, hysterectomy, and chemotherapy are unnecessary in these patients. In women under the age of 40 years, about 60–70% of nonbenign ovarian neoplasms are borderline, whereas in women over 40 years, only 10% are borderline.^{11, 89} Histologic criteria for borderline tumors include (1) the presence of epithelial cell proliferation with a “piling up” of cells, the so-called pseudostratification; (2) cytologic atypia, but with rare mitoses; and (3) no evidence of stromal invasion. Borderline tumors tend to remain confined to the ovary but may be associated with peritoneal disease, which represents either dissemination or the multifocal evolution of the disease. In those rare patients with peritoneal involvement, death can occur by progressive intestinal obstruction.

Figure 5 Borderline serous tumor.

Peritoneal carcinomas

Epithelial malignancies that coat the surface of the ovary and peritoneum are referred to as peritoneal carcinomas.¹⁴ These cancers are distinct from the very rare peritoneal mesotheliomas that exhibit a different natural history, as well as response to chemotherapy.⁹⁰ The cells of the peritoneum have the ability to recapitulate any of the histologic patterns seen in ovarian cancers, although serous carcinomas occur most frequently and the other histologic types are rarely seen. Many of these high-grade serous primary peritoneal cancers are likely to arise from fimbriae of the fallopian tube, although some may be derived from developmental remnants of the secondary Müllerian system.¹²

Recognition of peritoneal carcinomas explains the occurrence of ovarian cancer after oophorectomy.⁹¹ In addition, peritoneal cancers can involve the surface of the ovaries without ovarian enlargement. Thus, ovaries can be innocent bystanders in a process originating in the peritoneal cavity. Therapeutically, peritoneal malignancy should be treated as one would manage an epithelial ovarian cancer.

Patterns of spread

Ovarian epithelial tumors spread primarily by direct exfoliation and implantation of cells throughout the peritoneal cavity but also metastasize via the lymphatic and hematogenous routes. GCTs (see [Chapter 105](#)) have a greater predilection for spread via the retroperitoneal lymphatics, which must be evaluated carefully when staging those tumors that appear to be confined to the ovary.^{11, 92}

Exfoliated ovarian cancer cells spread directly to the pelvic and abdominal peritoneal surfaces and tend to follow the path of circulation of peritoneal fluid from the right pericolic gutter cephalad to the right hemidiaphragm. At primary surgery, the parietal and visceral peritoneum can be studded with dozens to hundreds of metastatic nodules. The intestinal mesenteries can become involved by peritoneal metastases. Adhesions form between loops of small intestine producing mechanical obstruction, even though involvement of the lumen of the intestine by direct extension is uncommon. The intestinal dysfunction can also result from involvement by tumor of the myenteric plexus, the autonomic innervation of the intestine that is found in the mesentery. This condition has been referred to as “carcinomatous ileus.” Large pelvic masses can compress the rectum producing colonic obstruction.

Spread via the lymphatics is common in epithelial ovarian cancer. Apparent stage I and II tumors have retroperitoneal lymphatic dissemination in about 5–10% in most series, whereas lymphatic dissemination in stage III has been reported to be as high as 42–78% in carefully explored patients.⁹³ Most of these lymph nodes are not enlarged but are microscopically positive for malignant cells. Spread through the

retroperitoneal and diaphragmatic lymphatics can result in metastasis to the supraclavicular lymph nodes on the left and right, respectively. Bloodborne metastasis of ovarian cancer is uncommon at diagnosis and is often a late finding in the disease. Hematogenous dissemination at the time of diagnosis to the parenchyma of the liver or lung is seen in a minority of patients. In advanced recurrent disease, parenchymal metastases are seen more frequently in the parenchyma of the lung and even of the brain.

Clinical symptoms

Some patients with ovarian cancers confined to the ovary are asymptomatic, but the majority will have nonspecific symptoms that do not necessarily suggest an origin in the ovary. In one survey of 1725 women with ovarian cancer, 95% recalled symptoms before diagnosis, including 89% with stage I/II disease and 97% with stage III/IV disease.⁹⁴ Seventy percent had abdominal or GI symptoms, 58% pain, 34% urinary symptoms, and 26% pelvic discomfort. At least some of these symptoms could have reflected pressure on the pelvic viscera from the enlarging ovary. Goff et al. have developed an ovarian cancer symptom index and reported that symptoms associated with ovarian cancer were pelvic/abdominal pain, urinary frequency/urgency, increased abdominal size or bloating, and difficulty eating or feeling full when they were present for less than 1 year and occurred >12 days a month. The index had a sensitivity of 56.7% for early ovarian cancer and 79.5% for advanced-stage disease.⁹⁵ Interestingly, a population-based study from Australia found that there did not appear to be a significant difference in the duration of symptoms or the nature of symptoms in patients with early as opposed to advanced-stage ovarian cancer.^{96, 97}

Metastatic ovarian cancer is rarely asymptomatic. In addition to the GI and urinary symptoms noted in early-stage disease, formation of ascites can produce an increase in abdominal girth. Pleural effusion may lead to dyspnea as the first complaint. Acute symptoms, such as those of adnexal rupture or torsion, are uncommon. Vaginal bleeding is also an uncommon symptom in postmenopausal women, although premenopausal patients may present with irregular or heavy menses. Detection of an adnexal mass by pelvic examination can permit the early diagnosis of ovarian cancer. As malignancy is rare and the majority of palpable adnexal masses are benign, an enlarged ovary discovered on pelvic examination is not likely to be an ovarian malignancy. In premenopausal women, ovarian cancer is uncommon and represents less than 7% of all adnexal masses.¹¹ Even in postmenopausal women, 70–80% of adnexal tumors are benign. In some patients who complain primarily of abdominal symptoms, however, a pelvic examination frequently is omitted and the tumor missed. Signs of advanced disease include abdominal distention and a fluid wave consistent with ascites. These signs are nonspecific and can be associated with many conditions arising in the abdominal cavity, especially malignancies of other primary sites or carcinomatosis from metastatic tumors of the GI tract and breast.

Diagnosis

The diagnosis of ovarian cancer is usually made at laparotomy, but occasionally at laparoscopy. If a pelvic mass is suspicious and the most likely diagnosis is ovarian cancer, surgery should not be unnecessarily delayed. In premenopausal patients, however, simple cystic ovarian lesions can be observed over a period of 1–2 months. Lesions that are essentially mobile, are unilateral, and have a smooth contour are much less likely to be neoplastic, and are unlikely to be malignant. In premenopausal patients with cystic lesions of less than 8 cm, attempted suppression with oral contraceptives is indicated. In women who are definitely postmenopausal, cystic masses larger than 5 cm should be removed unless they represent a chronic finding. Those masses that regress in size can be managed with continued observation, whereas those that persist or enlarge must be evaluated surgically. Conversely, patients

whose lesions are irregular, predominantly solid, and somewhat immobile should undergo an exploratory laparotomy.

The preoperative evaluation of patients can be aided by the use of blood biomarkers. Three algorithms have been developed for distinguishing malignant from benign pelvic masses. Ultrasound, CA125, and menopausal status have been combined to create a risk of malignancy index (RMI) that has achieved a sensitivity of 71–88% with a reciprocal specificity of 97–74% for predicting the presence of ovarian cancers in women with pelvic masses.⁹⁸ An OVA1 panel including CA125, apolipoprotein A1, transthyretin, transferrin, and B2-microglobulin combined with imaging and menopausal status provides 92% sensitivity at 42% specificity in postmenopausal women and 85% sensitivity at 45% specificity for premenopausal women.⁹⁹ The negative predictive value for women judged at low risk is 94%–96%. Similar sensitivity and higher specificity have been attained with a risk of malignancy index (ROMA) calculated from CA125 and HE4 values combined with menopausal status alone, without imaging.¹⁰⁰ In an initial trial of patients referred to academic centers, the sensitivity for predicting a malignant pelvic mass was 93%, specificity 75%, and negative predictive value 94%. In a subsequent community-based trial, a sensitivity of 94%, specificity of 75%, and negative predictive value of 99% were attained.¹⁰¹ The ROMA has been shown superior to the RMI.¹⁰⁰ Both the OVA1 and the ROMA panels have been approved for use by the US FDA. Utilization of these panels could assure that women with ovarian cancer receive optimal surgery. At present, less than half of women in the United States with ovarian cancer have their initial operation with a gynecologic oncologist trained to perform optimal cytoreductive surgery.

Ultrasonographic signs of malignancy include an adnexal pelvic mass with areas of complexity, such as irregular borders; multiple echogenic patterns within the mass; and dense, multiple irregular septae. Bilateral tumors are more likely to be malignant, although the individual characteristics of the lesions are of greater significance. Transvaginal ultrasonography may have a somewhat better resolution than transabdominal ultrasonography for adnexal neoplasms. Newer techniques using Doppler color-flow imaging may enhance the specificity of ultrasonography for demonstrating findings consistent with malignancy.

Radiographic techniques, including abdominal radiographs, computed tomography (CT) scans, PET-CT (positron emission tomography) scans, and nuclear MRI, are not useful before the surgical diagnosis of ovarian cancer. The preoperative evaluation of patients who have a suspicious pelvic mass can omit these studies when blood chemistries and enzymes suggest normal hepatic and pancreatic function. In patients with ascites and no pelvic mass, however, a CT or MRI may be useful in identifying other potential sites of origin. Paracentesis is not recommended because of the frequency of metastatic implantation and growth in the needle tract. Liver–spleen scans, brain scans, and bone scans are unnecessary unless specific symptoms suggest metastasis to these sites.

In premenopausal women, radiographic studies of the intestines are not required unless there is the finding of occult blood in the rectum or there are symptoms indicating upper or lower intestinal obstruction. A barium enema or endoscopy is appropriate in postmenopausal patients. Mammography should be performed to exclude primary breast cancer, which can coexist with ovarian cancer or spread to the ovaries. Cervical cytology should be performed, although ovarian cancer cells are unlikely to exfoliate through the uterus to the cervix. In patients with irregular or heavy menses, an endometrial biopsy should be performed to exclude primary endometrial pathology.

The differential diagnosis of an adnexal mass includes a variety of functional changes of the ovary, benign neoplasms of the reproductive tract, and inflammatory lesions of these organs. A hydrosalpinx, endometriosis, and pedunculated uterine leiomyomata can simulate an ovarian neoplasm. Nongynecologic

diseases, such as inflammatory processes of the colon and rectum, must be excluded.

Screening

There is no well-established strategy for early detection of ovarian cancer. Discovery of a pelvic mass on routine physical examination can lead to surgery before the dissemination of a malignancy, but conventional diagnosis detects less than 20% of patients in stage I. Given the prevalence of ovarian cancer in the postmenopausal population, any screening strategy must be highly specific (>99.6%) as well as highly sensitive for early-stage disease (>75%) to achieve a PPV of 10% (i.e., 10 laparotomies for each case of ovarian cancer detected). Two approaches have been evaluated for early detection of ovarian cancer: ultrasonography and serum tests such as CA125.

Ultrasonography

Transvaginal sonography (TVS) has proved superior to transabdominal sonography (TAU) for the detection of a pelvic mass. In three large studies that screened 66,620 women with TVS, 565 operations were performed to detect 45 ovarian cancers, 34 of which were invasive.^{102–104} Overall, the sensitivity for early-stage disease was 78%, but the specificity fell just short of that required for a PPV of 10% with 12 operations per case of ovarian cancer detected. The most promising single study achieved a PPV of 9.9%. Confirmatory tests with Doppler ultrasound have not proved consistent, but additional studies with 3-D power Doppler are underway to improve specificity in distinguishing malignant from benign ovarian abnormalities.

CA125

CA125 is elevated in 50–60% of patients with stage I and in 90% with stage II ovarian cancer.¹⁰⁵ CA125 levels can rise 10–60 months before diagnosis with an average estimated lead time of 1.9 years before diagnosis of disease in all stages.¹⁰⁶ In the Prostate, Lung, Colorectal and Ovarian (PLCO) screening trial, 37,500 postmenopausal women had an annual CA125 and TVS for 3 years.¹⁰⁷ If either were abnormal, women were referred to a gynecologist. CA125 alone had a PPV of 3.7%; TVS alone had a PPV of 1%. If both were abnormal, the PPV rose to 23.5%, but 60% of the invasive ovarian cancers would have been missed. Thus, the specificity for a single determination of CA125 or a single TVS is not adequate to screen a population at average risk, but specificity can be improved with a two-stage strategy that utilizes CA125 followed by ultrasound in a subset of women with elevated CA125. Use of CA125 to trigger ultrasound has been evaluated in trials in Sweden and in the United Kingdom.^{108, 109} The latter randomized 22,000 women to conventional surveillance or to annual CA125 with TAU if the value were elevated. When TAU was abnormal, surgery was undertaken. Among 10,985 women screened, 29 operations were performed to detect 6 cancers, providing a PPV of 21%. During 7 years of follow-up, 10 more cancers were diagnosed in the screened group. Over the same intervals, 21 ovarian cancers were diagnosed in the control group. Median survival in the screened group (72.9 months) was significantly greater ($p = 0.0112$) than that in the control group (41.8 months).

Risk of ovarian cancer (ROC) algorithm

Arising CA125 is a more specific indicator of ovarian cancer. Analyzing serum samples stored from screening studies in Stockholm and in the United Kingdom with an improved CA125 II assay, it has been possible to improve the specificity of CA125 as a screening tool by following the values of an individual over time.^{110, 111} Elevated CA125 levels in women without ovarian cancer remain static or decrease with

time, whereas levels associated with ovarian malignancy tend to rise. This finding has been incorporated into an algorithm that uses age, rate of change of CA125, and absolute levels of CA125 to calculate an individual's "risk of ovarian cancer" (ROCA, risk of ovarian cancer algorithm). Patients at sufficient risk undergo TVS. Over the past 15 years, a trial has been conducted with the ROCA in the United States coordinated by the MD Anderson SPORE in Ovarian Cancer. Some 18 patients have undergone surgery based on the algorithm. Six have had benign disease, two have had borderline tumors (stage I) and ten have had invasive ovarian cancers with seven in early stage (I–II) and three in stage III. Only three operations have been required to detect each case of ovarian cancer.¹¹² Currently, accrual to a larger trial has been completed in the United Kingdom that includes 200,000 postmenopausal women who were randomized to three groups: a control group (~100,000) that has been followed with conventional pelvic examinations; a second group (~50,000) that had annual TVS; and a third group (~50,000) that had CA125 determined at least annually. On the basis of the ROCA, patients in the third group were referred for TVS and/or surgery. Women were screened for 3 years and followed for 7 years. Results from the initial 3 years of the "prevalence phase" of accrual suggested that a higher fraction of early stage disease could be detected (48%) with the ROCA and that no more than 3–4 operations would be required for each case detected.¹¹³ Results of the study will become available in late 2015, but it is already apparent that use of the ROCA doubled the number of screen-detected ovarian cancers compared to use of an arbitrary threshold for CA125.¹¹⁴ Results from the first year of screening suggest that the ROCA followed by TVS will have substantially higher specificity and no less sensitivity than annual TVS, but data in subsequent years will be required to determine whether screening improves survival.

Whatever the outcome of the current trial in the United Kingdom, strategies based on CA125 alone are not likely to exceed a sensitivity of 80%, as CA125 is not expressed by 20% of epithelial ovarian cancers. Greater sensitivity might be attained through the use of multiple serum markers in combination, provided that specificity was not compromised. Two other biomarkers—HE4 and CA72.4—detect a fraction of patients (15%) missed by CA125. Autoantibodies against TP53 can also detect 18% of patients missed by CA125 and provide 13–33 months of lead time.

Current recommendations for screening women at average risk

The application of screening techniques other than pelvic examination for ovarian cancer in the entire female population is unwarranted at this time. The sensitivity and specificity of ultrasound or CA125 alone are inadequate. Use of annual CA125 followed by TVS appears more promising, but application of this approach outside of a research study will depend on the outcome of the UKCTOCS trial. If a significant improvement in survival and mortality are observed, the MD Anderson trial has shown that this approach is feasible in the United States.

Current recommendations for screening women at high risk

Although ultrasound and CA125 screening have been advocated for women at increased genetic ROC, the efficacy of surveillance to reduce mortality or detect cancers at an earlier stage is unproved. Many of the occult cancers found after PBSO (prophylactic bilateral salpingo-oophorectomy) have been in the fimbrial end of the fallopian tube, and this consistent finding suggests that ultrasound of the ovaries is unlikely to detect cancers at an early stage in women at high genetic risk. Screening can be problematic because this high-risk population generally includes premenopausal women who have a higher incidence of false-positive CA125 elevations and ultrasound abnormalities. In these high-risk populations, initial screening trials using ultrasound alone or in combination with color-flow Doppler were associated with high false-positive rates (2.5–4.9%). The current trend among those who support screening is to combine

ultrasound every 6–12 months with CA125 every 3–6 months.

There are five prospective studies where combined screening has been undertaken in high-risk populations.^{33, 115–118} In three screening programs involving a total of 1228 women with a family history of ovarian cancer, no invasive ovarian cancer was detected and false-positive rates have ranged from 0.4% to 3.9%.^{33, 48, 49, 115–119} In one of the remaining two studies, one case of ovarian cancer was detected on screening 137 high-risk women with a false-positive rate of 0.7%; in the other study, nine ovarian cancers were detected in screening 180 women with a false-positive rate of 3.9%.^{117, 118} The findings of two prospective studies of annual transvaginal ultrasound and CA125 screening in 888 *BRCA1* and *BRCA2* mutation carriers in the Netherlands and 279 mutation carriers in the United Kingdom are not encouraging and suggest a very limited benefit of screening in high-risk women.^{48, 49} Therefore, it is unlikely that annual screening will reduce mortality from ovarian cancer in *BRCA1/2* mutation carriers. Women in the high-risk population who request screening should be counseled about the current lack of evidence for the efficacy for either CA125 or sonography as well as the associated false-positive rates. Many will still opt for screening despite the risks and limitations of the available strategies.

Staging

Ovarian, fallopian tube and peritoneal malignancies are staged according to the new FIGO system of 2014 ([Table 5](#)) that is based on the findings at surgical exploration. A preoperative evaluation should exclude the presence of extraperitoneal metastases. A thorough surgical exploration is important because subsequent treatment will be determined by the stage of disease. In patients whose exploratory laparotomy does not reveal any macroscopic evidence of disease by inspection and palpation of the entire intra-abdominal space, a careful search for microscopic spread must be undertaken. In an earlier series in which patients did not undergo careful surgical staging, the overall 5-year survival for patients with apparent stage I epithelial ovarian cancer was only about 60%.⁴ Survival rates of 90–100% have been reported for properly staged patients found to have stage IA or IB disease.⁴

Table 5 FIGO staging of ovarian, fallopian tube, and peritoneal cancer (2014)

Stage I: Tumor confined to ovaries or fallopian tube(s)	T1-N0-M0
IA: Tumor limited to one ovary (capsule intact) or fallopian tube; no tumor on ovarian or fallopian tube surface; no malignant cells in the ascites or peritoneal washings	T1a-N0-M0
IB: Tumor limited to both ovaries (capsules intact) or fallopian tubes; no tumor on ovarian or fallopian tube surface; no malignant cells in the ascites or peritoneal washings	T1b-N0-M0
IC: Tumor limited to one or both ovaries or fallopian tubes, with any of the following	
IC1: Surgical spill	T1c1-N0-M0
IC2: Capsule ruptured before surgery or tumor on ovarian or fallopian tube surface	T1c2-N0-M0
IC3: Malignant cells in the ascites or peritoneal washings	T1c3-N0-M0
Stage II: Tumor involves one or both ovaries or fallopian tubes with pelvic extension (below pelvic brim) or primary peritoneal cancer	T2-N0-M0
IIA: Extension and/or implants on uterus and/or fallopian tubes and/or ovaries	T2a-N0-M0
IIB: Extension to other pelvic intraperitoneal tissues	T2b-N0-M0
Stage III: Tumor involves one or both ovaries or fallopian tubes, or primary peritoneal cancer, with cytologically or histologically confirmed spread to the peritoneum outside the pelvis and/or metastasis to the retroperitoneal lymph nodes	T1/T2-N1-M0
IIIA1: Positive retroperitoneal lymph nodes only (cytologically or histologically proven):	
IIIA1(i) Metastasis up to 10 mm in greatest dimension	
IIIA1(ii) Metastasis more than 10 mm in greatest dimension	
IIIA2: Microscopic extrapelvic (above the pelvic brim) peritoneal involvement with or without positive retroperitoneal lymph nodes	T3a2-N0/N1-M0
IIIB: Macroscopic peritoneal metastasis beyond the pelvis up to 2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes	T3b-N0/N1-M0
IIIC: Macroscopic peritoneal metastasis beyond the pelvis more than 2 cm in greatest dimension, with or without metastasis to the retroperitoneal lymph nodes (includes extension of tumor to capsule of liver and spleen without parenchymal involvement of either organ)	T3c-N0/N1-M0
Stage IV: Distant metastasis excluding peritoneal metastases	
Stage IVA: Pleural effusion with positive cytology	
Stage IVB: Parenchymal metastases and metastases to extra-abdominal organs (including inguinal lymph nodes and lymph nodes outside of the abdominal cavity)	Any T, any N, M1

Metastases in clinically apparent stage I or II epithelial ovarian cancer are common. About 30% of patients whose ovarian epithelial cancers appear to be confined to the pelvis have occult metastatic disease in the upper abdomen or in the retroperitoneal lymph nodes.¹²⁰ Histologic grade was a significant predictor of occult metastasis, that is, 16% of patients with grade 1 lesions were upstaged, compared to 34% with grade 2 and 46% with grade 3 disease.

Although the literature has emphasized the importance of thorough surgical exploration in patients with disease apparently localized to the ovaries, scant recognition is made of the semantic difficulty presented by the concept of extension to other pelvic (i.e., stage II) or abdominal (i.e., stage III) organs. No problem exists when the surgeon encounters discrete implants, or seeds, separate from the primary tumor, or when solid tumor is found growing into adjacent structures. A more common situation, however, is the apparently benign adherence of the tumor to adjacent structures in the absence of metastatic implants or obvious direct tumor extension. There is a considerable body of evidence that such benign adherence, when it is dense, is associated with a relapse risk equivalent to stage II, and that these patients should not be included in stage I but rather in stage II.¹²⁰ Adherence is considered dense when sharp dissection is required to mobilize the tumor, when a raw area is left at the site of adherence, or when rupture of a cyst results from dissecting free the adhesions. It is the practice at most North American centers to advance the stage of densely adherent tumors to stage II, and this was done in a recent multicenter study of stage I and II disease.¹²⁰

After a comprehensive staging laparotomy, less than 25% of women are found to have local or regional disease (FIGO stages I and II). Although accounting for only 15–20% of all cases, approximately one-third to one-half of all cured patients are derived from stage I, highlighting its importance. An in-depth understanding of the management of stage I is hampered by the small fraction of patients with limited disease, as well as by their excellent long-term prognosis (over an 80% 5-year relapse-free rate). Consequently, phase III randomized trials are difficult to conduct with this group owing to their small numbers and relatively low rate of recurrence and death.

Prognosis

The prognosis of epithelial ovarian cancer can be correlated with numerous clinical and biologic factors. Tumor stage, grade, and size of metastatic disease after resection correlate best with outcome.^{121, 122} As discussed in the following text, among patients with low-stage disease, tumor grade correlates with prognosis (i.e., patients with stage I high-grade lesions have a higher risk of recurrence and shorter survival than do those of low-grade lesions).¹²² In patients with advanced-stage disease, the size of residual disease after surgery correlates most clearly with survival.¹²³ Complete removal of all visible tumor has the best prognosis. The rapidity with which disease regresses during chemotherapy also correlates with survival. A short apparent half-life of the serum tumor marker CA125 has correlated with improved survival in more than a dozen studies.¹²⁴ Normalization of CA125 by the third course of chemotherapy has been associated with a favorable prognosis. The presence of malignant ascites has been shown to also adversely impact on prognosis.

Treatment of early-stage epithelial cancer

The treatment of early-stage epithelial ovarian and fallopian tube cancer must be individualized. Thorough surgical exploration and staging are indicated for all patients with early-stage disease.

Adjuvant treatment with chemotherapy is appropriate for those women at highest risk of recurrence.

Surgery

The initial treatment for invasive stage I epithelial ovarian cancer is surgical, that is, the performance of a total abdominal hysterectomy, BSO, and surgical staging. In certain circumstances, a unilateral salpingo-oophorectomy may suffice, as discussed in the following sections.

Adjuvant chemotherapy

The GOG reported the results of a randomized study comparing three cycles of carboplatin and paclitaxel with six cycles in 457 patients with early-stage ovarian cancer.¹²⁵ An unexpectedly large number of patients (126, 29%) had incomplete or inadequately documented surgical staging in this study. The recurrence rate for six cycles was 24% lower (hazard ratio [HR] 0.76 CI 0.5–1.13 $p = 0.18$) for six cycles versus three cycles, but this was not statistically significant. The estimated probability of recurrence at 5 years was 20.1% for six cycles and 25.4% for three cycles. They concluded that three cycles of adjuvant carboplatin and paclitaxel was a reasonable option for women with high-risk early-stage ovarian cancer, particularly in women with nonserous cancers although many oncologists would recommend six cycles, if chemotherapy is given to early-stage patients with high-grade serous. Two large parallel randomized phase 3 clinical trials were conducted on women with early-stage disease: the International Collaborative Ovarian Neoplasm Trial 1 (ICON1) and the Adjuvant Chemotherapy Trial in Ovarian Neoplasia (ACTION).^{126, 127} When the data from the two trials were combined and analyzed,¹²⁸ a total of 465 patients was randomized to receive platinum-based adjuvant chemotherapy and 460 to observation until disease progression. After a median follow-up of more than 4 years, the overall survival was 82% in the chemotherapy arm and 74% in the observation arm (HR = 0.67, $p = 0.001$). Recurrence-free survival was also better in the chemotherapy arm: 76% versus 65% (HR = 0.64, $p = 0.001$). The results of this analysis must be interpreted with caution because most of the patients did not undergo thorough surgical staging, but the findings suggest that platinum-based chemotherapy should be given to patients who have not been optimally staged.

Management of invasive early-stage low-risk disease (stages IA and IB, low grade)

In patients who have undergone a thorough staging laparotomy where there is no evidence of spread beyond the ovary, the performance of an abdominal hysterectomy and BSO is appropriate therapy. The uterus and contralateral ovary can be preserved in women with stage IA diploid lesions who wish to preserve fertility. These women should be followed carefully with periodic pelvic examinations and CA125 levels. Generally, the other ovary and uterus are removed at the completion of childbearing. In a recent report by Guthrie et al.,¹²⁹ the outcome of 656 patients with early-stage epithelial ovarian cancer was studied. No patients who had a properly documented stage I, grade 1 cancer died of their disease; that is, there was a 100% survival in this condition when patients were surgically staged, and thus adjuvant chemotherapy is unnecessary in patients with low-risk low-stage ovarian cancer.

Management of invasive early-stage high-risk disease (stage IA and IB, high grade, stage IC and stage II)

High-risk stage I is defined as stage IA or IB, grade 3, stage IC, or clear cell carcinomas. In patients whose disease is more poorly differentiated or in whom there are malignant cells either in ascitic fluid or

in peritoneal washings, additional therapy is indicated. Patients with grade 2 and grade 3 tumors, with densely adherent tumors, with large-volume ascites, and/or with positive peritoneal cytology, have a relapse risk of 20–45%, and postoperative treatment is warranted. Regrettably, it would appear that thorough staging with negative findings, including random peritoneal biopsies and lymph node sampling, does not eliminate the risk of relapse in patients with these characteristics. Patients with early-stage high-risk epithelial ovarian cancer have been treated with single-agent carboplatin or a combination of carboplatin and a taxane. Given a risk of recurrence and death of >20%, it is recommended that six cycles of chemotherapy with carboplatin (area under the curve [AUC] 5–6) and paclitaxel be considered in patients with high-risk low-stage ovarian cancer.

Management of early-stage borderline tumors

The principal treatment for borderline ovarian tumors is the surgical resection of the primary tumor. There is no evidence that either subsequent chemotherapy or radiation therapy improves survival. After performing a frozen section and determining that the histology is borderline, premenopausal patients who desire preservation of ovarian function may be managed with a conservative operation, such as a unilateral salpingo-oophorectomy. Thus, hormonal function and fertility can be maintained. In patients in whom an ovarian cystectomy has been performed and a borderline tumor is documented in the permanent pathology, no additional surgery is warranted.

There has been considerable controversy regarding the optimum treatment of patients with localized borderline ovarian tumors. This has been due, in part, to lack of unanimity regarding the histopathologic criteria for borderline tumors. For all stages of ovarian cancer, borderline tumors have a more favorable natural history than have invasive tumors. There is no evidence to suggest any benefit of adjuvant chemotherapy for patients with stage I or stage II borderline tumors. In a large GOG trial, a total of 51 patients were reclassified as having borderline tumors. In these carefully staged patients, there have been no deaths directly attributable to cancer. While a substantial number of patients did receive adjuvant chemotherapy in these trials, there is no evidence that it was necessary or beneficial. If, after careful histologic review of multiple slides sectioned at 1-cm intervals, no evidence of stromal invasion is found, patients with localized borderline tumors should not receive adjuvant chemotherapy.

Treatment of advanced stage epithelial cancer

A scheme for the management of patients with advanced-stage epithelial cancer is shown in [Figure 6](#). The components of this approach are discussed in the following sections.

Figure 6 Treatment scheme for patients with advanced-stage ovarian cancer. *Perform in a research setting where treatment will be based on outcome.

Cytoreductive surgery

Patients who have advanced-stage epithelial ovarian cancer documented at initial exploratory laparotomy should undergo cytoreductive surgery to remove as much of the tumor and its metastases as possible in order to facilitate the effectiveness of subsequent therapies. The operation usually includes the performance of a total abdominal hysterectomy and BSO, a complete omentectomy, and resection of metastatic lesions on the peritoneal surfaces or from the intestines. In addition, the pelvic tumor may

directly involve the rectosigmoid colon, the terminal ileum, and the cecum. In some patients, most or all of their disease is confined to the pelvic viscera and the omentum, so that removal of these organs results in the extirpation of all gross tumor and patients with no macroscopic residual disease, a situation that is associated with a reasonable chance of complete response.

The rationale for cytoreductive surgery relates to the following three general theoretical considerations: (1) potential physiologic benefits from excising the tumor; (2) improved tumor perfusion and increased growth fraction, which may increase the likelihood of a response to chemotherapy or radiation therapy; and (3) enhanced immunologic competence of the patient.^{131, 132}

The principal goal of cytoreductive surgery is to remove all of the primary cancer and, if possible, its metastases. If resection of all metastases is not feasible, the goal is to reduce the tumor burden by resection of all individual tumors to an optimal status. The definition of “optimal” was initially proposed by Griffiths, who found that the survival of patients whose metastatic disease was resected to less than 1.5 cm in maximum dimension was significantly longer than the survival of those whose residual lesions were larger than 1.5 cm.¹³³ The optimal category of patients had a higher subsequent response rate to chemotherapy and longer disease-progression-free interval (PFI). Subsequently, Hacker et al.¹³⁴ showed that patients whose largest residual lesions were less than 5 mm (defined as minimal residual disease [MRD]) survived much longer than did those with larger nonresectable tumor deposits. The median survival of patients in this category was 40 months, compared with 18 months for patients whose disease was >1.5 cm ([Figure 6](#)). Resectability of the metastatic tumor is often determined by the size of nodules, the extent of carcinomatosis, and the location of the disease.¹³⁵ The greatest benefit is observed in patients with no gross residual disease ([Table 6](#)).

Table 6 Nomenclature for patient status-residual ovarian cancer

Residual disease		Status
None	Pathologic	Complete remission
Microscopic disease	Only	Microscopic
Macroscopic disease	<5 mm	Minimal residual
Macroscopic disease	<1–2 cm	Optimal residual
Macroscopic residual disease	>1–2 cm	Suboptimal
Macroscopic disease	>2–3 cm	Bulky residual

Nomenclature for status of patient based on the extent of residual ovarian cancer before treatment.

An analysis of the retrospective data available suggests that these operations are feasible in 70–90% of patients when performed by gynecologic oncologists.^{131, 134–143} Complete resection is achievable, however, in only 30% of cases. Major morbidity is in the range of 5% and operative mortality is 1%.¹³⁶ Intestinal resection in these patients does not appear to increase the overall morbidity of the operation. The median survival and PFI of patients after cytoreductive surgery relate to the extent of residual disease at the completion of the laparotomy. A meta-analysis has been performed with 81 cohorts of patients that included 6885 women with stage III or stage IV disease.¹⁴³ A statistically significant positive correlation was found between percent maximal cytoreduction and log median survival time that remained significant after controlling for all other variables ($p < 0.001$). Each 10% increase in maximal cytoreduction was associated with a 5.5% increase in median survival time. Cohorts with 25% or less maximal cytoreduction had a median survival time of 22.7 months compared to 33.9 months in cohorts with greater

than 75% maximal cytoreduction.

Adjuvant chemotherapy with platinum compounds and taxanes

Systemic chemotherapy is the standard primary treatment for advanced epithelial ovarian cancer.^{144–169} A variety of regimens containing combinations of cytotoxic drugs have been tested in the treatment of advanced epithelial ovarian cancer. Combination chemotherapy has been shown to be superior to single-agent therapy in most adjuvant studies in patients with advanced epithelial ovarian cancer.

Meta-analyses have suggested that cisplatin and carboplatin are equally effective against epithelial ovarian cancer.¹⁶⁴ Paclitaxel was shown to be a very active agent against ovarian cancer.^{144, 145} The overall response rates for paclitaxel in phase 2 trials were 36% in previously treated patients, which is a higher rate than was seen for cisplatin when it was first tested. In previously untreated patients with suboptimally cytoreduced disease (GOG132), single agent cisplatin produced a 70% response rate, paclitaxel a 42% response rate, and the combination a 70% response rate.¹⁴⁸ Two of the three large, prospective randomized trials demonstrated an overall and progression-free survival (PFS) advantage for combining paclitaxel and platinum over platinum alone.^{146, 147, 160} Two randomized, prospective clinical studies have compared the combination of paclitaxel and carboplatin to that of paclitaxel and cisplatin.^{157, 158} In both studies, response rates and duration of survival are similar, but the carboplatin-containing regimens have had more acceptable toxicity.

Docetaxel versus paclitaxel

Docetaxel has produced a 23–28% overall response rate in platinum-resistant ovarian cancer, and a combination of docetaxel and cisplatin or carboplatin has achieved a 66–81% overall response rate in phase 2 trials.¹⁶⁸ A combination of *docetaxel* (75 mg/m² over 1 h) and *carboplatin* (AUC 5) has been compared to *paclitaxel* (175 mg/m²) and *carboplatin* (AUC 5) in the SCOTROC trial.¹⁶⁹ Similar efficacy was observed, but docetaxel/carboplatin was associated with significantly less neurotoxicity. Consequently, a combination of carboplatin and docetaxel should be considered for treatment of ovarian cancer in patients with significant neuropathy from comorbid disease such as diabetes.

Other doublets and triplets

Use of platinum compounds and taxanes has improved median and OS, but the outcome in patients with advanced ovarian cancer is still disappointing. Ultimately, drug resistance develops in the majority. A number of drugs have exhibited activity against recurrent disease including liposomal doxorubicin, gemcitabine, topotecan, navelbine, and etoposide. A five-arm study, GOG-182, compared the standard combination of *carboplatin* and *paclitaxel* in combination with *gemcitabine*, *topotecan*, or *liposomal doxorubicin* in sequential doublets or triplets.¹⁷⁰ This was the largest randomized trial ever carried out in women with advanced ovarian cancer and recruited over 4000 patients. There was no apparent difference between any of the arms in terms of PFS or median survival, but there were differences in the side effects experienced in the different arms. On the basis of this study as well as others, carboplatin and paclitaxel remain the standard of care.

Dose-dense chemotherapy

There is preclinical evidence as well as clinical evidence to suggest that dose-dense, dose-fractionated chemotherapy with carboplatin and paclitaxel may be more active than the same treatments given every 3 weeks. There are a number of explanations for this, including an antiangiogenic effect of weekly

metronomic paclitaxel, as well as decreasing the accelerated repopulation of cancer cells between cycles, and reducing the acquisition of drug resistance.^{171, 172}

A phase III study by the Japanese Gynecologic Oncology Group (JGOG) randomized 637 women with FIGO stage II to IV ovarian cancer to receive either weekly paclitaxel at a dose of 80 mg/m² in combination with three-weekly carboplatin (AUC 6) or three-weekly dosing of both drugs (carboplatin AUC 6 and paclitaxel 180 mg/m²).¹⁷³ After a median follow-up of 29 months, they reported that the median PFS was 17.2 months in the standard three-weekly paclitaxel arm, compared to 28 months in the weekly paclitaxel arm (HR 0.71; 95% CI 0.58–0.88, $p = 0.0015$) and the 3-year OS (at 42 months follow-up) was 65.1% and 72.1%, respectively (HR 0.75; 95% CI 0.57–0.98, $p = 0.03$) (Figure 11.19). The median PFS in patients with residual disease at least 1 cm was 17.6 months in the dose-dense arm compared to 12.1 months in the conventional arm. The median PFS in the patients with residual disease <1 cm was not statistically different between the two arms. The median overall survival in the patients with residual disease at least 1 cm was better in the dose-dense arm compared to the conventional arm (51.2 months vs 33.5 months).

They concluded that dose-dense treatment offered better survival than conventional treatment and was a potential new standard of care for first-line chemotherapy for patients with advanced epithelial ovarian cancer. The improvements in PFS and overall survival exceed any benefits seen previously in any phase III trial in ovarian cancer. It is unclear whether these benefits relate to pharmacogenomic or pharmacodynamic differences in the Japanese population. This and other studies have suggested that Asian patients with ovarian cancer have a significantly better survival than do Caucasian patients.¹⁷⁴ A GOG phase III study of patients with advanced-stage ovarian cancer (Protocol 218) revealed that the overall survival was significantly higher in Asian patients when adjusted for age, stage, residual disease, performance status, and histology.¹⁷⁵

It is essential that the JGOG study be confirmed in a predominantly Caucasian population. An Italian trial (MITO-7; NCT00660842) investigated a different schedule of weekly carboplatin (AUC 2 mg/mL/min) plus weekly paclitaxel (60 mg/m²) compared with carboplatin (AUC 6 mg/mL/min) and paclitaxel (175 mg/m²) administered every 3 weeks. The weekly regimen did not significantly improve PFS compared with the conventional regimen (18.8 months vs 16.5 months; $p = 0.18$), but was associated with better quality of life and fewer toxic effects.¹⁷⁶ The GOG 262 study was presented recently.¹⁷⁷ The design of GOG 262 was similar to the JGOG 3016 trial, the main difference being that patients could be treated also with IV bevacizumab 15 mg/kg every 3 weeks in both arms. The decision to receive bevacizumab was dependent on the treating doctors and patient wishes. The vast majority of patients (84%) received bevacizumab until progression. The population of patients included a large fraction with gross residual disease (63%) and 13% of patients received neoadjuvant chemotherapy. Only 24% had microscopic residual disease. The median PFS was the same in both arms and was just over 14 months. Only 112 patients did not have bevacizumab, with approximately equal numbers in both arms and interestingly, the median PFS was 14.2 months with dose-dense paclitaxel and only 10.3 months with three-weekly scheduling of paclitaxel. This was a subset analysis and definitive conclusions are difficult to draw.

Intraperitoneal chemotherapy

As cancer spreads over the surface of the peritoneum and often recurs at this site, investigators have evaluated intraperitoneal (IP) administration of chemotherapy that can achieve high local concentrations of drug. A randomized, prospective trial performed by the Southwest Oncology Group (SWOG) and the GOG compared IP cisplatin (100 mg/m²) to intravenous (IV) cisplatin (100 mg/m²), each given with II

cyclophosphamide (600 mg/m²), in patients with disease less than 2 cm in diameter.¹⁷⁸ The IP cisplatin arm had a significantly longer overall median survival than the intravenous arm, 49 months versus 41 months ($p = 0.03$). In the patients with the least residual disease (<0.5 cm maximum residual), however, there was not a statistically significant difference in median survival between the two treatments, 51 months versus 46 months ($p = 0.08$).

Results of this randomized trial became available as paclitaxel was being incorporated into clinical practice. In a follow-up trial conducted by the GOG, a standard regimen of IV cisplatin (75 mg/m²) and IV paclitaxel (135 mg/m² over 24 h) was compared to a dose-intense regimen that was initiated by giving moderately high-dose carboplatin (AUC = 9) for two induction cycles followed by IP cisplatin 100 mg/m² and IV paclitaxel (135 mg/m² over 24 h).¹⁷⁹ The dose-intense arm produced slightly better progression-free median survival (27.6 months vs 22.5 months, $p = 0.02$), but there was not a statistically significant difference in overall survival (52.9 months vs 47.6 months, $p = 0.056$).

A pivotal landmark randomized prospective GOG study¹⁸⁰ compared IP cisplatin and paclitaxel with IV cisplatin and paclitaxel and was reported in late 2006. Four hundred and twenty-nine patients were randomly assigned and 415 were eligible. The median PFS was 23.8 months in the IP arm versus 18.3 months in the IV arm ($p = 0.05$). The median overall survival was 65.6 months in the IP group and 49.7 months in the IV group ($p = 0.03$)—90% of patients in the IV arm received the six planned cycles of therapy, whereas only 42% of patients received the assigned six cycles of IP therapy with the remainder switching to IV therapy. The reasons for discontinuing were primarily for catheter-related problems, but there were also significantly more side effects in the IP group with more patients experiencing severe fatigue, abdominal pain, hematological toxicity, nausea and vomiting, as well as metabolic and neurotoxicity. In all likelihood, the toxicity can be reduced with more experience, appropriate dose modifications, and better antiemetics. The results of this study together with the previous studies led to an NCI Clinical Announcement recommending that women with optimally cytoreduced stage III ovarian cancer be considered for IP chemotherapy, and this is widely used in the United States.

There has been a *Cochrane Review* as well as a separate meta-analysis that concluded that IP chemotherapy was associated with better outcomes than IV chemotherapy.^{181, 182} The meta-analysis included six randomized trials with a total of 1716 ovarian cancer patients. The pooled HR for PFS of IP cisplatin as compared to IV treatment regimens was 0.792 (95% CI = 0.688–0.912, $p = 0.001$), and the pooled HR for OS was 0.799 (95% CI: 0.702–0.910, $p = 0.0007$). The authors conclude that these findings strongly support the incorporation of an IP cisplatin regimen to improve survival in the frontline treatment of stage III, optimally debulked ovarian cancer. Similar conclusions were reached in the *Cochrane Review*. The reviewers concluded that their analysis establishes the benefit of IP chemotherapy and that it is associated with an increased overall survival and PFS in patients with optimally debulked stage III advanced ovarian cancer. However, they also commented on the potential for catheter-related complications and increased toxicity with IP therapy and concluded that the optimal dose, timing, and mechanism of administration should be addressed in the next phase of clinical trials. The role of IP chemotherapy, however, is still contentious with some arguing that the trials to date were not pure tests of IP therapy and were flawed, and, in addition, they have raised concerns about the technical difficulties as well as increased toxicity of IP therapy.¹⁸³ Although decisions regarding primary therapy must be individualized, IP therapy should be seriously considered for all optimally cytoreduced patients with ovarian cancer, given the difference in overall survival. This is underscored by the recent updated survival results reported from GOG172. The median survival with IP therapy was 61.8 months (95% CI, 55.–69.5), compared with 51.4 months (95% CI, 46.0–58.2) for intravenous therapy. IP therapy was associated with a 23% decreased risk of death (adjusted HR 0.77; 95% CI, 0.65–0.90; $p = 0.002$).

Survival improved with increasing number of IP cycles.¹⁸⁴

Neoadjuvant chemotherapy

Some authors have suggested that, for patients with suboptimal stage III and stage IV disease, chemotherapy may be given in lieu of cytoreductive surgery. A series performed at Yale by Schwartz et al.¹⁸⁵ suggested that the survival of patients treated with “neoadjuvant” or cytoreductive chemotherapy was comparable to those patients treated historically with cytoreductive surgery followed by conventional chemotherapy in the same institution. However, two or three cycles of chemotherapy before cytoreductive surgery may be helpful in patients with massive ascites or large pleural effusions. Chemotherapy may eliminate the effusions, improve the patient's performance status, and decrease postoperative morbidity, particularly within the chest. Bristow et al.¹⁸⁶ reported the results of a systemic overview of neoadjuvant chemotherapy and concluded that neoadjuvant chemotherapy represents a viable alternative management strategy for the limited number of patients felt to be optimally unresectable by an experienced ovarian cancer surgical team; however, currently available data suggest that the survival outcome achievable with initial chemotherapy is inferior to successful upfront cytoreductive surgery.

A prospective randomized study of “interval” cytoreductive surgery was reported by the European Organization for the Research and Treatment of Cancer (EORTC) in 1995. Interval surgery was performed after three cycles of platinum-combination chemotherapy in patients whose primary attempt at cytoreduction was suboptimal. Patients in the surgical arm of the study demonstrated a survival benefit when compared with those who did not undergo interval debulking.¹⁸⁷ In a 10-year follow-up analysis, the risk of mortality was reduced by more than 40% in the group that was randomized to the debulking arm of the study.¹⁸⁸ A prospective phase III study of interval cytoreductive surgery conducted by the GOG¹⁸⁹ failed to confirm these findings: The median survival of the 216 women who underwent interval cytoreduction was 32 months, compared with 33 months for the 209 women who did not undergo cytoreduction. This analysis reflected the fact that all patients had been operated on initially by a gynecologic oncologist, so they had already undergone a maximal attempt at tumor resection.¹⁹⁰

Several investigators suggested that neoadjuvant chemotherapy followed by an interval cyto-reduction might be appropriate in women whose performance status was poor.^{185, 191, 192} In 2010, Vergote et al.¹⁹³ reported the results of a randomized EORTC-NCIC (National Cancer Institute of Canada) study of primary debulking surgery (PDS) versus three cycles of neoadjuvant chemotherapy followed by interval debulking surgery in 670 patients with stages IIIC–IV epithelial ovarian, fallopian tube, and peritoneal cancer. All the patients were reported to have had extensive stage IIIC or IV disease. Just over 60% had metastatic lesions that were larger than 10 cm in diameter, and 74.5% had lesions larger than 5 cm. Patients were randomly assigned either to PDS followed by at least six courses of platinum-based chemotherapy or to three courses of neoadjuvant platinum-based chemotherapy followed by interval debulking surgery in all patients whose disease has responded or is stable, followed by at least three additional courses of platinum-based chemotherapy. The median overall survival was 29 months in the primary-surgery group and 30 months in the neoadjuvant chemotherapy group. The median PFS in both groups was 12 months suggesting that the study included a relatively poor prognostic subset of patients. There was lower postoperative morbidity and mortality reported in the group that received neoadjuvant chemotherapy.

Complete tumor resection was the strongest independent predictor of overall survival in both groups. The results of this study have been widely debated and the findings criticized by a number of authors.^{194–197} In an analysis of this study, Du Bois et al.¹⁹⁴ noted that the patients recruited to this study had a poorer

performance status than those in most upfront randomized trials, and that the complete resection rates varied considerably from country to country and were considered to be low. In the PDS group, only about 20% of patients were completely cytoreduced to no residual disease, which is much lower than what would be expected in experienced centers. Indeed, there were very different optimal debulking rates reported in different countries, ranging from 62% in Belgium to 3.9% in the Netherlands suggesting highly variable surgical expertise. The median OS was only 30 months, which is considerably less than the 60+ months expected with optimal cytoreduction followed by chemotherapy, suggesting that the study included a poor performance status cohort of patients with very advanced disease.

There have been two other randomized trials of neoadjuvant chemotherapy that have completed enrollment. The first study is the chemotherapy or upfront surgery (CHORUS) trial, which had a similar design to the EORTC trial, was conducted in the United Kingdom and was reported recently.¹⁹⁸ The CHORUS study had very similar findings to the EORTC study. Five hundred and fifty-two patients were randomized to receive either neoadjuvant chemotherapy followed by interval debulking and then three additional cycles or PDS followed by six cycles of platinum-based chemotherapy. The optimal debulking rate was only 16% in the PDS group, compared to 40% following neoadjuvant chemotherapy. The median duration of surgery was only 120 min in both groups, which is clearly not long enough for aggressive debulking surgery. There was a 5.6% postoperative mortality rate in the PDS group, which is much higher than expected and may reflect patient selection. The median PFS was 12 months, which is clearly not long enough for aggregate compared to the primary chemotherapy group and the median overall survival was 22.6 months in the primary-surgery group versus 24.1 months in those who had primary chemotherapy. The HR for death was 0.87 in favor of primary chemotherapy, with the upper bound of the one-sided 90% CI 0.98 (95% CI 0.72–1.05). There were more serious adverse events and deaths within 28 days of surgery in the primary surgery group, and the authors concluded that in women with stage III or IV ovarian cancer, survival with primary chemotherapy was noninferior to primary surgery and a reasonable option in selected patients.

There remain very divergent views regarding the place of neoadjuvant chemotherapy. A survey of SGO members found that 82% felt there was not enough evidence to justify the use of neoadjuvant chemotherapy.¹⁹⁹ In contrast, 70% of ESGO members felt there was sufficient evidence to recommend neoadjuvant chemotherapy. On the basis of the above-mentioned considerations, the performance of a debulking operation as early as possible in the course of the patient's treatment should be considered the standard of care.²⁰⁰ Neoadjuvant chemotherapy followed by interval cytoreduction should be reserved for patients with a poor performance and nutritional status, as these patients will usually have decreased postoperative morbidity if chemotherapy is given before cytoreduction.

Bevacizumab adjuvant therapy

Inhibition of angiogenesis with drugs such as bevacizumab has demonstrated activity and benefit in women with recurrent ovarian cancer and in view of this there are two large randomized trials investigating the impact of the addition of bevacizumab to standard carboplatin and paclitaxel for adjuvant therapy in patients with advanced ovarian cancer. There is evidence in other tumor types such as colon cancer and lung cancer that the addition of bevacizumab to chemotherapy increases response rates and PFS and also survival in some studies.^{201, 202}

Two large phase III studies (GOG 218 and ICON 7) have investigated the role of bevacizumab in the first-line setting. The GOG 218 trial was a three-arm randomized study that recruited 1873 patients with stage III–IV ovarian, fallopian tube, and peritoneal cancer.²⁰³ Patients with stage III disease were required to have macroscopic residual disease. The patients were randomly assigned to one of the

following: (1) a control group that received 6 cycles of carboplatin and paclitaxel chemotherapy with concurrent placebo in cycles 2 through 6, followed by placebo alone every 3 weeks for a total of 22 cycles; (2) a group that received standard chemotherapy for 6 cycles in combination with bevacizumab (15 mg/kg) in cycles 2 through 6, followed by placebo alone for a total of 22 cycles; and (3) a group that received standard chemotherapy for 6 cycles with bevacizumab in cycles 2 through 6, followed by the continuation of bevacizumab alone, for a total of 22 cycles. At a median follow-up of 17.4 months, the hazard of progression or death was the same in the bevacizumab with chemotherapy group compared with the control group (HR, 0.908; $p = 0.16$) and significantly lower in the bevacizumab with chemotherapy and maintenance group (HR, 0.717; $p < 0.001$). In an analysis of PFS, in which patients with an elevated CA-125 were censored, the median PFS was 12 months in the control group but 18 months in the bevacizumab maintenance group (HR, 0.645; $p = 0.001$). This was confirmed in a recent analysis on independent radiologic review of all patients in GOG 218. To date, there does not appear to be any significant difference in OS, and this may be due to many patients receiving multiple subsequent regimens at relapse, including crossover to bevacizumab or other anti-VEGF agents that could potentially influence overall survival.

The ICON7 trial had a similar design and enrolled 1528 patients with high risk (clear cell or grade 3 tumors).²⁰⁴ Patients with stage I and II ovarian, fallopian tube, or peritoneal cancer, as well as stages III and IV, were included. They were randomized to six cycles of chemotherapy alone or 6 cycles of chemotherapy plus bevacizumab (7.5 mg/kg), followed by 12 cycles of maintenance bevacizumab every 3 weeks. With a median follow-up of 19.4 months, the median PFS was 17.3 months in the control group and 19 months in the bevacizumab group (HR, 0.81; $p = 0.004$). The improvement in PFS with bevacizumab was maintained with a median follow-up of 28 months. An exploratory OS analysis showed a significant improvement in survival in the high-risk subgroups (stage III with >1 cm residual and stage IV [HR, 0.64; $p = 0.002$]). This was confirmed in a recently presented update of the survival data, which showed that there was a 4-month improvement in median survival from 35 to 39 months in the high-risk subgroup.²⁰⁵ However, there was no survival advantage found between the two arms in ICON7. Bevacizumab was associated with an increase in toxicity, which included bleeding (mainly grade 1 mucocutaneous bleeding), grade 2 or higher hypertension (18% with bevacizumab vs 2% with standard therapy), grade 3 or higher thromboembolic events (7% with bevacizumab vs 3% with standard therapy), and gastrointestinal perforations (occurring in 10 patients in the bevacizumab group vs 3 patients in the standard-therapy group).

In contrast to the GOG 218 study, the ICON7 study enrolled patients with advanced-stage cancer with no visible residual disease, as well as patients with high-risk early-stage disease. In the ICON7 study, a lower dose of bevacizumab was used (7.5 mg/kg vs 15 mg/kg in GOG 218) for a shorter maintenance period (12 cycles vs 16 cycles). In both studies, PFS curves converged a few months after bevacizumab was discontinued, suggesting that antiangiogenic treatment may delay, but not prevent, disease progression. This raises the issue of the advisability of patients with high-risk disease continuing treatment indefinitely. This is currently under investigation but has significant cost-benefit implications. There are still no good biologic markers to identify which patients are most likely to benefit from the incorporation of bevacizumab into the first-line setting. The optimal dose is also unclear.

Management of advanced invasive ovarian cancer

The treatment of choice for patients with advanced invasive epithelial ovarian cancer is cytoreductive surgery followed by six to eight cycles of chemotherapy with a combination of carboplatin (AUC 5-6) and paclitaxel (175 mg/m² over 3 h) every 3 weeks ([Table 7](#)). As discussed earlier, a dose-dense regimen or

IP regimen are both evidence-based options as is the addition of bevacizumab, and the choice of treatment should be individualized. In patients at risk for severe neuropathy, diabetics, for example, a combination of docetaxel (75 mg/m²) and carboplatin (AUC 5) provides an alternative that is less neurotoxic. In women who cannot tolerate the toxicity of taxanes, carboplatin alone (AUC 5-6) is a reasonable option.

Table 7 Chemotherapy for advanced epithelial ovarian, fallopian tube, and peritoneal cancer: recommended regimens

Drugs	Dose	Administration (h)	Interval	Number of treatments
<i>Standard regimens</i>				
Carboplatin Paclitaxel	AUC = 5–6 175 mg/m ²	3	Every 3 weeks	6–8 cycles
Carboplatin Paclitaxel	AUC = 5 80 mg/m ²	3	Every 3 weeks Every week	6 cycles 18 weeks
Carboplatin Docetaxel	AUC = 5 75 mg/m ²	3	Every week Every 3 weeks	6 cycles
Cisplatin Paclitaxel	75 mg/m ² 135 mg/m ²	3 24	Every 3 weeks	6 cycles
Carboplatin (single agent) ^a	AUC = 4–6	3	Every 3 weeks	6 cycles, as tolerated

^a In patients who are elderly, frail or poor performance status.

AUC, are under the curve dose by Calvert formula.

Management of advanced borderline tumors

The place of chemotherapy in patients with advanced-stage borderline tumors is uncertain and controversial. The GOG is evaluating the use of chemotherapy in patients with advanced-stage borderline tumors who have recurrent disease after initial surgery. Until the results of this trial are known, the current approach to treatment is primarily surgical. Patients should undergo cytoreductive surgery and observation. Borderline tumors, even in advanced stage, have a favorable prognosis. The first symptomatic recurrence may be several years after diagnosis. In contrast to the 20–25% survival rates for advanced epithelial invasive carcinoma of the ovary, the survival rate for patients with stage III borderline tumors is over 60%. Consequently, secondary cytoreductive surgery frequently will lead to another prolonged interval of symptom free survival. Chemotherapy can be administered to the patients in whom cytoreductive surgery is no longer feasible, although its efficacy is uncertain and response rates very low.

Assessment of response in patients who are clinically free of disease

Many patients who have undergone optimal cytoreductive surgery and subsequent therapy for epithelial ovarian cancer will have no evidence of disease at the completion of treatment. Tumor markers and radiologic assessments have proved to be too insensitive to exclude accurately the presence of subclinical disease.^{206–208} A technique used to evaluate residual disease has been the second-look operation, which is no longer routinely used^{209, 210} because second-look laparotomies have not been shown to influence patient survival with currently available chemotherapy; they should be done only in a

research setting, to test second-line or salvage therapies that are likely to be affected by the volume of disease, such as immunotherapies or antiautophagic therapies.

Maintenance chemotherapy

The optimal management of patients who do achieve a clinical complete remission after induction chemotherapy remains to be determined. Even patients who achieve a surgically confirmed complete remission have a 30–50% recurrence rate. Some investigators have suggested that second-look laparotomy should be performed to identify patients who may be candidates for IP therapy.²¹¹ There is no evidence, however, that the routine sequential administration of IP chemotherapy after IV induction chemotherapy prolongs survival.

Clinical trials have been performed to determine whether maintenance chemotherapies are of benefit in patients who achieve a surgically confirmed clinical complete remission. A study conducted by the GOG and SWOG compared 3 and 12 monthly cycles of “consolidation” chemotherapy with paclitaxel (135–175 mg/m² IV over 3 h) for patients who had achieved a clinical remission following primary paclitaxel and carboplatin chemotherapy.²¹² PFI was 21 and 28 months in the 3-cycle and 12-cycle paclitaxel arms ($p = 0.035$), respectively. Consequently, 9 months of additional chemotherapy provided an additional 7 months of PFS. To date, there is no difference in OS between the two arms. Two placebo-controlled randomized trials have been performed in Europe using consolidation with four cycles topotecan given to patients in clinical remission following chemotherapy with carboplatin and paclitaxel, and in both trials, there was no improvement in survival compared with placebo.^{213, 214}

Follow-up examinations

The optimal frequency of follow-up examinations is unknown, but for those patients who have completed chemotherapy and who are in clinical remission, a pelvic examination and a CA125 every 3 months for 1–2 years is reasonable. An elevated CA125 (>35 U/mL) can provide lead time of approximately 3–6 months before there are clinical signs or symptoms of recurrence. The Gynecologic Cancer Inter Group (GCIG) developed a standard definition for CA125 progression, which is now widely used in clinical trials. Patients with elevated CA125 pretreatment and subsequent normalization of CA125 must show evidence of CA125 greater than or equal to 2× the upper normal limit on two occasions at least 1 week apart, or patients with elevated CA125 pretreatment that never normalizes must show evidence of CA125 greater than or equal to 2× the nadir value on two occasions at least 1 week apart.

A rising CA125 may prompt the performance of a CT scan. The role of PET scanning in this setting has not been defined. A recent review concluded that PET has a sensitivity of 90% and a specificity of 85% approximately for the detection of recurrent ovarian cancer and that it appears to be particularly useful for the diagnosis of recurrence when CA125 levels are rising and conventional imaging is inconclusive or negative, although the value of this is debatable. Combined ¹⁸fluorodeoxyglucose (FDG)-PET/CT devices, which perform contemporaneous acquisition of both ¹⁸FDG-PET and CT images, may be more valuable to detect recurrent ovarian cancer; this technique may be useful for the selection of patients with late recurrent disease who may benefit from secondary cytoreductive surgery.²¹⁵

A rising CA125 level in the absence of changes on physical examination or CT scan in a patient in initial remission poses a dilemma. At present, additional cytotoxic therapy is not recommended based on a rising CA125 alone in the absence of clinical symptoms or radiologic evidence of recurrence. Treatment with tamoxifen or anastrozole has sometimes been given and although stabilization or a fall in CA125 may be observed in approximately 20% of patients, the value of this intervention is uncertain. The GOG has

compared tamoxifen to thalidomide in patients with a rising CA125 without other evidence of disease recurrence. Similar efficacy was observed, although tamoxifen was less toxic. There are also trials using a rising CA125 to evaluate a paradigm to evaluate the activity of novel cytostatic targeted drugs. As more effective salvage therapy becomes available, serum markers such as CA125 may have greater utility. In patients whose disease was never found to be metastatic to the chest or who never had a pleural effusion, chest radiograph surveillance is not mandatory. In the absence of a rising CA125, follow-up CT or MRI scans should be used with discretion during the first 3 years after chemotherapy.

Treatment of recurrent epithelial cancer

The majority of women who relapse will be offered further chemotherapy with the likelihood of benefit related in part to the initial response and the duration of response. The goals of treatment include improving control of disease-related symptoms, maintaining or improving quality of life, delaying time to progression, and possibly prolonging survival, particularly in women with platinum-sensitive recurrences. Many active chemotherapy agents (platinum, paclitaxel, topotecan, liposomal doxorubicin, docetaxel, gemcitabine, pemetrexed, and etoposide) as well as targeted agents (bevacizumab) are available and the choice of treatment is based on many factors, including likelihood of benefit, potential toxicity, and patient convenience.^{216, 217} Women who relapse >6 months after primary chemotherapy are classified as “platinum-sensitive” and usually receive further platinum-based chemotherapy with response rates ranging from 27% to 65% and a median survival of 12–24 months.^{218, 219} Patients who relapse within 6 months of completing first-line chemotherapy are classified as “platinum-resistant” and have a median survival of 6–9 months and a 10–30% likelihood of responding to chemotherapy. Patients who progress while on treatment are classified as having “platinum-refractory” disease. Objective response rates to chemotherapy in patients with platinum-refractory ovarian cancer are very low, typically less than 10%.²¹⁶

Platinum-sensitive disease

In general, randomized trials have shown that response rates, median PFS, and overall survival rates are superior for platinum-based combination chemotherapy compared to single-agent platinum chemotherapy. The use of combination *platinum plus paclitaxel* chemotherapy versus *single-agent platinum* has been tested in two multinational randomized phase III trials²²⁰ and a randomized phase II study.²²¹ In a report of the ICON4 and AGO-OVAR-2.2 trials, 802 women with platinum-sensitive ovarian cancer who relapsed after being treatment free for at least 6–12 months were randomized to platinum-based chemotherapy (72% carboplatin or cisplatin alone; 17% CAP; 4% carboplatin plus cisplatin; and 3% cisplatin plus doxorubicin) or paclitaxel plus platinum-based chemotherapy (80% paclitaxel plus carboplatin; 10% paclitaxel plus cisplatin; 5% paclitaxel plus both carboplatin and cisplatin; and 4% paclitaxel alone). The AGO-OVAR-2.2 trial did not accrue its planned number of patients. In both trials, a significant proportion of the patients had not received paclitaxel initially. Combining the trials for analysis, there was a significant survival advantage for the paclitaxel-containing therapy (HR = 0.82), with a median follow-up of 42 months. The absolute 2-year survival advantage was 7% (57% vs 50%), and there was a 5-month improvement in median survival (29 months vs 24 months). PFS was better with the paclitaxel regimen (HR = 0.76); there was a 10% difference in 1-year PFS (50% vs 40%) and a 3-month prolongation in median PFS (13 months vs 10 months). The toxicities were comparable, except there was a significantly higher incidence of neurologic toxicity and alopecia in the paclitaxel group, whereas myelosuppression was significantly greater with the non-paclitaxel-containing regimens.

Two randomized trials have compared *carboplatin alone* to *carboplatin and gemcitabine* or *carboplatin and liposomal doxorubicin*.^{222, 223} There was a higher response rate with the combination therapy and a longer PFS, but the studies were not powered to look at overall survival. In the GCIG study comparing carboplatin and gemcitabine with carboplatin alone, the response rate was 47.2% for the combination and 30.9% for carboplatin, with the PFSs being 8.6 and 5.8 months, respectively. A SWOG study of carboplatin versus carboplatin and liposomal doxorubicin was closed early because of poor accrual, but with 61 patients recruited, the response rate was 67% for the combination and 32% for carboplatin. The PFS was 12 months versus 8 months; intriguingly, the overall survival was 26 months compared to 18 months ($p = 0.02$).²²⁴ A phase II study from France confirmed the high response rate of 67% with carboplatin and liposomal doxorubicin in patients with platinum-sensitive recurrent ovarian cancer.

A large GCIG study (CALYPSO) comparing carboplatin and liposomal doxorubicin (CD) with carboplatin and paclitaxel (CP) recruited almost 1000 patients. With a median follow-up of 22 months, PFS for the CD arm was statistically superior to the CP arm (HR, 0.821; 95% CI, 0.72–0.94; $p = 0.005$); median PFS was 11.3 months versus 9.4 months, respectively. Overall, severe nonhematologic toxicity (36.8% vs 28.4%; $p = 0.01$) leading to early discontinuation (15% vs 6%; $p = 0.001$) occurred more frequently in the CP arm. More frequent grade 2 or greater alopecia (83.6% vs 7%), hypersensitivity reactions (18.8% vs 5.6%), and sensory neuropathy (26.9% vs 4.9%) were observed in the CP arm; more hand–foot syndrome (grade 2 to 3, 12% vs 2.2%), nausea (35.2% vs 24.2%), and mucositis (grade 2 to 3, 13.9% vs 7%) in the CD arm. This trial demonstrated superiority in PFS and better therapeutic index of carboplatin and liposomal doxorubicin compared to carboplatin and paclitaxel, and this regimen is now widely used.

Some researchers have hypothesized that treating patients with nonplatinum drugs to prolong the platinum-free interval will allow the tumor to again become more platinum sensitive over time.²²⁵ However, there are no data to support the hypothesis that the interposition of a nonplatinum agent will result in an increase in platinum sensitivity because of a longer interval since the last platinum treatment.

Nonplatinum regimens have been investigated as second-line therapy,^{226, 227} including a large phase III trial of *trabectedin plus liposomal doxorubicin* compared to *liposomal doxorubicin alone*.²²⁸ This trial included patients with platinum-resistant as well as platinum-sensitive recurrent disease. In patients with “platinum-sensitive” recurrence, response rates were higher for the combination of trabectedin plus liposomal doxorubicin (35% vs 23%) and the median PFS was 9.2 months versus 7.5 months, respectively (HR, 0.73; 95% CI, 0.56–0.95; $p = 0.0170$).²²⁸ The authors did not report on the response rates to subsequent platinum-based chemotherapy in patients with either platinum-sensitive or platinum-resistant disease and whether there was any apparent increased likelihood of response to platinum as a result of increasing the platinum-free interval.

OCEANS is a randomized trial of bevacizumab in 484 women with platinum-sensitive recurrent ovarian cancer. Patients with recurrence ≥ 6 months after first-line platinum-based therapy and measurable disease were randomly assigned to *carboplatin and gemcitabine* plus either *bevacizumab* or *placebo* for 6–10 cycles. Bevacizumab or placebo was then continued until disease progression. The primary end point was PFS by RECIST. The PFS for the bevacizumab arm was superior to that for the placebo arm (HR, 0.484; 95% CI, 0.388–0.605; $p < 0.0001$). The median PFS was 12.4 months in the bevacizumab arm compared to 8.4 months in the placebo arm. The objective response rate (78.5% vs 57.4%; $p < 0.0001$) and duration of response (10.4 months vs 7.4 months; HR, 0.534; 95% CI, 0.408–0.698) were also significantly improved with the addition of bevacizumab. Quality of life was not assessed but there were no new or unexpected toxicities observed. There are no data regarding the impact on overall survival. The findings of this study support the role of bevacizumab in selected patients with platinum-sensitive recurrent

ovarian cancer.

Other forms of antiangiogenic therapy are being evaluated in clinical trials.²²⁹ *VEGF Trap* (aflibercept) functions as a soluble decoy receptor soaking up ligand before it can interact with its receptor and is being evaluated in phase 2 trials in patients with recurrent ovarian cancer. There are also a number of other oral agents that target angiogenesis through tyrosine kinase inhibition.

Platinum-resistant/refractory disease

In platinum-refractory patients—defined as those progressing on treatment—the response rates to second-line chemotherapy are less than 10% ([Table 7](#)). The management of women who are platinum-resistant (i.e., progressing within 6 months of completion of chemotherapy) is complex and these patients should be offered clinical trials if available. However, the Aurelia trial recently demonstrated the added benefit of *bevacizumab to chemotherapy*, and this is likely to change the standard of care as the FDA recently approved the use of bevacizumab in patients with platinum-resistant ovarian cancer based on the results of Aurelia.²³⁰

All randomized trials of combination versus single-agent chemotherapy in resistant/refractory ovarian cancer have failed to show superiority of combination chemotherapy over single-agent treatment. There are a variety of potentially active single agents, the most frequently used being *paclitaxel*, *docetaxel*, *topotecan*, *liposomal doxorubicin*, *gemcitabine*, *ifosfamide*, *trabectedin*, *oral etoposide*, *tamoxifen*, *pemetrexed*, and *bevacizumab*.^{226, 227, 231–234}

Almost 200 patients with platinum-resistant ovarian cancer were randomized to receive either *gemcitabine* or *liposomal doxorubicin*. In the gemcitabine and liposomal doxorubicin groups, median PFS was 3.6 months versus 3.1 months, median overall survival was 12.7 months versus 13.5 months, and overall response rate was 6.1% versus 8.3%, respectively. In the subset of patients with measurable disease, overall response rate was 9.2% versus 11.7%, respectively. None of the efficacy end points showed a statistically significant difference between treatment groups. The liposomal doxorubicin group experienced significantly more hand–foot syndrome and mucositis, whereas the gemcitabine group had significantly more constipation, nausea and vomiting, fatigue, and neutropenia.²³⁵

These findings are similar to the results of a large randomized phase III trial comparing *patupilone* to *liposomal doxorubicin* in 829 patients with platinum-refractory/resistant ovarian cancer.²³⁶ Patupilone is a microtubule-stabilizing agent that induces cell-cycle arrest and apoptosis after binding to its molecular target, β -tubulin, and has been reported to have a 16% overall response rate in patients with platinum-refractory and platinum-resistant recurrent ovarian cancer. The primary endpoint of the study was overall survival. There was no difference in patient outcomes between the two treatments. The median PFS was 3.7 months in both arms, and the overall survival was 13.2 months in the patupilone arm and 12.7 months in the liposomal doxorubicin arm; 20% of patients in the experimental arm discontinued treatment because of toxicity. Frequently observed adverse events of all grades were common and included diarrhea (85%) and peripheral neuropathy (39%) in the patupilone arm and stomatitis/mucositis (43%) and hand–foot syndrome (41.8%) in the liposomal doxorubicin arm. The majority of patients in this trial had platinum resistant, not platinum-refractory disease. Furthermore, almost all had a WHO performance status of 0 or 1, so this selected population is not necessarily representative of the large group of women with platinum-resistant/refractory ovarian cancer. The results highlight the poor prognosis of these patients, and underscore the importance of symptom benefit and quality-of-life considerations. Arguably, these should be the primary aim of chemotherapy and should be used as coprimary end points, along with traditional endpoints such as PFS and OS in clinical trials.

Single-agent paclitaxel has shown objective responses in 20–30% of patients in phase II trials of women with platinum-resistant ovarian cancer.^{237–242} The main toxicities have been asthenia and peripheral neuropathy. Weekly paclitaxel is more active than three-weekly dosing and is also associated with less toxicity. In a study of 53 women with platinum-resistant ovarian cancer, weekly paclitaxel (80 mg/m² over 1 h) had an objective response of 25% in patients with measurable disease, and 27% of patients without measurable disease had a 75% decline in serum CA125 levels.²⁴⁰

Docetaxel also has some activity in patients with platinum-resistant disease.^{243–245} The GOG studied 60 women with platinum-resistant ovarian or primary peritoneal cancer.²⁴⁵ Although there was a 22% objective response rate, the median response duration was only 2.5 months, and therapy was complicated by severe neutropenia in three-quarters of the patients.

Topotecan is an active second-line treatment for patients with platinum-sensitive and platinum-resistant disease.^{246–259} In a study of 139 women receiving topotecan 1.5 mg/m² daily for 5 days, response rates were 19% and 13% in patients with platinum-sensitive and platinum-resistant disease, respectively.²⁴⁶ The predominant toxicity of topotecan is hematologic, especially neutropenia. With the 5-day dosing schedule, 70–80% of patients have severe neutropenia and 25% have febrile neutropenia, with or without infection.^{246, 251} In some studies, regimens of 5 days produce better response rates than regimens of shorter duration,^{246–256} but in others, reducing the dose to 1 mg/m²/day for 3 days is associated with similar response rates but lower toxicity. In a study of 31 patients, one-half of whom were platinum-refractory,²⁵⁹ topotecan 2 mg/m²/day for 3 days every 21 days had a 32% response rate. Continuous infusion topotecan (0.4 mg/m²/day for 14–21 days) had a 27–35% objective response rate in platinum-refractory patients.²⁵² Weekly topotecan administered at a dose of 4 mg/m²/week for 3 weeks with a week off every month produced a response rate similar to the 5-day regimen with considerably less toxicity. Therefore, this is now considered the regimen of choice for this agent.

Liposomal doxorubicin (Doxil in the United States and Caelyx in Europe) has activity in platinum- and taxane-refractory disease. Its predominant severe toxicity is the hand–foot syndrome, also known as palmar–plantar erythrodysesthesia or acral erythema, which is observed in 20% of patients who receive 50 mg/m² every 4 weeks.^{260, 261} Liposomal doxorubicin does not cause neurologic toxicity or alopecia. It is administered every 4 weeks, which makes it convenient, and it is relatively well tolerated at the lower dose of 40 mg/m², which is widely used. In a study of 89 patients with platinum-refractory disease, including 82 paclitaxel-resistant patients, liposomal doxorubicin (50 mg/m² every 3 weeks) produced a response in 17% (one complete and 14 partial response). In another study, an objective response rate of 26% was reported, although there were no responses in women who progressed during first-line therapy.²⁶²

There have been two randomized trials comparing *liposomal doxorubicin with either topotecan or paclitaxel*. In a study of 237 women who relapsed after receiving one platinum-containing regimen, 117 of whom (49.4%) had platinum-refractory disease, liposomal doxorubicin 50 mg/m² over 1 h every 4 weeks was compared with topotecan 1.5 mg/m²/day for 5 days every 3 weeks. The two treatments had a similar overall response rate (20% vs 17%), time to progression (22 weeks vs 20 weeks), and median overall survival (66 weeks vs 56 weeks). The myelotoxicity was significantly lower in the liposomal doxorubicin-treated patients. In a second study comparing liposomal doxorubicin with single-agent paclitaxel in 214 platinum-treated patients who had not received prior taxanes,²⁶³ the overall response rates for liposomal doxorubicin and paclitaxel were 18% and 22%, respectively, and median survivals were 46 and 56 weeks, respectively. Neither was significantly different. In practice, most patients are

treated with a starting dose of 40 mg/m² of liposomal doxorubicin every 4 weeks because dose reduction is common when 50 mg/m² is used initially.

Gemcitabine is a nucleoside analog of cytidine and has been reported to have response rates of 10–20% in patients who have platinum-resistant disease and 6% in those with platinum-refractory disease.^{231–233, 264, 265} The principal toxicities are myelosuppression and gastrointestinal.

The most common toxicities with *oral etoposide* are myelosuppression, nausea, and vomiting. Grade 4 neutropenia is observed in approximately one-fourth of patients, and 10–15% have severe nausea and vomiting.²³⁴ Although an initial study of intravenous etoposide reported an objective response rate of only 8% among 24 patients,²³⁴ a subsequent study of oral etoposide given for a prolonged period (50 mg/m² daily for 21 days every 4 weeks) had a 27% response rate in 41 women with platinum-resistant disease, three of whom had durable complete responses. In 25 patients with platinum- and taxane-resistant disease, eight objective responses (32%) were reported. Oral etoposide should be considered in patients with paclitaxel- and platinum-resistant disease.

Immunotherapy

There is considerable interest in the use of check-point inhibitors in ovarian cancer. The results of anti-PD1 and anti-PDL1 antibodies in melanoma and in lung cancer-stimulated trials in ovarian cancer. Hamanishi and colleagues from Kyoto, Japan, presented a phase II study using *nivolumab* (anti-PD1 antibody) in which there was an objective response rate of 17% in patients who were heavily pretreated and had platinum-resistant disease, including a complete response in a patient with an ovarian clear cell carcinoma.²⁶⁶ Other reports in solid tumors including ovarian cancer are encouraging.²⁶⁷ Cell-based therapy using genetically engineered CAR T cells is being developed against several targets, including mesothelin and ESO-NY.²⁶⁸

Hormonal therapy

Epithelial ovarian tumors frequently contain elevated levels of estrogen and androgen receptors, particularly in low-grade cancers. Some patients with epithelial ovarian tumors have had responses to endocrine therapy, although it appears that the overall response rate in high-grade cancer is approximately 10–20%. Progestational agents, tamoxifen, aromatase inhibitors, and GNRH agonists have been used either alone or in combination with cytotoxic chemotherapy in patients with advanced disease.^{269–272} In a study of patients with advanced, largely high-grade epithelial ovarian cancer, tamoxifen exhibited only a 13% partial response rate, but disease progression was delayed in 30%. Higher response rates have been reported in small studies with aromatase inhibitors in recurrent low-grade ovarian cancers with strong ER expression.

Targeted therapy and PARP inhibitors

With the exception of bevacizumab that has exhibited a 20% objective response rate and a 40% 6 month PFS, a variety of single targeted drugs (sorafenib, temsirolimus, gefitinib, imatinib, mifepristone, enzastaurin, lapatinib, and vorinostat) have produced less than a 10% objective response and <25% 6-month PFS in patients with recurrent epithelial ovarian cancer. Current research is focused on identifying combinations of drugs that might exhibit synthetic lethality.

The concept of synthetic lethality is deceptively simple and explains the selective and targeted effect of PARP inhibitors in cells with dysfunction in the homologous repair pathway. Loss of function of BRCA 1

or 2 results in increased sensitivity to inhibition of PARP1 due to accumulation of unrepaired single-strand DNA breaks in proliferating cells which results in collapse of replication forks and, consequently, to double-strand DNA breaks (DSBs).²⁷³ These DSBs are not repaired in BRCA 1 or 2 tumour cells, which are deficient in homologous repair and this leads to genetic instability and cell death. The synthetic lethal interactions between PARP1 and BRCA 1 or 2 have been confirmed *in vitro* as well as in a number of phase 1 and 2 clinical trials in women with recurrent ovarian cancer.^{274, 275} The initial phase I trial of olaparib (AZD2281) reported an impressive clinical benefit rate (CBR) of 63% in women with BRCA mutations and recurrent ovarian cancer.²⁷⁵ This led to the enrollment of an expanded cohort of 50 patients with *BRCA1/2* mutations, which confirmed activity in a heavily pretreated group of patients with recurrent ovarian cancer with a CBR of 46%.²⁷⁶ A Response Evaluation Criteria in Solid Tumors (RECIST) radiological response or GCIG CA125 response was seen in 40% of patients. There was a correlation between response to olaparib and platinum sensitivity; platinum-sensitive patients had a 69% CBR compared with 46% and 23% in platinum-resistant and refractory patients, respectively.²⁷⁶ These findings led to a number of randomized phase 2 trials and a large amount of interest in the role of PARP inhibitors to treat not only women with BRCA mutations but also those with “sporadic” ovarian cancer. The molecular heterogeneity of high-grade sporadic serous ovarian cancer is now better appreciated and it is apparent that at least 50% of these tumors have dysfunction of the homologous repair DNA repair pathway and may also be sensitive to PARP1 inhibition.²⁷⁷ The challenge is to be better able to identify which tumors have impaired homologous repair and are, therefore, most likely to respond to PARP inhibition and there are a number of pharmaceutical companies developing companion diagnostic tests to help identify patients most likely to respond or benefit from PARP inhibitors.

The maintenance studies with PARP inhibitors have been particularly interesting. Ledermann et al.²⁷⁸ reported significant prolongation in PFS in patients with platinum-sensitive recurrent ovarian cancer randomized to maintenance olaparib or placebo after responding to chemotherapy. The benefit was much greater in women with BRCA mutations (HR = 0.18; 95% CI 0.11, 0.31; $p < 0.00001$; median PFS 11.2 months vs 4.3 months).²⁷⁹ In view of the results of this study, large confirmatory trials have been carried out with olaparib as well as a number of other PARP inhibitors. It seems likely that PARP inhibitors will play an increasingly important role in the management of women with BRCA-related ovarian cancer as well as in patients with HRD in the near future. There are studies combining PARP inhibitors with chemotherapy as well as with angiogenesis inhibitors, and this is a very active area of research with at least five different PARP inhibitors being investigated by different pharmaceutical companies. The recent report by Liu et al of extraordinary high response rates with olaparib and cediranib of 79% as well as very impressive increase in PFS compared with olaparib alone (17.7 months vs 9 months) have led to new studies with the hope that these novel treatments may be used instead of chemotherapy in the future.²⁸⁰

In a multi-institutional phase III, randomized placebo-controlled trial of maintenance niraparib in patients with platinum-sensitive, recurrent ovarian cancer, a progression-free survival advantages were observed: 21 vs. 5.5 mos in women who carry germ-line mutations in BRCA1-2, 12.9 months vs. 3.8 months in those with homologous-recombination defects (HDR), and 9.3 months vs. 3.9 months in BRCA1-2 negative (all significant differences $p < 0.001$).

Palliative radiotherapy

Radiotherapy as a palliative modality in ovarian cancer may be very useful if the sole dominant symptomatic problem for the patient is localized to a site and volume that may be safely encompassed in a limited radiation field. For example, a fixed pelvic mass eroding the vaginal mucosa causing bleeding,

pain, or bowel or bladder dysfunction may occur without obvious disseminated symptomatic peritoneal disease. Localized masses in the retroperitoneal nodes or in extra abdominal sites such as the supraclavicular or inguinal node regions or bony or brain metastases may benefit from palliative irradiation as would painful hepatomegaly from hepatic capsular distention. An objective and subjective response rate of patients treated with radiation for recurrent ovarian cancer after resistance to available chemotherapeutic agents has been reported. A study from Memorial Sloan-Kettering Cancer Center documented subjective or objective responses in 70% of patients who had platinum-refractory disease.²⁸¹ While the optimal dose for palliation has not been established, it is clear that durable palliation may be achieved with local radiotherapy for ovarian cancer recurring after chemotherapy even in the presence of chemoresistant disease. Palliative whole brain irradiation is indicated for documented cerebral metastases in those whose life expectancy is several weeks to months.

Chapter 105

Nonepithelial ovarian malignancies

Jonathan S. Berek, MD, MMS, FASCO ■ Michael L. Friedlander, MD, MBChB, PhD ■ Robert C. Bast Jr. MD

Overview

Compared with epithelial ovarian cancers, nonepithelial ovarian tumors are uncommon, constituting <10% of all ovarian malignancies.^{1, 2} They include germ cell malignancies, sex-cord–stromal tumors, carcinomas metastatic to the ovary, and a variety of extremely rare ovarian cancers, including sarcomas and lipoid cell tumors. Although there are many similarities in the presentation, evaluation, and management of patients, these tumors also have unique features that require special approaches to management.^{1–5} Germ cell malignancies are derived from primordial germ cells of the ovary and can be distinguished by histotype and expression of the biomarkers alpha-fetoprotein (AFP) and/or human chorionic gonadotropin (hCG). They include dysgerminomas (AFP–hCG–), embryonal carcinomas (AFP+hCG+), immature teratomas (AFP–hCG–), endodermal sinus (yolk sac) tumors (AFP+hCG–), and ovarian choriocarcinomas (AFP–hCG+). Germ cell tumors occur in premenarchal girls and young women, grow rapidly, and can present with a symptomatic pelvic mass. As preservation of fertility is often an important priority, unilateral salpingo-oophorectomy can often be performed followed by adjuvant platinum-based therapy. Among the germ cell tumors, dysgerminomas can be bilateral in 10–15% of cases and are associated with gonadal dysgenesis in 5% of cases. Metastatic germ cell cancers can be quite sensitive to chemotherapy and the long-term survival rate is high, even in advanced stages. At some institutions, young patients with stage IA germ cell tumors are followed carefully after resection and chemotherapy given only if there is recurrence with excellent outcomes. Sex-Cord-Stromal tumors include Granulosa-Stromal tumors, Juvenile Granulosa tumors, and Sertoli–Leydig cell tumors. Granulosa-Stromal tumors can occur at all ages and produce estrogen resulting in pseudoprecocious puberty in a small fraction of girls, amenorrhea in pre-menopausal women, and endometrial hyperplasia in postmenopausal adults. Granulosa-Stromal tumors are indolent and often confined to one ovary where surgery can cure stage I disease in more than 75% of cases. Adjuvant chemotherapy is generally not given after complete resection. Late recurrence has, however, been observed. Persistent or recurrent disease has responded to platinum based and hormonal therapy, including progestational agents, luteinizing hormone-releasing hormone agonists, and aromatase inhibitors. Inhibin B has been a useful biomarker. Sertoli–Leydig cell tumors generally present in the third or fourth decade, produce androgens, and induce virilization in more than 70% of patients. As many Sertoli–Leydig cell tumors are in early stage and rarely bilateral, unilateral salpingo-oophorectomy is often performed with 70–90% 5-year survival.

Germ cell malignancies

Germ cell tumors are derived from the primordial germ cells of the ovary and occur with only about one-tenth the incidence of malignant germ cell tumors of the testis. Although they can arise in extragonadal

sites such as the mediastinum and the retroperitoneum, the majority of germ cell tumors arise in the gonad from undifferentiated germ cells. The variation in the site of these cancers is explained by the embryonic migration of the germ cells from the caudal part of the yolk sac to the dorsal mesentery before their incorporation into the sex cords of the developing gonads.^{1, 2}

Germ cell tumors are a model of a curable cancer. The management of patients with ovarian germ cell tumors has largely been extrapolated from the much greater experience of treating males with the more common testicular germ cell tumors. There have been many randomized trials for testicular germ cell tumors, which have provided a strong evidence base for treatment decision making.^{6, 7} The outcome of patients with testicular germ cell tumors is better in experienced centers, and it is reasonable to suggest that the same will be true for the less common ovarian counterparts. The cure rate is high, and attention is now being directed at reducing toxicity without compromising survival. There are still a small number of patients who die from the disease, and studies are in progress to try to improve the outcome for this high-risk, poor-prognostic subset.^{6, 7}

In one of the largest reported series, which included 113 patients with advanced ovarian germ cell tumors treated with cisplatin-based chemotherapy, Murugaesu et al.⁸ reported that stage and elevated tumor markers were independent poor prognostic indicators. These findings are important because they identify similar prognostic factors for ovarian and testicular germ cell tumors, and are in accordance with the clinical observation that testicular and ovarian germ cell tumors behave similarly. This is relevant for the management of patients with ovarian germ cell tumors because it may help to identify a poor prognostic subset of patients who require more intensive treatment.⁸

Histology and biomarkers

A histologic classification of ovarian germ cell tumors is presented in [Table 1](#).^{1, 10} Both alpha-fetoprotein (AFP) and human chorionic gonadotropin (hCG) are secreted by some germ cell malignancies. An elevated AFP and β -hCG can be clinically useful in the differential diagnosis of patients with a pelvic mass and in monitoring patients after surgery. Placental alkaline phosphatase (PLAP) and lactate dehydrogenase (LDH) are elevated in up to 95% of patients with dysgerminomas, and serial monitoring of serum LDH levels may be useful for monitoring the disease. PLAP is more useful as an immunohistochemical marker than as a serum marker. The classification of germ cell tumors is based both on histologic features and the expression of tumor biomarkers ([Figure 1](#)).^{12, 13}

In this scheme, embryonal carcinoma, which is composed of undifferentiated cells that synthesize both hCG and AFP, is the progenitor of several other germ cell tumors.^{4, 13} More differentiated germ cell tumors—such as the endodermal sinus tumor (EST), which secretes AFP, and choriocarcinoma, which secretes hCG—are derived from the extraembryonic tissues; immature teratomas are derived from the embryonic cells and do not secrete hCG, but may be associated with an elevated AFP. Elevated hCG levels are seen in 3% of dysgerminomas and the level is typically less than 100 International Unit. AFP is never elevated in pure dysgerminomas.¹

Epidemiology

Although 20–25% of all benign and malignant ovarian neoplasms are of germ cell origin, they account for only about 5% of all malignant ovarian neoplasms.¹ In Asian and Black societies where epithelial ovarian

cancers are much less common, they may account for as many as 15% of ovarian cancers. In the first two decades of life, almost 70% of ovarian tumors are of germ cell origin, and one-third of these are malignant.^{1, 2} Germ cell tumors account for two-thirds of the ovarian malignancies in this age group. Germ cell cancers also are seen in the third decade, but thereafter they become quite rare.

Symptoms

In contrast to the relatively slow-growing epithelial ovarian tumors, germ cell malignancies grow rapidly, and often are characterized by subacute pelvic pain related to capsular distention, hemorrhage, or necrosis. The rapidly enlarging pelvic mass may produce pressure symptoms on the bladder or rectum, and menstrual irregularities also may occur in menarchal patients. Some young patients may misinterpret the symptoms as those of pregnancy, and this can lead to a delay in diagnosis. Acute symptoms associated with torsion or rupture can develop. These symptoms may be confused with acute appendicitis. In more advanced cases, ascites may develop, and the patient may present with abdominal distention.³

Signs

In patients with a palpable adnexal mass, the evaluation can proceed as outlined earlier for epithelial cancers. Some patients with germ cell tumors will be premenarchal. If the lesions are principally solid, or a combination of solid and cystic on an ultrasonographic evaluation, a neoplasm is probable and a malignancy is possible. The remainder of the physical examination should search for signs of ascites, pleural effusion, and organomegaly.

Diagnosis

Adnexal masses measuring 2 cm or more in premenarchal girls or complex masses 8 cm or more in premenopausal patients will usually require surgical exploration. In young patients, preoperative blood tests should include serum hCG, AFP, LDH, and CA125 levels, a complete blood count, and liver function tests. A radiograph of the chest is important because germ cell tumors can metastasize to the lungs or mediastinum. A karyotype should ideally be obtained preoperatively on all premenarchal girls because of the propensity of these tumors to arise in dysgenetic gonads, but this may not be practical.^{3, 14} A preoperative computed tomographic (CT) scan or magnetic resonance imaging (MRI) may document the presence and extent of retroperitoneal lymphadenopathy or liver metastases, but unless there is very extensive meta-static disease, is unlikely to influence the decision to operate on the patient initially. If postmenarchal patients have predominantly cystic lesions up to 8 cm in diameter, they may undergo observation or a trial of hormonal suppression for two cycles.¹⁵

Dysgerminomas

Dysgerminomas are the most common malignant germ cell tumor, accounting for approximately 30–40% of all ovarian cancers of germ cell origin.^{2, 12} They represent only 1–3% of all ovarian cancers, but represent as many as 5–10% of ovarian cancers in patients younger than 20 years of age. Seventy-five percent of dysgerminomas occur between the ages of 10 and 30 years, 5% occur before the age of 10 years and they rarely occur after age 50.^{1, 4} They typically occur in young women and 20–30% of ovarian malignancies associated with pregnancy are dysgerminomas.

Association with abnormal ovaries

Approximately 5% of dysgerminomas occur in phenotypic females with abnormal gonads.^{1, 14} Dysgerminomas can be associated with patients who have pure gonadal dysgenesis (46XY, bilateral streak gonads), mixed gonadal dysgenesis (45X/46XY, unilateral streak gonad, contralateral testis), and the androgen insensitivity syndrome (46XY, testicular feminization). Therefore, in premenarchal patients with a pelvic mass, the karyotype should be determined, particularly if a dysgerminoma is considered as the likely diagnosis ([Figure 2](#)).

Figure 2 Dysgerminoma.

In most patients with gonadal dysgenesis, dysgerminomas arise in a gonadoblastoma, which is a benign ovarian tumor composed of germ cells and sex-cord stroma. If gonadoblastomas are left *in situ* in patients with gonadal dysgenesis, more than 50% will subsequently develop ovarian malignancies.¹⁶

Approximately 65% of dysgerminomas are stage I at diagnosis.^{1, 3, 5, 17–21} Eighty-five to ninety percent of stage I tumors are confined to one ovary, while 10–15% are bilateral. All other germ cell tumors are rarely bilateral. In patients whose contralateral ovary has been preserved, a dysgerminoma can develop in 5–10% of them over the next 2 years.¹ This figure includes patients who have not received systemic chemotherapy, as well as patients with gonadal dysgenesis.

Pattern of spread

In the 25% of patients who present with metastatic disease, the tumor most commonly spreads via the lymphatics, particularly to the higher para-aortic nodes.¹⁹ They can also spread hematogenously or by direct extension through the capsule of the ovary with exfoliation and dissemination of cells throughout the peritoneal surfaces. Metastases to the contralateral ovary may be present when there is no other evidence of spread. An uncommon site of metastatic disease is bone, and when metastasis to this site occurs, the metastases are seen typically in the lower vertebrae. Metastases to the lungs, liver, and brain are rare and seen most often in patients with long-standing or recurrent disease. Metastasis to the mediastinum and supraclavicular lymph nodes is also usually a late manifestation of disease.^{17, 18}

Treatment

The treatment of patients with early dysgerminoma is primarily surgical, including resection of the primary lesion and limited surgical staging—washings, omental biopsy, careful palpation of all peritoneal surfaces and retroperitoneal nodes, and biopsy of anything suspicious. Chemotherapy is administered to patients with metastatic disease. Because the disease principally affects young women, special consideration must be given to the preservation of fertility.^{19, 22} A comparison of outcomes based on treatment at the Norwegian Radium Hospital clearly demonstrates the superiority of chemotherapy over radiation. Survival was better and morbidity was lower in the group treated with chemotherapy.²²

Surgery

The minimum operation for ovarian dysgerminoma is unilateral oophorectomy.^{20, 23} If there is a desire to preserve fertility, as is usually the case, the contralateral ovary, fallopian tube, and uterus should be left *in situ* even in the presence of metastatic disease because of the sensitivity of the tumor to chemotherapy. If fertility preservation is not required, it may be appropriate to perform a total abdominal hysterectomy and bilateral salpingo-oophorectomy in patients with advanced disease,⁵ although this will be appropriate in

only a very small minority of patients. In patients whose karyotype contains a Y chromosome, both ovaries should be removed, although the uterus may be left *in situ* for possible future embryo transfer. Cytoreductive surgery is of unproven value, but bulky disease that can be readily resected (e.g., an omental cake) should be removed at the initial operation. It is important not to undertake surgery that is potentially morbid and may delay the initiation of chemotherapy.

In patients in whom the dysgerminoma appears on inspection to be confined to the ovary, a careful staging operation should be undertaken to determine the presence of an occult metastatic disease. These tumors often metastasize to the para-aortic nodes around the renal vessels. Peritoneal washings should be taken for cytology, and a thorough exploration made of all peritoneal surfaces and retroperitoneal lymph nodes, with biopsy or resection of any noted abnormalities. The contralateral ovary should be carefully inspected because dysgerminoma is the only germ cell tumor that tends to be bilateral, and not all of the bilateral lesions have obvious ovarian enlargement. Therefore, careful inspection and palpation of the contralateral ovary and excisional biopsy of any suspicious lesion are desirable.^{5, 20, 21, 23} If a small contralateral tumor is found, it may be possible to resect it and preserve some normal ovary.

Many patients with a dysgerminoma will have a tumor that is apparently confined to one ovary and will be referred after unilateral salpingo-oophorectomy without surgical staging. The options for such patients are (1) repeat laparotomy for surgical staging, (2) regular pelvic and abdominal CT scans, or (3) adjuvant chemotherapy.¹⁹ Because most dysgerminomas are confined to the ovary at presentation and are rapidly growing tumors, the author's preference is to offer regular and close surveillance to such patients.^{24, 25}

Radiation

Loss of fertility and second malignancies are important late effects of radiation therapy, so it is no longer used for primary treatment.²² Radiation can be used selectively to treat recurrent disease.^{5, 21, 22} Dysgerminomas are very sensitive to radiation therapy, and doses of 2500 to 3500 cGy may be curative; however, it is uncommonly used because these tumors are very sensitive to platinum-based chemotherapy and have a high likelihood of cure.

Chemotherapy

Chemotherapy is regarded as the treatment of choice.^{23, 26–35} The obvious advantage is the preservation of fertility in most patients, and the reduced risk of second malignancies compared with radiation.^{23, 36–40} The most frequently used chemotherapeutic regimen is BEP (bleomycin, etoposide, and cisplatin). In the past, VBP (vinblastine, bleomycin, and cisplatin) and VAC (vincristine, actinomycin, and cyclophosphamide) were commonly used but are now rarely prescribed ([Table 2](#)).^{23, 26–30}

Table 2 Combination chemotherapy for GCTs of the ovary

Regimens and drugs	Dosage and schedule ^a
BEP	
Bleomycin	30 IU weekly to a maximum of 12 weeks
	15 U/m ² /week × 5; then on day 1 of course 4
Etoposide	100 mg/m ² /day × 5 days every 3 weeks
Cisplatin	20 mg/m ² /day × 5 days, or 100 mg/m ² /day × 1 day every 3 weeks

^a All doses given intravenously.

The Gynecologic Oncology Group (GOG) studied three cycles of EC (etoposide plus carboplatin): Etoposide (120 mg/m² intravenously on days 1, 2, and 3 every 4 weeks) and carboplatin (400 mg/m² intravenously on day 1 every 4 weeks) in 39 patients with completely resected ovarian dysgerminoma, stages IB, IC, II, or III.³³ The results were excellent, and GOG reported a sustained disease-free remission rate of 100%. For patients with advanced, incompletely resected germ cell tumors, the GOG studied cisplatin-based chemotherapy on two consecutive protocols.²⁷ In the first study, patients received four cycles of vinblastine (12 mg/m² every 3 weeks), bleomycin (20 unit/m² intravenously every week for 12 weeks), and cisplatin (20 mg/m²/d intravenously for 5 days every 3 weeks). Patients with persistent or progressive disease at second-look laparotomy were treated with six cycles of VAC. In the second trial, patients received three cycles of BEP initially, followed by consolidation with VAC, which was later discontinued in patients with dysgerminomas.²⁷ VAC does not appear to improve the outcome following the BEP regimen and is no longer used.

A total of 20 evaluable patients with stages III and IV dysgerminoma were treated in these two protocols and 19 were alive and free of disease after 6–68 months (median = 26 months). Fourteen of these patients had a second-look laparotomy, and all findings were negative. A study at MD Anderson Hospital³⁰ used BEP in 14 patients with residual disease, and all patients were free of disease with long-term follow-up. In another series of 26 patients with pure ovarian dysgerminomas who received BEP chemotherapy, 54% of whom had stage IIIC or IV disease, 25 (96%) remained continuously disease free following three to six cycles of therapy.³⁵

These results indicate that patients with an advanced-stage, incompletely resected dysgerminoma have an excellent prognosis when treated with cisplatin-based combination chemotherapy.^{34–39, 41} The optimal regimen is three to four cycles of BEP based on the data from testis cancers^{40–42} with the number of cycles depending on the extent of disease and the presence or absence of visceral metastases. If bleomycin is contraindicated or omitted because of lung toxicity, consideration should be given to four cycles of cisplatin and etoposide rather than three cycles of BEP.

There is no need to perform a second-look laparotomy in patients with dysgerminomas.^{43–45} The role of surgery to resect residual masses following chemotherapy for dysgerminomas is not clear, as the vast majority of these patients will only have necrotic tissue and nonviable tumor. In general, these patients should be closely monitored with scans and tumor markers. A positron emission tomography (PET–CT) scan should be considered in patients who have bulky residual masses larger than 3 cm more than 4 weeks after chemotherapy. A positive PET–CT scan appears to be a sensitive predictor of residual seminoma in males in these circumstances,⁴⁶ with residual disease being evident in 30–50% of patients. If the PET–CT is positive or if there is a suggestion of progressive disease on scans, ideally there should be histologic confirmation of residual disease before embarking on salvage therapy.⁴⁷

Recurrent disease

Although recurrences are uncommon, 75% will occur within the first year after initial treatment,^{1–4} with the most common sites being the peritoneal cavity and the retroperitoneal lymph nodes. These patients should be treated with either chemotherapy or radiation, depending on the location of disease and the primary treatment. Patients with recurrent disease who have had no therapy other than surgery should be treated with chemotherapy. If previous chemotherapy with BEP has been given, an alternative regimen such as TIP (paclitaxel, ifosfamide, and cisplatin), a commonly used salvage regimen in testicular germ cell tumors,⁴⁸ may be tried.

These treatment decisions should be made in a multidisciplinary setting with the input of physicians experienced in the management of patients with germ cell tumors. Consideration may be given to the use of high-dose chemotherapy with peripheral stem cell support in selected patients. A number of high-dose regimens have been used in phase II studies, and the choice depends on the previous chemotherapy, the time to recurrence, and the residual toxicity from the previous therapy.^{49, 50} It is unclear whether high-dose chemotherapy is superior to conventional dose chemotherapy as first-line salvage therapy for patients with relapsed disease. The only randomized trial, conducted by the European Group for Blood and Marrow Transplantation (EBMT)-IT-94, did not demonstrate superiority for three cycles of VIP or vinblastine, ifosfamide, and cisplatin (VeIP) followed by high-dose chemotherapy compared with four cycles of conventional dose chemotherapy. An international randomized trial (TIGER) plans to randomize 390 patients with recurrent germ cell tumors to four cycles of conventional dose cisplatin-based chemotherapy with TIP, compared with two cycles of paclitaxel-ifosfamide followed by three cycles of high-dose carboplatin and etoposide with autologous stem-cell support (TICE).⁵⁰

Radiation therapy may be considered in selected patients with dysgerminomas with a localized recurrence, but this has the major disadvantage of causing loss of fertility if pelvic and abdominal radiation is required and may also compromise the ability to deliver further chemotherapy if unsuccessful.²²

Pregnancy

Because dysgerminomas tend to occur in young patients, they may coexist with pregnancy. When a stage IA cancer is found, the tumor can be removed intact and the pregnancy continued. In patients with more advanced disease, continuation of the pregnancy will depend on gestational age. Chemotherapy can be given in the second and third trimesters in the same dosages as given for the nonpregnant patient without apparent detriment to the fetus.^{36, 51} Relatively few patients have been treated with BEP during pregnancy and some fetal malformations and complications have been reported, underscoring the importance of ensuring that only patients who definitely require chemotherapy during pregnancy should be treated.⁵²

Prognosis

In patients with stage IA dysgerminoma, unilateral oophorectomy alone results in a 5-year disease-free survival rate of greater than 95%.^{5, 21} The features that have been associated with a higher tendency to recurrence include tumors larger than 10–15 cm in diameter, age younger than 20 years, and microscopic features that include numerous mitoses, anaplasia, and a medullary pattern.^{1, 12}

Kumar et al.⁵³ abstracted data on malignant ovarian germ cell tumors from the Surveillance, Epidemiology, and End Results (SEER) program from 1988 to 2004. There were a total of 1296 patients with dysgerminomas, immature teratomas, or mixed germ cell tumors, 613 (47.3%) of whom had lymphadenectomies. Lymph node metastases were present in 28% of dysgerminomas, 8% of immature teratomas, and 16% of mixed germ cell tumors ($p < 0.05$). The 5-year survival for patients with negative nodes was 95.7% compared to 82.8% for patients with positive nodes ($p < 0.001$). The same group updated the results recently and reported on 1083 patients with ovarian germ cell tumors who had surgery and who were believed to have disease clinically confined to the ovary.⁵⁴ This included 590 (54.5%) who had no lymphadenectomy and 493 (45.5%) who had a lymphadenectomy. Of the latter, 52 (10.5%) were upstaged to FIGO (International Federation of Gynecology and Obstetrics) stage IIIC owing to nodal metastases. The 5-year survival was 96.9% for patients who did not have a lymphadenectomy, 97.7% for those who did, and 93.4% for patients who were found to have stage IIIC disease after lymphadenectomy.

These survivals were not statistically different and underscore the excellent prognosis for patients with dysgerminomas.^{26–39}

Immature teratoma

Immature teratomas typically contain immature neuroepithelium and may be pure immature teratomas or occur in combination with other germ cell tumors as mixed germ cell tumors. The pure immature teratoma accounts for fewer than 1% of all ovarian cancers, but it is the second most common germ cell malignancy and represents 10–20% of all ovarian malignancies seen in women younger than 20 years of age.¹ Approximately 50% of pure immature teratomas of the ovary occur between the ages of 10 and 20 years, and they rarely occur in postmenopausal women.

Semiquantification of the amount of neuroepithelium correlates with survival in ovarian immature teratomas and is the basis for the grading of these tumors.^{55–57} Those with less than one lower-power field⁴ of immature neuroepithelium on the slide with the greatest amount of immature neuroepithelium (grade 1) have a survival of at least 95%, whereas greater amounts of immature neuroepithelium (grades 2 and 3) appear to have a lower overall survival (~85%).⁵⁷ This may not apply to immature teratomas of the ovary in children because they appear to have a very good outcome with surgery alone, regardless of the degree of immaturity. These findings are from an era when not all patients would have received platinum-based chemotherapy.^{58, 59}

Some pathologists have recommended a two-tiered grading system, suggesting that immature teratomas be categorized as either low grade or high grade because of the significant inter- and intraobserver difficulty with a three-grade system,⁵⁵ which is the author's current practice.

Immature ovarian teratomas may be associated with gliomatosis peritonei, which has a favorable prognosis if composed of completely mature tissues. Recent reports have suggested that these glial “implants” are not tumor derived, but represent teratoma-induced metaplasia of pluripotential müllerian stem cells in the peritoneum.^{58, 60, 61} The researchers have exploited a unique characteristic of ovarian teratomas. The latter typically contain a duplicated set of maternal chromosomes and are therefore homozygous at polymorphic microsatellite loci, while DNA (deoxyribonucleic acid) from matched normal tissue contains genetic material of both maternal and paternal origin, so exhibits heterozygosity at many of these same polymorphic microsatellite loci.

Malignant transformation of a mature teratoma is a rare event. Squamous cell carcinoma is the most frequent subtype of malignancy, but adenocarcinomas, primary melanomas, and carcinoids may also rarely occur (see the following discussion).³² The risk is reported to be between 0.5% and 2% of teratomas and usually occurs in postmenopausal patients.

Diagnosis

The preoperative evaluation and differential diagnosis are the same as for patients with other germ cell tumors. Some of these tumors will contain calcifications similar to mature teratomas, and this can be detected by a radiograph of the abdomen or by ultrasonography. Rarely, they are associated with the production of steroid hormones and can be accompanied by sexual pseudoprecocity.⁴ AFP may be elevated in some patients with a pure immature teratoma but hCG is not elevated.

Surgery

In a premenopausal patient where the tumor appears confined to a single ovary, unilateral oophorectomy and limited surgical staging should be performed. In the rare postmenopausal patient with an immature teratoma, a total abdominal hysterectomy and bilateral salpingo-oophorectomy may be performed. Contralateral involvement is rare, and routine resection or wedge biopsy of the contralateral ovary is unnecessary.² Any suspicious lesions on the peritoneal surfaces should be sampled and submitted for histologic evaluation. The most frequent site of dissemination is the peritoneum and, much less commonly, the retroperitoneal lymph nodes. Bloodborne metastases to organ parenchyma such as the lungs, liver, or brain are uncommon. When present, they are usually seen in patients with late or recurrent disease and most often in tumors that are high grade.⁴

It is unclear whether debulking of metastases improves the response to combination chemotherapy.^{62, 63} Cure ultimately depends on the ability to deliver chemotherapy promptly. Any surgical resection that may be potentially morbid and therefore delay chemotherapy should be resisted, although surgical resection of any residual disease should be considered at the completion of chemotherapy.

Chemotherapy

Patients with stage IA, grade 1 tumors have an excellent prognosis, and no adjuvant therapy is required. In patients with high-grade, stage IA immature teratomas, adjuvant chemotherapy has commonly been given, although this has been questioned, as excellent results have also been reported with close surveillance and treating only patients who have a recurrence.^{19, 22, 28–30, 44, 59, 64–78}

The most frequently used combination chemotherapeutic regimen in the past was VAC,^{72–74} but a GOG study reported a relapse-free survival rate in patients with incompletely resected disease of only 75%.⁷⁴ The approach over the past 20 years has been to incorporate cisplatin into the primary treatment of these tumors, and most of the experience has been with the VBP in the past and BEP more recently.⁶⁷

The GOG prospectively evaluated three courses of BEP therapy in patients with completely resected stage I, II, and III ovarian germ cell tumors. Overall, the toxicity was acceptable, and 91 of 93 patients (97.8%) with nondysgerminomatous tumors were clinically free of disease. In nonrandomized studies, the BEP regimen is superior to the VAC regimen in the treatment of completely resected nondysgerminomatous germ cell tumors of the ovary. Some patients can progress rapidly postoperatively, and, in general, treatment should be initiated as soon as possible after surgery, preferably within 7–10 days, in those patients who require chemotherapy.

The switch from VBP to BEP has been prompted by the experience in patients with testicular cancer, where the replacement of vinblastine with etoposide has been associated with a better therapeutic index (i.e., equivalent efficacy and lower morbidity), with less neurologic and gastrointestinal toxicity, and improved outcomes.^{67, 68} Furthermore, the use of bleomycin appears to be important in this group of patients. In a randomized study of three cycles of etoposide plus cisplatin (EP) with or without bleomycin (EP vs BEP) in 166 patients with germ cell tumors of the testes, the BEP regimen had a relapse-free survival rate of 84% compared with 69% for the EP regimen ($p = 0.03$).⁴⁰

Cisplatin is superior to carboplatin in metastatic germ cell tumors of the testis. One hundred and ninety-two patients with good prognosis germ cell tumors of the testes were entered into a study of four cycles of EP versus four cycles of EC. There were three relapses with the EP regimen versus seven with the EC regimen.⁴² A German group randomized patients to (1) a BEP regimen of three cycles at standard doses given days 1–5 versus (2) a CEB regimen of carboplatin [target AUC of 5 (mg/dL/min) on day 1], etoposide 120 mg/m² on days 1–3, and bleomycin 30 mg on days 1, 8, and 15.⁷⁹ Four cycles of CEB were

given, with the omission of bleomycin in the fourth cycle so that the cumulative doses of etoposide and bleomycin in the two treatment arms were comparable. Fifty-four patients were entered on the trial; 29 were treated with BEP and 25 with CEB chemotherapy. More patients treated with CEB relapsed after therapy (32% vs 13%). Four patients (16%) treated with CEB died of disease progression in contrast to one patient (3%) after BEP therapy. The trial was terminated early after an interim analysis. The inferiority of carboplatin was confirmed in a larger randomized trial reported by Horwich et al.⁸⁰ In view of these results, BEP is the preferred treatment regimen.^{67, 81–83} The 3-day schedule has been found to be equivalent to a 5-day schedule for BEP chemotherapy. A cycle of BEP consisted of etoposide 500 mg/m², administered at either 100 mg/m² days 1–5 or 165 mg/m² days 1–3, and cisplatin 100 mg/m², administered at either 20 mg/m² days 1–5 or 50 mg/m² days 1 and 2. Bleomycin 30,000 International Unit is administered on days 1, 8, and 15 during cycles 1–3.

Recurrent disease

The principles and approach are identical to the management of recurrent dysgerminoma, as discussed earlier.

Second-look laparotomy

Second-look operation for ovarian germ cell tumors^{44, 45} is not indicated in patients who have received adjuvant chemotherapy (i.e., stage IA, grades 2 and 3). However, surgery should be considered in patients with metastatic immature teratomas who have residual disease at the completion of chemotherapy because they may have residual mature teratoma and are at risk of growing teratoma syndrome, a rare complication of immature teratomas.^{84–86} Furthermore, cancers can arise at a later date in residual mature teratoma, and it is important to resect any residual mass and exclude persistent disease, as further chemotherapy may be indicated.

The principles of surgery are based on the much larger experience of surgery in males with residual masses following chemotherapy for germ cell tumors with a component of immature teratoma.⁸⁷ Mathew et al.⁸⁸ reported their experience of laparotomy in assessing the nature of postchemotherapy residual masses in ovarian germ cell tumors. Sixty-eight patients completed combination chemotherapy with cisplatin regimens, of whom 35 had radiologic evidence of residual masses. Twenty-nine of these 35 patients underwent laparotomy, and 10 patients (34.5%) had viable tumor, including 7 cases (24.2%) of immature teratoma. Nineteen patients (65.5) had no evidence of malignancy, including 3 (10.3%) cases showing mature teratoma, and 16 (55.2%) showing necrosis or fibrosis only. None of the patients with a dysgerminoma or embryonal carcinoma and a radiologic residual mass of less than 5 cm had viable tumor present, whereas all patients with primary tumors containing a component of teratoma had residual tumor, strengthening the case for surgery in patients with metastatic immature teratoma and any residual mass.^{88, 89}

Prognosis

The most important prognostic feature of the immature teratoma is the grade of the lesion.^{1, 55} In addition, the stage of disease and the extent of tumor at the initiation of treatment also have an impact on prognosis.⁴ Overall, the 5-year survival rate for patients with all stages of pure immature teratomas is 70–80%, and it is 90–95% for patients with surgical stage I tumors.^{11, 44, 55, 64}

The degree or grade of immaturity generally predicts the metastatic potential and prognosis. The 5-year

survival rates have been reported to be 82%, 62%, and 30% for patients with grades 1, 2, and 3, respectively,⁵⁵ but many of these patients were treated in an era before optimal chemotherapy was available, and these figures do not match current experience and more recently published data.⁶⁹ For example, Lai et al.⁹⁰ reported on the long-term outcome of 84 patients with ovarian germ cell tumors, including 29 immature teratomas, and the 5-year survival was 97.4%.

Occasionally, these tumors are associated with mature or low-grade glial elements that have implanted throughout the peritoneum. Such patients have a favorable long-term survival.⁴ Mature glial elements can grow and mimic malignant disease and may need to be resected to relieve pressure on surrounding structures.

Endodermal sinus tumor

ESTs have also been referred to as yolk sac carcinomas because they are derived from the primitive yolk sac.¹ They are the third most frequent malignant germ cell tumor of the ovary. ESTs have a median age of 18 years at diagnosis.^{1–3, 91, 92} Approximately one-third of the patients are premenarchal at presentation. Abdominal or pelvic pain occurs in approximately 75% of patients, whereas an asymptomatic pelvic mass is documented in 10% of patients.¹¹ Most ESTs secrete AFP and rarely may also elaborate detectable alpha-1-antitrypsin (AAT). There is a good correlation between the extent of disease and the level of AFP, although discordance also has been observed. The serum level of AFP is useful in monitoring the patient's response to treatment, as well as in follow-up.^{91–98}

Surgery

The treatment of an EST consists of surgical exploration, unilateral salpingo-oophorectomy, a frozen section for diagnosis, and limited surgical staging. A hysterectomy and contralateral salpingo-oophorectomy should not be done.^{4, 94, 95} Conservative surgery and adjuvant chemotherapy allow fertility preservation as with other germ cell tumors.²³ In patients with metastatic disease, all gross disease should be resected if possible. At surgery, the tumors tend to be solid and large, ranging in size from 7 to 28 cm (median 15 cm) in the GOG series. Bilaterality is not seen in EST, and the other ovary is involved with metastatic disease only when there are other metastases in the peritoneal cavity. Most patients have early-stage disease: 71% stage I, 6% stage II, and 23% stage III.^{95, 99}

Chemotherapy

All patients with ESTs should be treated with chemotherapy shortly after recovering from surgery. Before the routine use of combination chemotherapy, the 2-year survival rate was approximately 25%. After the introduction of the VAC regimen, the survival rate improved to 60–70%, which highlights the chemosensitivity of the majority of these tumors.^{73, 74} All patients should be treated with a cisplatin-based regimen such as BEP, which is considered the standard of care. The chance of cure now approaches 100% for patients with early-stage disease and is at least 75% for patients with more advanced-stage disease.⁹⁵

The optimal number of treatment cycles has not been established in ovarian germ cell tumors, but it is reasonable to extrapolate from the much larger experience in testicular germ cell tumors where three cycles of BEP are considered optimal for good prognosis, low-risk patients, and four cycles for patients with intermediate to high-risk tumors.¹⁰⁰ In patients for whom bleomycin is omitted or discontinued because of toxicity, four cycles of cisplatin and etoposide are recommended. An alternative approach is

to use VIP (etoposide, ifosfamide, and cisplatin) in patients with more advanced disease in whom bleomycin is contraindicated. Four cycles of VIP are equivalent to four cycles of BEP, but it is more myelotoxic and requires growth-factor support.^{6, 7, 101} These patients should only be treated by clinicians experienced in the management of germ cell tumors as the outcomes of patients in inexperienced hands are compromised.

Neoadjuvant chemotherapy followed by fertility-sparing surgery may also be a reasonable option for patients with advanced ovarian germ cell tumors not suitable for optimal cytoreduction, as shown in a recent study of 21 patients from India.¹⁰²

Embryonal carcinoma

Embryonal carcinoma of the ovary is an extremely rare tumor that is distinguished from a choriocarcinoma of the ovary by the absence of syncytiotrophoblastic and cytotrophoblastic cells. The patients are very young, their ages ranging between 4 and 28 years (median 14 years) in two series.¹⁰³ Older patients have been reported.¹⁰⁴ Embryonal carcinomas may secrete estrogens, with the patient exhibiting symptoms and signs of precocious pseudopuberty or irregular bleeding.¹ The presentation is otherwise similar to that of the EST. The primary lesions tend to be large, and approximately two-thirds are confined to one ovary at the time of presentation. These lesions frequently secrete AFP and hCG, which are useful for following the response to subsequent therapy.⁹⁶ The treatment of embryonal carcinomas is the same as that for ESTs.⁵⁷

Choriocarcinoma of the ovary

Pure nongestational choriocarcinoma of the ovary is an extremely rare tumor. Histologically, it has the same appearance as gestational choriocarcinoma metastatic to the ovaries.¹⁰⁵ The majority of patients with this cancer are younger than 20 years. The presence of hCG can be useful in monitoring the patient's response to treatment. In the presence of high hCG levels, isosexual precocity has been seen, occurring in approximately 50% of patients whose tumors appear before menarche.^{106, 107}

There are only a few limited reports on the use of chemotherapy for these nongestational choriocarcinomas, but complete responses have been reported to the MAC regimen (methotrexate, actinomycin D, and cyclophosphamide) as described for gestational trophoblastic disease.¹⁰⁵ These tumors are so rare that no good data are available, but the options also include the BEP or POMB-ACE regimens ([Table 3](#)). The prognosis for ovarian choriocarcinomas has been poor. The majority of patients have metastases to organ parenchyma at the time of initial diagnosis, and they should be managed as high-risk germ cell tumors.

Table 3 POMB/ACE chemotherapy for GCTs of the ovary

POMB	
Day 1	Vincristine 1 mg/m ² IV; methotrexate 300 mg/m ² as a 12-h infusion
Day 2	Bleomycin 15 mg by 24-h infusion, folinic acid rescue started 24 h after the start of methotrexate in a dose of 15 mg every 12 h for 4 doses
Day 3	Bleomycin 15 mg by 24-h infusion
Day 4	Cisplatin 120 mg/m ² as a 12-h infusion, given together with hydration and 3 mg magnesium sulfate supplementation
ACE	
Days 1–5	Etoposide (VP16) 100 mg/m ² , days 1 to 5
Days 3–5	Actinomycin D 0.5 mg IV, days 3, 4, and 5
Day 5	Cyclophosphamide 500 mg/m ² IV, day 5
OMB	
Day 1	Vincristine 1 mg/m ² IV; methotrexate 300 mg/m ² as a 12-h infusion
Day 2	Bleomycin 15 mg by 24-h infusion; folinic acid rescue started at 24-h
Day 3	Bleomycin 15 mg by 24-h infusion

The sequence of treatment schedules is two courses of POMB followed by ACE. POMB is then alternated with ACE until patients are in biochemical remission as measured by hCG and AFP, PLAP, and LDH. The usual number of courses of POMB is three to five. Following biochemical remission, patients alternate ACE with OMB until remission has been maintained for approximately 12 weeks. The interval between courses of treatment is kept to the minimum (usually 9–11 days). If delays are caused by myelo-suppression after courses of ACE, the first 2 days of etoposide are omitted from subsequent courses of ACE.

Polyembryoma

Polyembryoma of the ovary is another extremely rare tumor, which is composed of “embryoid bodies.” This tumor replicates the structures of early embryonic differentiation (i.e., the three somatic layers: endoderm, mesoderm, and ectoderm).^{1, 12} They occur in very young, premenarchal girls with signs of pseudopuberty, and AFP and hCG levels are elevated. Women with polyembryomas confined to one ovary may be followed with serial tumor markers and diagnostic-imaging techniques to avoid cytotoxic chemotherapy. In patients who require chemotherapy, the BEP regimen is appropriate.⁷³

Mixed germ cell tumor

Mixed germ cell malignancies of the ovary contain two or more elements of the tumors described earlier.

In one series, the most common component of a mixed germ cell tumor was dysgerminoma, which occurred in 80%, followed by EST in 70%, immature teratoma in 53%, choriocarcinoma in 20%, and embryonal carcinoma in 16%. The most frequent combination was a dysgerminoma and an EST. The mixed germ cell tumors may secrete either AFP or hCG—or both or neither—depending on the components.

These tumors should be managed with combination chemotherapy, preferably BEP. The serum marker, if positive initially, may become negative during chemotherapy, but this may reflect regression of only a particular component of the mixed lesion. Therefore, a second-look laparotomy may be indicated if there is residual disease following chemotherapy, particularly if there was an immature teratomatous component in the original tumor.

The most important prognostic features are the size of the primary tumor and the relative percentage of its most malignant component.⁷⁴ In stage IA lesions smaller than 10 cm, survival is 100%. Tumors composed of less than one-third EST, choriocarcinoma, or grade 3 immature teratoma also have an excellent prognosis, but it is possibly less favorable when these components comprise the majority of the tumor.

Surveillance for stage I ovarian germ cell tumors

Surveillance is a common approach to the management of young men with apparent stage I testicular germ cell tumors. There is a large body of evidence to support this approach, as well as guidelines on what constitutes appropriate surveillance.^{6,7} Although as many as 20–30% of patients will relapse, almost all will be cured with salvage chemotherapy with BEP, and the potential adverse effects of chemotherapy can be avoided in most patients.

Although this is a very common approach in young men, it has not been widely adopted in females with ovarian germ cell tumors. However, some data are now available to support surveillance in selected patients whose disease is confined to the ovary. Cushing et al.¹⁰⁸ reported a study of 44 pediatric patients with completely resected ovarian immature teratomas who were followed carefully for recurrence of disease with appropriate diagnostic imaging and serum tumor markers. Thirty-one patients (70.5%) had pure ovarian immature teratomas with a tumor grade of 1 ($n = 17$), 2 ($n = 12$), or 3 ($n = 2$). Thirteen patients (29.5%) had an ovarian immature teratoma plus microscopic foci of yolk sac tumor. The 4-year event-free and overall survival for the ovarian immature teratoma group and the ovarian immature teratoma plus yolk sac tumor group was 97.7% (95% confidence interval, 84.9–99.7%) and 100%, respectively. The only yolk sac tumor relapse occurred in a child with ovarian immature teratoma and yolk sac tumor who was then treated and salvaged with chemotherapy.¹⁰⁸

The Charing Cross Group initially reported a prospective study of 24 patients with stage IA ovarian germ cell tumors who were also enrolled in a surveillance program. The group consisted of nine patients (37.5%) with dysgerminoma, nine (37.5%) with pure immature teratoma, and six (25%) with ESTs (with or without immature teratoma). Treatment consisted of surgical resection without adjuvant chemotherapy, followed by a surveillance program of clinical, serologic, and radiologic review. A second-look operation was performed, and all but one patient were alive and in remission after a median follow-up of 6.8 years. The 5-year overall survival was 95%, and the 5-year disease-free survival was 68%. Eight patients required chemotherapy for recurrent disease or a second primary germ cell tumor. This included three patients with a grade II immature teratoma, three patients with a dysgerminoma, and two patients with dysgerminoma who developed a contralateral dysgerminoma 4.5 and 5.2 years after their first tumor. All but one, who died of a pulmonary embolus, was successfully salvaged with chemotherapy.¹⁰⁹

The same group updated its experience and reported on the safety of the ongoing surveillance program of

all stage IA female germ cell tumors.²⁵ Thirty-seven patients (median age 26, range 14–48 years) with stage I disease were referred to Mount Vernon and Charing Cross Hospitals between 1981 and 2003. Patients underwent surgery and staging followed by intense surveillance, which included regular tumor markers and imaging. The median period of follow-up was 6 years. Relapse rates for stage IA nondysgerminomatous tumors and dysgerminomas were 8 of 22 (36%) and 2 of 9 (22%), respectively. In addition, one patient with mature teratoma and glial implants also relapsed. Ten of these 11 patients (91%) were successfully cured with platinum-based chemotherapy. Only one patient died from chemoresistant disease. All relapses occurred within 13 months of initial surgery. The overall disease-specific survival of malignant ovarian germ cell tumors was 94%.

More than 50% of patients who underwent fertility-sparing surgery went on to have successful pregnancies. They concluded that surveillance of all stage IA ovarian germ cell tumors was safe and feasible, and that the outcome was comparable with testicular tumors. They questioned the need for potentially toxic adjuvant chemotherapy in all patients with nondysgerminomas who have greater than 90% chance of being salvaged with chemotherapy if they relapse.

This strategy is appealing and is supported by a larger pediatric literature, but there is much less experience in adults. It deserves further study, but this will require international collaboration. If a surveillance program is to be instigated, it is essential that the protocols used by the Charing Cross group are closely adhered to and that patients understand that the data for adults are limited.

The surveillance policy is very strict and includes a CT scan of chest, abdomen, and pelvis after surgery, if not done preoperatively. At 12 weeks following surgery, a repeat MRI/CT of the abdomen and pelvis or a second-look laparoscopy should be performed if there has been inadequate initial staging. If all of these are negative, MRI/CT imaging should be repeated at 12 months. Patients are reviewed monthly in year one, every 2 months in year two, every 3 months in year three, and so on until year five, after which they are seen every 6 months for another 5 years. A pelvic ultrasound and chest X-ray should be done on alternate visits. Tumor markers including AFP, β -hCG, CA125, and LDH measurements should be done every 2 weeks for 6 months and then monthly for 6 months, every other month in year two, every third month in year three, and so on until year five when they are repeated every 6 months for 5 years.^{25, 109}

Late effects of treatment of malignant germ cell tumors of the ovary

Although there are substantial data regarding late effects of cisplatin-based therapy in men with testicular cancer, much less information is available for women with ovarian germ cell tumors. The toxicity of BEP chemotherapy has been well documented in men and includes significant pulmonary toxicity in 5% of patients, with fatal lung toxicity in 1%; acute myeloid leukemia or myelodysplastic syndrome in 0.2–1% of patients; neuropathy in 20–30%; Raynaud phenomenon in 20%; tinnitus in 24%; and high-tone hearing loss in as many as 70% of patients. In addition, late effects occur on gonadal function, there is an increased risk of hypertension and cardiovascular disease, and some degree of renal impairment occurs in 30% of patients.^{110, 111} These side effects underscore the importance of limiting BEP to three cycles for low-risk and to four cycles for high-risk patients, and emphasize the need for these patients to be referred to major referral centers.^{89, 112}

Gonadal function

An important cause of infertility in patients with ovarian germ cell tumors is unnecessary bilateral salpingo-oophorectomy and hysterectomy. Although temporary ovarian dysfunction or failure is common with platinum-based chemotherapy, most women will resume normal ovarian function, and childbearing is

usually preserved.^{14, 21, 23, 36–40} In one representative series of 47 patients treated with combination chemotherapy for germ cell malignancies, 91.5% of patients resumed normal menstrual function, and there were 14 healthy live births and no birth defects.²³ Factors such as older age at initiation of chemotherapy, greater cumulative drug dose, and longer duration of therapy all have adverse effects on future gonadal function.^{37, 89, 112–114}

A large study of reproductive and sexual function after platinum-based chemotherapy in ovarian germ cell tumor survivors was recently reported by the GOG, and 132 survivors were included in the study. Surprisingly, only 71 (53.8%) had fertility-sparing surgery; of these, 87.3% were still having regular menstrual periods. Twenty-four survivors had 37 offspring after cancer treatment.^{82, 115}

Secondary malignancies

An important cause of late morbidity and mortality in patients receiving chemotherapy for germ cell tumors is the development of secondary tumors.⁸⁹ Etoposide in particular has been implicated in the development of treatment-related leukemias.

The chance of developing treatment-related leukemia following etoposide is dose related. The incidence of leukemia is approximately 0.4–0.5% (representing a 30-fold increased likelihood) in patients receiving a cumulative etoposide dose of less than 2000 mg/m²¹¹⁶ compared with as much as 5% (representing a 336-fold increased likelihood) in those receiving more than 2000 mg/m²¹¹⁷ In a typical three- or four-cycle course of BEP, patients receive a cumulative etoposide dose of 1500 or 2000 mg/m², respectively.

Despite the risk of secondary leukemia, risk–benefit analyses have concluded that etoposide-containing chemotherapy regimens are beneficial in advanced germ cell tumors; one case of treatment-induced leukemia would be expected for every 20 additionally cured patients who receive BEP as compared with PVB (cisplatin, vinblastine, and bleomycin). The risk–benefit balance for patients with low-risk disease, or for high-dose etoposide in the salvage setting, is less clear.¹¹⁷

Sex-cord–stromal tumors

Sex-cord–stromal tumors of the ovary account for approximately 5–8% of all ovarian malignancies.^{1–4, 118–123} They are derived from the sex cords and the ovarian stroma or mesenchyme, and are usually composed of various combinations of elements, including the “female” cells (i.e., granulosa and theca cells) and “male” cells (i.e., Sertoli and Leydig cells), as well as morphologically indifferent cells. A classification of this group of tumors is presented in [Table 4](#).^{10, 124}

Table 4 Sex cord–stromal tumors

A. Granulosa-stromal cell tumors
1. Granulosa cell tumor
2. Tumors in the thecoma-fibroma group
a. Thecoma
b. Fibroma

Granulosa-stromal cell tumors

Granulosa–stromal-cell tumors include granulosa cell tumors, thecomas, and fibromas. The granulosa cell tumor is a low-grade malignancy. Thecomas and fibromas are benign but rarely may have morphologic features of malignancy and then may be referred to as fibrosarcomas.^{1, 125}

Granulosa cell tumors, which may secrete estrogen, are seen in women of all ages and are classified as either Adult Granulosa Cell tumors or Juvenile. Five percent of cases are found in prepubertal girls; the others are distributed throughout the reproductive and postmenopausal years.^{122, 123, 126, 127} They are bilateral in only 2% of patients ([Figure 3](#)).

Figure 3 Granulosa cell tumor.

Of the rare prepubertal lesions, 75% are associated with sexual pseudoprecocity because of the estrogen secretion.¹²³ In the reproductive age group, most patients have menstrual irregularities or secondary amenorrhea. In postmenopausal women, abnormal uterine bleeding is frequently the presenting symptom. Endometrial cancer occurs in association with granulosa cell tumors in at least 5% of cases, and 25–50% are associated with endometrial hyperplasia.^{1, 120, 122, 123, 126} Rarely, granulosa cell tumors may produce androgens and cause virilization.

The other symptoms and signs of granulosa cell tumors are nonspecific and the same as most ovarian malignancies. Ascites is present in approximately 10% of cases, and rarely a pleural effusion.^{122, 123} Granulosa tumors tend to be hemorrhagic; occasionally, they rupture and produce a hemoperitoneum.

Granulosa cell tumors are usually stage I at diagnosis but may recur 5–30 years after initial diagnosis.¹²¹ The tumors may also spread hematogenously, and metastases can develop in the lungs, liver, and brain years later. Malignant thecomas are extremely rare, and their presentation, management, and outcome are similar to those of the granulosa cell tumors.^{125, 127}

A somatic missense point mutation in the gene encoding the forkhead box protein L2 (FOXL2) has been found to be present in all adult-type granulosa cell tumors of the ovary. FOXL2 402 CG leads to a gain or change of function and is believed to be a driver mutation for adult granulosa cell tumors. There is an effort to see if it can be targeted.^{128–130}

Diagnosis

Inhibin is secreted by granulosa cell tumors and is a useful tumor marker for diagnosis and surveillance.^{131–135} It is a polypeptide hormone secreted primarily by granulosa cells and is an inhibitor of pituitary FSH secretion. Inhibin decreases to nondetectable levels after menopause. However, certain ovarian cancers (mucinous epithelial ovarian carcinomas and granulosa cell tumors) produce inhibin, which may predate clinical recurrence.^{136–138} An elevated serum inhibin level in a premenopausal woman presenting with amenorrhea and infertility is suggestive of a granulosa cell tumor.

In the past, inhibin assays could not distinguish between the two inhibin subunits, inhibin A and B, and total inhibin has been measured. However, there are now specific immunoassays for inhibin A and B. Inhibin B is the predominant form of inhibin secreted by granulosa cell tumors and has been reported to reflect disease status more accurately than inhibin A. Measurement of serum inhibin B concentrations rather than total inhibin or inhibin A may be better for the follow-up of granulosa cell tumors.^{134, 139}

Antimüllerian hormone (AMH), also called Müllerian inhibitory substance (MIS), is produced by granulosa cells and is emerging as a potential marker for these tumors.¹³⁵ An elevated AMH level appears to have high specificity. The test is commercially available, and its role in the management of granulosa cell tumors is being investigated.¹⁴⁰ An elevated estradiol level is not a sensitive marker of this disease.¹³⁷

The histologic diagnosis can be facilitated by staining for markers of ovarian granulosa cell tumors (e.g., inhibin, CD99, and AMH).^{131, 132} Antibodies against inhibin appear to be the most useful, but they are not specific.¹²⁸ In one report, positive staining for inhibin was present in 94% of granulosa cell tumors and in 10–20% of ovarian endometrioid tumors and metastatic carcinomas to the ovary.¹³⁵ The latter demonstrated significantly weaker staining. Molecular testing for a mutation in FOXL2 is now available to help with the diagnosis if it is in doubt.^{129, 130}

Treatment

The treatment of granulosa cell tumors depends on the age of the patient and the extent of disease. For most patients, surgery alone is sufficient primary therapy, with radiation and chemotherapy reserved for the treatment of recurrent or metastatic disease.^{122, 123, 126, 127}

Surgery

Because granulosa cell tumors are bilateral in approximately 2% of patients, a unilateral salpingo-oophorectomy is appropriate therapy for stage IA tumors in children or in women of reproductive age.¹¹⁹ At the time of laparotomy, if a granulosa cell tumor is identified by frozen section, then a limited staging operation is performed, including an assessment of the contralateral ovary.^{141–144} As with germ cell malignancies, staging is limited to washings, omental biopsy, careful palpation of the peritoneal surfaces and retroperitoneal nodes, and biopsy of any suspicious lesions. If the opposite ovary appears enlarged, it should be biopsied. If there is metastatic disease, an effort should be made to resect all disease because these tumors are typically slow growing and do not respond well to chemotherapy. In perimenopausal and postmenopausal women for whom ovarian preservation is not important, a hysterectomy and bilateral salpingo-oophorectomy should be performed. In premenopausal patients in whom the uterus is left *in situ*, a dilation and curettage of the uterus should be performed because of the possibility of a coexistent adenocarcinoma of the endometrium.¹²²

Radiation

There is no evidence to support the use of adjuvant radiation therapy for granulosa cell tumors, although pelvic radiation may help to palliate isolated pelvic recurrences.^{121, 122, 138} Radiation can induce clinical responses and occasional long-term remission in patients with persistent or recurrent granulosa cell tumors, particularly if the disease is surgically cytoreduced.^{138, 145, 146} In one review of 34 patients treated at one center for more than 40 years, 14 (41.2%) were treated with measurable disease.¹⁴⁵ Three (21%) were alive without progression for 10–21 years following treatment.

Chemotherapy

There is no evidence that adjuvant chemotherapy in patients with stage I disease will prevent recurrence. Patients with metastatic granulosa cell tumors have been treated with a variety of different anti-neoplastic drugs over the years. There has been no one consistently effective regimen, although complete responses have been reported anecdotally in patients treated with the single agents cyclophosphamide and melphalan, as well as the combinations VAC, PAC (cisplatin, doxorubicin, and cyclophosphamide), PVB, and BEP.^{4, 119, 147–158} More recently, carboplatin and paclitaxel¹³⁸ as well as bevacizumab¹⁵⁹ have shown benefit.

The rarity of these tumors has made it impossible to conduct well-designed randomized studies for patients with stages II to IV disease. In retrospective series, postoperative chemotherapy has been associated with a prolonged progression-free interval in women with stage III or IV disease,^{138, 149} but an overall survival benefit has not been shown.¹⁵⁰ Despite the absence of data supporting a survival benefit, some experts recommend postoperative chemotherapy for women with completely resected stage II to IV disease because of the high risk of disease progression and the potential for long-term survival after platinum-based chemotherapy.^{138, 151–154} Acceptable options include BEP, EP, PAC, and carboplatin and paclitaxel.¹³⁸

For patients with suboptimally cytoreduced disease, combinations of BEP have produced overall response rates of 58–83%.^{138, 151, 155} In one study, 14 of 38 patients (37%) with advanced disease undergoing second-look laparotomy following four courses of BEP had negative findings.¹⁵¹ With a median follow-up of 3 years, 11 of 16 patients (69%) with primary advanced disease and 21 of 41 patients (51%) with recurrent disease were progression free. This regimen was associated with severe toxicity and two bleomycin-related deaths. Carboplatin and etoposide,¹⁵⁶ PVB,^{122, 157} and PAC^{147, 158} have also been reported to have relatively high response rates.

There is a need to develop less toxic and equally active regimens for this older group of patients. Paclitaxel is an active agent, and the combination of platinum with a taxane has been reported to have a response rate of 60%, which makes it a more attractive alternative.^{160–162}

Recurrent disease

The median time to relapse is approximately 4–6 years after initial diagnosis.^{119, 121, 142, 154} There is no standard approach to the management of relapsed disease. A common site of recurrence is the pelvis, although the upper abdomen may also be involved. Further surgery can be effective if the tumor is localized, but diffuse intra-abdominal disease is difficult to treat. Chemotherapy or radiation may be useful in selected patients.

Approximately 30% of these tumors are estrogen receptor-positive and 100% are progesterone receptor-positive on immunostaining.^{163, 164} The use of hormonal agents such as progestins or luteinizing hormone-releasing hormone (LHRH) agonists has been suggested, but there are limited available data.¹³⁷ LHRH agonists have been reported to have a 50% response rate in 13 patients from small clinical series and case reports,^{164–166} whereas four of five patients (80%) were reported to respond to a progestational agent.¹⁶⁷ Freeman recently reported two patients with recurrent adult granulosa cell tumors who had received multiple treatment modalities, including chemotherapy, and had previously progressed on leuprolide. Both patients were treated with anastrozole. Inhibin B levels normalized, as did clinical findings. Both were maintained on treatment for 14 and 18 months, respectively.¹⁶⁸

The numbers are too small to draw any conclusions, and it is likely that there has been significant publication bias, with more reports of responses to treatment.¹⁶⁹

Prognosis

The prognosis for granulosa cell tumor of the ovary depends on the surgical stage of disease.^{121, 123, 138, 170–173} Most granulosa cell tumors are indolent and are confined to one ovary at diagnosis; the cure rate for stage I disease is 75–92%.^{123, 144, 154, 173} However, late recurrences are not uncommon.^{119, 121, 123} In one report of 37 women with stage I disease, survival rates at 5, 10, and 20 years were 94%, 82%, and 62%, respectively. The survival rates for stages II to IV at 5 and 10 years were 55% and 34%, respectively.¹³⁸

In adult tumors, cellular atypia, mitotic rate, and the absence of Call-Exner bodies are the only significant pathologic predictors of early recurrence.¹⁵³ Neither an abnormal tumor karyotype nor p53 overexpression appears to be prognostic.¹⁷⁴ The DNA ploidy of the tumors has been correlated with survival. Holland et al.¹⁴⁸ reported DNA aneuploidy in 13 of 37 patients (35%) with primary granulosa cell tumors. The presence of residual disease was found to be the most important predictor of progression-free survival, but DNA ploidy was an independent prognostic factor. Patients with no residual disease and DNA diploid tumors had a 10-year progression-free survival of 96%.

Juvenile granulosa cell tumors

Juvenile granulosa cell tumors of the ovary are rare and make up less than 5% of ovarian tumors in childhood and adolescence.¹⁵⁶ Approximately 90% are diagnosed in stage I and have a favorable prognosis. The juvenile subtype behaves less aggressively than the adult type. Advanced-stage tumors have been successfully treated with platinum-based combination chemotherapy (e.g., BEP).¹³⁸

Sertoli–Leydig cell tumors

Sertoli–Leydig tumors occur most frequently in the third and fourth decades, with 75% of the lesions seen in women younger than 40 years. They account for less than 0.2% of ovarian cancers.¹³ Sertoli–Leydig cell tumors are most frequently low-grade malignancies, although poorly differentiated tumors may behave more aggressively.

The tumors typically produce androgens, and clinical virilization is noted in 70–85% of patients.^{175, 176} Signs of virilization include oligomenorrhea followed by amenorrhea, breast atrophy, acne, hirsutism, clitoromegaly, a deepening voice, and a receding hairline. Measurement of plasma androgens may reveal elevated testosterone and androstenedione, with normal or slightly elevated dehydroepiandrosterone sulfate.¹ Rarely, the Sertoli–Leydig tumor can be associated with manifestations of estrogenization (i.e., isosexual precocity, irregular or postmenopausal bleeding).¹⁷⁶

Treatment

Because these low-grade tumors are bilateral in less than 1% of cases, the usual treatment is unilateral salpingo-oophorectomy and evaluation of the contralateral ovary in patients who are in their reproductive years.¹⁷⁶ In older patients, hysterectomy and bilateral salpingo-oophorectomy are appropriate.

There are limited data regarding the utility of chemotherapy in patients with persistent disease, but responses in patients with measurable disease have been reported with cisplatin in combination with doxorubicin or ifosfamide or both¹⁷⁶ as well as the regimens mentioned earlier for granulosa cell tumors. Because of their rarity, most series have included them with granulosa cell tumors.¹⁵² Pelvic radiation can also be used for recurrent pelvic tumor but with limited responses.

Prognosis

The 5-year survival rate is 70–90%, and recurrences thereafter are uncommon.^{1, 2, 176} The majority of fatalities occur with poorly differentiated lesions.

Uncommon ovarian cancers

There are several varieties of malignant ovarian tumors, which together constitute only 0.1% of ovarian malignancies. These lesions include lipoid (or lipid) cell tumors, primary ovarian sarcomas, and small cell ovarian carcinomas.

Lipoid cell tumors

Lipoid cell tumors are thought to arise in adrenal cortical rests that reside in the vicinity of the ovary. More than 100 cases have been reported, and bilaterality has been noted in only a few.¹ Most are associated with virilization and occasionally with obesity, hypertension, and glucose intolerance, reflecting glucocorticoid secretion. Rare cases of estrogen secretion and isosexual precocity have been reported.

The majority of these have a benign or low-grade behavior, but approximately 20% develop metastatic lesions in the peritoneal cavity, or rarely at distant sites. The primary treatment is surgical, and there are no data regarding radiation or chemotherapy for this disease.

Sarcomas

Malignant mixed mesodermal sarcomas of the ovary are usually heterologous, and 80% occur in postmenopausal women.^{177–183} The lesions are biologically aggressive, and their presentation is similar to that of most epithelial ovarian malignancies.

Such patients should be treated by cytoreductive surgery and postoperative platinum-containing combination chemotherapy. Silasi et al.¹⁸⁴ reported their experience with 22 patients from Yale, all but two of whom presented with advanced-stage disease. The median survival for the entire cohort was 38 months. The median survival was 46 months for 18 optimally debulked (<1 cm) patients and 27 months for four suboptimally debulked (>1 cm) patients. After optimal cytoreduction, six patients were treated with cisplatin and ifosfamide; they had a median progression-free interval of 13 months and a median survival of 51 months. The combination of carboplatin and paclitaxel was administered to four patients following optimal cytoreduction; their median progression-free interval was 6 months, and median survival was 38 months. The difference in survival between the cisplatin and ifosfamide group and the carboplatin and paclitaxel group was not statistically significant ($p = 0.48$). First-line cisplatin and ifosfamide or carboplatin and paclitaxel can achieve survival rates comparable to those observed in epithelial ovarian cancer.

Leiser et al.¹⁸⁵ reported the Memorial Sloan-Kettering experience with platinum and paclitaxel in 30 patients with carcinosarcomas of the ovary. Twelve patients (40%) had a complete response, seven (23%) a partial response, two (7%) stable disease, and nine (30%) progression of disease. The median time to progression for responders was 12 months; with a median follow-up of 23 months, the median overall survival was 43 months for survivors. The 3- and 5-year survival rates were 53% and 30%, respectively.

Small cell carcinomas

This rare tumor occurs at an average age of 24 years (range 2 to 46 years).¹⁸⁶ The tumors are all bilateral. Approximately two-thirds of the tumors are accompanied by paraneoplastic hypercalcemia. This tumor accounts for one-half of all of the cases of hypercalcemia associated with ovarian tumors. Approximately 50% of the tumors have spread beyond the ovaries at the time of diagnosis.^{1, 2}

Management consists of surgery followed by platinum-based chemotherapy. Radiation therapy may be considered in selected patients. In addition to the primary treatment of the disease, control of the hypercalcemia may require aggressive hydration, loop diuretics, and the use of bisphosphonates.

In a collaborative Gynecologic Cancer Intergroup study, data were collected for 17 patients treated in Australia, Canada, and Europe.¹⁸⁷ The median follow-up was 13 months for all patients and 35.5 months for surviving patients. Ten patients (58.8%) had FIGO stage I tumors, six (35.3%) stage III, and in one patient, stage was unknown. All underwent surgical resection and adjuvant platinum-based chemotherapy. Seven received adjuvant pelvic, whole-abdominal, or extended-field radiation. The median survival for stage I tumors was not reached, whereas it was 6 months for stage III tumors. For the 10 patients with stage I tumors, 6 also received adjuvant radiotherapy, with 5 alive and disease-free; 4 received no adjuvant radiotherapy, with 1 alive and disease-free. Of the seven patients with stage III or unknown tumor stage, all but one have died. The only long-term survivor was treated with platinum-based chemotherapy (BEP) followed by para-aortic and pelvic radiotherapy. Recurrences were most frequent in the pelvis and the abdomen. Patients receiving salvage treatment with chemotherapy and radiotherapy did

poorly.

Although the optimal approach to management is not known, in view of these findings, the authors advocate a multimodality treatment approach, including surgical resection of gross disease, chemotherapy with carboplatin and paclitaxel or cisplatin and etoposide, and the addition of various fields of pelvic radiotherapy either sequentially or concurrently. Others have advocated high-dose chemotherapy with stem cell support and have reported a number of long-term survivors.^{188, 189}

Metastatic tumors

Approximately 5–6% of ovarian tumors are metastatic from other organs, most frequently from the female genital tract, the breast, or the gastrointestinal tract.^{190–207} The metastases may occur from direct extension of another pelvic neoplasm, by hematogenous spread, by lymphatic spread, or from transcoelomic dissemination, with surface implantation of tumors that spread in the peritoneal cavity.

Gynecologic primary

Nonovarian cancers of the genital tract can spread by direct extension or metastasize to the ovaries.¹ Under some circumstances, it is difficult to know whether the tumor originates in the fallopian tube or in the ovary when both are involved, especially because many high-grade serous carcinomas that were thought to be primary ovarian malignancies are now believed to actually arise in the fallopian tube, as discussed earlier.²⁰⁸ Cervical cancer spreads to the ovary only in rare cases (<1%), and most of these are at an advanced clinical stage or are adenocarcinomas. Although adenocarcinoma of the endometrium can spread and implant directly onto the surface of the ovaries in as many as 5% of cases, two synchronous primary tumors probably occur with greater frequency. In these cases, an endometrioid carcinoma of the ovary is usually associated with the adenocarcinoma of the endometrium.²⁰⁹

Nongynecologic primary

The frequency of metastatic breast carcinoma to the ovaries varies according to the method of determination, but is relatively common, particularly in patients with estrogen receptor positive metastatic breast cancer. In autopsy data of women who die of metastatic breast cancer, the ovaries are involved in 24% of cases, and 80% of the involvement is bilateral.^{190–196} Similarly, when ovaries are removed as treatment for metastatic breast cancer in premenopausal women, approximately 20–30% of patients have evidence of ovarian metastases, 60% bilaterally. The involvement of ovaries in early-stage breast cancer is considerably lower, but precise figures are not available. In almost all cases, ovarian involvement is occult but in some patients, a pelvic mass is discovered after other metastatic disease becomes apparent.

Krukenberg tumor

Krukenberg tumors account for 30–40% of metastatic cancers to the ovaries, and are characterized by mucin-filled, signet-ring cells in the ovarian stroma.^{200, 201} The primary tumor is most frequently the stomach but less common primaries include the colon, breast, or biliary tract. Rarely, the cervix or the bladder may be the primary site. Krukenberg tumors can account for approximately 2% of ovarian cancers, and they are usually bilateral. The tumors are usually not discovered until the primary disease is advanced, and therefore, most patients die of their disease within a year. In some cases, a primary tumor is never found.

Other gastrointestinal tumors

In other cases of metastasis from the gastrointestinal tract to the ovary, the tumor does not have the classic histologic appearance of a Krukenberg tumor; most of these are from the colon and, less commonly, the small intestine. One to two percent of women with intestinal carcinomas will develop metastases to the ovaries during the course of their disease.^{192, 197–199, 202, 203} Before exploration for an adnexal tumor in a woman more than 40 years of age, a colonoscopy or gastroscopy should be performed to exclude a primary gastrointestinal carcinoma with metastases to the ovaries if there are any gastrointestinal symptoms.

Metastatic colon cancer can mimic a mucinous cystadenocarcinoma of the ovary histologically, and the histologic distinction between the two can be difficult.^{202–206} Tumors that arise in the appendix may also be associated with ovarian metastasis and have frequently been confused with primary ovarian malignancies, especially when associated with pseudomyxoma peritonei.^{202, 206} When the ovaries are involved with metastasis, a bilateral salpingo-oophorectomy should be performed at the time of surgery for colon cancer.^{197, 207}

Melanoma

Rare cases of malignant melanoma metastatic to the ovaries have been reported,²¹⁰ and must be distinguished from the rare case of a melanoma arising in an ovarian teratoma.²¹¹ In cases of metastatic disease, the melanomas are usually widely disseminated. Removal would be warranted for palliation of abdominal or pelvic pain, bleeding, or torsion.

Carcinoid

Metastatic carcinoid tumors represent fewer than 2% of metastatic lesions to the ovaries.²¹² Conversely, only some 2% of primary carcinoids have evidence of ovarian metastasis, and only 40% of these patients have the carcinoid syndrome at the time of discovery of the metastatic carcinoid.²¹³ In perimenopausal and postmenopausal women explored for an intestinal carcinoid, it is reasonable to remove the ovaries to prevent subsequent ovarian metastasis. Furthermore, the discovery of an ovarian carcinoid should prompt a careful search for a primary intestinal lesion.

Lymphoma and leukemia

Lymphomas and leukemia can involve the ovary. When they do, the involvement is usually bilateral.^{214–217} Approximately 5% of patients with Hodgkin disease will have lymphomatous involvement of the ovaries, but this occurs typically with advanced-stage disease. With Burkitt lymphoma, ovarian involvement is very common. Other types of lymphoma involve the ovaries much less frequently, and leukemic infiltration of the ovaries is uncommon.

Sometimes, the ovaries can be the only apparent sites of involvement of the abdominal or pelvic viscera with a lymphoma—in this circumstance, a careful surgical exploration may be necessary. An intraoperative consultation with a hematologist–oncologist should be obtained to determine the need for such procedures if frozen section of a solid ovarian mass reveals a lymphoma. In general, most lymphomas no longer require extensive surgical staging, although enlarged lymph nodes should generally be biopsied. In some cases of Hodgkin disease, a more extensive evaluation may be necessary. Treatment involves that of the lymphoma or leukemia in general. Removal of a large ovarian mass may improve patient comfort and facilitate a response to subsequent radiation or chemotherapy.²¹⁶

Chapter 106

Molar pregnancy and gestational trophoblastic neoplasia

Donald P. Goldstein, MD ■ Ross S. Berkowitz, MD ■ Neil S. Horowitz, MD

Overview

Gestational trophoblastic neoplasia (GTN) is among the rare human malignancies that can be cured in the presence of widespread metastases. GTN includes a spectrum of interrelated tumors, including hydatidiform mole, invasive mole, choriocarcinoma, placental-site trophoblastic tumor (PSTT), and epithelioid trophoblastic tumor (ETT), which has varying propensities for local invasion and metastasis. With the exception of PSTT and ETT, all GTNs arise from the cytotrophoblast and syncytial cells of the villous trophoblast and produce abundant amounts of human chorionic gonadotropin (hCG). Measurement of hCG levels serves as a reliable tumor marker for diagnosis, monitoring of treatment response, and follow-up to detect recurrence. PSTT and ETT originate from the intermediate cells of extravillous trophoblast and produce hCG sparsely, making its use as a tumor marker that is less reliable. Although GTN most commonly follows a molar pregnancy, it may follow any gestational event, including therapeutic or spontaneous abortion and ectopic or term pregnancy. Before the development of effective chemotherapy in 1956, the majority of patients with GTN localized to the uterus were cured with hysterectomy, but metastatic disease was almost always fatal. Most women can now be cured and their reproductive function preserved if treated early and according to well-established guidelines. GTN patients are categorized using a prognostic scoring system into low- and high-risk disease based on response to single-agent chemotherapy. Low-risk GTN generally responds to monotherapy while high-risk disease requires multiagent regimens to achieve remission. Despite chemotherapy, subsequent pregnancy outcomes are similar to the general population.

Molar pregnancy and gestational trophoblastic neoplasia (GTN) comprise a group of interrelated diseases that includes complete hydatidiform (CHM) and partial hydatidiform (PHM) mole, invasive mole, choriocarcinoma (CCA), placental site trophoblastic tumor (PSTT), and epithelioid trophoblastic tumor (ETT). Molar pregnancy and GTN produce a distinct tumor marker, human chorionic gonadotropin (hCG), which can be used for diagnosis, monitoring the effects of therapy, and follow-up to detect relapse. Complete and partial moles are noninvasive, localized tumors that develop as a result of an aberrant fertilization event that leads to a proliferative process. The other trophoblastic tumors which as a group are referred to as GTN represent malignant disease because of their local invasion and metastases. GTN most commonly develops from a molar pregnancy but can rise *de novo* after any gestation. Although these tumors are rare, it is important for medical oncologists to understand their natural history and management because of their life-threatening potential in reproductive-age females and their high degree of curability with preservation of reproductive function if treated early and appropriately.^{1, 2} Despite the advances made in the management of GTN over the past 60 years, patients with protracted delays in diagnosis, particularly after nonmolar pregnancies, still present with extensive tumor burdens and are at substantial risk for treatment failure and death.

Incidence

The reported incidence of molar pregnancy and GTN varies substantially in different regions of the world.³ The incidence of complete and partial molar pregnancy in North America and Europe is approximately 1 : 1250 and 1 : 650, respectively, whereas the incidence in Asian countries is 3–10 times greater.^{4, 5} Variations in the incidence rates of molar pregnancy throughout the world may result from differences between reporting hospital-based versus population-based data.

The incidence of GTN is also difficult to establish with certainty because accurate epidemiologic data is not available in most countries. Approximately 50% of GTN cases arise from molar pregnancy, 25% from miscarriages or tubal pregnancies, and 25% from term or preterm pregnancy.⁶ GTN which develops after a non-molar pregnancy is usually due to CCA, whereas PSTT and ETT occur rarely. The incidence of GTN following a non-molar pregnancy in Europe and North America is estimated at 2–7 per 100,000 pregnancies, whereas in Southeast Asia and Japan, the incidence is higher at 50–200 per 100,000 pregnancies, respectively.^{7, 8}

Risk factors

The two main risk factors for molar pregnancy and GTN are extremes of maternal age (especially over 35 and under 16) and a history of previous mole.^{9–13} Parazzini et al.¹¹ noted that the risk for CHM was increased twofold for women older than age 35 years and 7.5-fold for women older than age 40 years. Ova from older women may be more susceptible to abnormal fertilizations. Most cases of molar disease and GTN occur in women under 35 because of the greater number of pregnancies in this age group. The risk for PHM has not been associated with maternal age.

Histopathologic classification of GTN

Hydatidiform mole may be categorized as either complete or partial based on gross morphology, histopathology, and karyotype.^{14, 15} CHM is characterized by hydropic villi with trophoblastic hyperplasia. Embryonic or fetal tissues are not identifiable. Partial moles are characterized by the presence of two populations of chorionic villi, some appearing normal and some exhibiting focal swelling and focal trophoblastic hyperplasia. Fetal and embryonic tissues are commonly present. Locally invasive or metastatic GTN that develops after either a complete or partial mole can have the histologic features of either molar tissue or CCA.

CCA does not contain chorionic villi but is composed of sheets of both anaplastic cyto- and syncytiotrophoblasts. Although CCA is most commonly preceded by a CHM, it may develop after any gestation. After a non-molar pregnancy, persistent GTN usually has the histologic pattern of CCA but rarely can be present as PSTT or ETT. CCA is a highly vascular tumor that disseminates via the blood stream initially to the lungs. Distant sites such as the brain, liver, kidney, gastrointestinal tract, and spleen are usually late manifestations of the disease in patients where there has been delayed diagnosis.

PSTT and ETT are uncommon variants of CCA, which are composed almost entirely of mononuclear intermediate trophoblast and do not contain chorionic villi.^{16, 17} Both PSTT and ETT tend to infiltrate the myometrium and, in contrast to CCA, metastases are a late manifestation of the disease. These tumors display a wide clinical spectrum and when metastatic can be difficult to control even with surgery and chemotherapy. They are characterized by low hCG levels so a large tumor burden may be present before

the disease is diagnosed.

Clinical presentation and diagnosis

Post-molar GTN

Complete moles develop uterine invasion or metastasis in about 15% and 4% of patients, respectively.¹⁸ Approximately 1–4% of patients with PHM develop persistent tumor, which is generally non-metastatic.¹⁹ After molar evacuation, all patients must be monitored for the development of post-molar GTN, defined as those patients who develop persistently elevated hCG levels, require chemotherapy and/or excisional surgery, or have evidence of metastases. According to the International Federation of Gynecology and Obstetrics (FIGO) criteria, the presence of post-molar GTN should be diagnosed if the following is present: (1) serum hCG values that plateau (decline of <10% for at least four values over 3 weeks); (2) serum hCG levels rise (increase more than 10% over 2 consecutive weeks); and (3) persistence of detectable serum hCG for more than 6 months after molar evacuation.²⁰

Patients on rare occasion present with a false positive elevation in their serum hCG concentration owing to a number of factors other than GTN. The differential diagnosis of an elevated hCG value includes (1) pregnancy, (2) germ cell tumor of the ovary or other site, (3) non-trophoblastic gonadotropin-producing tumor (e.g., hepatoma), or (4) phantom hCG caused by heterophilic antibody.²¹ Post-menopausal women have also been reported to have detectable low hCG levels of pituitary origin, which can be suppressed by hormone replacement therapy.²²

Non-metastatic GTN

Locally invasive GTN also occurs infrequently after non-molar pregnancies.¹⁸ These patients may present with persistently elevated hCG levels, irregular vaginal bleeding, uterine subinvolution, or asymmetric uterine enlargement. Theca lutein ovarian cysts are rare in the absence of high levels of hCG (>100,000 mIU/mL). The trophoblastic tumor may erode into uterine vessels, causing vaginal hemorrhage, or may perforate through the myometrium, producing intra-abdominal bleeding. Bulky necrotic tumors in the endometrial cavity may also serve as a nidus for sepsis, causing pelvic pain and purulent discharge.

Metastatic GTN

Metastases develop in approximately 4% of patients after complete mole and infrequently after other gestations.¹⁸ When metastases occur, the pathology is usually CCA because this tumor has a propensity for early vascular invasion and dissemination. The presenting signs and symptoms in these patients depend on the sites of metastasis: hemoptysis from lung lesions, acute neurologic deficits from intracranial hemorrhage, and so on.

The most common site of metastasis is the lung. Eighty percent of patients with metastatic GTN have pulmonary involvement on chest radiographs or computed tomography (CT). Because respiratory symptoms and radiographic findings may be striking, the patient may be thought to have a primary pulmonary process. Pulmonary hypertension can develop as a result of pulmonary arterial occlusion by trophoblastic emboli. The development of early respiratory failure requiring intubation is associated with a dismal outcome.²³ Gynecologic symptoms may be minimal or absent even when the patient has extensive metastases. *The diagnosis of GTN should be considered in any woman in the reproductive age group with unexplained pulmonary or systemic symptoms.*

Vaginal metastases are present in 30% of patients with metastatic GTN. Because these lesions are highly vascular, they may hemorrhage if biopsied.¹⁸

Hepatic and cerebral metastases occur in approximately 10% of patients with metastatic GTN. Hepatic and cerebral lesions invariably have the histologic pattern of CCA and usually follow a non-molar pregnancy. These patients characteristically have protracted delays in diagnosis and extensive tumor burdens. Virtually, all patients with hepatic and cerebral metastases have concurrent pulmonary or vaginal involvement.^{24, 25}

Staging and risk assessment

An anatomic staging system for GTN was adopted by the FIGO in 1982²⁰:

Stage I: Lesion confined to uterus.

Stage II: Lesion outside uterus but confined to vagina and pelvis.

Stage III: Lung metastases with or without evidence of uterine or pelvic disease.

Stage IV: Distant metastatic sites such as the brain, liver, kidney, gastrointestinal tract, and spleen.

In addition to anatomic staging, the World Health Organization (WHO) has adopted a prognostic scoring system ([Table 1](#)) that reliably predicts the risk of drug resistance and assists in selecting the appropriate chemotherapy.^{20, 27} Prognostic scores <7 are associated with a low risk of resistance to single agent chemotherapy. When the prognostic score is 7 or greater, the patient is considered to be at high risk of developing drug resistance to single agent therapy and requires intensive combination chemotherapy. Patients with stage I GTN usually have a low-risk score and those with stage IV disease generally have a high-risk score. Therefore, the distinction between low and high risk mainly applies to patients with stages II and III disease. The FIGO stage is designated by a Roman numeral and is followed by the modified WHO prognostic score designated by an Arabic number separated by a colon (e.g., II:6).

Table 1 Scoring system for gestational trophoblastic tumors based on prognostic factors

	Score ^b			
	0	1	2	4
Age (years)	<39	>39	—	—
Antecedent pregnancy	Mole	Abortion	Term	—
Interval ^a	<4	4–6	7–12	—
hCG (IU/L)	<10 ³	10 ³ –10 ⁴	10 ⁴ –10 ⁵	—
ABO groups (female × male)	—	O × A	B	—
		A × O	AB	—
Largest tumor, including uterine tumor	—	3–5 cm	5 cm	—
Site of metastases	—	Spleen, kidney	Gastrointestinal tract and liver	Brain
Number of metastases identified	—	1–4	4–8	>8
Prior chemotherapy	—	—	Single drug	Two or more drug

^a Interval is the time (months) between end of antecedent pregnancy and start of chemotherapy.

^b The total score for a patient is obtained by adding the individual scores for each prognostic factor. Total score: <7 = low risk; and ≥7 = high risk.

Source: Data from Matsui et al. 2004.²⁶

Data from Charing Cross Hospital indicate that only 30% of low-risk patients with a WHO prognostic score of 5–6 can be cured with monotherapy, which suggests that a multidrug regimen should be administered initially. These patients characteristically present with pre-treatment hCG levels >100,000 mIU/mL and ultrasound evidence of a large tumor burden.²⁸

Management of GTN

Pretreatment evaluation and staging of GTN

Patients with GTN must undergo a thorough evaluation in order to determine their stage and risk status, which will guide the clinician in selecting the appropriate treatment ([Figure 1](#)). The physical examination should always include a vaginal speculum examination to detect implants, which can hemorrhage. Radiographic evaluation should include a pelvic ultrasound to look for evidence of retained trophoblastic tissue in the uterine cavity, myometrial invasion, and to evaluate the pelvis for local spread. Chest imaging is also required, as the lungs are the most common site of metastases. Although chest CT scans are more sensitive than a chest X-ray, they are not included in staging as detection of occult pulmonary metastases does not affect outcome. Pulmonary metastases can be detected by chest CT in up to 40% of patients with a negative chest X-ray.²⁹ In the absence of pulmonary and vaginal metastases, involvement of distant organs such as the brain and liver is rare. As long as the clinical picture is compatible with GTN, metastases need not be biopsied because of their vascularity and the risk of hemorrhage.

Figure 1 Algorithm for the management of gestational trophoblastic disease (GTD).

Management of low-risk GTN

Primary therapy of low-risk GTN

Low-risk GTN includes patients with both stage I (non-metastatic) and stages II and III (metastatic) GTN whose prognostic score is <7 . In patients with stage I GTN, the selection of primary therapy is based on the patient's desire to preserve fertility. If the patient has completed her childbearing, hysterectomy should be considered.³⁰ At the time of surgery, we recommend the administration of one course of adjuvant single-agent chemotherapy, either methotrexate (MTX) or actinomycin D (ACTD) for treatment of occult metastases.

Single-agent chemotherapy with sequential MTX/ACTD is the preferred treatment in patients with stage I GTN who desire to retain fertility, as well as in patients with low-risk metastatic GTN. MTX with folinic acid (MTX-FA) is the preferred single-agent regimen at the New England Trophoblastic Disease Center (NETDC).³¹ MTX-FA induced complete remission in 147 (90.2%) of 163 patients with stage I GTN and in 15 (68.2%) of 22 patients with low-risk stages II and III GTN. One course of MTX-FA induced remission in 132 (81.5%) of these patients. ACTD is used as primary therapy in those patients with pre-existing hepatic dysfunction, who develop hepatic toxicity to MTX, or sequentially in those patients who prove resistant to MTX.³²

Single-agent chemotherapy with either MTX or ACTD has achieved excellent and comparable remission rates in both non-metastatic (80–90%) and low-risk metastatic (60–70%) GTN.^{2, 18, 32} Several protocols using MTX and ACTD have been used effectively in the treatment of GTN, but until recently, there has been no prospective randomized study comparing all of these regimens ([Table 2](#)).³² Single-agent chemotherapy should be administered at a fixed time interval. A decline in the hCG level less than a one log indicates that the patient's tumor is relatively resistant to that drug, and an alternative agent is substituted.

Table 2 Single-agent regimen

<i>Methotrexate treatments</i>
MTX-FA
MTX 1.0 mg/kg IM on days 1, 3, 5, and 7
FA 0.1 mg/kg IM or po on days 2, 4, 6, and 8
5-day MTX
MTX 0.4 mg/kg/day IV or IM daily for 5 days
Pulse MTX
MTX 50 mg/m ² IM weekly
<i>Actinomycin D treatments</i>
5-day Act-D
Act-D 12 µg/kg/day IV for 5 days
Pulse Act-D
Act-D 1.25 mg/m ² IV every 2 weeks

Abbreviations: FA, folinic acid; IM, intramuscular; and IV, intravenous.

Salvage therapy of low-risk GTN

Patients with low-risk GTN who develop resistance to sequential single-agent chemotherapy can usually achieve remission with combination chemotherapy consisting of MTX, ACTD, cyclophosphamide, etoposide, and Oncovin^R (EMA/CO) (etoposide, methotrexate, actinomycin D, cyclophosphamide, vincristine) ([Table 3](#)).³³ The use of etoposide, particularly in patients with low-risk GTN, has been of concern because of a report by Rustin et al.³⁴ that its use was associated with an increased risk of secondary malignancies. A more recent report from the same institution on a larger number of patients has shown that the risk is limited.³⁵ If the disease is resistant to both single-agent and combination chemotherapy, hysterectomy or local resection (if the patient wants to preserve fertility) may be considered. Ultrasonography, MRI (magnetic resonance imaging) scan, pelvic arteriography, and/or PET (positron emission tomography) scan may aid in identifying the site of resistant uterine tumor when local resection is planned. The administration of three additional courses of the last effective agent reduces the risk of relapse in patients with low-risk disease.³⁶

Table 3 EMACO regimen

Time	Treatment
Day 1	Etoposide 100 mg/m ² by IV infusion in 200 mL of saline over 30 min
	Act-D 0.5 mg IV push
	MTX 100 mg/m ² IV push
	MTX 200 mg/m ² by IV infusion over 12 h
Day 2	Etoposide 100 mg/m ² by IV infusion in 200 mL of saline over 30 min
	Act-D 0.5 mg IV push
	FA 15 mg IM or po every 12 h for 4 doses beginning 24 h after starting MTX
Day 8	Cyclophosphamide 600 mg/m ² IV in saline Oncovin (vincristine) 1.0 mg/m ² IV push

Abbreviations: Act-D, actinomycin D; FA, folinic acid; IM, intramuscular; IV, intravenous; MTX, methotrexate; and po, per os (by mouth).

Management of high-risk GTN, stages II and III

Primary therapy

Women with FIGO stages II and III and a WHO score of 7 or higher are at high risk for developing chemotherapy resistance and disease recurrence and should be treated with primary combination chemotherapy with EMACO, which is associated with complete remissions in 76–86% of patients.^{37–39}

Salvage therapy

Patients with disease resistant to EMACO may be treated by modifying that regimen by substituting cisplatin and etoposide (EMA/CE) on day 8.³³ Combination chemotherapy is administered at 2–3 week intervals, toxicity permitting, until the patient attains *three* consecutive weekly undetectable hCG levels, after which at least three additional courses of chemotherapy should be administered to reduce the risk of relapse.

Management of stage IV GTN

Patients with stage IV disease *include patients who* are the highest risk of developing rapidly progressive disease and chemoresistance. The use of primary combination chemotherapy in conjunction with the selective use of radiation and surgical treatment has resulted in significantly improved survival. At the NETDC, before 1975, only 30% of patients with stage IV disease survived. After 1975, when the concept of early intensive multi-agent treatment was introduced, complete sustained remission was achieved in 80% of patients.

All patients with stage IV GTN are managed with primary combination chemotherapy with EMA/CO. When CNS metastases are present, the MTX dosage in the infusion is increased to 1 g/m².⁴⁰ Patients who develop resistance to EMA/CO should then be treated with EMA/CE ([Table 4](#)). A number of other salvage regimens have been reported to achieve remission in small series of patients. Second-line therapy with etoposide in combination with cisplatin and bleomycin (BEP) or vinblastine in combination with cisplatin and bleomycin (PVB) have also been shown to be effective in patients with resistant GTN.^{41–44}

Table 4 EMACE regimen

Time	Treatment
Day 1	Etoposide 100 mg/m ² by IV infusion in 200 mL of saline over 30 min
	Act-D 0.5 mg IV push
	MTX 100 mg/m ² IV push
	MTX 1,000 mg/m ² by IV infusion over 12 h
Day 2	Etoposide 100 mg/m ² by IV infusion in 200 mL of saline over 30 min
	Act-D 0.5 mg IV push
	FA 30 mg IM or PO every 12 h for 6 doses beginning 32 h after starting MTX
Day 8	Cisplatin 60 mg/m ² IV with prehydration etoposide 100 mg/m ² by IV infusion in 200 mL of saline over 30 min

Abbreviations: Act-D, actinomycin D; FA, folinic acid; IM, intramuscular; IV, intravenous; MTX, methotrexate; and po, per os (by mouth).

The potential role of autologous bone marrow transplantation or stem cell rescue in GTN has yet to be defined. However, individual cases have been reported where ultra-high-dose chemotherapy with autologous bone marrow or stem cell support has induced complete remission in patients with refractory disease.^{45, 46}

Despite the efficacy of well-recognized regimens, efforts continue to identify new agents effective in treating resistant disease. Although ifosfamide and paclitaxel have been used successfully, further studies are needed to define their potential role in either primary or second line therapy.^{47, 48} Osborne et al.⁴⁹ have reported that a novel 3-drug doublet regimen consisting of paclitaxel, etoposide, and cisplatin (TE/TP) induced complete remission in two patients with relapsed high-risk GTN. Wan et al.⁵⁰ demonstrated the efficacy of floxuridine (FUDR)-containing regimens in drug-resistant patients. Matsui et al.²⁶ found that 5FU (5-fluorouracil) in combination with ACTD could also be used effectively as salvage therapy.

Role of surgery

Surgery is performed to either treat complications or excise sites of resistant tumor.⁵¹ Hysterectomy may be necessary to control uterine hemorrhage or sepsis or to reduce the tumor burden and thereby limit the need for chemotherapy. Bleeding from vaginal metastases may be managed by packing, wide local excision, or arteriographic embolization of the hypogastric arteries.⁵² Thoracotomy may be performed to excise persistent viable tumor despite intensive chemotherapy.⁵³ However, fibrotic nodules may persist indefinitely on chest roentgenograms after complete gonadotropin remission is attained. An extensive metastatic survey should be undertaken to exclude other sites of persistent tumor. A PET scan may be useful to identify occult sites of viable tumor.⁵⁴ Hepatic resection may be required to manage bleeding metastases although embolization has also been utilized in this setting.⁵⁵ Craniotomy may be necessary to provide acute decompression or to control bleeding, in addition to its role in the primary resection of solitary metastatic disease.³²

Role of radiation therapy

When cranial metastases are identified whole-brain irradiation and systemic chemotherapy are promptly instituted at the NETDC to reduce the risk of cerebral hemorrhage. Yordan et al.⁵⁶ reported that deaths as a result of cerebral involvement occurred in 11 (44%) of 25 patients treated with chemotherapy alone, but in none of 18 patients treated with brain irradiation and chemotherapy. Excellent results have also been achieved in selected cases with local resection, particularly when the tumor is solitary and located peripherally.^{32, 40, 51}

Excellent cure rates have also been reported in patients with cerebral metastases with intensive chemotherapy alone. Newlands et al.⁴⁰ have documented excellent remission rates in patients with brain involvement who were treated with chemotherapy alone. Intensive combination chemotherapy including high-dose intravenous and intrathecal MTX induced sustained remission in 30 (86%) of 35 patients with cerebral lesions. The patients with superficial solitary brain metastases underwent craniotomy at the start of therapy.

Craniotomy may also be necessary to provide acute decompression or control bleeding. Craniotomy should also be performed to manage life-threatening complications thereby providing an opportunity to control the disease with chemotherapy. Infrequently cerebral metastases may be resectable when they become resistant to chemotherapy. Athanassiou et al.⁵⁷ reported that four of five patients undergoing craniotomy for acute intracranial complications were ultimately cured. Fortunately, most patients with cerebral metastases who achieve remission have no residual neurological deficit unless a bleed has occurred.

However, we have observed rare cases of significant dementia and progressive memory loss in patients who received whole head irradiation. Although the controversy regarding the optimal treatment protocol for cerebral metastases has not been resolved, Neubauer et al.⁵⁸ have reported that multimodal therapy including chemotherapy, surgical resection, and radiation therapy(whole brain or stereotactic) has improved overall survival from 46% to 64%.

Management of PSTT and ETT

Patients with PSTT and ETT require special consideration because of the unique nature of their disease. We believe that the primary therapy of all patients with non-metastatic PSTT and ETT should be hysterectomy without adjunctive chemotherapy because this variant of CCA is relatively resistant to chemotherapy.^{16, 59, 60} If deep myometrial involvement is present, it is our policy to also perform a pelvic lymphadenectomy. Unlike CCA, these tumors tend to remain localized in the uterus for long periods of time before metastasizing. Once metastases occur both PSTT and ETT have a high mortality rate. Kingdon et al.⁶¹ in their review of deaths from GTN found that 30% of those dying from GTN had PSTT histology. In the absence of demonstrable metastases, no further treatment is required.

Although universally accepted guidelines on how to manage PSTT and ETT are not available because of their rarity, given their aggressive clinical behavior the use of multimodal therapy with surgery, radiation and chemotherapy has improved survival. The use of EMA/EP in PSTT has been shown to be curative in patients with metastases.⁶² Papadopoulos et al.⁶² reported that a long interval from the antecedent pregnancy to clinical presentation was the most important prognostic factor. While all 27 patients survived when the interval was <4 years, all seven patients died when the interval exceeded 4 years. Although not applicable to the majority of patients, fertility-sparing surgery has also been employed

successfully.^{63, 64}

Results of therapy

Stage I GTN

Between July 1965 and December 2013, 624 patients with stage I GTN were treated at the NETDC and all attained remission. 478 out of 582 patients (82%) who were treated with primary single-agent chemotherapy achieved remission with sequential MTX/ACTD. All 35 patients managed with primary hysterectomy and adjuvant single-agent chemotherapy achieved remission with no further treatment. Seven patients with high-risk scores achieved remission with primary combination chemotherapy. The remaining 104 patients resistant to primary treatment were treated successfully with either combination chemotherapy or surgical intervention.

Stages II and III GTN

Complete remission was achieved at the NETDC in all 37 patients with stage II GTN and in 225 out of 226 patients with stage III GTN. Single-agent chemotherapy induced remission in 16 (76.2%) of 21 patients with low-risk stage II disease and in 113 (73.3%) of 154 patients with low-risk stage III disease. All patients with disease resistant to single-agent chemotherapy attained remission with combination chemotherapy. Sixteen patients with high-risk stage II and 12 (92.3%) of 13 patients with high-risk stage III GTN achieved remission with combination regimens. There was one death in the high-risk stage III group.

Stage IV GTN

Before 1975, only 6/20 patients (30%) with stage IV GTN achieved remission at the NETDC. However, after 1975, 25 (75.5%) of 33 patients with stage IV disease attained remission. This dramatic improvement in survival resulted from the use of intensive multimodal therapy early in the course of treatment. While brain irradiation is commonly employed in the United States for cerebral metastases, excellent remission rates have been reported in patients with cerebral metastases who were treated with chemotherapy alone.⁴⁰ Recently, Alifrangis et al.⁶⁵ reported that the use of induction chemotherapy with low-dose etoposide and cisplatin resulted in improved survival in patients with high-risk GTN and large tumor volumes.

hCG follow-up and relapse

All patients with stages I, II, and III GTN are followed with weekly hCG values until undetectable for three consecutive weeks and then monthly until undetectable for 12 months. Patients with stage IV GTN are followed monthly for 24 months because they are at greater risk for late relapse. All patients must be encouraged to use effective contraception during the entire interval of monitoring. Relapse rates at the NETDC are as follows: stage I, 2.9%; stage II, 8.3%; stage III, 4.2%; and stage IV, 9.1%. The mean time to recurrence from the last nondetectable hCG level was 6 months, and this did not differ among the four stages.⁶⁶

When relapse occurs, the patient should be restaged, and appropriate therapy begun with a new regimen not previously utilized in this patient. All relapsed patients in the series with stages I, II, and III achieved remission, whereas both patients with relapsed stage IV GTN died.

Quiescent GTN

A rare cause of persistent (at least 3 months) low-level hCG is quiescent GTN (range 0.5–200 mIU/mL) that most commonly follows a molar pregnancy. Quiescent GTN is thought to be due to the presence of highly differentiated, non-invasive syncytiotrophoblast cells. This condition is characterized by the following: (1) foci of disease are not readily identifiable clinically; and (2) hCG level unresponsive to therapy, presumably because the growth cycle of these cells is comparable to normal cells. Patients with quiescent GTN should not be treated with chemotherapy, but close follow-up is indicated because 6–10% will eventually develop active GTN requiring treatment. The presence of low levels of hyperglycosylated hCG indicates the presence of quiescent GTN. Increasing levels of hyperglycosylated hCG indicate the development of active GTN that requires treatment.²¹

Subsequent pregnancies

Patients with complete and partial mole can anticipate normal reproduction in the future.⁶⁷ However, these patients are at increased risk of developing molar pregnancy in later conceptions. Patients treated for GTN with chemotherapy can also expect normal reproduction in the future.⁶⁸ Importantly, the frequency of later major and minor congenital malformations is not increased. Data from the NETDC and 10 other centers have been reported concerning the outcome of 3191 pregnancies after chemotherapy.⁶⁷ These subsequent pregnancies resulted in 2342 (73.4%) live births, 89 (4.7%) premature deliveries, 40 (1.3%) stillbirths, and 457 (14.3%) spontaneous abortions. Although the frequency of stillbirths appears to be somewhat increased, congenital malformations were noted in only 46 (1.6%) infants, which is consistent with the general population. Woolas et al.⁶⁸ noted that there was no difference in either the conception rate or pregnancy outcome between women treated with single-agent MTX and those receiving combination therapy. Furthermore, only 7% of women who wished to become pregnant failed to conceive.

Because the risk of a repeat molar pregnancy is increased 10-fold, an obstetrical ultrasound should be obtained in the late first trimester of subsequent pregnancies to confirm normal fetal development. In addition, an hCG test should be performed 6 weeks after completion of any subsequent pregnancy to rule out occult GTN. Later products of conception should also be evaluated by a pathologist following any spontaneous miscarriage or therapeutic abortion.

Chapter 107

Gynecologic sarcomas

Jamal Rahaman, MD ■ Carmel J. Cohen, MD

Overview

Sarcomas are extremely rare and account for less than 1.5% of gynecologic cancers. Carcinosarcoma and leiomyosarcoma each account for 35–40% of uterine sarcomas, with endometrial stromal sarcoma (ESS) accounting for 10–15% and other sarcomas including adenosarcomas comprising 5–10%. Uterine carcinosarcoma should be classified as a metaplastic carcinoma of the uterus. Most adenosarcomas and ESSs have good prognosis and respond to hormonal therapy. Undifferentiated endometrial sarcoma (UES) and adenosarcomas with sarcomatous overgrowth are rare and have poor prognosis and require chemotherapy. ESS are histologically and clinically distinct from UES and each have distinct gene rearrangements. More than 50% of Stage I leiomyosarcomas (LMSs) and carcinosarcomas patients will recur. Chemotherapy is required for advanced or recurrent disease. In LMSs, the active drugs are doxorubicin, ifosfamide, gemcitabine, and docetaxel. For uterine carcinosarcomas, the drugs of choice are ifosfamide, cisplatin/carboplatin, and paclitaxel. Adjuvant radiation therapy may provide locoregional control in select cases of uterine carcinosarcomas. Hormonal therapy, including progestational agents, GnRH analogues, and aromatase inhibitors, has a role in the treatment of advanced or recurrent low-grade ESSs and adenosarcomas.

Historical perspective

Sarcomas (including mesenchymal and mixed epithelial–mesenchymal malignancies) of the vulva, vagina, cervix, uterus, and ovaries account for less than 1.5% of the cancers of these organs. Classification of these cancers was a taxonomic dilemma until Ober, in 1959,¹ proposed a classification which Kempson and Bari² revised in 1970 and the World Health Organization³ and the College of American Pathologist⁴ reclassified in 2003 ([Table 1](#)). Uterine carcinosarcomas are not classified as a uterine sarcoma any longer and should be classified as a metaplastic carcinoma of the uterus⁵ but is discussed in this chapter.

Table 1 Classification of uterine sarcomas. College of American Pathologist Classification of Uterine Sarcomas

Histologic type (select all that apply)
Leiomyosarcoma
Low-grade endometrial stromal sarcoma#
Low-grade endometrial stromal sarcoma with: <ul style="list-style-type: none">• Smooth muscle differentiation• Sex cord elements• Glandular elements
Other (specify): _____
High-grade endometrial stromal sarcoma
Undifferentiated uterine/endometrial sarcoma
Adenosarcoma
Adenosarcoma with: <ul style="list-style-type: none">• Rhabdomyoblastic differentiation• Cartilagenous differentiation• Osseous differentiation• Other heterologous element (specify): _____
Adenosarcoma with sarcomatous overgrowth
Other (specify): _____

Low-grade endometrial sarcoma is distinguished from benign endometrial stromal nodule by infiltration into the surrounding myometrium and/or lymphovascular invasion. Minor marginal irregularity in the form of tongues <3 mm (up to 3) is allowable for an endometrial stromal nodule. This protocol does not apply to endometrial stromal nodule.

Data from Tavassoli³ and Otis.⁴

Incidence and epidemiology

The most common site for sarcoma in the female pelvis is the uterus comprising only 4–9% of uterine cancers, with an annual incidence rate of less than 20 per million females.^{6, 7} Overall incidence for Blacks is twice that of Whites, but there were no differences in survival for women receiving similar therapy.^{6, 7} Risk of carcinosarcoma increases sharply with age. Incidence rate per million women per year is 8.2 for carcinosarcomas, 6.4 for leiomyosarcomas (LMSs), 1.8 for endometrial stromal sarcomas (ESSs), and 0.7 for unclassified sarcomas.^{6, 7} Authors have reported that carcinosarcoma and LMS each account for 35–40% of uterine sarcomas, ESS accounting for 10–15%, and other sarcomas comprising 5%.⁷

Risk factors

Epidemiologic risk factors for uterine sarcoma are undefined except for radiation exposure^{8, 9} and previous tamoxifen use.^{10, 11}

Pathology

The uterus is the most common site of gynecologic sarcomas arising from the endometrium only (ESS), the myometrium only (LMS), or contributions from both (carcinosarcomas).^{1, 12} The homologous tumors include carcinoma plus a sarcoma indigenous to the uterus, while the heterologous tumors includes a sarcoma resembling tissue from some extrauterine source (bone, cartilage, striated muscle). Müllerian adenosarcomas are mixed müllerian tumors composed of malignant stroma and benign epithelium.^{3, 13, 14}

Endometrial stromal lesions

Endometrial stromal nodules (ESN) are rare. They are characterized by a well-defined noninfiltrating border without evidence of myometrial or vascular invasion. Two-thirds are found as isolated lesions within the myometrium with no apparent connection to the endometrium.³

ESS is low grade with metastatic potential. Like ESN, they are composed of uniform cells that mimic proliferative endometrium. However, they exhibit myometrial and/or vascular invasion.³ Histologically, they are characterized by densely uniform stromal cells with minimal cellular pleomorphism, mild nuclear atypia, and rare mitotic figures. Of note, an isolated finding of increased mitotic figures does not confer an adverse prognosis in an otherwise typical low-grade ESS.¹⁵

The diagnosis of ESS may be complicated by variant morphologic features ([Table 1](#)).³ In tumors with focal smooth muscle differentiation, the tumor is categorized as ESS if the smooth muscle component involves <30% of the total tumor volume. Tumors composed of a larger smooth muscle component are designated as mixed endometrial stromal and smooth muscle tumors.^{3,16}

Undifferentiated endometrial sarcoma (UES—previously referred to as high-grade ESSs) is characterized by marked cytologic atypia, nuclear pleomorphism, high mitotic activity, and extensive invasion. In addition, UES usually show destructive myometrial invasion.³

Molecular and genetic alterations

The following molecular features are characteristic of ESS and are also found in ESN: The majority are immunoreactive for the estrogen receptor (ER) and progesterone receptor (PR). They are typically immunohistochemically positive for CD10 and negative for desmin and h-caldesmon and loss of heterozygosity of PTEN, and deregulation of the Wnt signaling pathway.^{5, 17, 18}

UES shows increased staining for proliferation markers (Ki67, p16, and p53) and does not generally exhibit immunoreactivity against ER, PR, desmin, or smooth muscle antigen (SMA).⁵ UES also expresses the receptor tyrosine kinase CD117 (c-KIT),¹⁹ cyclin D1,²⁰ and human epidermal growth factor receptor 2 (HER2 or ERBB2), which are not typically found in ESS.⁵

Gene rearrangements have been described and validated in patients with ESSs with at least 75% having a gene rearrangement.^{21, 22} The t(7;17) translocation resulting in the *JAZF1-SUZ12* gene fusion is the most common translocation found in approximately 35–50% of ESSs.²² Other noted gene fusions are *JAZF1-*

PHF1, *EPC1-PHF1*, *JAZF1* only, and *PHF1* only.^{21–25}

UESs lack these *JAFZ1*-based rearrangements but instead appear to frequently harbor the *YWHAE-FAM22A/B* genetic fusion,^{26–29} which may be specific to these tumors as this rearrangement was not detected in 827 other cases representing 55 tumor types.²⁷

Patterns of spread

Uterine sarcomas are spread by lymphatic, hematogenous, local extension, and peritoneal dissemination.^{30–38}

Rose et al.³⁰ studied the autopsy findings of 73 patients with uterine sarcoma, including 43 patients with carcinosarcoma, 19 with LMS, 9 with ESS, and 2 with endolymphatic stromal myosis. The peritoneal cavity and omentum were the most frequently involved sites (59%), followed by lung (52%), pelvic (41%) and paraaortic (38%) lymph nodes, and liver parenchyma (34%). Of note, the presence of lung metastasis was often a sole metastatic site.

Lymph node metastasis in adult soft-tissue sarcomas is <3%, with some variation among histologic subtypes.³⁹ The risk of lymph metastasis in LMS overall was approximately 6.4% in a series of 357 patients.⁴⁰ However, the rate of occult lymph node metastasis in clinically normal nodes and disease clinically confined to the uterus was only 3.5% among 57 surgically staged patients with LMS.³⁵ Carcinosarcomas have a higher rate of both overall (25%)⁴¹ and occult (18%)³⁵ lymph node metastasis. The rate of overall and occult lymph node metastasis in ESS is 16% and 6%, respectively.⁴² Deep myometrial invasion and extensive lymph–vascular space invasion (LVSI) further increase the risk of occult metastasis.^{32, 43} The rate of lymph node metastasis in adenosarcomas is approximately 3%.⁴⁴

Clinical profile

Uterine endometrial stromal tumors

Patients with endometrial stromal tumors are commonly perimenopausal with irregular vaginal bleeding. The tumor tissue may protrude through the cervical overall survival (OS) and may grow large without penetrating through the uterine wall. The diagnosis is usually made by endometrial sampling.^{16, 45, 46}

LMS

LMS commonly occurs during the fourth and fifth decades of life, with a peak incidence at 45 years, after which there is a gradual decline in incidence until the eighth decade. The lesion is frequently associated with benign leiomyomas, although among leiomyomas, sarcoma is found less than 1% of the time.⁴⁷ There is debate over whether the lesion “develops” from a benign leiomyoma or occurs independently. Ferenczy et al.⁴⁸ were unable to demonstrate a developmental relationship, whereas Spiro and Koss⁴⁹ found intermediate changes in leiomyomas and proposed malignant transformation. Often LMSs are discovered by chance at the time of myomectomy or hysterectomy.^{47, 50}

Carcinosarcoma

The incidence of carcinosarcoma increases at 50 years and plateaus after age 75 years. Vaginal bleeding, heavy discharge, and abdominal pain are characteristic. Endometrial sampling is more often diagnostic

than in LMS because LMS invades the endometrial cavity infrequently.

Tumor biomarkers

Goto et al. reported that serum lactate dehydrogenase (LDH) was elevated in a small series of LMS and was useful in combination with dynamic MRI. The positive predictive value was 91% using the combined assessment compared to 39% for LDH alone and 71% for MRI alone.⁵¹

Imaging studies

ESS has a nonspecific appearance on ultrasound.⁵² The characteristic pattern of ESS consists of worm-like tumor projections along the vessels or ligaments, which are best visualized on MRI with diffuse-weighted imaging.⁵³ There are few studies describing the characteristic appearance of UES.⁵⁴

Kurjak et al.⁵⁵ evaluated the role of transvaginal color Doppler ultrasonography in differentiating uterine sarcomas from leiomyomas. Computed tomography will identify extrauterine spread, and magnetic resonance imaging can assess the depth of myometrial invasion. Imaging studies are performed preoperatively to characterize the uterine mass and evaluate for lymph node involvement and other metastases but cannot reliably differentiate between a uterine sarcoma and other uterine findings. There are few data suggesting the best choice of imaging.^{54, 56} The FDG-PET showed a better detection rate than the abdominal CT scan for extrapelvic metastatic lesions.^{57–59}

Diagnosis

Of patients with uterine sarcomas, 75–95% present with abnormal vaginal bleeding.^{60, 61} Pelvic pain, discharge, and aborting tissue occur frequently. Endometrial biopsy may confirm carcinosarcoma in the majority of cases⁶²; however, LMS and ESS are missed in at least 40% and 20% of cases, respectively.^{34, 63, 64}

TNM and FIGO staging classification

Uterine sarcomas require surgical staging. The International Federation of Gynecology and Obstetrics (FIGO) did not have a sarcoma-specific system until recently and the Endometrial Staging criteria were applied until 2009. FIGO devised a uterine sarcoma-specific staging system in 2009 for LMS, EES, and UES and another specific for adenosarcoma ([Tables 2](#) and [3](#)).

Table 2 STAGING—Leiomyosarcoma, endometrial stromal sarcoma, and undifferentiated uterine sarcoma

TNM categories	FIGO stages	Definition
Primary tumor (T)		
TX		Primary tumor cannot be assessed
T0		No evidence of Primary Tumor
T1	I	Tumor is limited to the uterus
T1a	IA	Tumor is 5 cm or less (≤ 5 cm) in greatest dimension
T1b	IB	Tumor is greater than 5 cm (> 5 cm) in greatest dimension
T2	II	Tumor extends beyond the uterus, but is within the pelvis (tumor extends to extrauterine pelvic tissue)
T2a	IIA	Tumor involves the adnexa
T2b	IIB	Tumor involves other pelvis tissue
T3	III	Tumor invades abdominal tissues (not just protruding into the abdomen)
T3a	IIIA	Tumor invades abdominal tissues at one site
T3b	IIIB	Tumor invades abdominal tissues at more than one site
T4	IVA	Tumor invades bladder mucosa and/or rectum
Regional lymph nodes (N)		
NX		Regional lymph nodes cannot be assessed
N0		No regional lymph node metastasis
N1	IIIC	Regional lymph node metastasis to pelvic lymph nodes
Distant metastasis (M)		
M0		No distant metastasis
M1	IVB	Distant metastasis (excluding adnexa, pelvic and abdominal tissues)
		Specify site(s), if known: _____

Data from Otis⁴ and D'Angelo and Prat.⁵

Table 3 STAGING—Uterine adenosarcoma

TNM categories	FIGO stages	Definition
<i>Primary tumor (T)</i>		
TX		Primary tumor cannot be assessed
T0		No evidence of primary tumor
T1	I	Tumor limited to the uterus
T1a	IA	Tumor is limited to the endometrium/endocervix without myometrial invasion
T1b	IB	Tumor invades less than or equal to 50% (≤50%) total myometrial thickness
T1c	IC	Tumor invades greater than 50% (>50%) total myometrial thickness
T2	II	Tumor extends beyond the uterus, but is within the pelvis (tumor extends to extrauterine pelvic tissue)
T2a	IIA	Tumor involves the adnexa
T2b	IIB	Tumor involves other pelvis tissue
T3	III	Tumor invades abdominal tissues (not just protruding into the abdomen)
T3a	IIIA	Tumor invades abdominal tissues at one site
T3b	IIIB	Tumor invades abdominal tissues at more than one site
T4	IVA	Tumor invades bladder mucosa and/or rectum
<i>Regional lymph nodes (N)</i>		
NX		Regional lymph nodes cannot be assessed
N0		No regional lymph node metastasis
N1	IIIC	Regional lymph node metastasis to pelvic lymph nodes
<i>Distant metastasis (M)</i>		
M0		No distant metastasis
M1	IVB	Distant metastasis (excluding adnexa, pelvic and abdominal tissues)
		Specify site(s), if known: _____

Modified from Otis⁴ and D'Angelo and Prat.⁵

Carcinosarcomas are to be staged using the 2009 revised FIGO Staging for endometrial carcinomas (see [Chapter 103](#)).

Prognostic factors and prognosis

Prognostic factors differ for the three major types of uterine sarcomas. Major and colleagues reported the GOG clinicopathologic study of clinical stage I and II uterine sarcoma, which included 59 patients with LMS and 301 patients with carcinosarcoma.³⁵ Of the 453 patients eligible for analysis, 430 underwent complete surgical staging that included lymphadenectomy. The median survival was 62.6 months for homologous carcinosarcoma, 22.7 months for heterologous carcinosarcoma, and 20.6 months for LMS. The overall recurrence rate for homologous carcinosarcoma was 56%.

In patients with LMS, lymph vascular space involvement and involvement of the cervix and isthmus were common, whereas lymph node metastases, adnexal metastases, and positive peritoneal cytology were infrequent findings. The only surgicopathologic finding that correlated with progression-free interval was the mitotic index.^{2, 35, 37, 65} While there were no treatment failures among the three women who had less than 10 mitoses per 10 high-power fields, 61% of women with 10–20 mitoses per 10 high-power fields and 79% of women with greater than 20 mitoses per 10 high-power fields developed recurrences.

In contrast to patients with LMS, surgicopathologic factors of carcinosarcoma that related to progression-free interval included adnexal spread, lymph node metastasis, histologic cell type (heterologous vs homologous), and the grade of sarcoma. Of note, patients with carcinosarcoma had high rates of nodal and adnexal metastases and positive peritoneal cytology. Pelvic nodes were involved twice as often as aortic nodes (15% vs 7.8%), and both nodal groups were involved in 5% of the patients.³⁵

Morcellation

In patients undergoing laparoscopic hysterectomy for a presumed uterine sarcoma, power morcellation should not be attempted. Wright (2014) used a large insurance database to identify 36,470 women undergoing minimally invasive hysterectomy with power morcellation performed to demonstrate that the prevalence of uterine cancers was 27 per 10,000 (99 cases).⁶⁶ In addition to this cohort, 26 cases of other gynecologic malignancies were found (a prevalence of 7/10,000), 39 uterine neoplasms of uncertain malignant potential (11/10,000), and 368 cases of endometrial hyperplasia (101/10,000).⁶⁶

LMS

Morcellation of a uterine leiomyosarcoma is associated with a worsened outcome.⁶⁷ Park et al.⁶⁸ reported a series in which the 5-year disease-free survival (DFS) was 40% in women who underwent tumor morcellation and were subsequently diagnosed with leiomyosarcoma, compared to 65% in those with leiomyosarcoma who had not undergone morcellation ($p = 0.04$). Similarly, the 5-year OS was 46% after morcellation compared to 73% in those not morcellated ($p = 0.04$).⁶⁸

ESS

In one study, tumor morcellation in women with ESS was associated with a lower 5-year DFS compared with those who did not have a morcellation (55% vs 84%, respectively, odds ratio 4.03, 95% CI 1.06–15.3).⁶⁹ However, no significant impact on OS was reported.

Surgical treatment

The initial therapy for sarcomas of the gynecologic tract is surgical except for embryonal rhabdomyosarcomas. Patients with uterine sarcoma require total abdominal hysterectomy and careful staging including pelvic and paraaortic lymph node sampling. In patients with carcinosarcoma limited to the uterus by pathologic staging, the cytologic presence of malignant cells in the peritoneal washings is a poor prognostic factor.

The ovaries could be retained in premenopausal patients with LMS because this appears to improve their prognosis.^{12, 64, 70, 71} However, a bilateral salpingo-oophorectomy should be performed in all other

patients, including those with low-grade ESS,^{72, 73} because these tumors may be hormone dependent or responsive and have a propensity for extension into the parametria, broad ligament, and adnexal structures.

For carcinosarcoma, a high percentage of patients with clinical stage I or II disease is upstaged at the time of laparotomy^{74, 75}; thus, it appears reasonable to surgically stage these patients. There is a paucity of data regarding the role of lymph node sampling in patients with LMS and ESS, but it appears that almost all patients with these sarcomas who have lymph node metastases also have evidence of intraperitoneal disease spread.⁴⁷

Unlike other gynecologic malignancies, there is a role for thoracotomy or video-assisted thoracoscopy in patients with uterine sarcoma metastatic to the lung. Levenback and colleagues reviewed 45 patients whose pulmonary metastases from uterine sarcoma were resected at Memorial Sloan-Kettering Cancer Center, the majority of which were LMS (84%).⁷⁶ The mean survival of patients with unilateral disease (39 months) was significantly greater than that of patients with bilateral disease (27 months). Recurrent or metastatic low-grade ESS may also be amenable to surgical excision of pelvic disease or pulmonary metastases.

Postsurgical therapy for gynecologic sarcomas

Although complete surgical removal is the ideal initial therapy for patients with sarcoma of the gynecologic tract, there is no randomized study proving that surgical cytoreduction influences OS for patients with advanced or recurrent disease. Similarly, the therapeutic benefit of lymphadenectomy has not been proven but is rational. For patients with sarcoma of the uterus or ovary, no formal trial has evaluated the role of lymphadenectomy in addition to hysterectomy and bilateral salpingo-oophorectomy.

For patients with uterine sarcoma, there is no definitive evidence from prospective trials that adjuvant therapy of any type leads to overall improvement in survival. To review the currently understood role of radiotherapy and chemotherapy in sarcomas, LMS is separated from the remaining homologous and heterologous carcinosarcomas because the patterns of relapse for the former are somewhat different from those of the latter group.

Radiation oncology

Radiation therapy for LMS

In contrast to other sarcomas, patients with LMS confined to the uterus appear to have a dominant pattern of failure outside the pelvis and abdominal cavity (65%) with a minority of patients with a first recurrence confined to the abdomen and/or pelvis (28%).^{77–79} Thus, in LMS, although the rate of failure in the pelvis is not insubstantial, little is to be potentially gained by delivering pelvic irradiation as a postoperative adjuvant treatment insofar as two-third of patients have some component of distant disease at first recurrence. Radiation treatment is reserved for isolated pelvic relapse only.

Radiation therapy for carcinosarcoma

Historically, pre- or postoperative pelvic irradiation has been used as an adjunct to surgery for carcinosarcoma. Many retrospective reviews illustrate this common use.^{60, 75, 80–86} In several reports for carcinosarcoma, the pelvic recurrence rate was 56%, while the distant metastasis rate was 45%. This

represents a higher risk of pelvic recurrence than that seen in patients with LMS.^{60, 80–82, 86} It also demonstrates that surgery alone, even for disease apparently confined to the uterus, is inadequate for control of disease in the pelvis. Some but not all studies have shown benefit from postoperative irradiation,^{87, 88} especially in local control.^{60, 84, 88–93} Rates of distant metastases in series of patients treated with or without adjuvant pelvic irradiation are similar, in the order of 35–45%.^{60, 81, 84}

There has been only one randomized clinical trial evaluating the role of adjuvant pelvic radiotherapy in stage I and II Uterine Sarcomas. The EORTC enrolled 224 patients (103 LMS, 91 carcinosarcoma, and 28 ESS) from 1998 to 2001 and demonstrated an improved local control rate for patients with carcinosarcoma (24% recurrence in RT vs 47% in observation) but no survival benefit. There was no improvement in local control for LMS (20% local recurrence in RT vs 24% in observation group).⁹³

The morbidity associated with pelvic recurrence in uterine sarcomas may be substantial; therefore, it is reasonable to offer adjuvant pelvic irradiation to patients with carcinosarcoma to improve locoregional control rates. The doses of radiation have not been standardized; however, it is probable that doses should be at least 50 Gy, fractionated over 5 weeks.

The GOG⁹⁴ also conducted a phase III study of whole-abdomen irradiation (WAI) versus three cycles of cisplatin-ifosfamide and mesna (CIM) in 206 eligible patients with optimally debulked stage I–IV carcinosarcoma. Although there was no significant advantage, the observed difference favored the use of chemotherapy. The adjusted recurrence rate was 21% lower for CIM patients and the adjusted death rate was 29% lower. Moreover, there was a significant increase in late adverse events in the WAI patients.⁹⁵

Primary pelvic irradiation has been employed rarely in patients with sarcoma deemed inoperable. Literature reports suggest that in approximately half or two-thirds of patients, pelvic disease could be controlled with standard fractionated irradiation; a small proportion of patients are cured with such treatment.^{60, 80–82}

Finally, radiation may be useful as a palliative measure for recurrent or uncontrolled pelvic tumor causing pain or bleeding.

Chemotherapy

Two characteristics of uterine sarcomas increase the likelihood that systemic therapy will be required: a recurrence rate of at least 50% even in stage I disease and a tendency to recur at distant sites. Nevertheless, the amount of meaningful data on the use of systemic therapy is limited by the low incidence of these lesions. Studies by the GOG first identified the differential sensitivity of carcinosarcoma and LMS to drug therapy.⁹⁶ Because these two cell types respond differently to chemotherapy, they are discussed separately.

Single-agent therapy

Several drugs have been studied in advanced or recurrent carcinosarcoma and/or LMS ([Tables 3](#) and [4](#)), including cisplatin,^{101–102} ifosfamide,^{97–99} doxorubicin,^{96, 104} liposomal doxorubicin,¹⁰⁵ etoposide,^{106–108} mitoxantrone,¹⁰⁹ paclitaxel,^{110, 111} topotecan,¹¹² gemcitabine,¹¹³ trimetrexate,¹¹⁶ and docetaxel.^{117, 115}

Abbreviations: ESS, endometrial stromal sarcoma; LMS , leiomyosarcoma; CS, carcinosarcoma.

Carcinosarcoma

Ifosfamide is the most active single agent in the treatment of advanced or recurrent carcinosarcoma of the uterus with a 32.2% overall response rate in chemo-naïve patients.⁹⁷ Paclitaxil¹¹¹ and cisplatin¹⁰⁰ are the two other very active single agents with overall response rates of 18.2% and 18%, respectively.

Leiomyosarcoma

Of the single agents that have been tested in patients with LMS ([Table 4](#)), the most active are doxorubicin,⁹⁶ gemcitabine,¹¹³ and ifosfamide⁹⁸ with response rates of 25%, 20.5%, and 17.2%, respectively.

Endometrial stromal sarcoma

There are few data in the gynecologic literature regarding the use of chemotherapy for ESS.^{34, 63, 118} Ifosfamide⁹⁹ had an overall response rate of 33.3% in 21 women with metastatic ESS.

Combination chemotherapy

Leiomyosarcoma

The most active combination is Gemcitabine 900 mg/m² intravenously on days 1 and 8 plus docetaxel 100 mg/m² intravenously on day 8, with granulocyte colony-stimulating factor subcutaneously on days 9–15. The GOG conducted two phase II studies with this regimen with gemcitabine at a fixed dose rate of 10 mg/m²/min as first-line and second-line therapy for metastatic LMS. As initial therapy for metastatic uterine leiomyosarcoma, this combination achieved a 36% response rate among 42 patients and an additional 26% with stable disease.¹¹⁹ This doublet achieved a 27% response rate in the second-line study among the 48 patients with an additional 50% with stable disease (median duration 5.4 months).¹²⁰

The other very active combination is Adriamycin and ifosfamide. The GOG¹²¹ reported a 30% response rate in 33 patients treated as first line with conventional doses of ifosfamide. Leyvraz et al.¹²² achieved a 49% response rate in 37 patients treated with a dose-intensive regimen with ifosfamide, 10 g/m² as a continuous infusion over 5 days, plus doxorubicin intravenously, 25 mg/m²/day for 3 days.

Carcinosarcoma

In uterine carcinosarcoma, three randomized clinical trials have defined the best combination chemotherapy regimens. GOG-0108 evaluated the combination of ifosfamide-mesna with or without cisplatin as first-line therapy in patients with advanced, persistent, or recurrent uterine CS. The combination regimen demonstrated a significantly improved overall response rate (54%) when compared to the single-agent regimen (36%) but no survival advantage.

In the GOG-0161, there was a 31% decrease in the adjusted hazard of death and a 29% decrease in the adjusted hazard of progression in those patients receiving paclitaxel-ifosfamide/mesna-growth factor relative to ifosfamide alone for uterine CS.¹²³ Thus, paclitaxel/ ifosfamide became the standard arm for future GOG studies testing combination chemotherapy for uterine CS.

The GOG Phase II trial (GOG-0232B) formally tested the efficacy of paclitaxel and carboplatin (T/C) in 55 patients with advanced uterine CS. The proportions of patients with confirmed complete and partial responses were 13% and 41%, respectively, resulting in a total overall response rate of 54% with a median progression-free survival of 7.0 months and median survival was 14.4 months.¹²⁴ Thus, the GOG

current Phase III trial for uterine CS (GOG 261) was designed as a noninferiority trial to test the efficacy of T/C compared to paclitaxel/ifosfamide. The trial has completed accrual and it is expected that it will confirm paclitaxel and carboplatin to be the best backbone chemotherapy regimen for carcinosarcoma.

Adjuvant chemotherapy for limited disease

LMS

The role of adjuvant chemotherapy following complete resection of early stage uterine leiomyosarcoma is still under investigation but preliminary results of studies of adjuvant systemic chemotherapy are promising. The only randomized trial (GOG Protocol 20) of adjuvant chemotherapy in early stage uterine sarcomas to date assigned patients to either doxorubicin 60 mg/m² every 3 weeks for eight cycles or no further therapy. There were only 48 patients in the LMS subset and with these small numbers it was underpowered to assess a significant difference in recurrence or survival.¹²⁵

The Sarcoma Alliance for Research through Collaboration conducted a phase II, multicenter study of four cycles of adjuvant fixed-dose-rate gemcitabine docetaxel followed by four cycles of doxorubicin in 47 patients with uterus-limited leiomyosarcoma. Although 78% of the patients remained progression free at 2 years, this dropped to 50% at the 3-year follow-up.¹²⁶ A phase III multicenter randomized trial (GOG 277) comparing gemcitabine and docetaxel followed by doxorubicin to the current standard approach of observation is currently being conducted.

Carcinosarcoma

The GOG also reported a study (GOG Protocol 117) of adjuvant ifosfamide, mesna, and cisplatin in 65 patients with completely resected stage I or II carcinosarcoma of the uterus in which no postoperative radiotherapy was allowed. Progression-free survival and OS rates, respectively, were 69% and 82% at 24 months and 54% and 52% at 84 months. The overall 5-year survival rate was 62%.¹²⁷ As more than half of the recurrences involved the pelvis, the study suggested that a combined sequential approach with chemotherapy and radiotherapy might be beneficial for this group of patients.

Hormone and biologic therapy

Receptors for estrogen and progesterone are identified in patients with uterine sarcoma.^{45, 128} Sutton and colleagues studied 43 patients with various uterine sarcomas and found ERs in 55.5% of the tumors and PRs in 55.8%.¹²⁸ The presence of receptors was not influenced by stage or grade, but levels were much higher and more prevalent in patients with ESS of low grade, and this group of tumors frequently responds to progestational hormone treatment.^{45, 46, 118, 129–131} The cessation of estrogen replacement therapy and tamoxifen is also advised.^{45, 132}

Recent use of aromatase inhibitors^{59, 133} and gonadotropin-releasing hormone analogues¹³⁴ has been described in ESS, with dramatic and prolonged responses.^{45, 132, 135} The addition of bevacizumab to fixed-dose rate gemcitabine-docetaxel failed to improve overall response rate, PFS, or OS in a GOG phase III trial of 102 chemo-naïve patients with metastatic uterine leiomyosarcoma.

Mullerian adenosarcomas

The term “mullerian adenosarcoma” was coined in 1974 for a distinctive uterine tumor characterized by a malignant, usually low-grade, stromal component, and a generally benign, but occasionally atypical, glandular epithelial component.¹³ Most adenosarcomas arise in the endometrium and, rarely, in the endocervix, lower uterine segment, and myometrium.^{14, 136, 137} In a Gynecologic Oncology Group study in 1993, adenosarcomas accounted for 7% of uterine sarcomas.³⁵ Uterine adenosarcoma occurs in all age groups but is most common in women after the menopause. In the largest reported series, the peak incidence was in the eighth decade with 38% occurring in patients aged below 50 years.¹³⁶ The most common presenting symptom is abnormal vaginal bleeding but some patients present with pelvic pain, an abdominal mass, or vaginal discharge.

Grossly, the majority are solitary polypoid masses with a spongy appearance secondary to the presence of small cysts.^{14, 136} Minimal histologic criteria were described by Clement and Scully¹³⁶ in a review of 100 cases of adenosarcoma published in 1990. They include at least one of the following: two or more stromal mitoses per 10 HPF, marked stromal hypercellularity, and significant stromal cell atypia. A minority of cases have “sarcomatous overgrowth,” when more than 25% of the tumor is composed of pure sarcoma. In these cases, the sarcoma is typically high grade and the lesions are aggressive.^{14, 138} Most adenosarcomas without stromal overgrowth express ER and PR in the sarcomatous component and this may be used for therapeutic purposes. However, hormonal receptors are negative in adenosarcomas with stromal overgrowth.^{14, 139, 140} Besides stromal overgrowth, the only other histopathological feature associated with decreased survival is myometrial invasion.^{14, 44, 136, 138, 140}

Müllerian adenosarcomas have been described in extrauterine sites including the ovary and areas of endometriosis in the vagina, rectovaginal-septum, gastrointestinal tract, urinary bladder, pouch of Douglas, peritoneum, and liver.^{14, 137, 140–142} Ovarian adenosarcomas are much more likely to exhibit malignant behavior than their uterine counterparts, probably owing to the lack of an anatomic barrier to peritoneal dissemination.^{14, 142}

Nonuterine gynecologic sarcomas

The vulva

Fewer than 500 patients with vulvar sarcoma have been described in the literature. LMS, rhabdomyosarcoma, and fibrosarcoma are the most frequently diagnosed vulvar tumors.¹⁴³ The clinical behavior of these tumors is related to their grade, mitotic count, histology, and stage.^{143, 144} For the lowest grade tumors, wide local excision should suffice. However, for the more aggressive histologic patterns, radical vulvectomy with lymphadenectomy followed by cytotoxic chemotherapy should be considered, although the role of adjuvant chemotherapy has not been studied in these tumors.¹⁴⁴

The vagina

Sarcomas represent 3% of primary vaginal cancers.¹⁴⁵ LMSs are the most common vaginal sarcoma in adults and present most commonly with vaginal bleeding in a patient above the age of 40. Although¹⁴⁶ this tumor is highly virulent, survivors are among those treated by hysterectomy, oophorectomy, and vaginectomy.

Embryonal rhabdomyosarcomas (RMS), formerly termed sarcoma botryoides, occur most frequently in children and have a typical grape cluster-like appearance. The disease was once uniformly fatal, provoking radical extirpative surgery that resulted in exenteration for young girls. Pediatric embryonal

RMS of the vagina is best approached with induction multiagent-combination therapy, such as VAC, followed by local resection with or without brachytherapy, with radical surgery being reserved for those with persistent or recurrent disease.¹⁴⁷

The ovary

Most types of sarcomas described in the vagina, vulva, or uterus have been found in the ovary as well.^{148, 149} Ovarian carcinosarcomas are rare and aggressive tumors, associated with a poor prognosis and accounts for only 1–4% of all ovarian cancer.¹⁵⁰ The mainstay of treatment remains maximal cytoreductive surgical effort for metastatic disease followed by platinum-based chemotherapy. Survival is better for patients with early stage disease and those whose tumors have homologous stromal elements.¹⁵⁰

The fallopian tube

The fallopian tube is the least frequent site of primary sarcomas in the gynecologic tract. The most common histologic type is carcinosarcoma,^{151, 94, 152–154} with treatment identical to ovarian carcinosarcomas with maximal cytoreduction for metastatic disease followed by platinum-based chemotherapy.¹⁵¹

Chapter 108

Neoplasms of the breast

Hope S. Rugo, MD ■ Melanie Majure, MD ■ Anthony Dragun, MD ■ Meredith Buxton, PhD ■ Laura Esserman, MD, MBA

Overview

Breast cancer in women remains a major medical problem with significant public health and societal ramifications, including issues related to screening, risk factors, prevention, diagnosis, treatment, and survival following diagnosis. Major advances have markedly improved the understanding of clinical phenotypes, as well as the biologic pathways that drive tumor growth and resistance. This research has led to dramatic changes in treatment that have contributed to a significant reduction in breast cancer mortality over the last two decades, and is the basis of ongoing clinical research. Molecular profiling has provided insights into the heterogeneity of breast cancer subtypes; combining biology and tumor burden has allowed stratification of both risk and treatment to begin the process of individualizing screening, prevention, and treatment. As new information accumulates, new paradigms of management become the standard of care reflected in international guidelines. Our challenge is to apply new formation and treatment appropriately and effectively, and to understand both response and resistance. Information obtained from molecular, biologic, and pathologic investigations and clinical trials provides the major focus of this chapter.

Epidemiology

Breast cancer is the most common malignancy in North American women and in women throughout the industrialized world. In the United States, breast cancer accounts for 29% of all cancers in women. The American Cancer Society (ACS) estimated 231,840 women to be diagnosed with breast cancer in 2015.¹

The lifetime risk for a woman being diagnosed with breast cancer is 1 in 8 or 12%.² Age-specific probabilities of developing breast cancer are provided in [Table 1](#). This risk is even higher for women with certain risk factors, such as a strong family history or known genetic mutations. These figures exclude the 64,640 expected cases of in situ breast cancer. In addition, 2350 men are expected to be diagnosed with breast cancer.

Table 1 Age-specific probabilities of developing invasive breast cancer (cancers diagnosed in females of all races between 2008 and 2010)

Current age	Probability of developing breast cancer in the next 10 years (%)	Corresponding to a risk of
20	0.06	1 in 1732
30	0.44	1 in 228
40	1.45	1 in 69
50	2.31	1 in 43
60	3.49	1 in 29
70	3.84	1 in 26
Lifetime risk	12.29	1 in 8

Source: DeSantis 2014.³ Reproduced with permission of Wiley.

The incidence of breast cancer increased about 30% between 1980 and the late 1990s in Western countries, with a marked decline between 2002 and 2003. This increase in diagnosis was attributed to increased screening, as well as to increased use of postmenopausal hormone replacement therapy (HRT) and changes in reproductive factors. In 2002, the first results of the Women's Health Initiative Trial were published, revealing a significant increase in the risk of breast cancer in postmenopausal women undergoing HRT. These results led to a major decrease in the use of HRT, and correspondingly between 2002 and 2003, breast cancer rates dropped 7%, primarily affecting Caucasian women aged 55 and higher.^{4, 5} Since 2004, the incidence of breast cancer in the United States has been relatively stable.^{2, 3} It varies significantly by race and ethnicity, as described in [Table 2](#). However, rates between white and African-American women in the United States are now converging (see below).³

Table 2 Rates by race or ethnicity: United States, 2007–2011

	Non-Hispanic White	African-American	Hispanic-Latino	American Indian/Alaskan Native	Asian/Pacific Islander
Incidence rates (per 100,000)	127.6	123.0	86	91.7	86.0
Mortality rates (per 100,000)	22.2	31.4	14.5	15.2	11.3

Source: Siegel 2015.¹ Reproduced with permission of Wiley.

Breast cancer is the most frequently diagnosed cancer in women worldwide. In 2012, it was estimated that 1.7 million cases would be diagnosed, accounting for 25% of all cancer cases in women.⁶ The rates vary by geographic region, with about one-half of the incidences occurring in more developed countries, with generally higher rates found in Northern America, Australia/New Zealand, and Northern and Western Europe. By contrast, the rates are intermediate in Central and Eastern Europe, Latin American, the Caribbean, and Western Asia, and low in most of Africa and Southern and Eastern Asia. The cumulative risk of developing breast cancer in less developed areas is a 3.3% (until age 74) compared to an 8% risk in more developed areas. The variation in international incidence rates is likely due to differences in risk factors as well as the availability of early detection methods.⁷ The incidence of breast cancer has been

increasing in many countries in Asia, South America, and Africa, possibly because of changes in lifestyle, including reproductive patterns, diet, obesity, and physical activity.^{6, 8}

The mortality rate from breast cancer in the United States slowly increased by 0.4% from 1975 to 1990, then decreased by 34% from 1990 to 2010.³ This decrease has been attributed to improvements in treatment as well as early detection,⁹ with the largest decrease in women below 50 years of age (an annual decrease of 3.1% vs 1.9% in those aged 50 years and higher). Breast cancer is the second leading cause of cancer-related deaths in women in the United States (after lung cancer) and the leading cause of cancer death in those between the ages of 20 and 59. The ACS estimated 40,290 deaths of women from breast cancer in 2015, representing 6.8% of all cancer deaths in the United States. Mortality rates vary by race and ethnicity with African-American women experiencing the highest annual breast cancer death rate, despite having a lower incidence rate than white women. This difference has been attributed to variations in biologic subtype, later stage of disease at diagnosis, and poorer survival by stage, driven in large part by differences in socioeconomic status. Death rates declined in almost all racial and ethnic groups from 2001 to 2010, with a much higher reduction in white than African-American women.

A majority of breast cancers are diagnosed at an early stage, with 61% diagnosed when the disease is localized to the breast; another 32% are diagnosed after the cancer has spread to the regional lymph nodes and only 6% have metastasized at the time of initial diagnosis. Five year survival rates depend on the stage of tumor detection, with 98.6% alive when diagnosed at a localized stage, 84.9% alive when the tumor has spread to regional lymph nodes, and only 26% when diagnosed with distant spread of disease.

Risk factors

Although breast cancer is common, the risk of developing the disease varies depending on a number of factors, with female gender and increasing age being the most important ones. Germline mutations in DNA repair genes markedly increase the lifetime risk of developing breast and other cancers and increase the risk at younger ages. Other lifestyle-related factors have a more modest impact on risk, and the effect of altering modifiable factors on an individual's risk of developing breast cancer is largely unknown.¹⁰ The risk factors associated with the development of breast cancer are clearly defined in [Table 3](#).

Table 3 Risk factors associated with the development of breast cancer

<i>Major increase</i>
Mutations in <i>BRCA1</i> , <i>BRCA2</i> , <i>tp53</i> (Li–Fraumeni syndrome)
Increasing age
Developed countries
Family history of breast or ovarian cancer in first-degree relatives
Atypical hyperplasia, LCIS before the age of 45
Exposure to ionizing radiation
<i>Moderate increase</i>
Prior diagnosis of breast cancer
Early menarche
Late menopause
Nulliparity or delayed first full-term pregnancy (above age 30)
High socioeconomic status
Alcohol intake
Atypical hyperplasia, LCIS over the age of 45
Obesity (postmenopausal women only)
High breast density
Diagnosis of soft-tissue sarcoma in son or daughter
Prior diagnosis of uterine, ovarian, or colon cancer
<i>Modest increase</i>
Benign breast disease with hyperplasia (no atypia)
Oral contraceptives (for longer than 10 years)
Postmenopausal estrogen replacement therapy
<i>Questionable increase (no evidence to support)</i>
Interrupted first pregnancy
High-fat diet
Complex fibroadenoma
<i>Decrease</i>
Full-term pregnancy before age 20
Multiple pregnancies
Ovariectomy before age 45
Regular exercise, particularly during adolescence and early adulthood
Breast-feeding
<i>No effect</i>
Breast reduction

Gender

The incidence rate of age-adjusted breast cancer is more than 100-fold higher in women than in men in the United States, a ratio that is similar worldwide. Male breast cancer represents less than 1% of all cancer in men and about 1% of all breast cancer. Germline mutations in BRCA1 and BRCA2 are the best understood risk factors for breast cancer in men, with a range of lifetime risk of just over 1% (BRCA1) to almost 7% (BRCA2). Worldwide, mortality has decreased less in men than women, and clinical trials have been unsuccessful to date because of low accrual. An international consortium has recently started collaborative clinical trials focusing on male breast cancer.

Age

The median age of breast cancer diagnosis in women in the United States is 61, with the majority of cases diagnosed in women between the ages of 55 and 64. In other parts of the world, where life expectancy is shorter, the median age of development of breast cancer is 10–15 years younger. Age-related mortality rates parallel this pattern.

Socioeconomic class

Breast cancer is diagnosed more frequently in women of higher economic class and educational status.¹⁰ ¹¹ This finding is likely related to lifestyle factors such as diet, age at first childbirth, exogenous hormonal use, and alcohol consumption. However, mortality is higher in women of lower socioeconomic classes, correlating with observed differences including higher stage at diagnosis, more aggressive tumor biology, and reduced access to care.

Ethnicity

The incidence and mortality rates of breast cancer vary considerably by ethnicity and race, as outlined in [Table 2](#). In the United States, from 2010 to 2012, the risk of being diagnosed with and dying from breast cancer was 12.64% and 2.66% for whites, 11.14% and 3.26% for blacks, 10.25% and 1.74% for Asian/Pacific Islanders, 9.81% and 2.08% for Hispanics, and 8.15% and 1.66% for American Indians/Alaskans.¹ Studies of migrant populations showed that when people living in low-risk geographic areas move to high-risk areas (e.g., a move from Asia to the United States), their incidence of breast cancer increases, approaching the rates of the host population within one to two generations, suggesting an important role of lifestyle in determination of risk even within ethnic and racial groups.¹²

Family history and genetic mutations

Family history is a significant risk factor for breast cancer, but existing data are complicated by associations established before routine genetic testing (see below).¹³ In general, compared with a woman with no affected relatives, a single affected first-degree relative approximately doubles the risk. Two first-degree relatives triple the risk, and three or more quadruples the risk. A first-degree relative affected at an early age increases risk further to about threefold, twofold, and 1.5-fold if diagnosed below 40 years, from 40 to 59 years, and from 50 to 60 years of age, respectively. There is little impact from breast cancer diagnosed at older ages unless multiple family members are diagnosed.

Individuals inheriting a germline mutation in either BRCA1 or BRCA2 have a markedly higher lifetime risk of breast and ovarian cancers than the general population. The risk of developing breast cancer is estimated to be 50–85% in women and is often at a younger age of onset.¹⁴ There is also an increased risk

of second primary breast cancers, estimated to be about 40–60%. These mutations are inherited by autosomal dominant transmission, and more than 2000 different mutations, polymorphisms, and variants have been reported in BRCA1 on chromosome 17 and BRCA2 on chromosome 13.^{15, 16} There is clearly a higher risk of carrying a mutation in populations with homogeneous ethnicity, such as those with Ashkenazi Jewish heritage, with associated characteristic *BRCA1* (185delAG, 5382insC) and *BRCA2* (6174delT) mutations; the combined frequency of these genes in the general population exceeds 2%.^{17–19} Similar “founder” mutations have been identified in Belgium, Denmark, Finland, France, Holland, Hungary, Iceland, Norway, Russia, and West Africa, among other ethnic communities.²⁰ The BRCA genes encode DNA repair enzymes that play a major role in double-stranded DNA repair through the homologous recombination pathway. The resulting defect in DNA repair in cells with dysfunctional BRCA activity has been currently used to design specific therapies such as PARP inhibitors that further damage DNA, leading to tumor cell death (see treatment sections).

Familial breast cancer accounts for less than 10% of all breast cancers, and *BRCA1*- and *BRCA2*-related familial breast cancers appear to be responsible for only about two-thirds of these cases. A number of other genes have been identified, which increase the risk of developing breast and other cancers, including TP53 (Li–Fraumeni syndrome), PTEN (Cowden syndrome), ATM, CHECK2 and PALB2, as well as others.^{21–25} A large number (>75) of more common risk variants (>5%) have been identified by genome-wide association studies (GWAS) over the last decade and validated by large consortia^{26, 27} that have a moderate impact on risk [relative risk (RR) < 1.5].²⁸ While being individually associated with a modest effect on breast cancer, in combination they can contribute substantially to overall risk.

Interestingly, certain breast cancer phenotypes have been associated with specific mutations, although all phenotypes have been reported. Triple-negative [estrogen receptor (ER) and progesterone receptor (PR) and HER2/neu nonamplified] tumors occur more frequently in women with BRCA1 mutations, hormone receptor-positive (HR+) tumors in those with mutations in BRCA2 or CHEK2, and HER2/neu and HR+ in those with the Li–Fraumeni syndrome.^{29, 30} Importantly, many of the common risk alleles are more strongly associated with the development of HR+ breast cancer.^{28, 31} A total of seven variants are associated with the more aggressive hormone receptor-negative (HR–) disease,³² with four new loci recently identified.³³ Multigene testing panels are now widely available and have the potential to detect an additional 4% of individuals with potentially deleterious mutations, for whom counseling and testing may be of value.³⁴

The National Comprehensive Cancer Network® (NCCN®) recommends that patients with a personal history of breast cancer and one or more of the following should be tested for germline mutations: A family history of a deleterious mutation in BRCA1 or BRCA2, diagnosis at age ≤45, diagnosis at age ≤50 with an additional primary cancer, ≥1 close blood relative with breast cancer at any age, an unknown or limited family history, or diagnosis at age ≤ 60 with triple-negative breast cancer (TNBC). Additional criteria include patients diagnosed at any age with breast cancer and ≥1 close blood relative with breast cancer diagnosed ≤50 or ovarian cancer, ≥2 close blood relatives with breast cancer or with pancreatic cancer and/or prostate cancer at any age. Patients with a personal history of ovarian cancer, male breast cancer, as well as several other criteria are also included in this recommendation. In general, testing should first be performed on the affected family member with testing for those without a cancer diagnosis reserved for situations when the affected family member is not available for testing.³⁷⁸ One recent series of more than 200 patients with TNBC found BRCA mutations in 15.4%; this rate increased to 18.3% in those meeting NCCN Clinical Practice Guidelines In Oncology (NCCN Guidelines®) for screening; rates vary based on age, ethnicity, and race.³⁵

Additional criteria for genetic screening include diagnosis at any age with breast cancer; a close blood relative with ovarian cancer, pancreatic cancer, or prostate cancer; or any male relative with breast cancer. Those with ethnicities associated with higher mutation frequency should always be considered for testing. Indeed, one trial found that approximately 12% of breast cancers in Ashkenazic women could be attributed to mutations in BRCA1 or BRCA2.¹⁷

Identification of germline mutations in women with breast cancer, and in women at risk for mutations, is extremely important. Screening and risk-reducing surgery have been found to reduce mortality from cancer.^{36–39} Educating people about these strategies as well as the mechanism of identifying tumors is critical.

Endocrine and reproductive risk factors

Duration and extent of exposure to estrogen and progesterone clearly affects the risk of developing breast cancer, regardless of subtype. Longer duration of ovulation, as indicated by earlier age of menarche, and later age at menopause are associated with an annual increase of 3–4% in the risk of breast cancer.¹¹ Younger age at first childbirth decreases the risk of breast cancer about 3% per year from age 30 to 20, with multiparity having a lesser protective effect. Women having their first child at age >30 years have a higher risk of breast cancer than nulliparous women, particularly within the first 5 years after delivery. The possible mechanism for this apparent enhancement in risk might be the stimulatory effect of pregnancy (and its altered hormonal environment) on an otherwise involuting epithelium. Prolonged breast-feeding appears to reduce risk, with short durations providing little impact and with higher protection when lactation is at younger ages.⁴⁰ In a recent meta-analysis, each birth decreased the RR of breast cancer by 7%, and each year of breast-feeding decreased the RR by an additional 4.3%.⁴¹

Exogenous hormones

Although controversial for many years, results from the large Women's Health Initiative randomized controlled trial provided definitive evidence of the risks associated with postmenopausal HRT with combined estrogen and progesterone. In this study, 16,608 postmenopausal, otherwise healthy, women were randomly assigned to conjugated estrogen plus medroxy progesterone acetate or placebo.⁴² The combined estrogen and progesterone arm was stopped in July 2002 after a median 5.6 years of follow-up, because health risks exceeded health benefits. There were a 29% increase in coronary heart disease, 26% increase in breast cancer, 41% increase in stroke, and 13% increase in pulmonary embolism associated with HRT. Simultaneously, there were a 47% reduction in colorectal cancer and 34% reduction in hip fractures among women on hormonal replacement. No protective effect was found for memory loss or other measures of intellectual function. Although risk decreased right after stopping HRT, the overall increased risk persisted during long-term follow-up. The Million Women Study and the HERS II study reached similar conclusions.^{43–45}

The United States Preventive Services Task Force (USPSTF) concluded that the harmful effects of combined estrogen and progestin exceed the prevention of chronic disease effects in most women. Although short-term use of HRT might be beneficial for control of vasomotor symptoms related to menopause, long-term use is not indicated.

The use of oral contraceptives has long been associated with a slight increased risk of breast cancer. A recent large study of a US health care delivery system in women between the ages of 20 and 49 years has found increased risk in recent users taking high-dose estrogen preparations, but not in those taking low-dose estrogen contraceptives.⁴⁶ Risk does not appear to be sustained after cessation of use.

Exercise and obesity

There is convincing evidence that lack of physical activity is a risk factor for postmenopausal breast cancer and that active women have a relative reduction in breast cancer risk.^{47, 48} This benefit is clearly modified by weight, with little to no benefit from exercise seen in obese women. In the Women's Health Initiative, women engaging in regular strenuous exercise at age 35 had a 14% relative decrease of risk of breast cancer. Even 1.25–2.5 h per week of brisk walking was associated with an 18% relative decrease in breast cancer risk compared with sedentary women, with a slightly higher risk reduction in those who reported an additional 10 h of brisk walking or equivalent exercise per week.⁴⁹

A high body mass index ($>25 \text{ kg/m}^2$), particularly when associated with weight gain after menopause and abdominal obesity, has been clearly associated with an increased risk of postmenopausal breast cancer.^{10, 50–52} The RR for postmenopausal women is about 1.5 for those with a body mass index > 25 and 2 for those who are obese (body mass index > 30). In the Women's Health Initiative trials, obesity was also associated with an increased risk of HR+ breast cancer and more advanced disease at diagnosis.⁵³ The data in premenopausal women are more complicated, without a clear relationship between weight and risk of breast cancer.⁵⁴

Higher physical activity and reduced body mass index have been associated with lower relative levels of estradiol and estrone as well as serum insulin levels, which may in part explain the impact of exercise on breast cancer risk.^{55–57} The ACS has published guidelines on exercise and nutrition to reduce cancer risk.^{58, 59} Adherence to these guidelines has been associated with lower risk of breast cancer.⁵⁴

Metformin and diabetes mellitus

In the Women's Health Initiative, use of metformin in diabetic women reduced the risk of breast cancer.⁶⁰ Metformin is known to increase insulin sensitivity and reduce hyperinsulinemia, and hyperinsulinemia has been associated with carcinogenesis and proliferation in preclinical models.⁶¹ In addition, signaling through expression of the insulin-like growth factor receptor is related to both proliferation and therapeutic resistance in breast cancer, and metformin may inhibit downstream signaling through the mammalian target of rapamycin (mTOR).^{62–65} Diabetes mellitus has been associated with a higher risk of breast cancer in some studies, but not in others; however, it is more clearly shown to worse outcome after diagnosis of breast cancer.^{52, 66–69} Metformin is currently being tested in women with early-stage breast cancer (ESBC) in a multicenter clinical trial.^{70, 71}

Breast density

Breast density is a common and significant risk factor for breast cancer across ethnicities and is inversely associated with age and body mass index.^{72–76} Numerous state laws require reporting of breast density information to women at the time of screening mammography.⁷⁵ The highest quartile of breast density appears to have significantly elevated risk, with a 4.5- to 5-fold higher risk than those with the least dense breast tissue. Using the density reported on standard mammography (1, 2, 3, and 4 relating to fatty, scattered fibroglandular, heterogeneous, and homogeneous densities, respectively), studies reproducibly show strong correlation with breast cancer risk. The impact of breast density is modified by individual risk factors, as measured by the Breast Cancer Surveillance Consortium (BCSC) 5-year risk model, where women at moderate or high risk for breast cancer using this model and extremely high density had the highest risk for interval cancer.⁷⁶ The hazard ratio for interval cancer cases was 1.62 for those with high or very high BCSC 5-year risk and extremely dense breasts, rising to 3.45 in those aged 70–74 years.

A risk model has been developed for this purpose combining the BCSC risk model and breast density and benign breast disease (BBD), which can assist in accurately identifying high-risk women who might be eligible for primary prevention.⁷⁰ The Gail Risk model for estimating 5-year and lifetime risks for breast cancer has also been modified by using a multiplier of breast density and Gail model risk, with a modest impact on breast cancer risk assessment.^{77, 78} In addition, these patients could possibly be referred for additional imaging, although to date there have been no definitive data that alternate imaging modalities will provide better information and improve cancer detection, stage at diagnosis or breast cancer specific survival.

Alcohol

Numerous studies suggest that alcohol increases the risk of breast cancer. This is thought to be due to increased serum and tissue concentrations of estradiol mediated by the impact of ethanol on hepatic clearance. Alcohol was associated with a modest increase in risk of breast cancer in the Women's Health Initiative observational study, with the maximum increase observed with the highest daily consumption. This impact appeared to be subtype specific.⁷⁹ When compared with women who never drink, those who were reported to consume more than seven drinks per week had almost a twofold increased risk of invasive lobular cancer (hazard ratio 1.82 with a 95% confidence interval (CI) of 1.18–2.81), but there was no difference in the risk of invasive ductal cancer, even when both subtypes were HR+.

Radiation exposure

Exposure to ionizing radiation is a known risk factor for breast cancer. Atomic bomb survivors and patients treated in the past with irradiation for postpartum mastitis, acne, hirsutism, or arthritic conditions and repeated fluoroscopic chest radiography used to monitor tuberculosis have an increased incidence of breast cancer, even after low or moderate radiation doses.^{80, 81} Survivors of Hodgkin's disease who received radiation therapy to the chest in adolescence or at a young age, particularly when the radiation was combined with chemotherapy, have a marked increase in breast cancer risk.⁸² The latency period between radiation exposure and development of breast cancer is long, with a median of 30 years although this time is shorter in those treated with both radiation and chemotherapy. The risk of developing breast cancer as a result of common diagnostic radiologic procedures is minimal, and radiology technicians do not have an increased incidence of breast cancer.⁸³ Recent evidence has suggested that therapeutic radiation administered to treat primary breast cancer modestly increases (~30%) the risk of developing contralateral breast cancer more than 5 years after treatment.⁸⁴

Benign breast disease

Most forms of BBD appear to be unrelated to an increased breast cancer risk, and the majority of women with lumpy breasts and most of those with BBD do not have a significantly increased risk of breast cancer.

However, a number of studies, including a recent meta-analysis, suggest that the presence (or history) of BBD, particularly in those with a previous biopsy for benign disease, is associated with an increase in breast cancer risk.⁸⁵ This association is generally limited to biopsy-proven lesions with histologic atypia or proliferation (atypical ductal or lobular hyperplasia) ([Table 4](#)).^{87, 88} When compared with women who never had a breast biopsy, women with BBD without hyperplasia had an odds ratio of developing breast cancer of 1.5, women with hyperplasia without atypia had an odds ratio of 1.9, and women with hyperplasia and atypia had an odds ratio of 2.6–5.3, and this increased to 11 in women with both atypia

and family history.^{86, 89} A study from Mayo Clinic on 9087 women with BBD suggested that the combination of young age (<45 years) and atypia had a hazard ratio of 6.99 for developing breast cancer.⁸⁸ The importance of identifying this risk factor is the ability to significantly reduce risk using chemoprevention with hormone therapy and to use a risk-based screening approach.^{87, 88}

Table 4 Relative risk^a of invasive breast carcinoma based on histologic examination of breast tissue without carcinoma

<i>No increased risk (no proliferative disease)</i>
Adenosis
Apocrine change
Duct ectasia
Mild epithelial hyperplasia of usual type
<i>Slightly increased risk (1.5–2 times) (proliferative disease without atypia)</i>
Hyperplasia of usual type, moderate, or florid
Papilloma (probably)
Sclerosing adenosis
<i>Moderately increased risk (4–5 times) (atypical hyperplasia or borderline lesion)</i>
Atypical ductal hyperplasia
Atypical lobular hyperplasia
<i>High risk (8–10 times) (carcinoma in situ)^b</i>
Lobular carcinoma in situ—both breasts
Ductal carcinoma in situ (noncomedo)—unilateral, local

^a Women in each category are compared with women matched for age who have had no breast biopsies for the risk of invasive breast cancer during the ensuing 10–20 years. These risks are not lifetime risks.

^b Only smaller examples of noncomedo ductal carcinoma have consistently been assessed as risk indicators after biopsy only.

Source: Dupont 1985.⁸⁶

Other

Bisphosphonates

The use of oral bisphosphonates has been associated with a reduced risk of invasive breast cancer, particularly the incidence of HR+ disease.^{90–92} Osteoporosis may be a marker for lower postmenopausal exposure to estrogen and has been associated with lower breast cancer risk, and hence the possibility of interaction between this variable and the cancer-inhibiting effects of bisphosphonates exists.^{93, 94} A recent meta-analysis suggested a 15% RR reduction in any breast cancer and 32% RR reduction in invasive disease, with the benefit seen in patients who used bisphosphonates for more than 1 year compared with nonusers.⁹⁵

Calcium and vitamin D

Although previous studies supported a possible role of vitamin D and calcium in reducing breast cancer

incidence, subsequent studies have failed to find an association between risk of breast cancer and dietary intake.⁹⁶ A large study showed a lower breast density in younger women taking supplemental vitamin D, and another demonstrated a possible impact in women with the highest mammographic breast density.^{93, 94}

Other dietary factors

A diet high in animal fat and low in fruits and vegetables has been associated with a higher risk of breast cancer. However, this is closely related to additional factors such as exercise and body fat. A primary prevention trial was conducted in more than 48,000 postmenopausal women without a history of breast cancer.⁹⁷ Women in the intervention group were assigned to a diet with low total fat intake (20% of energy) and consumption of five to six servings of vegetables, fruits, and grains daily. At 8 years of follow-up, there was no reduction in invasive breast cancer risk, but a trend toward decreased risk in the most adherent group was shown. Given that this diet is also associated with reduction in a number of other comorbid conditions and that a longer intervention might have more impact, this seems a reasonable and easily applied lifestyle modification.

Breast cancer risk assessment models

Statistical models can be used to estimate a woman's risk of breast cancer. Some models predict the risk of developing breast cancer framing both short-term and lifetime risk. The models are highly dependent on the age of the person; thus, a very low short-term risk for a young woman may be accompanied by a high lifetime risk. The Gail Risk Assessment model^{98–100} and the Claus model¹⁰¹ are the most frequently used models to predict a woman's risk of breast cancer.¹⁰² Other models such as BRCAPRO,¹⁰³ Frank,¹⁰⁴ and Couch¹⁰⁵ predict the risk or probability of carrying a genetic mutation. These models should be used to guide decisions to perform genetic testing for the presence of cancer-causing mutations in *BRCA1* or *BRCA2*. They do not identify the risk of developing cancer; rather, prediction will depend on the results of the test aiming at determining inherited predisposition for breast cancer. The interpretation of the results of genetic testing depends on knowing whether the proband (person with a cancer) is the one being tested and whether a known cancer-causing mutation is present in the family. Over the past 5 years, new models have emerged that include breast density, exposures, family history, and single nucleotide polymorphisms such as the Breast Cancer Surveillance Consortium model has been validated in over 1 million women.¹⁰⁶

Gail model

The Gail Risk Assessment model is the most commonly used statistical model for estimating the risk of developing breast cancer in women undergoing annual screening. Gail and colleagues used data from 284,780 predominantly white women in 28 participating centers of the Breast Cancer Detection Demonstration Project to develop the model. This is an unconditional logistic regression model based on the relationship between risk in a woman with specified risk factors and the risk in a woman with no risk factors. Risk factors used in this model include age, age at menarche, age at first live birth, number of first-degree relatives with breast cancer (mother, sisters, or daughters only), number of breast biopsies, and breast pathology exhibiting atypical hyperplasia.

The Gail model is applicable to the largest number of women. A score of 1.67 (which is the average 5-year Gail score for a 60-year-old woman) was used as the minimum risk criterion to join the National Surgical Adjuvant Breast and Bowel Project (NSABP) P-01 prevention trial in the United States. The Gail Risk model has been currently used widely for clinical decision making for individual patients, with many forms of access (National Cancer Institute's Web site, handheld, and computer applications). It is

good at predicting the risk for a population, but a cutoff of 1.67 does not show high discriminatory power.¹⁰⁷ Ozanne and colleagues developed improved methods for incorporating Gail Risk by comparing a woman's Gail Risk in context with other women. Being able to show women that they are in the highest quartile or decile of risk is much more discriminatory and much more helpful in identifying truly high-risk women.¹⁰⁸ A limitation of the model is the treatment of family history: neither paternal family history of breast cancer nor age at onset in affected relatives is accounted for in the model. As described earlier, a multiplier can be used to incorporate breast density with subsequent improvement in predictive performance of the model.^{74, 109}

The BCSC model, a similar tool that incorporates BI-RADS breast density, exhibited a better risk discrimination and calibration than the Gail model in a multiethnic cohort of more than one million American women.⁷⁴ Neither Gail nor BCSC incorporates modern knowledge of genetic risk factors. The addition of polygenic risk (76 single nucleotide polymorphisms) improved the performance of the BCSC model, including density and polygenic risk. Other models have also been developed to include multiple risk factors, including family history, more comprehensive genetic factors, and exposures.^{100, 103, 184–186}

Hereditary models

Models such as BRCAPRO,¹⁰¹ Frank,¹⁰² and Couch¹⁰³ are designed to predict the chance of carrying a BRCA1 or BRCA2 mutation based on an autosomal dominant pattern of inheritance and the incidence of mutations within high-risk populations, and the BRCAPRO model also predicts the risk for developing breast and ovarian cancer as a separate output. The models are based on multiple variables in both maternal and paternal cancer history, including age of diagnosis, multiple primary cancers, bilateral breast cancer, Ashkenazi Jewish ancestry, and the number of first-, second-, and third-degree relatives with breast cancer. The BRCAPRO model also includes ovarian and pancreatic cancers. This high-risk category rarely occurs.

The hereditary models are used clinically for women with a positive family history of breast cancer and are discriminatory and well calibrated for predicting the presence of a *BRCA* mutation. It is predicted that at most, 10–15% of diagnosed breast cancers are in women with either *BRCA1* or *BRCA2* GENE mutations. BRCAPRO performs well in predicting mutations in families of African-American descent similarly to Caucasian families. It has been suspected that approximately 20% of breast cancers are caused by unidentified hereditary factors. Indeed, the use of clinical genetic testing with panels of multiple genes known to be associated with hereditary breast or ovarian cancer is identifying patients who carry a mutation in one of these less common genes. This, in turn, increases the percentage of breast cancers that are related to hereditary factors. The remaining 70% are thought to be sporadic or nonhereditary cancers.

Biomarkers

Germline mutations such as BRCA1 and BRCA2 (BRCA1/2) predict lifetime risk and risk at a younger age. However, there are no tests that are predictive for a specific age of onset, or the short-term risk of developing breast cancer. Understanding individual risk at specific time points will help design effective screening and prevention strategies and will also provide markers for the effectiveness of preventive strategies. These markers would need to be modifiable like risk factors. Potential modifiable risk factors include atypia and breast density. The presence of atypia has also been shown to predict a higher benefit from the use of tamoxifen, with a risk reduction of up to 89% in the NSABP P-1 study.¹¹⁰ Multiple investigators are conducting biomarker studies to determine whether these markers are reliable surrogate

markers that change in response to interventions.¹¹¹ How would these biomarkers then be used to test prevention interventions? Agents such as selective estrogen modifiers or aromatase inhibitors (AIs) that are known to target ER-positive disease can be used to treat women with cytologically documented atypia and the impact of the intervention measured by reduction in atypia. Change in breast density can also be measured over the course of the treatment (6–12 months) and used as a surrogate to better define those populations most likely to benefit from preventive interventions. Other modifiable risks include exercise, diet, and weight. The use of frameworks for communicating risk and shared decision making for risk reduction is critical.^{112–114}

Regulation of breast cancer growth

Understanding the basis for the development and regulation of breast cancer growth provides us with a foundation for developing strategies for breast cancer prevention and treatment. The adult female breast is composed of epithelial lactiferous ducts terminating in secretory alveoli embedded in a fibrous tissue framework and fat. Normal breast growth and development are regulated by the complex interaction of many hormones and growth factors, some of which are secreted by the mammary cells themselves and may have autocrine functions. Estradiol regulates the expression of several genes corresponding to peptides and proteins involved in mammary cell growth control mechanisms. Binding to specific receptors triggers effects of these growth factors and hormones. Polypeptide hormone receptors are typically located on the cell membrane, whereas receptors of the steroid hormone family are found mostly in the nuclear compartment of the cell.^{115, 116} However, steroid hormone receptors can also be found localized to the cell membrane. The interaction of growth factors, cytokines, and hormones with specific membrane receptors triggers a cascade of intracellular biochemical signals, resulting in the activation and repression of various subsets of genes. Several of these hormones have been shown to play an active role in breast epithelial cell growth and development and in lactation. Because these hormones and their receptors regulate normal breast tissue, it is not surprising that malignant cells arising from breast tissue might also express receptors for many of these hormones and might retain some degree of hormonal dependence.

Genetic aberrations in growth factor signaling pathways, for the most part acquired, are inextricably linked to developmental abnormalities and to a variety of chronic diseases, including cancer. Malignant cells arise as a result of a stepwise progression of genetic events that include the unregulated expression of growth factors or components of their signaling pathways.

Growth regulation of breast cancer cells by hormones and growth factors is shown schematically in [Figure 1](#). The biological role of estrogens is mediated through high-affinity binding to ER by molecules belonging to a family of ligand-inducible nuclear receptors that have steroid and thyroid hormones and vitamins as known ligands.¹¹⁴

Figure 1 Growth regulation of breast cancer by hormones and growth factors. *Abbreviations:* E, estrogen; EGF, epidermal growth factors; I, insulin; IGFs, insulin-like growth factors; Pg, progesterone; Pr, prolactin; T3,4, thyroid hormones; TGF- α , transforming growth factor alpha; TGF- β , transforming growth factor beta.

Breast cancer cells under estrogen control can synthesize and secrete their own growth factors that could auto stimulate breast cancer cells or adjacent stromal tissues through autocrine or paracrine

mechanisms.¹¹⁷ Aromatase is abundantly expressed in many breast cancers, providing the malignant cell with the ability to synthesize its own major growth factor, estrogen. Stromal tissues may also secrete IGF-1 and IGF-2 that can stimulate breast cancer cells. The identified potential autocrine/paracrine growth factors include epidermal growth factor (EGF), TGF- α , IGF-2, platelet-derived growth factor, and fibroblast growth factor (FGF). EGF, TGF- α , IGF-1, and IGF-2 have been found to be expressed and secreted by cultured breast cancer cells and human breast cancer tissue specimens.¹¹⁸ They are potential mitogens for the epithelial (malignant) component of the tumor. Platelet-derived growth factor and FGF are secreted by breast cancer cells and may be responsible for the proliferation of the mesenchymal stromal component evident in many breast cancers.

Human breast cancer cells also secrete several peptides that may have autocrine inhibitory activity. TGF- β is a family of growth factors that inhibit the proliferation of epithelial tissues and stimulate the proliferation of stromal tissues.⁵⁰ Studies suggest that ER-negative breast cancer cells are more sensitive to TGF- β than cells expressing ER. The malignant potential of breast cancer is likely to depend, in part, on the balance between growth stimulators and growth inhibitors produced by the tumors. The epithelial and/or stromal cells within the tumor also secrete proteases, such as the cathepsins, stromelysins, gelatinases, or urokinase plasminogen activator, which may participate in tumor invasiveness and metastatic potential.

In ER-positive breast cancer cells, expression and secretion of certain autocrine growth factors, such as TGF- α and IGF-2, are stimulated by estrogen and inhibited by antiestrogens. In ER-negative breast cancer cells, secretion of these factors is not estrogen regulated. Investigators have hypothesized that changes in the expression of these secreted factors may mediate to some extent the growth effects of estrogens and antiestrogens. Estrogens and antiestrogens have a variety of other effects on breast cancer cells. Estrogen stimulates RNA, DNA, protein synthesis, and the activity of key regulatory enzymes. Antiestrogens have the opposite effects in most tissues. Estrogens ultimately regulate movement of the cells through the cell cycle and mitosis.

Disturbance of normal growth control mechanisms within a cell can result in uncontrolled cell division and the development of cancer. Such cellular transformation occurs through the activation of oncogenes, loss or mutation of tumor suppressor genes, or both. The normal counterparts of oncogenes, termed proto-oncogenes, function as growth regulators in normal cells. Alterations of proto-oncogenes are associated with the initiation, promotion, and/or maintenance of tumors in animals and humans. The products of oncogenes are frequently growth factors, growth factor receptors, molecular switching, or transcription factors. Oncogenes often found overexpressed in human breast cancer tissue include members of the *myc* and *ras* family (*c-myc*, *Ha-ras-1*), *int-2*, which is involved in mouse (and, presumably, human) mammary gland carcinogenesis, and the members of the epidermal growth factor receptor (EGFR, *erbB*) family, including *erbB-2* (also known as *HER2* or *neu*), *HER3*, and *HER4*. Overexpression and mutation of growth factor receptors often lead to constitutive activation of these receptors (i.e., signaling in the absence of their cognate ligands). Growth-promoting signals may be continuously transmitted into the cells, resulting in activation of multiple intracellular signal transduction pathways and unregulated cell growth. Genes normally involved in cell cycle control, particularly members of the cyclin D and E families, may also function as oncogenes. Overexpression of these oncogenes may contribute to the initiation and maintenance of the malignant phenotype. Tissue-specific expression of *myc*, *ras*, and *HER2* in mammary glands of transgenic mice has been shown to result in an increased incidence of both benign and malignant breast pathology. Altered expression of these otherwise normal genes can have profound effects on growth homeostasis of breast epithelium. Recent studies have shown that blockade of these growth factor receptors or pathways has therapeutic implications.⁶⁸ Monoclonal antibodies to *HER2* have

dramatic antitumor effects, and they downregulate the phosphatidyl inositol 3-kinase (PI3K) signaling pathway. Furthermore, these antibodies have synergistic interactions with cytotoxic agents, such as the anthracyclines, the platinum analogs, vinorelbine, and the taxanes. The EGFR, when overexpressed, confers an adverse prognosis to patients with EGFR-overexpressing tumors. However, EGFR does not seem to be a critical driver of malignant behavior in breast cancer, and monoclonal antibodies against this target have had only marginal success in clinical trials.

Quantification of the expression of these oncogenes in human breast cancer specimens has been shown to provide valuable information on tumor aggressiveness, prognosis, and sensitivity to therapy.⁶⁹ Signaling molecules downstream from the cell surface receptors are often activated or otherwise altered in malignant cells. The PI3K pathway and the MAP kinase pathway are frequently activated in breast cancer, even in the absence of EGFR or HER2 overexpression.

Tumor suppressor genes also play a role in breast carcinogenesis. Loss of the normal “suppressor” function of these genes through mutations or deletion may cause cancer. Alterations in known suppressor genes, such as the retinoblastoma gene (*RB1*) and the human *TP53* gene, have been identified in human breast cancer cells, as well as in other solid tumors. Mutations in the *TP53* gene have been found in families with the Li–Fraumeni syndrome, who have a markedly increased incidence of breast cancer and other neoplasms. In addition, up to 50% of breast cancers have been shown to have mutations in the *TP53* gene. The two mutated genes associated with familial breast cancer, *BRCA1/2*, are also considered tumor suppressor genes. The normal function of the protein products of these genes is to control cell proliferation (*RB1* and *TP53*) or facilitate/mediate DNA repair (*TP53*, *BRCA1/2*). Mutations lead to mutated proteins and thus to dysregulated transit of cells through the cell cycle. Recognition that mutational inactivation of suppressor genes is associated with breast cancer could lead to early recognition of high-risk families, as well as to new treatment strategies to reverse the malignant phenotype by introducing normal gene copies through gene therapy or by treatment with the normal suppressor protein itself. Such strategies are under active investigation, both in the laboratory and early clinical trials.

Estrogen and progesterone receptors

ERs are members of the nuclear hormone receptor superfamily and have several functional domains. There are two subtypes, with each subtype having several isoforms and splice variants. The ER α (alpha) gene has been mapped to the long arm of chromosome 6 (6q24-q27), whereas the ER β (beta) gene is located on band q22-24 of chromosome 14. There are at least three PR subtypes. Other estrogen-induced proteins regulate events leading to cell proliferation. When receptors are bound to antiestrogens, such as tamoxifen, transcription of growth-promoting genes is blocked, although other genes might be activated by tamoxifen.

Nuclear localization of ER leads to its genomic effects. Upon binding its ligand, the ER–ligand complex binds to the estrogenresponsive element and initiates transcription of estrogen-driven genes. In its cell membrane localization, ER mediates the nongenomic effects of ligand binding, mostly through cross talk with peptide growth factor receptors (EGFR and HER2). Upon development of antiestrogen resistance, there is marked increase in the nongenomic effects of ER.

The most important application of the ER assay is the selection of appropriate patients for endocrine therapy. Approximately 50–60% of patients with ER-positive tumors benefit from endocrine therapy. This percentage includes patients with metastatic disease who achieve a major objective remission (partial or complete) and those who derive long-term (>6 months) stability of the disease with endocrine therapy;

both groups have equivalent survival expectations. The ER status predicts equally well for all modalities of endocrine therapy. Patients with no detectable ER or PR in their tumors do not benefit from endocrine therapy; however, breast cancers with very low but detectable ER and/or PR respond, albeit infrequently, to endocrine therapy (see systemic therapy sections).

Tumor ER and PR status can change over time or with intervening therapy; thus, repeat biopsies of accessible tissue may be helpful in selecting sequential therapies. However, ER status on the primary tumor still predicts reasonably well for endocrine response at the time of relapse. It is not known why 40–50% of ER-positive tumors fail to respond to hormonal therapy despite the presence of receptor. Clearly, an assay that would identify truly hormone-sensitive tumors would be more clinically useful. At least one multigene assay, the Oncotype DX, is being used increasingly in the United States to characterize the risk of developing distant metastases after 5 years of tamoxifen for women with ER-positive disease.¹¹⁹

Variant and/or mutated ERs have been identified in breast cancer tissue.¹²⁰ Current data suggest that the frequency of mutations in ESR1 increases under pressure, so that it is increasingly common with progression of metastatic diseases. Some of these altered receptors are constitutively active (activate transcription in the absence of estrogen), some are inactive, and some have predominant negative activity. The presence of these mutations has been associated with resistance to some types of endocrine therapy, but response to others.

Pathology

Histologic types

Pathologic classifications of mammary carcinoma are frequently confusing to the individual who is not a specialist in breast disease. [Table 5](#) lists the distribution of various histologic types of invasive breast cancer.

Table 5 Distribution of histologic types of invasive breast cancers 2008–2012, selected

Histologic type	No.	%
Adenocarcinoma	287,384	97.4
Infiltrating duct carcinoma	216,104	73.2
Lobular carcinoma	26,726	9.1
Mixed ductal and lobular carcinoma	27,371	9.3
Inflammatory adenocarcinoma	1003	0.3
Mucinous adenocarcinoma	5737	1.9
Tubular adenocarcinoma	1850	0.6
Papillary adenocarcinoma	1754	0.6
Paget disease	1259	0.4
Other adenocarcinomas	3336	1.1
Adenocarcinoma, NOS	2176	0.7
Epidermoid carcinoma	145	0
Other specific carcinomas	2415	0.8
Medullary adenocarcinoma	815	0.3
Other	1600	0.5
Unspecified, carcinoma, NOS	3356	1.1

Abbreviation: NOS, not otherwise specified.

Epithelial neoplasms of the breast

Tumors arising from ductal epithelium may be found only within the lumen of the ducts of origin; that is, the carcinomas are intraductal and do not penetrate the basement membrane or invade surrounding stroma. Most frequently, such tumors arise from large ducts and may present as several types. If they grow into the ducts with a papillary configuration, they are recognized as papillary carcinomas (Figure 2). Such lesions are rare, accounting for only 1% of breast cancers. Histologically, pleomorphic duct epithelial cells with disturbed polarity can be demonstrated, as can their “heaping up” into papillae. Difficulty may be encountered in differentiating a papillary carcinoma from a benign atypical papilloma. Papillary carcinomas rarely invade the surrounding stroma. A survival rate approaching 100% may be anticipated upon complete excision of such tumors. When these tumors do invade surrounding tissue, they grow rather slowly and attain considerable bulk. Skin and fascial attachments are unusual, and axillary node involvement is a late feature. Clinically, noninvasive tumors are found to be movable, circumscribed lesions that have a soft consistency not unlike that of fibroadenomas.

Figure 2 Papillary carcinoma of the breast. This uncommon tumor, <1%, rarely infiltrates and has a favorable prognosis.

The noninvasive variety of ductal carcinoma, referred to as intraductal carcinoma or ductal carcinoma in

situ (DCIS), is a proliferation of a subgroup of epithelial cells confined to the mammary ducts without light microscopic evidence of invasion through the basement membrane into the stroma. The histologic diagnosis of DCIS poses certain problems. It is often difficult to distinguish between benign but highly atypical hyperplasia and DCIS, and it is sometimes difficult to identify small foci of stromal invasion. Occasionally, it is difficult to distinguish between DCIS and lobular carcinoma in situ (LCIS), as the former may extend into breast lobules and the latter may involve extralobular ducts. Some lesions may be intermediate between the two. A variety of histologic patterns of DCIS has been recognized. The most frequently encountered are comedo, cribriform, solid, papillary, and micropapillary ([Figure 3](#)). The different histologic patterns have been associated with differences in biologic behavior. The proliferative rate has been found to vary according to the histologic characteristics of DCIS. A high proliferative rate has been observed with comedo DCIS, and a low proliferative rate with cribriform, papillary, and solid DCIS. A type of carcinoma known as comedocarcinoma is characterized by ducts that are dilated and filled with carcinoma cells. These are necrotic and can be expressed as semisolid necrotic plugs. Such cancers are not usually regarded as a separate cell type, but they rather represent a descriptive variant of intraductal carcinoma. Patients whose DCIS exhibits comedo features have been shown to have increased rates of local recurrence and may progress more rapidly to invasive breast cancer than other types ([Figure 4](#)). Human EGF-receptor 2 (HER2/neu or HER2) protein overexpression has been observed in solid and comedo types of DCIS, but not in papillary or cribriform types.

Figure 3 Ductal carcinoma in situ (DCIS), cribriform type. Duct spaces are completely involved by a proliferation of ductal cells with relatively uniform nuclei, arranged in back-to-back (cribriform) glands. The glands are almost uniform in size and shape and exhibit rigid inner borders (so-called cookie-cutter appearance).

Lobular carcinoma arises from the small end ducts of the breast. The noninvasive variety—the so-called LCIS—is characterized by small cells of low nuclear grade that fill and expand lobules without penetration of the basement membrane ([Figure 5](#)). When this lesion extends beyond the boundary of the lobule or terminal duct from which it arises, it is known as invasive lobular carcinoma. Often the small cells interdigitate between collagen bundles in a single line, the so-called “Indian file.” At other times, lobular carcinoma may be almost indistinguishable from the conventional invasive ductal carcinoma ([Figure 6](#)). Noninvasive mammary carcinomas comprise almost 22% of all neoplastic lesions of the female breast, and LCIS accounts for about 60% of these, or 12% of all tumors. Whereas DCIS often accompanies invasive ductal carcinoma, and may well be its usual precursor, LCIS may be followed by invasive ductal or invasive lobular carcinomas in either breast. Thus, LCIS is more a systemic marker than a local precursor. With the increased use of mammography, a much higher proportion of noninvasive cancers is being detected.

Figure 5 Lobular carcinoma in situ (LCIS). Terminal ducts and acini are completely filled and dilated by a uniform small cell proliferation.

Invasive ductal carcinomas in which no special type of histologic structure is recognized are designated “not otherwise specified” (NOS) and are the most common duct tumors, accounting for almost 80% of breast cancers ([Figure 7](#)). They are characterized clinically by their stony hardness to palpation. When they are transected, a gritty resistance is encountered, and the tumor retracts below the cut surface. Yellowish chalky streaks that represent necrotic foci are observed. Histologically, varying degrees of fibrotic response are present. They frequently metastasize to axillary lymph nodes, and their prognosis is the poorest of the various tumor types. More than half (52.6%) of breast cancers are pure invasive ductal lesions (NOS).

Figure 7 Infiltrating ductal carcinoma of the breast, not otherwise specified (NOS). Approximately 80% of breast cancers exhibit this histology, about one-third of the time with additional types of differentiation.

Several other types of invasive carcinomas arise from large ducts, and each has its own distinct histopathologic image. Medullary carcinoma, comprising 3–6% of all mammary carcinomas, often attains large dimensions ([Figure 8](#)). This tumor is formed by cells of relatively high nuclear grade, and it usually exhibits an extensive infiltration of the tumor by small lymphocytes. Medullary carcinomas have a relatively well-circumscribed border, sometimes described as a “pushing” border, in contrast to the NOS tumors in which small nests of cells tend to infiltrate the adjacent stroma more extensively. A study of medullary cancer using 336 typical and 273 atypical medullary breast cancers from 6404 patients enrolled in various stage I and stage II NSABP trials indicated that the survival of patients with typical medullary cancers was higher than those with NOS invasive ductal carcinomas. Survival was comparable for those with atypical medullary and NOS types.¹²¹

Figure 8 Medullary carcinoma of the breast accounts for approximately 5–7% of breast cancers. Despite its relatively poor differentiation, this tumor has a better prognosis than does infiltrating ductal carcinoma.

Tubular carcinoma is an invasive carcinoma in which tubule formation is highly prominent. This tumor represents 1–2% of breast cancers and has a low nuclear grade with some cell polarity ([Figure 9](#)). Its prognosis is favorable, and, when combined with small size, it is a curable tumor.

Figure 9 Tubular carcinoma of the breast. This tumor is rare in its pure form, <1%, but has a better prognosis than infiltrating duct carcinoma not otherwise specified (NOS). Partial tubular differentiation is seen in 20% of infiltrating duct carcinomas NOS.

Mucinous or colloid carcinoma, which comprises about 1–2% of all mammary carcinomas, is characterized on microscopy by nests and strands of epithelial cells floating in a mucinous matrix. It usually grows slowly and can reach bulky proportions. When the tumor is predominantly mucinous, the prognosis tends to be good ([Figure 10](#)).

Figure 10 Mucinous or colloid carcinoma of the breast. This tumor is uncommon (~2%), but has a rather favorable prognosis.

Two entities represent special manifestations of mammary carcinoma. Paget disease of breast occurs in 1–4% of all patients with breast cancer. Clinically, the patient presents with a relatively long history of eczematoid changes in the nipple, with itching, burning, oozing, and/or bleeding. The nipple changes are associated with an underlying carcinoma in the breast that can be palpated in about two-thirds of the patients. The subjacent tumor may be either intraductal or of the invasive duct type. Prognosis is related to the invasiveness and histologic type of the associated tumor. Histologically, the nipple epithelium contains nests of carcinoma cells.

Inflammatory breast cancer (IBC), or “dermal lymphatic carcinomatosis” of the breast, is characterized clinically by skin redness, warmth, edema (peau d'orange), visible erysipeloid margin, induration of the underlying breast, and rapid evolution, usually less than 3 months from first sign to diagnosis. These features must be present at the time of primary diagnosis. Biopsies of the erythematous areas and adjacent normal-appearing skin often but not always reveal poorly differentiated cancer cells filling and obstructing the subdermal lymphatics. Inflammatory cells are rarely present. Patients typically have signs of advanced cancer, including palpable axillary nodes, supraclavicular nodes, and/or distant metastases. IBC represents about 1–2% of breast cancers in the United States and Western Europe, although its incidence is reportedly higher in North Africa and the Middle East.

Several other histologic types of mammary carcinomas have been described but are rarely (<1%) encountered. Adenocystic carcinoma, carcinosarcomas, pure squamous cell carcinoma, basal cell carcinomas, and the so-called lipid-rich carcinomas have been observed. Because of their rarity, clinical correlates are practically nonexistent. Metaplastic cancers, previously rare, are increasingly recognized as a distinct and poor prognosis subset of TNBCs.

Nonepithelial neoplasms of the breast

A variety of nonepithelial neoplasms of the breast have been described. Fibrosarcomas, leiomyosarcomas, rhabdomyosarcomas, and angiosarcomas are all infrequent.¹²² Non-Hodgkin lymphomas can have their initial onset in the breast and can also occur as a focus of generalized disease. These usually have a B-cell phenotype. Some cases resemble carcinoma on routine histology; immunohistochemistry (IHC) is often helpful in resolving this issue. Only a few cases of Hodgkin disease and leukemia have been reported with initial manifestation in the breast.

Phyllodes tumor (cystosarcoma phyllodes) is a rare biphasic neoplasm that is partially epithelial and partially mesenchymal ([Figure 11](#)). Phyllodes tumors may achieve a large size and, not infrequently, demonstrate some invasion of adjacent breast tissue. They are best managed by local excision with a rim of normal breast tissue. Phyllodes tumors are classified as benign, borderline or indeterminate, and malignant. Malignant phyllodes tumors can metastasize and are highly resistant to therapy, with no known effective therapy. High mitotic rate, cellular atypia, stromal overgrowth, infiltrative margins, hemorrhage, and necrosis are considered features of malignancy; however, these findings are extremely rare. Although

it is difficult to determine from clinical or histologic appearance the tumors that behave malignantly and metastasize, malignant histology and stromal overgrowth are predictive of metastasis.¹²³

Figure 11 Phyllodes tumor (cystosarcoma phyllodes). Leaf like projections, lined by benign epithelium, contain a hypercellular stroma.

Prognostic factors

Tumor size

In addition to being a determinant for optimal local therapy, tumor size has prognostic significance in the determination of additional therapy. As the size of the tumor increases, the risk of recurrence (ROR) or metastasis also increases, for both lymph node-negative and node-positive tumors. Because the risk of treatment failure is already high for patients with node-positive breast cancer, increasing tumor size adds relatively little prognostic value. However, tumor size is often the main prognostic indicator in node-negative breast cancer. This variable is particularly important to decide whether to use or not adjuvant systemic therapy in patients with node-negative breast cancer. Tumor size refers only to the invasive component and hence should be determined in all three dimensions by the pathologist. Approximately 25–30% of patients with negative lymph nodes and a primary tumor less than 2 cm in diameter will experience a recurrence within 20 years of follow-up.¹²⁴ Patients with tumors ≤ 1 cm in diameter have an excellent prognosis, with $<15\%$ recurring at 10 years without effective adjuvant therapy. The largest database demonstrating the relationship among tumor size, lymph node status, and breast cancer survival comes from the Surveillance, Epidemiology, and End Results (SEER) program.¹ Less than 2% of patients with tumors under 1 cm and negative nodes died of breast cancer within 5 years, and only 4% at 10 years.¹²⁵ Considering the excellent prognosis for this group of patients with very small tumors, as well as the expense and toxicity of treatment, routine use of chemotherapy is not indicated. The combination of poor nuclear grade and lymphatic vessel invasion identifies a small subset ($\sim 10\%$) of patients with T1a, b N0 M0 breast cancer with a significant risk of relapse, up to 30%, that warrants systemic adjuvant therapy.¹²⁶

Axillary lymph node involvement

Involvement of the ipsilateral axillary lymph nodes is still the most reliable and reproducible prognostic indicator for primary breast cancer. In general, 50–70% of patients with positive lymph nodes have a relapse, whereas only 15–45% of patients with all lymph nodes negative for metastatic disease have a relapse after locoregional treatments only. The risk of tumor recurrence in a patient with primary breast cancer is a continuum related to the number of positive axillary lymph nodes.¹²⁷ With each additional positive lymph node found, the ROR and metastasis increase by a few percentage points. Thus, patients with 4–10 positive lymph nodes have a higher risk than those with one to three positive nodes, and those with 10 or more positive nodes have a higher risk than 80% probability of recurrence and metastasis.

Both macro- and micrometastases within the lymph nodes have prognostic significance.¹²⁸ Recent data suggest that micrometastases (N1mic) result in an intermediate risk compared with macrometastases, although this remains controversial.^{129, 130} By contrast, isolated tumor cells (ITC, <0.2 mm) appear to be without prognostic significance.¹³¹

In recent years, primary breast cancer has been diagnosed in earlier and mostly localized stages. A classic axillary lymph node dissection (ALND) has no therapeutic benefit for patients with a node-negative axilla and is associated with considerable short- and long-term morbidity. An alternative (diagnostic) staging procedure for these patients is the sentinel lymph node biopsy (SLNB)¹³² that markedly limits the extent of the surgical procedure in the axilla and, for the high majority of patients with negative axillary lymph nodes, precludes the need for formal axillary dissection while providing similar (and in some cases superior) diagnostic and prognostic information. The identification of a single (or only a few) sentinel node also permits the pathologist to perform a more detailed assessment to detect micrometastases by combining light microscopy, IHC, and even more sensitive molecular techniques. The finding of ITCs does not convey prognostic impact and should not be used to direct either local or systemic therapy. Randomized trials comparing axillary dissection with SLNB have demonstrated that the latter is associated with significantly reduced morbidity. Because of these results, SLNB has replaced classic axillary dissection for early localized breast cancer in a substantial percentage of patients with clinically negative axillae.

Although axillary lymph node status is still the most powerful prognostic indicator, 15–45% of patients whose lymph nodes do not contain metastases still experience a recurrence and die. Because of this limitation, other prognostic markers have been developed to improve prognostic accuracy, particularly in the group of patients with node-negative tumors. Molecular tests based on gene expression suggest that biology of the tumor may be more important than its stage. Women with node-positive breast cancer who were determined to be of low risk based on the MP gene assay had excellent recurrence-free survival regardless of whether chemotherapy was administered or not. This contrasted with the recurrence-free survival of those with a high-risk score, whose outcome was significantly poorer, but appeared to be moderated by chemotherapy.¹³³ A similar finding has been seen with the Oncotype DX gene assay.¹³⁴ This will continue to be an important area of research, and molecular analysis of tumors is already a major tool for determining therapy.

Histologic type

Several histologic variables have been reported to have prognostic significance.¹²⁰ The prognoses of ductal and lobular carcinomas are sufficiently similar to prompt the same treatment modalities. Several less common cancers, including pure tubular carcinoma, mucinous or colloid carcinoma, papillary carcinoma, and all noninvasive breast cancers, have substantially better prognoses, particularly when found in a node-negative stage.¹³⁵ The more favorable prognosis of these histologic types often justifies omission of adjuvant systemic treatment, particularly for small tumors (<3 cm). Because most of these special types have small dimensions when diagnosed, and are node negative, regional treatment is usually all that is required.

Histologic grade or differentiation

Tumor grade has been shown to be an important prognostic indicator. In general, tumors expressing features that indicate a high degree of tumor differentiation are associated with the most favorable prognosis. Multiple studies have shown that higher grade is associated with higher rates of recurrence and metastases and poorer survival. These correlations are independent of tumor size and lymph node involvement. High tumor grade is also associated with HR– and increased response to cytotoxic therapy. Conversely, low grade is associated with hormonal sensitivity and lower response to chemotherapy.

The clear definition of various histologic differentiation grades led to the recognition that those grades had reproducible prognostic significance. A similar finding can be observed for nuclear grade, although

some find that histologic grade is a more reliable prognostic indicator as it includes cellular and tissue-related criteria. Nuclear grade can be determined in cytologic specimens.

The most frequently used grading system is the Elston–Ellis modification of the Scarff–Bloom–Richardson system.¹³⁶ In this system, invasive ductal breast cancers are categorized into three histologic grades, depending on their degree of tubular and/or gland formation, cellular pleomorphism, and the number of mitoses per high-power microscopic field. Within each of these categories, a score of 1–3 is assigned, with 1 representing the most favorable findings (e.g., prominent gland formation, little cellular pleomorphism, and low mitotic rate) and 3 indicating the least favorable ones. The scores for each of these categories are added together. Grade 1 carcinoma (well differentiated or low grade) is defined as having a total of 3–5 points, grade II (moderately differentiated or intermediate grade) 6–7 points, and grade 3 (poorly differentiated or high grade) 8–9 points.

Tumor necrosis

Tumor necrosis of varying degrees was encountered in 60% of 1539 patients with invasive breast cancer in NSABP protocol B-04. Necrosis, particularly when observed to be of marked degree, was positively correlated with increased rates of treatment failure. Although necrosis was observed to be significantly associated with a number of clinical and histopathologic features purportedly related to worse prognosis in this disease, it was not correlated with pathologic nodal status, and multivariate analysis revealed it to influence treatment failure independently of tumor size in lesions less than 5 cm in their highest diameter. It is likely that tumor necrosis is a marker of proliferation and not a unique prognostic factor.

Lymphatic and blood vessel invasion

Lymphatic and blood vessel invasion has been associated with poor prognosis in numerous clinical reports. One-third of NSABP patients exhibited extension into lymphatics within the predominant mass, and the remaining 23% were considered questionable ([Figure 12](#)). Such a finding was associated with other unfavorable characteristics. Blood vessel invasion was observed in only 5% of patients and was associated with the finding of four or more positive axillary nodes, lymphatic invasion, and certain other unfavorable findings ([Figure 13](#)).

Figure 12 Lymphatic invasion by breast cancer. The vessel walls are thin and lined with endothelial cells.

Figure 13 Blood vessel invasion by breast cancer. The vessel wall structure is recognizable, together with erythrocytes in the vessel.

Multicentricity

Many breast cancers are multicentric in origin. In an examination of 904 NSABP cases, either invasive or noninvasive cancers regarded as independent were found in 13.4% patients. The frequency of invasive and noninvasive multicentric cancers was 4.1% and 9.3%, respectively. Increased utilization of magnetic resonance imaging (MRI) of the breast for preoperative assessment of the extent of disease indicated that multicentricity is more common than that it was previously determined by mammography.

Despite the significant incidence of multifocal lesions in both breasts in a woman with a primary breast

cancer, two or more clinically overt primary cancers in the primary breast are uncommon. Similarly, synchronous bilateral tumors are uncommon, and the incidence of a second asynchronous primary tumor in the uninvolved or opposite breast (~4–6% in 10 years) fails to approach the incidence predicted by the number of occult lesions detected by random biopsy, autopsy, or MRI.

Markers of proliferative capacity

Measurement of the proliferation rates of malignant tissues found high prognostic values for several types of cancer, including breast cancer. Several techniques are used to evaluate the proliferative capacity of the malignant cell, including mitotic indices, thymidine-labeling indices (TLIs) and S-phase fraction (SPF). The mitotic index is determined by counting mitotic figures using light microscopy on a tumor specimen stained with hematoxylin and eosin. It has been validated by both univariate and multivariate analyses. Many proteins play a role in the control of the cell cycle or are expressed at higher levels during certain phases of the cell cycle. Ki-67 and proliferating cell nuclear antigen (PCNA) are additional markers for the proliferation rate of malignant tumors.^{92, 93} Of these, Ki-67 has been more extensively studied, and it correlates strongly with the results of SPF determination and, therefore, long-term prognosis. This technique can be performed on fresh or frozen tissues and archival paraffin-embedded material. A low value indicates a more slowly proliferating tumor and is associated with a lower rate of recurrence, regardless of axillary nodal status. A high Ki-67 fraction is strongly correlated with other adverse prognostic factors, such as high histologic and cytologic grades, aneuploidy, and a negative steroid receptor status. Not surprisingly, the predictive molecular assays that have emerged are driven in part by genes that regulate proliferation.

Immunologic factors

Tumor-infiltrating lymphocytes¹³⁷ have been associated with improved outcome in aggressive breast cancer subtypes, such as TNBC. Preliminary data demonstrating efficacy of immune checkpoint inhibitors in breast cancer have highlighted the need to better understand the individual immune environment in individual tumor cases.

Diagnosis and screening

Historically, the primary presenting symptom of breast cancer was a palpable mass, often first detected by the patient. At present, the increasing use of mammography, particularly in screening programs, has resulted in many cancers being found at a preclinical stage. A simple discussion of the signs and symptoms of breast cancer without consideration of these preclinical manifestations would be incomplete. To some extent, this indicates a higher complexity in selecting for biopsy patients who are suspected of having carcinoma. The clinical and mammographic signs and symptoms are best understood against the background knowledge of the anatomy and biology of breast cancer—how it grows and extends locally.

Patient history

The patient's history should include standard epidemiologic and reproductive information to assess the RR factors. Information about lumps, pain, or any changes in the breast should be obtained and correlated with physical findings. Although pain is probably the most frequent breast complaint, it is uncommonly the presenting factor in cancer. Breast cancer, particularly in its early stages, is usually painless. Most breast pain is related to hormone stimulation and swelling of breast tissue (although these symptoms may draw attention to a mass that proves to be cancer). Careful questioning of the patient usually reveals that the

pain is cyclic, beginning any time between ovulation and the onset of menstruation, and that commonly it is most intense a few days before menstruation. Pain usually disappears in the first or second day of the menstrual period, only to return in the next cycle. Cyclic pain is present at a mild level in more than 50% of women of childbearing age. Less frequently, the pain can reach intense proportions. Some patients report that, during the worst days, it is too painful even to take a shower.

The most effective treatment is explanation and reassurance, although some patients who are extremely symptomatic and incapacitated by the pain may require treatments with hormones or hormone-blocking drugs. There are occasional reports that caffeine limitation or low-fat diets help, but relief seems to be individual, and these reports are not supported by persuasive clinical trials.

A patient who reports a lump or any other physical change in her breast needs careful attention. The history should describe any change in the character or size of the lump and whether or not it has been tender. Pain should be described with respect to its timing in the menstrual cycle. Lumpy changes associated with a fibrocystic process may wax and wane, but it is distinctly unusual for a carcinoma to do anything but increase in size. If the physician is unsure, the patient should be reexamined after the menstrual period.

Other descriptive changes, such as skin thickening or discoloration, the presence of axillary masses, or nipple discharge, should be elicited. Nipple discharge may be serous, watery, or milk-like. It may be clear or have a yellow or greenish hue, or it may be sero sanguineous or bloody. Although the latter may indicate a neoplasm, this is most commonly an intraductal papilloma, which is benign. It is possible, but rare, for such a discharge to signal an intraductal papillary carcinoma; all bloody discharges require further investigation.

Clear or serous discharge, particularly if it involves more than one major duct opening on a nipple, is likely to be benign. Nonbloody discharge that is not spontaneous but requires manual compression to elicit is also likely to be benign. In an apocrine system such as the breast, there are always some cell desquamation and liquefaction and, therefore, some fluid present in the duct system. If this is not well absorbed, it can make its way through the collecting ducts to the nipple and present as a discharge. Similarly, if the duct is blocked by fibrosis or inspissated material, the pressure of secretion can cause dilation and cyst formation. Cytologic examination of the discharge is less accurate and not very useful.

Physical examination

The patient should be examined, first in a sitting and then in a supine position. When the patient is sitting erect, more useful information is obtained visually than by palpation. When the arms are raised and stretched upward, the contour of the skin is pulled tight, allowing for easier detection of contour abnormalities in the upper half of the breast. This position also emphasizes dimpling, particularly in the lower half of the breast. Because much of the breast tissue coalesces in the sitting position, it is very difficult when palpating to appreciate true masses and often easy to be confused by confluent tissue. The axilla is palpated by relaxing and adducting the patient's arm, but this is best done with the patient in the sitting position.

With the patient supine and the arm raised such that the hand is behind the head and the elbow lies flat on the pillow, the breast tissue can be spread across the chest wall, allowing for proper palpation. The patient should be slightly turned to the contralateral side to aid this process. It is important to proceed in a pattern, but whether it be performed by quadrants or strips is up to the examiner. Skin changes such as dimpling, peau d'orange (edema), erythema, or areas of fixation and ulceration suggest advanced cancer that has invaded the skin or the immediate subcutaneous tissue. Skin retraction is often more easily

detected when the patient is sitting with the arms raised or when the patient is leaning forward. Retraction or asymmetry of the nipple is another worrisome sign unless the patient reports that this has been present all her life. A subtle reddish thickening of the nipple and areola or flaking of the superficial epithelium may suggest Paget disease.

The examination is concluded with a search for axillary, infraclavicular, and supraclavicular nodes and palpation of the liver to detect enlargement. Although palpably enlarged axillary nodes increase the probability of metastases, careful studies have shown that clinical judgment is highly inaccurate. In a study conducted by the NSABP, a group of cancer patients were judged by their clinicians to have normal axillary nodes, where 38% showed histologic evidence of metastatic tumor when the specimens were examined pathologically.¹²⁰ Conversely, in 25% of such cases, nodes that appeared enlarged and were judged to contain cancer were found to be normal. Evaluation should include axillary ultrasound, with a fine-needle aspiration (FNA) of abnormal-appearing nodes.

The most difficult clinical decision is differentiating between a pathologic mass and physiologic density associated with fibroglandular (or fibrocystic) changes. A true lump has definite margins. Whether these are smooth, as in a gross cyst or fibroadenoma, or somewhat irregular, as in carcinoma, they delineate a discrete mass that requires further investigation. Invasive ductal carcinomas are usually hard, and predominant in the breast, in contrast to multiple firm masses that may exist in BBD. Lobular carcinomas are not usually so hard and thus are more difficult to recognize.

It is important to measure the size of a tumor so that subsequent examinations can more accurately establish any change in size. Advanced cancers may be fixed, but early palpable lesions will certainly be mobile with respect to skin or fascia and muscle of the chest wall. There is, however, a subtle difference in mobility (better called “movability”) characteristic of cysts or fibroadenomas, which have capsules and move much more easily within the surrounding breast tissue. Carcinoma, on the contrary, which has no capsule and is surrounded by an infiltrating desmoplastic process, tends to move with the neighboring breast tissue rather than within it, because the process “locks” it into the stroma and surrounding glandular tissues, even when it is not fixed to surrounding structures, such as the skin or muscle. Even an experienced examiner could fail to distinguish correctly between benign and malignant lesions.

Imaging

For almost 30 years, annual mammograms for women over 40 years of age have been a cornerstone of the strategy to reduce mortality from breast cancer. Advances in our understanding of breast cancer biology, and screening in general, have led to revise and improve our screening strategy.¹³⁸ In 2009, the USPSTF introduced changes to screening guidelines, recommending that annual mammograms for all women of age 40–75 years be replaced by biennial screening for women of age 50–75 and that screening between 40 and 50 years of age should be individualized by considering patient context, including the patient's values regarding specific benefits and harms. The 2015 update further supported these recommendations (<http://www.uspreventiveservicestaskforce.org/>). The ACS revised its mammography screening guidelines in October 2015.¹³⁹ Screening was still strongly recommended, but the age at its start was modified. Annual screening was recommended for women aged 45 between 54 years, and women of age ≥ 55 years could transition to screen every other year. However, the ACS also noted that women should have the opportunity of annual screening and should continue to screen as long as they have a life expectancy of at least 10 years or more. It also recommended that women between the 40 and 44 years of age should have the opportunity of annual screening, if advised ([Table 6](#)).

Table 6 International screening strategies

Country	Start age	Stop age	Frequency
USA	40	NA	Annually
Sweden	40	74	Biennially
UK	50	70	Triennially
The Netherlands	50	70	Biennially
France	50	74	Biennially
Italy	50	70	Biennially
Germany	50	70	Biennially

Screening recommendations continue to spark debate, and scientific opinion on the effectiveness of annual screening is greatly divided. One side argues that annual mammograms starting at 40 reduce interval cancers, but others believe that annual screening results in more false positives with unnecessary treatment and that a more targeted approach could result in fewer false negatives and less overdiagnosis without increasing interval cancers. For most women, the discomfort and inconvenience of the annual mammogram is offset by the belief that it is one of the best ways to find cancers at an earlier, more curable stage. Unfortunately, cancers that are most likely to present at a more advanced stage or have a worse prognosis are those that are most likely to develop in between screening or are less likely to be visualized by standard radiographic tests. The reduced screening frequency recommended by the 2009 USPSTF was meant to balance benefits and harms and is more in line with policies of most other Western nations.

An increasingly vocal group questions the effectiveness of screening altogether. The 25-year follow-up results of the Canadian National Breast Screening Study (CNBSS), one of the early pivotal trials of screening, were published in February 2014 when they concluded (confirming their previous findings from 10- to 15-year follow-ups) that annual mammograms do not reduce deaths versus simple clinical breast exams.¹⁴⁰ Switzerland has recommended ending mammography screening altogether because of lack of evidence that the benefits outweigh the harms.¹⁴¹ Editorials and perspectives regularly feature opposing viewpoints,^{142–144} highlighting the broad disagreement over screening guidelines.

The annual screening approach to mammography, which is still the current standard, has its roots in the large randomized screening trials of the 1980s.¹⁴⁵ The overview of the Swedish trials showed a relative reduction in breast cancer mortality of 21%, with the maximum benefit for women in their 60s. The screening interval in the Swedish trials ranged from 18 to 33 months. Much has changed since these initial studies. Most of the effective systemic therapies used today were not available at the time when these screening studies were initiated, but currently have a clear role in reducing breast cancer mortality.¹⁴⁶ At present, systemic therapy has been thought to constitute up to two-thirds of the reduction in mortality and mammography about one-third.^{9, 147} Importantly, the extensive use and effectiveness of endocrine therapy^{148, 149} may mitigate the impact of finding some cancers later.

The potential harm caused by mammographic screening that is most familiar to women is the “false-positive.” With each mammogram, a woman's risk of receiving a false-positive increases, and with it, the risk of a biopsy that turns out to be benign. After 10 years of annual screening, over half of all women will receive a false-positive recall, and 7–9% will have a false-positive biopsy.¹⁵⁰ In general, the specificity of mammography is approximately 90%, indicating a 1/10 probability of occurrence of a false-

positive result. However, only approximately 5 in 1000 women actually have breast cancer when they are screened, so the majority of abnormal mammograms are false-positives.¹⁵¹ These affect women in several ways. A recent systematic review has shown that psychological distress can endure for up to 3 years, reducing adherence to subsequent screening.¹⁵² Similarly, a study from Holland showed 93% of women return after negative screens, but after one false-positive, only 56% return, and after two false-positive recalls, only 44% return.¹⁵³ Biennial screening, relative to annual screening, was shown in the BCSC to reduce the false-positive rate by 50%, with only a small but statistically insignificant increase of late-stage cancer diagnoses.¹⁵⁴

Another potential harm of breast screening comes from “overdiagnosis.”¹⁵⁵ Two decades of research has shown us that breast cancer is a spectrum of disease, spanning indolent lesions of epithelial origin (IDLE)¹⁵⁶ to aggressive disease. Screening, by nature, is more likely to identify slow growing and IDLE tumors¹⁵⁶ as highlighted by the 25-year follow-up results of the CNBSS. Half of the mammography-detected cancers that would not otherwise have been found by regular breast examination were deemed to be clinically insignificant.¹³⁸ A recent meta-analysis estimated that 20% of all cancers (up to 50% of screen-detected cancers) fall into the category of overdiagnosis.¹⁵⁷ Data suggest that a woman has a greater chance of being overdiagnosed than of having her life saved by screening.¹⁵⁸ Similar results were obtained when molecular markers were used to identify ultralow-risk disease.^{159, 160}

Most precancerous breast lesions and DCIS likely qualify as overdiagnosis. DCIS was rarely diagnosed before screening was adopted but increased 500-fold afterward.¹⁶¹ The tumor cells comprising DCIS are morphologically similar to those of invasive cancer, and hence it has been assumed that DCIS ultimately progresses to invasive cancer. Because routine care for DCIS is mastectomy or lumpectomy and radiation, the natural history of DCIS is unclear.^{162, 163} Epidemiologic evidence suggests that only a subset progresses to invasive disease over a lifetime.¹⁶⁴ Furthermore, unlike cervical cancer, where the removal of precancerous lesions caused a sharp decline in invasive cervical cancer, after a decade of removing DCIS lesions from more than 50,000 women per year, there has been no decline in incidence of invasive cancers¹⁶² (there was a short period of decline, but it was due to the sharp reduction in HRT after results of the Women's Health Initiative study were released).^{4, 165} Molecular markers are now available that identify a low risk form of DCIS whose 5-year risk for developing breast cancer is about the same as that of an average 65-year-old woman (2.5%)^{166, 167} Yet DCIS diagnoses result in >20,000 mastectomies per year, many of which are bilateral.^{168, 169}

Research to improve screening is ongoing, focusing on identifying the populations of patients who are most likely to benefit and developing molecular signatures to identify cancers with an extremely low risk of progressing.^{156, 170, 171} Criteria and threshold for recall after an abnormal scan and biopsy are being actively evaluated and improved. The BI-RADS¹⁷² recommends biopsy with a score of 4, which has a >2–95% chance of being either invasive cancer or DCIS. BI-RADS 4A (low suspicion <10%), 4B (intermediate 10–50%), and 4C (moderate >50%, but <95% risk of cancer) categories could help better refine biopsy thresholds.¹⁷³

However, reducing the burden of overdiagnosis and false-positive recall could perhaps be best accomplished by modernizing our screening approach by incorporating our improved understanding of individual breast cancer risk.

The idea of risk-stratifying screening recommendations has been attracting attention recently.¹⁷⁴ The Institute of Medicine has advocated for technology integration and biology and risk stratification in the development of breast-screening models. They noted that personalization—more frequent screening of

those at highest risk—could improve the positive predictive value of the screening test and potentially lead to fewer unnecessary interventions.^{175, 176} Because most people have a relatively low risk, personalized screening will result in the majority of the population getting less-frequent examinations, reducing false-positive recalls and biopsy rates.¹⁵⁴ This was also the conclusion of the USPSTF following their comprehensive review of mammography in 2009¹⁵⁵ that the balance of benefits and harms of screening depends on individual risk factors for women in their 40s and comorbidities for women over 74 years of age.¹⁷⁷ Women in their 40s with twice the average risk were thought to obtain the same benefits from screening compared with women in their 50s.¹⁷⁸ As such, the decision whether to screen women in their 40s should be based on individual risk factors. The USPSTF urged clinicians to discuss the pros and cons of screening with their patients in the context of their individual risk. For women of ages 50–74, USPSTF found that screening every other year would preserve benefits and minimize risks compared with annual screening.

The USPSTF guidelines have met resistance^{179–181} and the medical community has failed to reach consensus on the issue. Women have also been reluctant to believe that less screening could somehow be beneficial, which, on the surface, is understandable.¹⁷⁷ Finally, USPSTF guidelines did not state how to integrate risk assessment into practice. Thus, while we have witnessed major advances in the diagnosis, prognosis, and treatment of breast cancer, our approach to screening has not fundamentally changed since the 1980s. It is imperative to move beyond the current debate and test new approaches to breast cancer screening to maximize the benefits and minimize the harms to women. Clearly, this means new studies to help us understand screening in the context of modern adjuvant therapies. However, it also indicates using three decades of knowledge on the natural history of breast cancer and the factors that contribute to an individual's personal risk of developing and/or dying from the disease. Just as our approach to treatment has evolved from one-size-fits-all to more individualized, patient-centered, evidence-based treatment, so too must our approach toward screening.¹⁴⁷

In the last decade, concomitant advances in our understanding of disease mechanisms and analytical capabilities have given us the ability to treat disease with a higher degree of precision than ever before. In breast cancer, this is reflected in how we select specific therapies based on measured characteristics of an individual's disease.^{117, 168, 182, 183} On the contrary, we largely approach breast cancer screening as if everyone is the same. A more risk-adapted approach has the potential to benefit patients, providers, and payors. The Patient-Centered Outcomes Research Institute (PCORI), established as part of the Affordable Care Act, has recently funded a randomized trial to test personalized screening versus annual screening, in an effort to focus forward on how to make screening better for women and their providers (wisdomstudy.org). The proposed pragmatic trial seeks to resolve this controversy by comparing an updated individualized approach to breast screening with annual screening. Despite our vastly improved understanding of breast cancer risk, the only criterion used to establish a woman's screening recommendations is her age (and BRCA status if known). However, currently, there have been models that incorporate family history and breast density, endocrine exposures, gene mutations, and atypia to assess breast cancer risk.^{100, 103, 184–186} Most recently, certain common gene variants have been confirmed predictors as well.¹⁸⁷ Advances in breast cancer biology, risk assessment (genomics), and imaging (density) have provided us with all the tools and knowledge required to implement a personalized model; one that provides recommendations on when to start, when to stop, and how often to screen, depending upon well-characterized measures of their personal risk. The study is being conducted by the University of California-wide Athena Breast Health Network. The potential benefits of risk-based screening to health care payers are numerous and enormous. Our current breast cancer screening costs \$8–10 billion and results in 600,000 benign biopsies annually. If we compare the costs of the most widely adopted

annual screening practice of women of age 40–80, with the USPSTF recommendations, the difference in cost would be approximately \$6.3 billion—a figure larger than the NCI's annual budget.^{188, 189}

MRI screening

MRI is increasingly being used in the management of breast cancer. MRI has the advantages of providing a three-dimensional (3D) view of the breast, performing with high sensitivity in dense breast tissue, and using nonionizing radiation. MRI has the following drawbacks as well: high cost, variability in performance, and moderate specificity that in combination with high sensitivity often leads to unnecessary workup.¹⁹⁰

MRI is not appropriate as a general screening tool. It is at least 10 times costlier than mammography. MRI should be reserved for those situations where there is a high prior probability of identifying a cancer (high risk) and very high sensitivity is preferred and where other less expensive, robust screening tools (e.g., mammography) are known to be less sensitive,^{156, 191} such as *BRCA1* or *BRCA2* mutation carriers, which have an 85% lifetime risk of developing breast cancer. Although an average 35-year-old woman would have a 1/10,000 chance of having a cancer, a mutation carrier would have a risk in the range of 1 to 5/100, and MRI would be much more sensitive in this population than mammography. Women with a very high 5-year Gail risk and very dense breast tissue may also fall into this category. Use of a density-modified Gail Risk score,⁵² which combines both risk and breast density as recorded on a mammogram (BI-RADS density), enables the identification of women both at high risk and at risk for false-negatives with mammography. The density-modified Gail risk is calculated by multiplying the lifetime Gail risk by 0.59, 1.00, 1.41, or 1.94 for a BIRADS of 1, 2, 3, or 4, respectively. Women with a lifetime risk of >50%, as calculated by the density-modified Gail model, are recommended for MRI screening. Consideration can be given to women with a 35–49% lifetime risk using this tool, although there has been no current evidence to support the addition of annual MRI screening.

The true measure of a screening test is not whether it finds more cancers, but whether finding the cancers decreases mortality and morbidity from breast cancer. No study has yet shown that cancers found by MRI decrease mortality from breast cancer. However, two large studies have shown that screening using MRI is more sensitive in high-risk women, with remarkably similar results.^{192, 193} If tumor size and lymph node involvement are used as surrogates for outcome, MRI does improve the stage at which tumors are identified in women in the highest risk cohort. In the Netherlands study, the cancers found in the 1909 women screened with mammography and MRI were compared with two appropriate control groups of mutation carriers and high-risk patients, none of whom had access to MRI screening. In the highest risk group (50–85% estimated lifetime risk), 63% of mutation carriers with screened cancers had negative nodes when screened with MRI compared with 47% with negative nodes in the controls. In the moderate-risk group (15–30% estimated lifetime risk), only 12% had lymph node involvement and 87% had negative nodes (compared with 52–56% positive nodes and 44–48% negative nodes in the control groups). Therefore, MRI appears to be capable of finding cancers at an earlier stage. However, the rate of detection of cancer is also important, and MRI should be used where that rate is high and significantly higher than that in the usual screened group. Of note, the cancer detection rates were 26.5, 5.4, and 7.8 per 1000 woman years for the mutation carriers, high-risk group, and moderate-risk group, respectively. This should be compared with the detection rate of 5 to 7/1000 women where mammography is most cost-effective, in women aged 50–70 years. The only group that had a higher rate of cancer development was the highest risk group, the mutation carriers, and we should be careful to restrict the use of MRI for those women.

Screening comes at a price, both financial and psychological. In the Netherlands study of 1909 women

screened for 10 years, 1200 extra procedures were performed. In the process of finding the 45 cancers, MRI led to twice as many extra procedures (420) compared with mammography (207) and three times as many unnecessary biopsies, 24 versus 7 for MRI and mammography, respectively.¹⁹⁰ It is common to recommend 3- or 6-month follow-up studies after an abnormal imaging test. However, MRI examinations cost US \$1000–2000, so it is inappropriate to order these tests unless there truly is a situation where the likelihood of finding an abnormality is much higher than in the general population and where mammography would be unlikely to be effective. The two key messages are that we need to find ways of stratifying risk to appropriately tailor the use of technology and MRI screening should be undertaken only in facilities that have the capability of investigating MRI abnormalities, both with ultrasound and MRI-guided biopsy, if necessary. The Blue Cross/Blue Shield technology assessment concluded in 2003, which showed that MRI screening was justified in women who carry an inherited predisposition to breast cancer. The studies conducted in the Netherlands and Canada^{190, 194} strengthened this conclusion. The moderate- and high-risk women probably gain less overall because the risk is not as high, suggesting that MR must become more specific and follow-up of abnormalities easier before we implement widespread screening of intermediate risk women.

Not all MRI exams are alike. There is a great deal of variability in technique, sequences, interpretation, and capability for follow-up and biopsy. Although the use of breast MRI has proliferated rapidly, standards have not. Clinicians ordering breast MRIs need to know that technique, time of menses (midcycle is optimal 4–14 days after starting menses¹⁹⁰), and the skill in interpretation affect results. Interpreting images performed in different institutions is also a challenge because of the relative inability to transfer and view images electronically. Each of these areas is under active investigation, and further research and technological improvements will substantially improve our ability to appropriately integrate MRI into breast cancer management.

MRI has also been used after a diagnostic test reveals an abnormality. The most definitive study on the performance characteristics of MRI for the evaluation of mammographic abnormalities and palpable masses is the multi-institutional International Breast MRI Consortium (IBMC) study. High sensitivity and moderate specificity were confirmed in this study. Diagnostic characterization of lesions by MRI is improving, but it is not sufficiently specific to substitute a biopsy. MRI after an abnormal diagnostic mammogram significantly increases false-positives. Currently, there has been no role for MRI in the diagnosis of breast cancer unless suspicious mammographic findings cannot be evaluated or localized or unless there is another compelling reason to order MRI (e.g., if a patient is a mutation carrier or has a very high risk of cancer and very dense breast tissue).

Perhaps, the most important role for MRI is the staging of known cancer in the breast and monitoring the response to therapy.¹⁹⁰ MRI reveals that tumors form distinct patterns in the breast, and different types of tumors, such as lobular and inflammatory cancers, are more commonly associated with distinct patterns. Initial imaging characteristics identify women likely to have a particularly poor response, such as diffuse tumors with large volumes.¹⁹⁵

Risk and prevention

If we can reduce the frequency of screening at those with lower risk, in accordance with the recommendations of the USPSTF, those at lower risk to develop breast cancer will be screened less, thus reducing false-positive results. The process of callbacks and biopsies from false-positives is extremely stressful, characterized by increased anxiety and changes in screening choices that have been shown to persist long after the issue is resolved.^{152, 193} Personal risk-assessment may improve the general

understanding of their *personal* breast cancer risk. At present, only one in 10 women has accurate perceptions of her personal risk, while four in 10 have never discussed their personal breast cancer risk with a doctor.¹⁹⁶ They are not aware that some tumors grow rapidly and present between screens (interval cancers) and need attention regardless of a prior normal screen.¹⁹⁷ There are effective, viable prevention options available to the estimated 2 million American women who are at high risk, yet many are completely unaware of their predisposition¹⁹⁸ and so cannot benefit from them. There are three level I studies that have demonstrated the ability of endocrine risk-reducing agents. The NSABP P-01 study of over 13,000 women with a Gail Risk of at least 1.67, randomized to tamoxifen versus placebo, showed that risk of developing invasive cancer or DCIS could be reduced by 50% and more (85%) in the setting of atypia.¹⁹⁹ This has been confirmed by the IBIS trial,²⁰⁰ and furthermore, younger women (below 50 years of age) had more to gain, and benefits continued for 10 years, even when therapy was stopped after 5 years. The STAR trial compared tamoxifen with raloxifene, and a selective estrogen receptor modulator (SERM) was developed to improve breast density, but noted to reduce hormone-positive breast cancer in postmenopausal women and reduce fracture risk in the MORE study.²⁰¹ Raloxifene does not stimulate the endometrial lining and has fewer endometrial side effects including bleeding and endometrial cancer, and although the risk-reducing impact was not quite as high as tamoxifen, it is considered the better choice for postmenopausal women.²⁰² This is supported by the long-term follow-up of the IBIS 2 trial,²⁰³ which showed an increased risk of death from endometrial cancer in postmenopausal women on tamoxifen. Finally, a prevention study (MAP.3) using the AI exemestane showed a 60% reduction in the risk of hormone-positive invasive breast cancer in postmenopausal women compared with those on tamoxifen.²⁰⁴ There has been a poor uptake of endocrine risk reduction in the United States and worldwide. This is likely from a combination of a failure to automate or integrate risk assessment into primary care, a failure to appreciate the benefits of risk reduction, a failure to assess whether a woman receives specific benefit. Cholesterol, for example, is a measure that is used to demonstrate the lowering of cardiac risk. Breast density has been proposed as a possible dynamic measure of risk, where women on tamoxifen who demonstrate a reduction in breast cancer density are the ones who derive the risk reduction benefit.^{205, 206} This is an important point of study and is likely incorporated into future prevention studies. Furthermore, we know that communicating individual risk can motivate increased screening uptake²⁰⁷ and that women are more motivated to use preventive interventions when they understand they are high risk¹¹² and specifically stand to benefit.

Biopsy

When a woman presents with diagnostic abnormality, a decision to intervene should be made in the context of the likelihood of the lesion being invasive cancer or in situ cancer, as well as the age, underlying health condition, and life expectancy of the patient. A decision about which type of biopsy to perform is made by thinking about the need for future procedures. The goal should be to minimize the total number of procedures (including definitive cancer surgery), discomfort and scarring, and diagnostic wait time and anxiety and to enable the optimal timing of procedures.

A number of options are available for the diagnosis of masses and mammographic abnormalities. For palpable lesions, the options include FNA, core biopsy, or excisional biopsy. Minimally invasive techniques, core biopsy, and FNA are quite accurate in experienced hands and when the “triple assessment” is used. Triple assessment is the consideration of the imaging, clinical, and pathologic findings. If there is significant discordance, further evaluation should be pursued. In general, excisional biopsy is not the optimal diagnostic procedure. Minimally invasive biopsy techniques can be performed immediately in the office and facilitate a rapid diagnosis and discussion of options and full evaluation of

the extent of disease in the breast before definitive surgery. FNA or core biopsies can also be used to confirm the suspicion of multicentric disease and thereby avoid multiple trips to the operating room and in general allow the optimal sequencing of interventions.

The type of biopsy performed should depend on the expertise at a given institution. FNA is highly accurate, with sensitivity and specificity of 98% and 99%, respectively. FNA both for palpable and mammographic lesions has been used extensively and successfully in Sweden and the United Kingdom, where it is the standard diagnostic tool. This technique requires practitioners who have training and experience in sampling the lesion (the aspect prone to the highest error), preparing the slides, and interpreting cytology.²⁰⁸ The advantage is that it can be performed right away and yields results within a day. Both FNA and core biopsy are preferred when there is a high suspicion of invasive cancer and the anticipation that a sentinel lymph node dissection (SLND) will be performed. When an SLND is performed, the type of biopsy performed affects the accuracy of the SLND. Core biopsy and FNA have a lower false-negative rate than excisional biopsy when a subsequent sentinel node dissection is performed: 8% compared with 14% for incisional biopsy and 15% for excisional biopsy. In the setting of a patient with a large obvious tumor, FNA can facilitate the rapid confirmation of a diagnosis and a discussion of options, including neoadjuvant therapy and clinical trials. For patients who opt for surgical management, no further test is needed. For those who opt for neoadjuvant therapy, a core biopsy should be obtained for histology to confirm invasive disease, to save for future studies in the event of complete pathologic response and potentially for clinical trials. In the event that cytology expertise does not exist in a given institution, a core biopsy can also be rapidly performed in the office setting.

Recall for mammographic abnormalities is common, and the likelihood of cancer being diagnosed from a mammographic biopsy (cancer to biopsy rate) is highly variable, from 10% to 40%. A low cancer to biopsy rate is not necessary for high sensitivity, and in fact, the most experienced and highly trained mammographers find more cancers and order fewer biopsies for what turns out to be benign.¹¹⁶ Cancer to biopsy rates decline over time in settings where quality improvement and feedback on performance are the rule. Several ways exist to avoid biopsies of noncancerous tissue. The first is to take the extra time to get old mammograms for comparison. Circumscribed mass lesions that have been stable for over 2 years will be converted to probably benign and not require a biopsy. If an experienced mammographer has not read the films, a second opinion can always be obtained.

In the event that a biopsy is recommended, it is important to make sure that the lesion is not palpable. If it is, and particularly if the lesion is suspicious for cancer, an FNA not only establishes the diagnosis but also confirms that the palpable mass is indeed the cancer, avoiding the need for wire localization at the time of lumpectomy. An attempt to locate nonpalpable suspicious mammographic masses with ultrasound will enable diagnostic and definitive procedures to be ultrasound-guided, which is more comfortable for patients. In the event that a mammographic lesion can only be seen on mammogram, a stereotactic biopsy can be performed using digital images to locate the lesion and direct the core biopsy. The sensitivity of this procedure is as high as 98% by experienced practitioners.²⁰⁶ A specimen radiograph is obtained to confirm that the target has been obtained (usually calcifications). If there is a risk that all calcifications will be removed, it is then critical to leave a clip to localize the area later.

It is important to perform procedures in the context of their value to the overall management of the patient. If cancer is not present, an adequate sampling of the calcifications or lesions should be performed. If cancer is present, the minimal amount to establish the diagnosis is sufficient. At this point, the diagnostic procedure is not definitive and wide excision is needed. Some radiologists take over 30 core biopsy samples. This is not necessary and can create hematomas, distortion of tissue, and difficulty assessing the true extent of the lesion. It is also unpleasant for the patient.

Some mammographic lesions cannot be biopsied using stereotactic techniques because either the lesion is too close to the chest wall or the breast compresses to less than 3 cm in the direction the biopsy needle would be placed. In this case, an excisional biopsy must be performed. A wire is placed by the radiologist to guide the surgery, with the tip of the wire just under or at the level of the calcifications or mass. The surgeon should use the radiologist's estimate for the likelihood of malignancy to determine the extent of resection. For lesions more likely to be cancer, the lesion and a 1-cm rim of tissue should be taken. For less-suspicion lesions, a smaller volume of tissue can be taken. In order to avoid taking unnecessary tissue, an incision should be made near the tip of the wire or the expected location of the abnormality. Starting the excision at the insertion site of the wire only leads to excessive tissue being removed and usually results in a close margin at the end of the wire. Making the incision over the lesion is helpful in locating the biopsy cavity in the event that an additional resection is necessary. All specimens need to be sent to mammography or evaluated using a Faxitron to assure the surgeon that the target lesion has been removed. Mammographers routinely recommend a biopsy of any lesion that is a BI-RADS 4 or higher. However, a BI-RADS classification of 4 includes lesions that have a risk of as low as 3% or as high as 75% for being malignant. The lesion may be suspicious for either in situ or invasive cancer—no distinction is implied by the categorization of a BI-RADS 4. The surgeon should understand both the type of lesion suspected and a more specific estimate of risk, because they may make a difference in how the patient is evaluated. An older woman with several comorbidities and a mammogram with a BI-RADS 4, if she has a lesion that is approximately 90% likely to be benign and 10% likely to be DCIS, may not need a biopsy. This is the type of lesion that could be followed on mammography. In general, we recommend that a minimally invasive biopsy be used to establish a diagnosis, but excisional biopsy may be the procedure of choice for a woman who has a confined cluster of linear calcifications that are highly suspicious for high-grade DCIS. In this situation, a core biopsy would likely reveal DCIS, and a negative biopsy would be discordant and require wire localization and excision. If the likelihood of associated invasive cancer is low, a sentinel node dissection or axillary sampling will not be necessary, and therefore, there is little value in starting with a stereotactic biopsy.

Ductal carcinoma in situ

DCIS is defined by cytologically malignant epithelial cells within the ductal system of the breast that have not invaded through the basement membrane into the breast parenchyma. [Figure 3](#) shows a histological example of DCIS.

Before the advent of screening, DCIS comprised about 3% of breast cancers detected. As the interest in finding smaller cancers increased, and targeted calcifications rather than only masses, we began to identify DCIS more frequently. DCIS now accounts for approximately 20–25% of screen-detected breast cancers. The cells that comprise DCIS appear similar to invasive cancer both pathologically and molecularly, and therefore the presumption was made that these lesions were the precursors of cancer and that early removal and treatment would reduce cancer incidence and mortality. However, long-term epidemiology studies have amply demonstrated that the removal of 50,000 to 60,000 DCIS lesions annually has not been accompanied by a reduction in the rate of occurrence of invasive breast cancers.²⁰⁹ This is in contrast to the experience with the removal of colonic polyps and cervical intraepithelial neoplasia (CIN) lesions of the cervix, where the removal of precursor lesions has led to a decrease in the incidence of colon and cervical cancer, respectively.¹⁶⁴ For low-grade DCIS, there is no evidence from SEER that women have the same survival whether they have any intervention or not. Of the 57,222 women diagnosed with DCIS, 2% (1169) had observation only. In women with low-grade DCIS, survival was identical at 10 years with and without surgery (98.6% vs 98.8%, respectively).²¹⁰

From the results of a large observational study of >100,000 women diagnosed with DCIS, Narod and colleagues showed that the risk of dying from breast cancer is extremely low.²¹¹ Less than 1% of patients in this 20-year study died of breast cancer (compared with 5% of patients who died of other causes). Using the Kaplan–Meier method, the breast cancer-specific mortality rate is 3.3% at 20 years, almost similar to the statistic listed by ACS as the chance that breast cancer will be responsible for a woman's death (ACS.org).

Two ongoing therapeutic questions related to the treatment of DCIS concern the use of radiation and hormonal therapy. While radiation decreases the chance of an invasive breast cancer occurrence, and a recurrence of DCIS, radiation after lumpectomy for DCIS does not result in a reduction in breast cancer mortality. This has been shown consistently.²¹² While some reports suggest that low-grade DCIS with wide margins (>10 mm) recur in as few as 3% of cases with surgery only without radiotherapy. Two large prospective studies by the Dana-Farber Cancer Institute and the Eastern Cooperative Oncology Group (ECOG) encountered local recurrence rates of 12.5% and 7% in low- and intermediate-grade DCIS, respectively.

One of the leading proponents of treating favorable DCIS with lumpectomy only has been Silverstein and colleagues, who, in 1995, developed the Van Nuys Prognostic Index (VNPI) to help define selection criteria for cases with low recurrence risk.¹³⁶ The original VNPI classes were determined from the retrospective analysis of 333 patients treated at two institutions between 1979 and 1995. Patients received 1–3 points for three factors: tumor grade and the presence or absence of necrosis (combined into one category), tumor size, and margin status. Over two-thirds of the patients had an intermediate-risk VNPI (cumulative score of 5–7), and, similar to the randomized data, radiation reduced the probability of breast cancer recurrence in this cohort (32% vs 15%; $p = 0.17$).¹⁶⁰ Less than one-third of their patients had small, low-grade disease with widely negative surgical margins, and the breast cancer recurrence rate was low after breast conservation surgery (BCS) only (3% breast cancer recurrence rate among 76 patients treated without radiation). Subsequently, this group has also incorporated patient age into their prognostic index. Similar data were subsequently reported from a population-based cohort study of 1036 women ≥ 40 years of age in San Francisco treated with lumpectomy only for DCIS. This study found overall a relatively high recurrence rate (20% and 10% for all recurrence and invasive recurrence, respectively, at 5 years) but reported that the subset of patients with mammographically detected low-grade disease treated with surgery that achieved widely negative margins had a lower ROR after surgery only.¹³⁷

Using an expansion of this original cohort, Silverstein and colleagues reanalyzed their data, focusing on the importance of margin status for patients treated with DCIS. In this analysis,¹³⁸ they reported that 93 patients with a margin width of 10 mm or more had an 8-year local recurrence rate of only 3%. This rate was found to be much higher after treatment with lumpectomy without radiation when the margin width was 1–10 mm (recurrence rate 20%) and margins were under 1 mm (58%). When this study was updated and expanded to include 212 patients with margin widths of ≥ 10 mm, the breast recurrence rate in this cohort increased to 14%.¹³⁹ In addition, the low recurrence rate noted in the setting of 10-mm margins could not be confirmed in a single-arm prospective trial conducted at the Dana-Farber/Harvard Cancer Center. In this study, 157 patients with grade 1 or 2 DCIS, ≤ 2.5 cm, underwent wide local excision only with achievement of negative margins of ≥ 1 cm.¹⁴² The trial was closed early because the recurrence rate met predefined stopping rules, with an estimated 5-year local recurrence rate of 12.5% (invasive cancer occurrence of 6%). The authors concluded that even in this highly selected group of patients, there was a substantial local recurrence rate. The ECOG has also conducted a prospective study of 711 patients with DCIS treated with surgery plus/minus tamoxifen without radiation. Two different patient strata were

enrolled: (1) low- or intermediate-grade DCIS, size < 2.5 cm, and (2) high-grade DCIS, size < 1 cm. All patients were required to have a negative post lumpectomy mammogram and negative margins of 3 mm or more. The 5-year risk of in-breast tumor recurrence (IBTR) was 7% in the low- and intermediate-grade stratum and 14% in the high-grade stratum.¹⁴¹ Given the success of salvage therapies and the low risk of cancer-associated death with surgical-only treatment, it is reasonable to inform patients about the available data and have them participate in their locoregional treatment decisions.

At present, a debate has been ongoing regarding the overdiagnosis and subsequent overtreatment of pure DCIS in the modern era, given the technologic improvements in breast screening over the past decade. At the same time, long-term combined follow-up of the NSABP B-17 and B-24 trials shows that an *invasive* recurrence after surgery only for DCIS increases the risk of breast cancer-related death and that radiation reduces this risk of invasive recurrence by more than half (19.4% vs 8.9%).²¹¹ Although the VNPI and ECOG studies cited above provide guidance in terms of identification of a low-risk subgroup of DCIS, they do not hold the same weight as a prospective randomized trial.

In 1998, the RTOG initiated such a trial for selected women with low-/intermediate-grade DCIS \leq 2.5 cm in the highest extent with \geq 3-mm margins, originally designed for 1800 patients.²¹³ Unfortunately, the study was ended in 2006 because of poor accrual; however, in the 636 patients enrolled, radiation reduced the local failure rate from 6.7% to 0.9% at 7 years ($p < 0.001$). The clinical impact of this statistical benefit is up for discussion, and patients must be counseled regarding the trade-offs of toxicity and inconvenience of adjuvant radiation versus the higher risk of a (possibly invasive) recurrence and need for subsequent salvage therapy. An emerging clinical tool to counsel patients and tailor adjuvant recommendations for DCIS may be genomic sequencing. In a tissue analysis of over 300 patients treated on the abovementioned phase II ECOG trial, the 21-gene Oncotype DX assay (see section on adjuvant therapy) was used to score patients according to the risk of invasive recurrence and was found to be predictive, independent of clinical factors.¹⁶⁵ It remains to be seen whether such a strategy provides cost-effective utility over the currently used clinical selection factors.

Radiation has small but real risks.²¹⁴ Given the lack of mortality benefit, it is appropriate to consider reserving external beam radiation for breast conservation when invasive cancer occurs in the setting of DCIS with many high-risk features. Many invasive lesions do not require radiation in the postmenopausal setting,^{215–217} and hence certainly it should not be a surprise that there is no benefit of radiation in the noninvasive setting.

The second major area of research and controversy regarding the management of DCIS concerns the use of hormonal therapy. After completion of the B-17 trial, the NSABP conducted the B-24 trial, which randomized 1802 patients treated with lumpectomy and radiation to receive either tamoxifen or placebo for 5 years.²¹⁸ The eligibility of this trial differed from B-17 in that it included patients with positive surgical margins, which ended up being present in 25% of the study population. In addition, the primary end point of the study was not ipsilateral breast recurrence, but rather the probability of having an ipsilateral recurrence or developing a contralateral breast cancer. Therefore, this trial was designed to investigate the combined therapeutic benefit of tamoxifen against the index DCIS and the chemopreventive benefit of tamoxifen in reducing subsequent independent breast cancers.

The results of the B-24 trial indicated that patients treated with tamoxifen, surgery, and radiation had a 5-year rate of noninvasive or invasive breast cancers of 8.2% compared with 13.4% for those treated only with surgery and radiation.¹⁴² Clearly, a component of this benefit was the chemoprevention effects of tamoxifen. In B-24, the use of tamoxifen resulted in a 41% reduction in the 5-year incidence of contralateral breast cancers. These data are consistent with the reduction in second primary breast

cancers seen in the adjuvant tamoxifen trials and the NSABP P-1 trial, which found that tamoxifen decreased breast cancer development in women at increased risk for breast cancer by 49%.¹¹⁰ In a subsequent retrospective analysis of ER expression from stored tumor material from 628 patients (327 placebo, 301 tamoxifen), it was found that the benefit of tamoxifen was limited to 482 patients (77%) with ER-positive disease. In this cohort, tamoxifen was associated with a significant reduction in both ipsilateral breast recurrence and the development of contralateral breast cancer. There was no apparent benefit of tamoxifen in those with ER-negative tumors, but the sample size precluded, detecting a small benefit.

The UK/ANZ trial provides additional information concerning the interaction of radiation and tamoxifen after lumpectomy in patients with DCIS.²¹⁹ In this study, use of tamoxifen decreased the rate of DCIS recurrence, but not invasive recurrence for patients who did not receive radiation. However, in patients treated with radiation after lumpectomy, tamoxifen provided no benefit in ipsilateral breast events. Unlike the B-24 trial, this study required all patients to have negative surgical margins after lumpectomy and did not include the development of a contralateral breast cancer as an event in their primary outcome measure.

These data suggest that, for patients treated with an adequate lumpectomy that achieves negative surgical margins and subsequently receive radiation, the therapeutic benefits of tamoxifen are likely to be very low in reducing ROR in the ipsilateral breast, but there will be a protective benefit in the contralateral breast. Interestingly, a survey found that 56% of US practitioners routinely recommend tamoxifen for women with DCIS compared with only 22% of European practitioners.¹⁴⁶ Despite the lack of clarity concerning the therapeutic benefits of tamoxifen in DCIS, for patients with ER-positive disease, the addition of tamoxifen is likely to have chemopreventive effects and minimize the risks of subsequent new breast cancers. NSABP B = 35 is a phase III trial that compared the effects of 5-year tamoxifen use to the AI anastrozole in 3104 postmenopausal women diagnosed with DCIS.²²⁰ With a median follow-up of 9 years, there was an absolute difference of 4.3% in breast cancer-free interval favoring anastrozole. This difference was magnified in women under the age of 60, where the absolute difference was 6.7%. Consistent with prior studies, no difference in overall survival (OS) was observed; less uterine cancers and more osteoporotic fractures were observed in patients treated with anastrozole.

Among DCIS patients, breast cancer-specific mortality is associated with age at diagnosis, ethnicity, and DCIS characteristics such as ER status, grade, size (>5 cm), and comedonecrosis. Despite their significance in a multivariable analysis, high-risk characteristics, such as ER-negativity and high grade, often overlap. Only a small minority of patients will have one or more of these high-risk characteristics. For young women (<40 years of age) who present with symptomatic DCIS, about 5% of the population, we should be cognizant that this is a different disease than the average DCIS. In addition, African-American women who are more likely to be at risk for hormone-negative breast cancer and women with hormone-negative or human epidermal growth factor receptor-2 positive (HER2+) breast cancer may be those that should continue to be treated according to the current aggressive standards. In total, these groups probably constitute about 20% of the population of DCIS.

There are uncommon cases where DCIS is associated with a higher risk than has been appreciated. When DCIS is diagnosed before the age of 35 or even 40, some of these lesions do pose an increased risk of breast cancer-specific mortality. DCIS diagnosed before the age of 40 is likely different, as it would present as a symptomatic event (e.g., a mass or bloody nipple discharge), as screening before the age of 40 is rare.

It has always been assumed that DCIS indicates a higher local risk—but the similarity of the ipsilateral

and contralateral invasive breast cancer risk (5.9% and 6.2%) with long-term follow-up²¹¹ suggests that DCIS may behave more as a risk factor like atypia. Oncotype DCIS, a gene expression score obtained on formalin-fixed tissues, demonstrated that low-risk lesions simply excised appear to carry the risk equivalent to a Gail Risk of 2.5¹⁶⁷ A unilateral recurrence of DCIS or contralateral DCIS event has no effect on mortality. However, an invasive cancer does: 18-fold for unilateral and 13-fold for contralateral, suggesting that all risk depends on the probability of the occurrence of an invasive cancer. DCIS may best represent an opportunity to alter the environment of the breast and approach using standard risk reduction or endocrine risk reduction. For premenopausal women, tamoxifen is a good choice for HR+ DCIS. For postmenopausal women, AIs have been shown to have a higher impact on risk reduction. If AIs produce adverse side effects, raloxifene is a good alternative. Tamoxifen should probably not be used for DCIS in postmenopausal women given the risks reported with longer duration hormone therapy in IBIS 2.²⁰³

High-risk lesions (e.g., HER2+, <40, ER–, large size) should be aggressively treated, but the Narod analysis suggests that our current approach of surgical removal and radiation may not suffice for the rare cases that lead to breast cancer mortality and new approaches need to be investigated. In a study characterizing the immune environment of high-risk lesions that are most likely to recur, we found that the tumor microenvironment associated with recurrence was replete with activated macrophages and a paucity of activated T cells.²²¹

Treatment of early-stage breast cancer

Staging and classification

The purposes of staging are to (1) plan a therapeutic strategy that is most appropriate for the patient, (2) allow for more intelligent projection of outcome based on the disease status of the patient, and (3) permit comparison of therapeutic results obtained from different sources by different means. The common staging methods are clinical and pathologic, but newer methods involving biologic assessments are under development and validation. Regardless of the staging method used, it is important to remember that the stage represents the state of disease or biologic potential of a patient's tumor. The benefits of a particular staging method must be judged against its accuracy in performing this task.

The tumor node metastasis (TNM) classification devised by the Union for International Against Cancer (UICC) and accepted by the American Joint Committee on Cancer Staging is of world standard.²²² The TNM is based on the clinical features of tumor (T), the regional lymph nodes (N), and the presence or absence of distant metastases (M) ([Table 7](#)).

Table 7 TNM stage definitions.

Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	Ductal carcinoma in situ
Tis (LCIS)	Lobular carcinoma in situ
Tis	Paget disease of the nipple with no tumor

(Paget's)	
T1	Tumor 2.0 cm or less in highest dimension
T1mic	Microinvasion 0.1 cm or less in highest dimension
T1a	Tumor more than 0.1 but not more than 0.5 cm in highest dimension
T1b	Tumor more than 0.5 cm but not more than 1.0 cm in highest dimension
T1c	Tumor more than 1.0 cm but not more than 2.0 cm in highest dimension
T2	Tumor more than 2.0 cm but not more than 5.0 cm in highest dimension
T3	Tumor more than 5.0 cm in highest dimension
T4	Tumor of any size with direct extension to (1) chest wall or (2) skin, only as described below
T4a	Extension to chest wall, not including only pectoralis muscle adherence/invasion
T4b	Edema (including peau d'orange) and/or ulceration of the skin of the breast and/or satellite skin nodules confined to the same breast
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma
<i>Regional lymph nodes (N)</i>	
NX	Regional lymph nodes cannot be assessed (e.g., previously removed)
N0	No regional lymph node metastasis
N1	Metastasis to movable ipsilateral axillary lymph node(s)
N2	Metastasis in ipsilateral axillary lymph node(s) fixed or matted, or in clinically apparent ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastasis
N3	Metastasis in ipsilateral infraclavicular lymph node(s) with or without axillary lymph node involvement, or in clinically apparent ipsilateral internal mammary lymph node(s) and in the presence of clinically evident axillary lymph node metastasis, or metastasis in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
<i>Pathologic classification (pN)</i>	
pNX	Regional lymph nodes cannot be assessed (previously removed or not removed for pathologic study)
pN0	No regional lymph node metastasis identified histologically; isolated tumor cell (ITC) clusters are no higher than 0.2 mm, single tumor cells, or a cluster of fewer than 200 cells in a single histologic cross section, detected by histology or immunohistochemistry (IHC)
pN0(i-)	No regional lymph node metastases histologically, negative IHC
pN0(i+)	Malignant cells in regional lymph node(s) no higher than 0.2 mm
pN0(mol-)	No regional lymph node metastases histologically, negative molecular findings by RT-PCR
pN0(mol+)	Positive molecular findings by RT-PCR, but no regional LN metastases detected by histology or IHC
pN1	Micrometastases, or metastases in 1–3 axillary lymph nodes, and/or in internal mammary

	nodes with metastases detected by sentinel lymph node biopsy, but not clinically detected
pN1mi	Micrometastases (>0.2 mm and/or more than 200 cells, but none higher than 2.0 mm)
pN1a	Metastases in 1–3 axillary lymph nodes, at least one metastasis higher than 2.0 mm
pN1b	Metastases in internal mammary nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy, but not clinically detected
pN1c	Metastases in 1–3 axillary lymph nodes and in internal mammary nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy, but not clinically detected
pN2	Metastases in 4–9 axillary lymph nodes, or in clinically apparent internal mammary lymph nodes in the absence of axillary lymph node metastasis
pN2a	Metastases in 4–9 axillary lymph nodes; or in clinically detected lymph nodes in the absence of axillary lymph node metastases
pN2b	Metastases in clinically detected internal mammary lymph nodes in the absence of axillary lymph node metastases
pN3	Metastasis in 10 or more axillary lymph nodes; or in infraclavicular lymph nodes; or in clinically apparent ipsilateral internal mammary lymph nodes in the presence of 1 or more positive level 1, II axillary lymph nodes; or in more than 3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy, but not clinically detected; or in ipsilateral supraclavicular lymph nodes
pN3a	Metastases in 10 or more axillary lymph nodes (or at least one tumor deposit higher than 2.0 mm), or metastases to the infraclavicular nodes
pN3b	Metastases in clinically detected ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes, or in more than 3 axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometastases detected by sentinel lymph node biopsy but not clinically detected
pN3c	Metastases in ipsilateral supraclavicular lymph nodes
<i>Distant metastasis (M)</i>	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present
<i>AJCC stage groupings</i>	
Stage 0	Tis, N0, M0
Stage IA	T1, N0, M0
Stage IB	T0, N1mi, M0
	T1, N1mi, M0
Stage IIA	T0, N1, M0
	T1, N1, M0
	T2, N0, M0
Stage IIB	T2, N1, M0

	T3, N0, M0
Stage IIIA	T0, N2, M0
	T1, N2, M0
	T2, N2, M0
	T3, N1, M0
	T3, N2, M0
Stage IIIB	T4, N0, M0
Stage IIIC	T4, N1, M0
	T4, N2, M0
	Any T, N3, M0
Stage IV	Any T, Any N, M1

In general, clinical staging systems underestimate the extent of disease. The inclusion of pathologic information improves staging accuracy and is the basis for most modern clinical trials. In all cases, it is wise to remember that the goal is to define the biologic activity of the tumor. Cox regression statistical models demonstrate that the presence of nodal metastases are the most important factor, and the number of nodes involved can be used to further subset the prognostic groups. It is generally acknowledged that nodal metastases that penetrate the capsule and extend into adjacent perinodal tissue carry a worse prognosis.

In a regression analysis model, tumor size is found to be closely related to axillary lymph node involvement.^{84, 223} Tumor size is not an important discriminant within axillary node groups, except for patients with more than four involved nodes. Thus, size, which can be a function of either time or growth rate, is less useful than axillary node involvement, which is a more specific indicator of biologic aggressiveness. Some patients with large masses may have slow-growing tumors, which have not metastasized. By contrast, patients are also diagnosed with small but aggressive tumors found by screening mammography, in whom distant metastases are already present. These patients may die rapidly despite the initial favorable local clinical features. A biologic classification would identify these women more accurately than does the TNM system; this is the goal of future modifications to current staging.

Surgery

Over the past three decades, revolutionary changes have occurred in the locoregional management of primary breast cancer. As a result, radical and extended radical mastectomy has been relegated to the archives of surgical history. The publication of a series of randomized controlled clinical trials comparing radical mastectomy to less-extensive surgical interventions led a National Institutes of Health (NIH)-sponsored consensus development conference (1990) to recommend that breast preservation is the preferable treatment for women with stages I and II breast cancer, because it provides survival figures equivalent to those of total mastectomy and axillary dissection while, at the same time, preserving the breast.²²⁴

Information from various sources indicates that many patients with breast cancer have disseminated disease by the time a clinical diagnosis is established. This is not surprising, because a breast tumor of 1

cm has already progressed through 30 of the theoretical 40 doublings that result in a tumor of approximately 1 kg, a size that could be lethal to the patient. However, at present, we know that breast cancer is a heterogeneous disease, and that some patients have tumors with a low potential for metastatic spread, and that some, even when small and confined to the breast, have a high risk for metastatic spread.^{86, 89} Molecular profiling is likely to add much to our ability to distinguish these types of tumors and tailor treatment accordingly.

Treatment failed in three of four patients with positive axillary nodal involvement and in almost nine of 10 patients with four or more involved nodes 10 years after radical mastectomy without adjuvant chemotherapy for what were considered clinically “curable” breast cancers. These findings emphasize the systemic nature of some breast cancers and indicate the inadequacy of extensive local and regional surgery when used as sole modalities of treatment in those women at high risk to develop metastases.

Breast-conserving treatments

The goal of breast conservation is to remove the tumor and a rim of normal tissue while preserving the contour and shape of the breast. Tumor left at a margin will increase the ROR. Recht and colleagues, in a study of 533 patients, showed that recurrence risk depends on the amount of tumor left at the margin: grossly positive margins, focally positive margins, and close margins were associated with a recurrence risk of 27%, 14%, and 7%, respectively. Close margins did not materially change the recurrence risk in this study where all women received radiation therapy. The presence of extensive intraductal carcinoma, once thought to be a contraindication to breast conservation, has now been shown not to be associated with higher risk of local recurrence if all of the DCIS has been excised. After breast conservation, 90% of all in-breast recurrences, in the first decade after diagnosis, are in the same quadrant and genetically identical to the primary breast cancer. Long-term follow-up studies of BCS versus mastectomy, however, show that there is an ongoing risk for developing new cancers in the breast after 10 years, but these often occur in other quadrants.

With the advent of lumpectomy, there was a need to adopt a two-stage approach to biopsy and then to definitive surgery. Preoperative core needle biopsies, either clinically or radiologically directed, should be considered standard, so that the surgeon has a definite diagnosis before any surgery takes place and can better plan the operation. A detailed algorithm describing an optimal surgical strategy for the management of primary breast cancer has been described and is presented in [Figure 14](#).

Figure 14 Recommended surgical strategy for management of primary breast cancer.

If an open breast biopsy must be carried out, it should be done as if a lumpectomy were being performed. Attention must be focused toward ensuring that specimen margins are likely to be free of tumor should a malignancy be encountered. In all circumstances where breast conservation is feasible, the operation carried out to establish the definitive diagnosis of a breast lesion becomes the definitive treatment, regardless of the time at which axillary surgery was performed. Most breast cancer operations—biopsy, lumpectomy, axillary dissection, and even mastectomy—can be performed as outpatient procedures with comparable low levels of surgical complications and equal or better personal and social adjustment to the procedure.

Technique and cosmetic considerations

In order to achieve the best cosmetic results, incision should be planned based on the extent of tumor in

the breast, the location of the tumor, and the original shape of the breast. Many options now exist for patients who require breast surgery. The extent of resection of tissue depends on breast size. Plastic surgery techniques can be used to improve symmetry, both with and without cosmetic surgery on the contralateral breast. Once breast tissue is removed, undermining the breast tissue at the level of the fascia provides the opportunity to arrange the closure of the breast tissue in a medial to lateral direction, thereby avoiding the displacement of the nipple either superiorly or inferiorly. Mastopexy or reduction can be performed on the contralateral breast to improve symmetry. If there is a significant degree of ptosis in the breast, a partial mastectomy can be accomplished by performing a breast reduction, thereby combining a cosmetic enhancement with the oncologic procedure of removing the breast tissue ([Figure 15](#)). In a breast reduction procedure, more than half of the breast tissue can be removed; thus, this technique can be used for larger tumors or when there is scattered in situ disease in a single quadrant. [Figure 15a](#) and [b](#) shows a patient with significant discomfort from her large breast, who had always wanted to undergo breast reduction surgery.

Figure 15 Example of a breast reduction technique to accomplish a breast reduction and partial mastectomy in a woman with extremely large, pendulous breasts. (a) Preoperative and (b) postoperative images.

Clear margins were easily obtained by removing over a quadrant of the breast tissue, leaving medial and lateral flaps of at least 1 cm, and achieving a very nice cosmetic result. Preoperative MRI can be very useful for planning the surgical approach. High-resolution scans should be used to maximize the anatomic detail provided by MRI. When breast surgery is required, it provides an opportunity to change the shape and size of the breast, which, if desired by the patient, may make the surgical resection easier and turn an unpleasant procedure to a more tolerable one.

In order to perform a satisfactory lumpectomy, it is essential that the incision be placed directly over the tumor. The use of a circumareolar incision for removing a lesion that is not in proximity to the areola is not optimal, nor is tunneling through breast tissue to remove a lesion that is not beneath the incision. Tumor-free specimen margins are difficult and often impossible to obtain when such an incision is made. Reexcision of the tumor site to obtain free margins through such an incision is equally difficult. If there is concern that a mastectomy may eventually be necessary, the incision should be made with some thought as to what type of incision would be made if a mastectomy were required. In instances where lumpectomy cannot be carried out because of the inability to obtain tumor-free margins, mastectomy incisions can be modified to accommodate the lumpectomy incision. Preoperative diagnosis with needle biopsy can be of significant importance in planning the incision and should be the standard.

Skin removal is not required for lumpectomy. If a prior biopsy was performed, skin encompassing the biopsy scar can be removed when lumpectomy is done, but it is not essential. The quality of cosmesis is inversely related to the amount of skin removed. A special point to be emphasized is that skin edges should not be undermined when the excision is being performed, that is, thin skin flaps are not desirable. Undermining of skin can result in an unfavorable cosmetic result, and hence removal of skin may be the better cosmetic option in some cases.

Tumor removal and examination of specimen margins

The tumor is removed so that it is completely enveloped in normal fat and/or breast tissue. This procedure does not necessitate the removal of a predefined amount of normal tissue around the lesion, just the amount adequate to achieve specimen margins grossly free of tumor. Orienting the specimen is

particularly important. Adopting a standard procedure to orient and ink specimens in your institution will improve communication among pathologists, surgeons, and radiation oncologists. A typical standard is to use a long stitch for the lateral margin and short stitch for the superior margin, secured to a piece of Telfa posteriorly to improve orientation. This is particularly beneficial for specimens requiring specimen radiography, by preserving the shape and improving the chance to identify and further resect a specific margin that may be close to the radiographic lesion ([Figure 16](#)).

Figure 16 (a) Image of gross specimen. (b) Radiograph of gross specimen showing calcifications.

If a prior excisional biopsy was performed and margins were not evaluated, it is obligatory that, at the time of node dissection, a reresection be performed to ensure tumor-free margins.

The specimen is immediately delivered to the pathologist, who must confirm or establish the diagnosis of cancer (if a needle biopsy was not done), aid the surgeon in deciding intraoperatively whether the specimen margins are grossly free of tumor, and take an aliquot of tumor for any special studies.

The pathologist receives the specimen and carefully orients it by means of the suture tags that the surgeon has placed. After measurement, the uncut specimen is inspected for gross margin involvement. If there is evidence that the tumor has been transected, the surgeon is immediately apprised of the precise location of the margin involvement so that additional tissue can be removed from that area while the pathologist is completing inspection of the specimen. The pathologist then coats the entire surface of the specimen with India ink, blots it dry, and then bisects the tumor and specimen transversely. Some pathologists use multiple colors (e.g., for the posterior, anterior superior half, and the anterior inferior half) to improve the ability to pinpoint the location of an involved margin. If tumor is found on gross examination to be close to the resected tissue margin, the pathologist may do a frozen section to determine margin involvement. Additional breast tissue can be removed to obtain a new true margin any time that margin involvement is considered uncertain. A multiplicity of frozen sections should not be carried out to determine whether the margins are tumor free. Margin assessment is better done with permanent sections in a detailed manner.

If the margin is later found to be involved microscopically following re-resection and no evidence of transaction of gross tumor is found, breast removal may not be recommended. In such circumstances, when it is clear that gross tumor has not been transected, it is likely that radiation and systemic therapy will provide adequate locoregional tumor control and that the majority of patients will remain free of local recurrence. An update on their series of reports on margin control from the Joint Center in Boston demonstrates that recurrence rates are the same for focally positive margins as for true negative ones.²²⁵ Similarly, when a breast tumor recurrence occurs following lumpectomy, it is likely that tumor control will be obtained by repeat lumpectomy if such tumors are small and can be removed with tumor-free specimen margins.

Pathologic criteria used for making a decision about whether the tumor involves specimen margins can vary. Many pathologists infer margin involvement by such subjective designations as tumor “very close” to margin. A review of cases showed that there was residual cancer in only 12% of total mastectomy specimens removed because the margin was close. Thus, it is most appropriate to regard lines of resection as involved only when cancer is transected.

For mammographically detected carcinomas requiring radiographic guidance, one or more wires are placed in the breast to either bracket calcifications or pinpoint the center of the lesion or calcifications. Specimen mammography is required once the lesion is removed to confirm the presence of the lesion as well as the location of the mammographic abnormality relative to the margins. Whenever possible,

nonpalpable lesions that can be identified using ultrasound should be localized using that technique, because these procedures are better tolerated by patients and do not use compression required for mammographic localization. Some surgeons are being trained to use ultrasound as it can better improve the targeted excision of solid lesions in the operating room. This reduces the need and time for communication between the operating room and radiology suite. However, it requires that surgeons be specially trained, very skilled in the technique, and able to determine which lesions they can accurately identify to avoid missing the lesion intraoperatively.

Mastectomy

Patients who undergo mastectomy can opt reconstruction or not. Cosmetic considerations are important, regardless of a woman choosing reconstruction. It is important to try to leave a flat surface on the chest wall so that wearing a prosthesis is possible and comfortable. Avoiding skin folds in the axillary line can be accomplished through fishtail incisions at the axillary portion of the axilla or contouring the incisions in the axilla using plastic surgery techniques to avoid excess skin.

Immediate reconstruction has been shown to be safe,²²⁶ even in the setting of locally advanced disease ([Figure 17](#)), when appropriate multimodal therapy is used. Therefore, any woman considering mastectomy should also be told about options for reconstruction, both immediate and delayed. Complications after reconstruction are common and should be expected by both the surgeon and patient. Expectations about outcomes should be appropriately set, and women should be prepared for the possibility of multiple surgical procedures to optimize the reconstructive outcome.

Figure 17 Preoperative and postoperative images of a skin-sparing mastectomy with immediate reconstruction with TRAM flap delayed nipple reconstruction in a 37-year-old women (a, b) and 65-year-old woman (c, d). Postoperative images at 12 weeks (b) and 8 weeks (d) show appearance 5 days after nipple reconstruction.

If the decision to use chemotherapy does not require additional tissue or definitive resection of the primary tumor, and if chemotherapy is going to be part of multimodal treatment for a given woman, and if she is strongly considering mastectomy, based on the extent of disease or patient preference, neoadjuvant chemotherapy should be recommended (see systemic adjuvant therapy: neoadjuvant therapy). Sequencing the surgery and reconstruction after systemic therapy minimizes the risk that a complication would delay adjuvant therapy and gives women much more time to consider surgical options and adjust to the diagnosis. Neoadjuvant systemic therapy increases breast conservation rates. In a recent study of carboplatin and bevacizumab added to anthracycline- and taxane-based chemotherapy, treatment before surgery led to a conversion rate of 42% from ineligible to eligible for breast conservation therapy.²²⁷ Breast conservation was successful in 93% of those who chose it. However, about 30% of women who were eligible for breast conservation chose mastectomy. Neoadjuvant chemotherapy allows many patients with large breast tumors to have clinically meaningful tumor reduction, indicating response that would affect ability to undergo breast conservation. However, response varies by imaging and tumor subtypes. In the ISPY-1 trial, concordance between tumor size on MRI and surgical pathology was higher in well-defined tumors, particularly those with a triple-negative subtype, and was lower in HR+ diffuse tumors.²²⁸

For women who are ambivalent about reconstruction, delayed reconstruction may be optimal. However, cosmetic outcomes are better when reconstruction is performed immediately, and scars can be minimized

and tailored to the type of reconstruction that has been chosen. It is difficult to make reconstruction decisions within days, and women who are deciding should be reassured that an extra week or two to study their options and make good decisions would not affect their survival outcome. They will likely live for decades with the consequence of this decision, and hence the investment of a few weeks, if necessary, to ensure that they are comfortable with their decision is important.

Two basic types of reconstruction can be offered: implant reconstruction and autologous tissue reconstruction. Implants can be placed as expanders or permanent implants. Expanders are the most commonly used form of reconstruction. They are placed under the pectoralis muscle and the pocket is gradually expanded until it is larger than the desired breast size. Then the expander is exchanged for a permanent implant and the breast shape is contoured. The entire process can take 6–8 weeks. An alternative technique, used in conjunction with skin-sparing mastectomy (SSM), is the placement of permanent implants. The majority of implants used for reconstruction are saline. Although silicone implants were pulled off the market because of a concern that they increased the risk for developing autoimmune disease, several large studies have failed to show a definitive connection; as a result, silicone implants are again being used.¹²⁸ There are specific instances where silicone products may be preferred (e.g., if a permanent implant is placed immediately, but the ability to expand the implant is desired). Autologous tissue flaps include TRAM, DIEP, or latissimus dorsi flaps ([Figures 18](#) and [19](#)).

Figure 18 Examples of total skin-sparing technique combined with various reconstruction techniques. (a) Placement of immediate implant using mastopexy incision and contralateral mastopexy. Mastectomy is on left; images are 3 weeks postoperative. (b) Bilateral mastectomy with placement of immediate implants in a woman at high risk after recurrence subsequent to prior lumpectomy for subcentimeter DCIS. Preoperative MRI demonstrated single small focus of lateral recurrence. (c) Mastectomy on right followed by immediate reconstruction using TRAM flap.

Decision about the type of reconstruction depends largely on patient preference, although treatment considerations can also play an important role. If radiation is anticipated, complications are less if autologous tissue is used. There is controversy about whether TRAM flaps can tolerate radiation, and several published reports suggest that radiation causes significant deleterious effects on the flap. It may be that free flaps, requiring an anastomosis, tolerate radiation as well as pedicle flaps, or more likely, institutions that use higher doses of radiation (up to 6500 Gy including the boost) may experience more complications. An institution from Dundee, Scotland, that limits radiation to the chest wall to 4500–5000 Gy recently reported excellent results in a large series of patients.

A new technique for mastectomy is the total skin sparing mastectomy (TSSM), which has become a standard procedure in many centers.^{229, 230} This technique removes all of the breast tissue, including the tissue of the areola and nipple, but preserves the overlying dermis. A report of 171 cases shows that over time, the technique has become reliable and that various incisions can be used to achieve excellent results. This technique results in 99% preservation of nipple and areola skin. Although follow-up is limited, early results show that the local recurrence rate is extremely low (<2%), and we anticipate that the total skin sparing technique will not affect recurrence risk. The key is the complete removal of the nipple duct tissue (Figures 18 and 19). This technique can be combined with any reconstructive technique except the use of permanent implants. The immediate expansion of the skin significantly increases the risk of skin necrosis. This exciting development in technique, while challenging, offers safety associated with the removal of all of the breast tissue combined with superior cosmetic results. The opportunity to use TSSM is particularly important when considering prophylactic mastectomy for women at highest risk and may enable them to feel comfortable about the cosmetic result to undergo the surgery.

Axillary dissection

Axillary dissection is not used with the intent of enhancing curability, because regional lymph nodes are regarded as indicators of distant metastatic disease rather than instigators of such tumor.

The incision for axillary dissection should be separate from that used for the removal of tumor in the breast. A longitudinal incision placed along the posterolateral margin of the pectoralis major muscle or a transverse incision just below the axillary hairline may be used. At present, an axillary dissection includes nodes from axillary levels I and II. Anatomic delineation of this dissection is the latissimus dorsi muscle laterally, the axillary vein superiorly, and the medial border of the pectoralis minor muscle

medially. Removal of the pectoralis minor muscle is not required. The nerves to the serratus anterior and latissimus dorsi muscles should be identified and preserved. The axillary vein should be visualized and followed under the pectoralis minor muscle to the medial border. These are the minimal limits for the dissection. The average number of nodes removed is about 15. Although the lumpectomy site in the breast is not drained, a suction drain is present in the axilla for several postoperative days.

The management of the axilla has changed significantly since the introduction of sentinel node dissection. This procedure limits considerably the extent of surgical procedure in the axilla and, for majority of patients with negative axillary lymph nodes, precludes the need for formal axillary dissection while providing similar (and in some cases superior) diagnostic and prognostic information. The identification of a single (or a few) sentinel node(s) also permits the pathologist to perform a more detailed assessment of multilevel sections of the sentinel node. The detection of micrometastases is significantly increased by combining light microscopy, IHC, and even more sensitive molecular techniques. However, the prognostic significance of identifying isolated metastatic cells in histologically negative lymph nodes by more sensitive techniques is still undetermined; therefore, at this time, it is not considered sufficient to constitute stage 2 disease. Sentinel node biopsy and assessment are under extensive evaluation by large cooperative research groups, including the NSABP and ACOSOG. ACOSOG Z-010 trial required clinicians not to use immunohistochemical analysis in their hospital, so that all nodes could be centrally stained and the results blinded to assess the prognostic significance of microscopic metastases to the lymph nodes. NSABP B-32 randomized 5611 women with negative sentinel lymph node (SLN) to either SLN biopsy only or SLN biopsy followed by ALND. Women who were found to have positive SLN also proceeded to full ALND. The strength of the study is that it is the largest randomized trial of SLND and that it is representative of a cross section of surgeons across the country with 232 surgeons participating across 80 centers. Although longer-term outcomes, regional control, and survival are not yet known, the technical results are. On average, three SLNs were removed per patient; the SLN identification rate was 97.2% and improved with surgeon experience, and 26% of patients had a positive sentinel node. In 61.5% of patients with a positive sentinel node, the additional nodes were negative (38.5% had additional positive nodes). The false-negative rate (axillary node involvement when the SLN was negative) was 9.7%, which did not change with experience, but was significantly affected by the type of biopsy used for diagnosis; the false-negative rates were 8.0%, 14.3%, and 15.2% for FNA/core, incisional biopsy, and excisional biopsy, respectively. The number of SLNs identified also affected SLN false-negative rates. The confidence in a negative result is higher if more than one SLN is identified, or if the prior probability of having a negative node is high, but may be less for the woman with a higher prior probability of having a positive node.

Sentinel lymph node dissection

The use of radiotracer material or visible blue dyes to locate and remove the SLN (the node that drains the tumor site most directly) is becoming a standard technique for evaluating the axilla. This technique was initially described for melanoma and then studied in breast cancer patients and has a high degree of accuracy once the operator has become proficient with the technique. The ability to identify a sentinel node ranges from 85% to 97%. The ACOSOG, in selecting surgeons to participate in a sentinel node registry trial as well as a trial to determine if full node dissection after SLN removal was beneficial, required proof that the sentinel node could be identified in 90% of cases and that the false-negative rate for SLN was less than 5%. Lymphedema rates after SLND are reported to be <7% compared with 17–25% with ALND.²³¹ SLND has been shown to exhibit similar performance after neoadjuvant chemotherapy²³²; although the identification of the SLN may be somewhat lower, the false-negative rate is very similar. Although still somewhat controversial, the potential benefits of using SLND after

neoadjuvant therapy are that the patient is spared an additional operation before starting chemotherapy—they may avoid an axillary dissection as tumor in the nodes may disappear with chemotherapy—and that the information about the presence of tumor in the nodes after chemotherapy is beneficial in predicting local recurrence rates and determining the need for radiation therapy.¹⁵¹ Intraoperative frozen section has not been as accurate in detecting nodal metastases as is specific analysis done later in the laboratory. Imprint cytology has recently been reported to have a very low false-negative rate, but the sensitivity is not as high as frozen section. In NSABP B-32, cytology was found to indeed have a low false-positive rate, 0.4%, but a sensitivity of 61.5%. Intraoperative detection of LN metastases is beneficial as it enables the surgeon to proceed to a full axillary dissection at the time of SLND, thereby avoiding a second procedure. Clinicians should use the technique in their own institution that yields the lowest false-positive rate to avoid further surgery.

Radioisotope injection with a gamma isotope-labeled colloid and scanning with a handheld probe is replacing blue dye injection, which provides a visible clue of blue lymphatics, leading to the blue sentinel node. Although some authors strongly favor one or the other of these, the majority of reports indicate that the combination of both results in the highest level of successful identification of the sentinel node. In NSABP B-32, the radioisotope had a higher SLN identification than blue dye. There is a small but real risk (<1%) of anaphylaxis with Lymphazurin blue dye. The risk of severe anaphylaxis was shown to be 0.2% in NSABP B-32. Anesthesiologists should be aware of this possibility if blue dye is used.

Need for axillary dissection

It is frequently asked whether all lumpectomy patients require axillary staging. If the need for systemic therapy, as well as the type of systemic therapy, can be determined by patient and tumor characteristics other than the status of the axillary nodes, then the need for axillary staging becomes less clear. Furthermore, if all node-negative and node-positive patients were to be given the same systemic adjuvant therapy, as is the case in trials of preoperative chemotherapy, there would seem to be no reason to know the nodal status, except for predicting patient outcome. The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) overview suggests that adjuvant chemotherapy benefits women with node-negative and node-positive cancers and that the proportionate reduction in risk of treatment failure is the same for both groups, and many oncologists offer adjuvant chemotherapy to all women except those that have such a low proportionate reduction as to be of little real gain. However, modified decision-making tools such as [adjuvantonline.com](#), a well-validated tool for predicting absolute benefit of chemotherapy,²³³ or molecular tools that provide a recurrence score (RS) such as the Oncotype DX²³⁴ have increased the ability of oncologists to refine recommendations for systemic therapy. The molecular characteristics of the tumor may be more important than stage in determining whether to perform adjuvant therapy and which type to use. Two molecular tests used in the United States (trial assigning individualized options for treatment (TAILORx) trial) and Europe microarray in node-negative disease may avoid chemotherapy (MINDACT) are in clinical trials to better answer these questions. As these data mature, the roles of sentinel node dissection and axillary dissection will need to be clarified. In the molecular age, there are still situations where removal of all possible locoregional tumor may be very important: for those women in whom surgical excision is the primary treatment, for example, in a setting with a low predicted ROR, or for women who have undergone neoadjuvant chemotherapy and have residual disease and possibly resistant to best available therapies. In the setting of complete pathologic response after neoadjuvant therapy, the probability of performing surgery may be low, and the increasing use of sentinel node dissection after neoadjuvant chemotherapy in women with clinically N0 disease, regardless of nodal status pretreatment, is an example of modifying the extent of surgical treatment to response to therapy. The need for axillary dissection may also be questioned, particularly in elderly women with ER-positive

disease who are planning to undergo adjuvant hormonal therapy. In this setting, the status of the axillary nodes would not likely alter the decision about administration of adjuvant therapy. In almost all cases with clinically negative axilla, however, sentinel node dissection is a standard part of staging and surgical management and can be successfully performed in most women with very low morbidity. In the setting of positive sentinel nodes, level I and II axillary dissections are considered standard management. Although it is generally accepted that axillary dissection provides optimal local control of the axilla, a randomized trial comparing total mastectomy with and without axillary dissection suggested that not all patients (~50%) with positive axillary lymph nodes would develop an axillary recurrence in the absence of an axillary dissection.

The multicenter ACOSOG Z011 trial randomized women having breast-conserving surgery with a positive sentinel node to either full axillary dissection or not.²³⁵ The target accrual was 1900; 991 were actually enrolled. There was no difference between the two arms between 5-year axillary or in-breast recurrence, and most importantly, there was no difference in either disease-free or OS. These important results have already had a significant impact on standard management of the axilla, sparing many women from the potential long-term toxicities of a full axillary dissection. Management of the axilla in women undergoing mastectomy with a positive sentinel node still mandates further axillary sampling unless radiation is planned for the primary tumor.

Since the routine use of mammographic screening, the vast majority of patients diagnosed with invasive breast cancer have T1 or T2 primary tumors that are amenable to a breast-conserving locoregional treatment. Breast conservation therapy has currently been firmly established as an appropriate standard of care for women with early-stage breast disease. This therapy consists of three important components: removal of the tumor with achievement of negative margins (often called a lumpectomy, tylectomy, or a segmental mastectomy), surgical assessment of axillary lymph nodes with either a sentinel lymph node surgery and/or a level I/II ALND, and breast irradiation. Most women treated with modern breast conservation approaches achieve excellent outcomes. When combined with systemic therapy, the annual local recurrence rate after appropriate breast conservation treatments has been reported to be less than 0.5% for women with favorable disease.^{236, 237} Furthermore, the complication rates of breast conservation therapy are very low and continue to improve with advances in surgical and radiotherapy techniques.

Despite these facts, breast conservation remains underutilized in the United States. In a recent multinational randomized trial comparing two hormonal therapies for women with early stage disease, the rate of breast conservation in the United States was only 49%.²³⁸ By contrast, the rate of breast conservation in the United Kingdom was 58%, and even higher rates were observed in Sweden, Germany, or Australia/New Zealand. Previous data had also indicated that the use of breast conservation varies within regions of the United States, with Southern and Midwestern women less likely to be treated with breast conservation than those from either the East or West Coast.²³⁹ The reasons for the underuse of breast conservation are likely multifactorial. Unfortunately, some women undergo mastectomy based on a misperception that mastectomy is likely to achieve a superior outcome. It is critical, therefore, that breast cancer providers understand the data concerning breast conservation, so that patients with newly diagnosed disease can be given the option of this treatment if appropriate.

Breast conservation therapy versus mastectomy

Breast conservation has been studied as an alternative locoregional treatment to mastectomy for over 40 years. After initial successful results were obtained in single institutions, a number of phase III clinical trials were initiated, which directly compared the outcome of patients treated with breast conservation

versus those of patients treated with mastectomy.^{240–242} The NSABP B-06 study was one of the most important trials.²³⁴ This trial began in 1976 and enrolled 1843 women. Patients with T1 or T2, N0, or N1, M0 breast tumors of 4 cm or less were randomly assigned to one of the following three treatment groups: (1) modified radical mastectomy, (2) lumpectomy and axillary dissection, and (3) lumpectomy, axillary dissection, followed by radiation therapy. With 20 years of follow-up, this trial demonstrated that breast conservation therapy provides survival equivalent to mastectomy.

Contraindications for breast conservation therapy

Selected patients with ESBC are not suitable for breast conservation therapy, because the primary tumor cannot be successfully removed with a lumpectomy. For example, patients presenting with diffuse suspicious calcifications that cannot be resected with a lumpectomy that leaves an acceptable aesthetic result are best treated with a mastectomy. Similarly, patients in whom repeated attempts of BCS did not achieve negative surgical margins are best managed with a mastectomy. Increasingly, however, women who present with stage II and III cancers can be treated with neoadjuvant chemotherapy or hormone therapy, and over 50% have sufficient shrinkage of the primary tumor to enable breast conservation. A second reason why some patients are not candidates for breast conservation is that they are at high risk for radiation complications. Specific examples of such patients include those previously treated with radiation, women who are pregnant, and patients with certain connective tissue diseases. For women early in the course of their pregnancy, internal radiation scatter from irradiation of the intact breast can reach lethal and teratogenic dose levels.²⁴³ Certain collagen vascular diseases, such as systemic sclerosis, polymyositis, dermatomyositis, lupus erythematosus, and mixed-connective tissue disorders have been associated with significant risks, including breast fibrosis and pain, chest wall necrosis, and brachial plexopathy.²⁴⁴

Radiation therapy

For more than 100 years, radiation has had a vital function in the effective treatment of breast cancer. From its crude and early history as the first adjuvant therapy to radical surgery to its role as the vehicle that drove the breast conservation revolution of the 1970s, radiation oncologists and surgeons formed the first “multidisciplinary” cancer teams. Radiation therapy is a component of care for the overwhelming majority of breast cancer patients at some point during the course of their disease. Therefore, it is crucial that radiation oncologists become involved at the time of diagnosis to collaborate with medical oncologists and breast surgeons in the prospective design of each patient's care path. At present, radiation therapy has been in the midst of a technological renaissance, creating challenges and controversies in the balance of evidence-based medicine and personalized, modified therapy.

Role of radiation in BCS for early-stage invasive disease

Defining the role of radiation in breast conservation therapy has been the focus of numerous randomized prospective clinical trials conducted over the past 30 years.^{241, 242} In conclusion, these trials have demonstrated that radiation after breast-conserving surgery significantly improves local control, minimizes the risk of subsequent distant metastases, and decreases breast cancer death rates.

Benefits of adjuvant radiation

The NSABP B-06 trial was one of the first randomized studies to evaluate the benefit of radiation after lumpectomy. This trial showed that for patients treated with breast conserving surgery, whole-breast

radiation therapy (WBRT) offered significant clinical benefits. After 20 years, the recurrence rates in the breast were 40% and 14% for those treated with lumpectomy only and lumpectomy plus WBRT, respectively. The almost two-thirds reduction in the ROR was very similar to reductions observed in other similarly designed trials.²³⁴ The data from NSABP B-06 and the other prospective clinical trials assessing the role of radiation for patients with invasive disease treated with breast conservation have been analyzed by the EBCTCG. In this important meta-analysis, the individual patient data from 7300 women were studied. Breast irradiation after lumpectomy reduced the 10-year rate of in-breast recurrence from 29% to 10% for patients with negative lymph nodes and from 47% to 13% for patients with positive lymph nodes. More importantly, radiation use significantly decreased the 15-year risk of dying from breast cancer. For patients with negative lymph nodes, breast cancer mortality decreased from 31% to 26% and for patients with positive lymph nodes, it decreased from 55% to 48%.²⁴²

Use of a “boost” after WBRT

A strategy to reduce local recurrence after WBRT even further is dose escalation via an additional boost of radiation to the tissue at the highest risk in the postoperative tumor bed. The first randomized trial investigating the impact of a 1000-cGy boost following 5000-cGy WBRT was performed in Lyons, France. The use of a boost led to a small but statistically significant reduction in the rates of local recurrence at 5 years (3.6% vs 4.5%, $p = 0.04$).²⁴⁵ Subsequently, the EORTC completed a much larger trial that randomized over 5000 patients to 5000-cGy WBRT with or without an additional tumor bed boost of 1600 cGy. This trial again demonstrated a reduced breast recurrence rate in patients treated with a boost (10.2% vs 6.2% at 10 years; $p < 0.001$).²⁴⁶ In a subset analysis, this benefit was noted across all ages but most pronounced in younger women.

Omission of radiation for selected patients

Although the data are conclusive that radiation is beneficial for the majority of patients treated with breast-conserving surgery, there remains an interest as to whether subsets of patients may do well with surgery only. Therefore, some trials have selected patients with more favorable disease characteristics to investigate the omission of radiation. An early trial conducted in Milan, Italy, randomized patients who underwent quadrantectomy and axillary clearance for tumors ≤ 2.5 cm to undergo WBRT versus no further therapy. The 10-year results from this trial showed that radiation reduced the breast recurrence rate from 24% to 6% ($p < 0.001$).²⁴⁷ For patients with even smaller primary tumors (stage I), separate randomized trials in Sweden and Finland showed that radiation reduced the 5-year breast recurrence rate from 18% to 2% ($p < 0.0001$) and from 14.1% to 6.2% ($p = 0.029$), respectively.^{248, 249}

Data from early trials have also indicated that the use of systemic treatment (either chemotherapy or tamoxifen) does not require breast radiation. In the aforementioned NSABP B-06 trial, chemotherapy was used in patients with lymph node-positive disease, and the 20-year breast recurrence rate for these patients was 44% when no radiation was used versus 9% when radiation was used.²³⁴ A trial from Scotland that required systemic treatment for all of the 589 enrolled patients yielded a 6-year breast recurrence rate of 6% in the surgery, systemic therapy, and radiation arm versus 25% in patients randomized to forego radiation.²⁵⁰

Four more modern trials conducted among very low-risk subgroups of patients diagnosed in the mammographic era have further refined the selection criteria.^{215, 216, 251, 252} In all four of these studies, radiation achieved a statistically significant reduction in breast recurrence rate, although the absolute benefit for some subcategories of patients treated with surgery only was relatively small. The NSABP B-

21 trial enrolled only patients with lymph node-negative breast cancers whose primary tumors measured ≤ 1.0 cm. All patients underwent lumpectomy and ALND and were randomized to tamoxifen only, radiation only, or tamoxifen plus radiation.²⁴⁹ A contemporary Canadian trial had very similar eligibility criteria and results. Finally, two trials recently tested the omission of radiation for older women with early stage, biologically favorable disease. Long-term results of the CALGB study showed that for patients over the age of 70, the 10-year recurrence rates were 10% and 2% in the tamoxifen only and tamoxifen plus radiation arms, respectively.²¹⁵ Furthermore, there were no differences in the rates of salvage mastectomy, distant metastases, or OS between the two groups. The similarly structured Scottish PRIME II trial enrolled over 1300 patients with early-stage disease of age ≥ 65 and found 5-year local recurrence rates of 4% and 1% for those on tamoxifen only and tamoxifen plus radiation ($p = 0.0002$), respectively.²¹⁶

In conclusion, almost all of the clinical studies to date have indicated that breast radiation reduces local recurrences following BCS and therefore should be considered a standard component of treatment for all women with early-stage invasive disease. Thus far, most attempts to define favorable subsets of ESBC patients who may not require radiation have been unsuccessful with the exception of older women with biologically favorable disease planning to undergo hormonal adjuvant therapy. In this cohort, the ROR is low, the overall benefit is small, and hence the addition of radiation should be based on the patients' life expectancy and personal preferences.

Radiation as a substitute for radical axillary surgery in early-stage node-positive patients

In the era of mammographic diagnosis, ubiquitous systemic therapy, and SLNB, there has been an enormous interest in reducing the use of axillary dissection for not only node-negative patients but also low-volume node-positive patients. The interest in eliminating radical axillary surgery is particularly important for patients in whom radiation is planned, as the risk of lymphedema and its impact on quality of life (QOL) are higher when these modalities are combined. The previously referenced ACOSOG Z0011 trial showed that for patients undergoing BCS with WBRT for early-stage disease with one to two positive nodes, the addition of axillary dissection to SLNB did not improve disease-free or OS at 5 years.²³³ The EORTC 10981-22023 (AMAROS) analyzed a similar patient population, including patients with more than two positive nodes (5%) and patients who had undergone mastectomy (18%).²⁵³ Over 1400 patients with a positive SNLB were randomized to receive either axillary dissection or axillary irradiation, and at 6 years there was no statistical difference in axillary recurrence. Although the trial was underpowered because of the low overall number of events, the rate of upper extremity lymphedema was significantly higher for patients who underwent dissection. These two trials taken together have had a broad, practice-changing effect on the locoregional treatment of early-stage node-positive patients, directing therapy away from radical surgery. Given that axillary recurrences are rare events, typically occurring within 2 years,^{234, 254} longer-term follow-up of these two trials is unlikely to alter their significant impact on clinical practice.

Role of radiation after mastectomy for locally advanced disease

A strong rationale exists for combining the beneficial effects of radiation and mastectomy for selected women with locally advanced breast cancer, in whom areas of subclinical disease extend beyond the operative field. The initial studies that investigated radiation after mastectomy began in the 1950s and represented some of the first controlled clinical trials in oncology history. After five decades of study, there still remain controversies over the selection criteria and value of postmastectomy radiation therapy

(PMRT), mainly due to two factors: the late-term morbidity of early radiation techniques and the addition of systemic therapy as a routine component of care. In general, however, as PMRT techniques have improved and systemic therapies decrease the competing risk of distant metastases, improvements in locoregional control gained by radiation have had a consequential positive effect on survival.

Modern data supporting PMRT

There have been several meta-analyses conducted to quantify the value and risk of PMRT, the most comprehensive and important being the work of the EBCTCG. This group was able to obtain the raw data from every randomized prospective trial of PMRT, including nearly 10,000 randomized to radiation versus observation following mastectomy and axillary clearance. For node-positive patients, PMRT reduced the risk of locoregional recurrence threefold (29–8%), which led to a 5% absolute decrease in breast cancer mortality (60% vs 55%) at 15 years. For patients with node-negative disease, the locoregional benefit was smaller (8–3%) and not associated with a difference in survival.²⁴² Overall, data from this meta-analysis suggested that a long-term survival benefit was only manifested in the trials where there was a $\geq 10\%$ improvement in 5-year locoregional control.²⁴² As such, there is a clear indication that the role of PMRT in eradication of persistent postsurgical microscopic disease is to prevent the development of a subsequent local source for distant metastasis, which eventually can lead to death.

The three PMRT randomized trials that most heavily influenced the EBCTCG meta-analysis all involved relatively modern radiation techniques and the judicious use of systemic therapy. The Danish Breast Cancer Cooperative Group (DBCCG) 82b trial, perhaps the most important study, randomized 1708 premenopausal women with stage II or III breast cancer to mastectomy and CMF-based chemotherapy with or without PMRT.²⁵⁵ The majority of patients entered in this trial had one to three positive lymph nodes; however, the median number of axillary lymph nodes resected was only seven, rather than a formal level I/II axillary dissection. Patients randomized to PMRT had an improved OS rate at 10 years (54% vs 45%, $p < 0.001$), likely a consequence of decreased locoregional recurrence (9% vs 32%, $p < 0.001$). Simultaneously, investigators in Vancouver, British Columbia, conducted a similar, albeit smaller trial in which 318 premenopausal women with lymph node-positive disease were randomized to receive mastectomy and CMF with or without PMRT.²⁵⁶ The results were nearly identical with PMRT providing a 10% absolute benefit in long-term OS (20-year rates: 47% vs 37%, $p = 0.03$) and an even higher benefit in locoregional control (87% vs 61%; $p < 0.0001$).

Finally, the DBCCG 82c randomized 1300 postmenopausal patients to mastectomy and tamoxifen with or without PMRT.²⁵⁷ The stage of disease and extent of axillary surgery were also very similar to the 82b trial. The magnitude of benefits in OS and local control was similar to the two previous studies in terms of 10-year OS (45% vs 36%, $p = 0.03$) and locoregional control (92% vs 65%; $p < 0.001$). At almost 20 years of follow-up, updates of the DBCCG 82b and 82c combined data continue benefits of PMRT for both locoregional control (86% vs 51%, $p < 0.0001$) and distant metastasis-free survival (47% vs 36%, $p < 0.0001$).²⁵⁸

Current indications for postmastectomy radiation

The American Society of Clinical Oncology (ASCO) consensus guidelines for PMRT, published almost 15 years ago, recommended treatment for patients with stage III disease (defined by T3 with involved lymph nodes, T4 primaries, or four or more involved lymph nodes)²⁵⁹ after mastectomy, standard axillary dissection, and chemotherapy due to the magnitude of survival benefit for these locally advanced patients.

However, the landmark publication left the role of PMRT for patients with stage II disease with one to three positive nodes unsettled and hence controversial. The reason for this is that although most of the patients in the Danish and British Columbia trials had one to three positive lymph nodes, the benefit of PMRT for this subset has been inquired by surgeons who indicate the inadequate clearance of the axilla in the standard arm of the larger Danish trial. Indeed, the long-term locoregional recurrence rate for these patients in the Danish trials, who were treated without PMRT, was 41% versus 21% in similar patients who underwent a more complete axillary clearance in the British Columbia trial.^{256, 260} It is important to note that inadequate axillary surgery may have led to an underestimation of the true number of positive lymph nodes and that many of these patients would likely have had four or more lymph nodes who already underwent more extensive surgery.

The findings and critiques of the Danish and Canadian Studies heavily influenced the ASCO consensus guidelines for PMRT (published in 2001), which in turn have guided clinical practice patterns for over a decade. More recently, a meta-analysis by the EBCTCG published in 2014 has sought to clarify the utility of PMRT for the most controversial patients, those with small primary tumors and one to three positive nodes.²⁵⁸ Data from 22 randomized trials including over 3700 patients treated with PMRT after axillary dissection to at least level II were analyzed for differences in 10-year locoregional recurrence and 20-year survival. For patients with one to three positive nodes in whom systemic therapy was followed ($n = 1133$), PMRT significantly reduced locoregional recurrence by more than three-quarters (20% vs 4%; $p < 0.0001$) and improved breast cancer-specific mortality by approximately 8% (50% vs 42%; $p = 0.01$). Interestingly, the magnitude of benefit in this controversial subgroup was nearly the same as that for patients with four or more positive nodes for both locoregional recurrence (32% vs 13%; $p < 0.00001$) and breast cancer mortality (80% vs 70%; $p = 0.04$).

Therefore, there should remain no doubt regarding the utility of PMRT for all patients with positive lymph nodes and a >10-year life expectancy. In addition to the number of positive lymph nodes, other adverse pathologic features such as the volume of nodal disease, the presence of extra nodal extension, and the percentage of nodes involved should be used to guide clinical decision making. In conclusion, the EBCTCG update,²⁶¹ together with the aforementioned AMAROS trial,²⁵³ indicated a trend of expanding the application of PMRT at a time when the role of axillary dissection is diminishing. It is likely that a more complete understanding of tumor biology and genomic profiling will play a role in further guiding clinical practice in the not-to0-distant future.

Integrating PMRT with breast reconstruction

Two trends on a collision course over the last decade have been the expanding indications for PMRT, particularly in younger patients, versus the increasing use of elective mastectomy combined with reconstruction in this population.²⁶² While breast reconstruction, both implant- and tissue flap-based, poses certain challenges for the treating radiation oncologist, it should never be considered a contraindication to PMRT. While plastic surgery practice patterns are highly variable and guided more by experience than randomized trials, there are certain common principles that have developed over time. In general, immediate reconstruction (in a patient requiring PMRT) is best accomplished with a tissue expander (TE)/implant-based technique.²⁵⁹ This is the most popular modality as it consolidates surgical procedures and allows full-tissue expansion through the month long course of adjuvant chemotherapy. The TE may be swapped for the permanent implant before PMRT²⁶³ or left in place through the course of PMRT, allowing its deflation to improve radiation dosimetry.²⁶⁴ Alternatively, autologous flap techniques are the procedures of choice for delayed reconstruction, where vascularized tissue is brought into the irradiated field for improved wound healing and cosmetic results.²⁶² While breast reconstruction after

mastectomy proves vital to many patients in terms of QOL posttreatment, it is important that patients not short change their oncologic therapy for fear of consequences that are cosmetic and rectifiable.

Role of radiation after neoadjuvant chemotherapy

Modified radical mastectomy followed by adjuvant chemotherapy and PMRT has been the historical standard locoregional therapy for patients with locally or regionally advanced primary tumors. However, over the past three decades, the use of neoadjuvant chemotherapy (chemotherapy before surgery) has significantly increased in patients with advanced disease. This strategy was first adopted for patients with unresectable or marginally resectable disease, and the initial clinical data from such patients indicated that chemotherapy achieved high rates of tumor response. Subsequently, this approach has also been investigated in patients with large, resectable breast cancers at diagnosis.

Breast conservation after neoadjuvant chemotherapy

One of the original main reasons to investigate sequencing chemotherapy before surgery was to determine whether breast conservation could be offered to selected patients with larger primary tumors whose residual disease would then be amenable to a breast-conserving operation. In order to investigate this, the NSABP and EORTC independently conducted clinical trials that compared neoadjuvant chemotherapy with adjuvant chemotherapy for patients with stage II or III breast cancer. Although both trials found that breast conservation rates were higher in the neoadjuvant chemotherapy arms,^{265, 266} the NSABP study showed that this increase was largely due to a near tripling of breast conservation use for patients with T3 disease postchemotherapy (22% vs 8%).²⁶⁴

The goal of breast conservation therapy for patients with advanced disease is to achieve an aesthetically acceptable cosmetic outcome and a low risk of breast recurrence. Accordingly, for patients with large initial primaries, resection must be directed at the postchemotherapy tumor bed rather than the initial volume of residual disease. However, one concern with resecting only the postchemotherapy volume of residual disease is that some advanced breast cancers do not shrink concentrically to a solitary nidus in response to neoadjuvant chemotherapy, but rather break up into nests of residual disease over the initially involved volume.¹⁹³ In such cases, surgery directed at the primary core may exert more pressure of microscopic disease around the tumor bed site, which may theoretically be associated with higher rates of breast cancer recurrence.

In the NSABP B-18 trial, the overall rate of breast cancer recurrence did not statistically differ in the patients treated with neoadjuvant chemotherapy compared with those treated with adjuvant chemotherapy (16-year rates of 13% vs 10%, respectively).²⁶⁷ However, breast cancer recurrence rate was higher in patients with large primary tumors in whom a response to neoadjuvant chemotherapy permitted a breast conserving surgery. In this subset of patients treated with neoadjuvant chemotherapy, the breast recurrence rate at 8 years was 16%, which was more than twice the rate in the patients with smaller tumors who were treated with breast-conserving surgery first.²⁶⁴ Other multicenter series have also shown relatively high breast cancer recurrence rates in patients who receive neoadjuvant chemotherapy.^{268, 269}

In contrast to these data, single-institution studies with careful selection criteria and a high degree of multidisciplinary coordination have reported excellent rates of local control. Investigators at the University of Texas MD Anderson Cancer Center have recently published the results of one of the largest studies investigating breast conservation after neoadjuvant chemotherapy.²⁶⁷ In this study, 340 carefully selected patients who had a favorable response to chemotherapy were treated with breast-conserving surgery and radiation. Despite the fact that 72% of patients in the study had clinical stage IIB or III

disease, the 5- and 10-year breast cancer recurrence rates were only 5% and 10%, respectively. Four tumor-related factors were associated with breast cancer recurrence and locoregional recurrence: clinical N2 or N3 disease, lymphovascular space invasion, a multifocal pattern of residual disease, and residual disease higher than 2 cm in diameter.²⁷⁰ These investigators subsequently developed a prognostic index from these factors and found that for patients with 0 or 1 index, breast conservation will offer similar excellent outcome as mastectomy and radiation. However, mastectomy and radiation were associated with a lower risk of locoregional recurrence in the patients with three or more adverse factors.²⁷¹

PMRT after neoadjuvant chemotherapy

While data indicate that breast conservation therapy is appropriate for patients with advanced primary tumors that have a favorable response to neoadjuvant chemotherapy, much less is known about the indications for and efficacy of PMRT for such patients. As previously discussed, for patients treated with up-front mastectomy, the decision to administer radiation therapy is made based on the pathological extent of disease. It is clear that neoadjuvant chemotherapy changes the extent of pathological disease in 80–90% of cases, and this may hold implications for locoregional recurrence.²⁶⁸ Therefore, both the pretreatment clinical stage and the extent of pathologically defined residual disease need to be considered when assessing the risk of locoregional recurrence in patients treated with neoadjuvant chemotherapy and mastectomy. Indeed, in an analysis of the patients treated with neoadjuvant chemotherapy, mastectomy, and no radiation, a multivariate analysis of locoregional recurrence predictors found that both pre- and posttreatment factors were independent predictors.²⁷² One large retrospective study of PMRT after neoadjuvant chemotherapy compared outcomes of 579 patients who received radiation following neoadjuvant chemotherapy and mastectomy with 136 patients who were treated with neoadjuvant chemotherapy and mastectomy only.²⁷³ Despite the fact that the PMRT cohort had more extensive disease than those treated without radiation, irradiated patients had a significantly lower locoregional recurrence rate at 10 years (8% vs 22%, $p = 0.001$). In the subgroup of patients with clinical T4 tumors, clinical stage IIIB/C disease, and in those with four or more positive lymph nodes after chemotherapy, the absolute improvement in locoregional recurrence risk was approximately 30–40%. The use of radiation in these same subgroups was associated with an approximately 15–20% improvement in overall and cause-specific survival. In a subsequent analysis from this group that focused only on patients who achieved a pathologic complete response (pCR), the locoregional recurrence rate for them with clinical stage III disease was improved with radiation therapy (33% vs 7%, $p = 0.04$).²⁷⁴

Whether to use PMRT for patients with clinical stage II disease who have positive lymph nodes after chemotherapy remains less clear. A report of 132 patients with clinical stage II disease who did not receive radiation therapy after neoadjuvant chemotherapy and mastectomy indicated that patients with clinical T3N0 disease or four or more positive lymph nodes had high rates of locoregional recurrence.²⁷⁵ The 5-year local recurrence rates in the remaining patients were less than 10%. In the patients with clinical stage II disease who had one to three positive lymph nodes after neoadjuvant chemotherapy, the 5-year rate of locoregional recurrence was 8%. It is important to recognize that this study had a small sample size and that the studied population was prone to selection biases, in that they represented only those patients for whom the treating physicians elected not to use radiation.

On the basis of the available data, it is reasonable to recommend PMRT for all patients with clinical stage III disease at initial presentation. It is also reasonable to infer that patients with clinical stage I or II disease who have four or more positive lymph nodes after chemotherapy or a primary tumor size >5 cm should receive radiation. The role of PMRT is currently controversial for patients with clinical stage I or II disease who have one to three positive lymph nodes after neoadjuvant chemotherapy²⁷⁶ and node-

positive disease at diagnosis, but proceed toward a pCR. Fortunately, these clinical conundrums are the subjects of two ongoing complementary prospective randomized trials in the United States. The NSABP B-51 trial is open to pathologically confirmed node-positive patients who convert to node-negative after neoadjuvant chemotherapy. Patients are then randomized to WBRT with or without regional nodal irradiation (postlumpectomy) or PMRT versus observation (postmastectomy).²⁷⁷ The Alliance A011202 trial randomizes similar patients who remain node-positive after chemotherapy to axillary dissection versus PMRT.²⁷⁸

Details of radiation treatment

The planning and design of the treatment fields and the delivery of radiation treatments for breast cancer are of critical importance and require modern equipment and attention to detail. It is clear that radiation treatments can have serious normal tissue consequences and even cause life-threatening radiation injuries, which can be avoided or minimized with modern treatment techniques.

There have been a number of recent advances in the field of radiation oncology that directly benefit breast cancer patients. One of these major advances has been the use of 3D imaging to assist in field design. Computed tomography (CT)-based simulation allows radiation oncologists to design treatment fields on CT images acquired from patients in their treatment positions, thereby permitting better visualization of the targeted regions and the normal tissues that one wishes to avoid, such as the heart. An example of a field design for a stage I left breast cancer treatment after lumpectomy is shown in [Figure 20](#). In this image, the tumor bed has been contoured on individual CT slices and reconstructed for the image. The breast is treated with a medial tangentially oriented beam, with a deep edge that enters near the midline and transverses the anterior thorax to exit near the midaxillary line. This field is opposed with a lateral tangent beam to match the decrease of dose as the beam travels through the breast and ultimately provides a homogeneous dose distribution. Other regions of interest, such as lymph nodes in the axilla, internal mammary chain, or supraclavicular fossa, can similarly be contoured to visualize their anatomical location with respect to treatment field borders. [Figure 21](#) shows a “beam’s eye view” of a medial tangent beam used to treat the breast (including the tumor bed), the upper internal mammary lymph nodes, and level I and a portion of level II of the axilla.

Figure 20 Cross-sectional image of radiation fields used for the treatment of left-sided invasive breast cancer. The red-shaded areas represent the volume included within the fields. The solid yellow object represents the tumor bed, which was reconstructed by contouring this region on sequential computed tomography slices. Two opposed treatment fields are used: a medial tangent that obliquely enters the medial breast and exits the lateral breast and an opposed lateral tangent field. The fields are opposed to match the falloff of radiation dose that occurs as beams travel through tissue.

Figure 21 A beams' eye-view of a medial tangent radiation treatment field designed to cover the breast, low axilla, and upper internal mammary lymph node chain. The reconstructed contours of a tumor bed (red), upper internal mammary lymph node region (blue) and the low axilla (yellow) are shown.

A second major advance has been the development of 3D dose calculation systems, which more accurately calculate and display the dose on the CT images throughout the 3D treatment volume. Finally, the currently used modern treatment tools also allow the dose to be modulated in three dimensions. The goal of such modulation is to provide a homogeneous dose distribution, which minimizes the risk of normal tissues and targeted areas receiving more than and less than the prescribed dose, respectively.

The treatment planning process is the initial critically important step in radiation treatments of breast cancer. Patients are conventionally immobilized in a supine position with the ipsilateral arm abducted and externally rotated. They then undergo a CT scan that acquires the image set used for treatment planning. Reference marks are placed on the patient's skin of the breast. The planning process, in which the fields are designed and the dose distribution optimized typically takes 2–3 days and does not require the patient to be present. Following completion of planning, daily treatments begin, which typically require 15 min each day in the treatment room. The therapy is painless and the patients' experience slightly differs from that of a diagnostic X-ray treatment. A number of alternative positioning²⁷⁹ and respiratory management²⁸⁰ techniques have recently been developed to improve dosimetry in large-breasted patients and further minimize heart exposure for left-sided cancers.

The most common course of treatment entails 25–28 treatments of 180–200 cGy per day to the breast or chest wall with or without inclusion of lymphatic regions at risk (total dose 4500–5040 cGy). This course is typically followed by five to eight supplemental treatments of 180–200 cGy per day to the tumor bed region (often called a tumor bed or chest wall boost) for an additional 1000–1600 cGy. In total, treatments are given 5 days a week for approximately 6–6.5 weeks. This strategy of delivering the lowest biologically effective daily dose over a protracted number of weeks is appropriate for patients in the postlumpectomy or postmastectomy setting, with or without inclusion of the regional lymph nodes and is referred to as conventionally fractionated radiation therapy (CFRT).

New radiation treatment approaches for early-stage breast cancer

Some patients treated for breast cancer fail to receive recommended radiation and a number of patients

who are excellent candidates for breast conservation therapy elect to be treated with mastectomy to avoid radiation.^{281, 282} A major factor that contributes to both of these scenarios concerns the inconvenience and expense associated with 5–7 weeks of CFRT. This schedule is particularly burdensome for patients who have significant home or work responsibilities, patients in rural areas who need to travel for access to the nearest radiation facility, and patients who rely on public transportation. In addition, worldwide, there are too few radiation oncologists, facilities, and equipment to offer this type of treatment schedule to all patients with breast cancer who will benefit from radiation.

For these reasons and others, a number of strategies have been developed to shorten the radiation treatment schedule and lessen the burdens of time and out-of-pocket expense. The simplest strategy is called hypofractionated radiation therapy (HFRT), where the amount of radiation delivered per treatment is increased to decrease the overall treatment course by about one-half. As the amount of radiation per fraction increases, the total dose delivered is commensurately adjusted downward to provide radiobiologic equivalence to CFRT dosing. Results of large randomized trials of HFRT are shown in [Table 8](#).

Table 8 Outcomes for selected randomized clinical trials comparing conventionally fractionated radiotherapy (CFRT) to hypofractionated radiotherapy (HFRT)

Trial	Median follow-up (years)	N	Dose (cGy)	# fractions	IBTR ^a (%)	LRR ^a (%)	DFS ^a (%)	OS ^a (%)	Cosmesis ^a (% good or excellent)	Acute toxicity ^a (% ≥ grade 3)
Canada ²⁸³	10	612	5000	25	6.7	—	—	84	71.3	3.0
		622	4250	16	6.2	—	—	85	69.8	3.0
Royal Marsden ²⁸⁴	10	470	5000	25	12	—	—	—	71	—
		466	4290	13	9.6	—	—	—	74	—
		474	3900	13	15	—	—	—	58 ^b	—
START A ^{285, 286}	9	749	5000	25	6.7	7.4	77	80	—	0.3
		750	4160	13	5.6	6.3	77	82	—	0.0
		737	3900	13	8.1	8.8	76	80	—	0.0
START B ^{286, 287}	10	1105	5000	25	5.2	5.5	78	81	—	1.2
		1110	4050	15	3.8	4.3	82 ^c	84 ^c	—	0.3

Abbreviations: N, number of patients; FRAC, fractions; IBTR, in-breast tumor recurrence; LRR, locoregional recurrence; DFS, disease-free survival; OS, overall survival.

^a All statistical *p* values are nonsignificant in the comparison of CFRT to HFRT, unless otherwise specified.

^b Measure found to be statistically inferior to CFRT (*p* < 0.05).

^c Measure found to be statistically superior to CFRT (*p* < 0.05).

In 1986, a clinical trial was initiated at the Royal Marsden Hospital, which included approximately 1500 patients randomized to receive CFRT versus one of two HFRT schedules, 3900–4290 cGy in 13 fractions over 5 weeks.²⁸⁴ The results were promising and led to the establishment of the UK Standardisation of Breast Radiotherapy (START) Trialists' Group, which developed two randomized trials comparing CFRT and HFRT for approximately 4500 women with ESBC. In the HFRT arms of the START A trial,²⁸⁵ patients received either 4160 cGy or 3900 Gy in 13 fractions over 5 weeks, and in START B,²⁸⁷ patients

received a dose of 4050 cGy in 15 fractions over 3 weeks. Long-term follow-up at 10 years in the START trials showed that HFRT is a safe and effective treatment for ESBC, equivalent in every way to CFRT.^{284, 286, 288} During the same period of time in Canada, Whelan and colleagues initiated a randomized trial evaluating HFRT (4256 cGy in 16 fractions) in more than 1000 patients with early-stage node-negative breast cancer. After 10 years of follow-up, patients in both arms were noted to have equivalent cosmetic outcomes and recurrence and survival rates.^{283, 287}

A second strategy, called accelerated partial breast irradiation (APBI), shortens the total treatment time to only 1 week by both increasing fraction size and minimizing the volume of breast tissue being irradiated. The rationale is that 80% of patients who undergo lumpectomy for small primary tumors have no residual disease after lumpectomy or disease that is within 2 cm of the index cancer.²⁸⁹ Most of the APBI outcome data with a follow-up of ≥ 5 years have been from studies that investigated interstitial brachytherapy as a method to deliver the radiation dose. For this procedure, patients have brachytherapy catheters surgically implanted around (multicatheter technique) or directly into (balloon catheter technique) the lumpectomy cavity. Subsequently, high-dose rate radioactive seeds are temporarily placed within the catheters in two sessions per day for 5 days. To date, the 10-year outcome data for highly selected patients with favorable disease characteristics using this approach in small prospective and randomized have been excellent.^{290, 291} However, others have noted higher rates of clinical fat necrosis and poorer efficacy than conventional breast external beam radiation.^{292, 293} The outcome data using balloon brachytherapy is also favorable, with the largest study of approximately 1500 patients on the American Society of Breast Surgeons (ASBS) registry showing a 4% risk of breast recurrence at 5 years.²⁹⁴ Because the placement of brachytherapy catheters at a separate surgical procedure carries with it its own logistical difficulties and risks, other methods of APBI radiation have been developed. Three-dimensional conformal external beam APBI uses sophisticated external beam planning to replicate the favorable dosimetry of brachytherapy with a noninvasive technique.²⁹⁵

Taken together, these data suggest that APBI warranted additional study in a large randomized prospective trial with rigid quality assurance to assure proper standardization and volumetric target coverage. In order to address this, the NSABP and RTOG were combined a decade ago to sponsor a phase III trial (NSABP B-39/RTOG 0413) of over 4000 patients with stage 0, I, or II breast cancer randomized to undergo CFRT or APBI (brachytherapy or external beam).²¹ This study closed to enrollment in 2013 after reaching its accrual goal, and it may be the most effective breast radiotherapy study in decades.

Another strategy of APBI that has already been compared to CFRT in a phase III trial uses specialized equipment to deliver a single large fraction of radiation directly into the tumor bed in the operating room at the time of lumpectomy. The largest phase III APBI trial published to date (TARGIT-A) randomized over 2200 postmenopausal women with early breast cancer to receive CFRT or single-dose intraoperative radiotherapy (2000 cGy to the tissue–applicator interface).²⁹⁶ At 4 years, the same risk of local recurrence was observed in each arm (1%), although 15% of intraoperative patients received additional breast irradiation because of adverse pathologic findings after surgery. The favorable results seen for selected early-stage patients treated with intraoperative APBI in such a well-controlled large study may be an early indication of what may ultimately be expected from NSABP B-39/RTOG 0413. Considering this, ASTRO developed consensus criteria for the use of APBI to aid in the selection of patients currently appropriate for one of these options.²⁹⁷ While not perfect, the guidelines serve as a stopgap compilation of the best available evidence for this popular strategy until the results of B-39 become available.

In the mean time, investigators have been developing even more novel techniques such as stereotactic

ablative radiotherapy to expand the limits of APBI, making it less invasive with even fewer treatments.^{298, 299} It is likely that as the future unfolds, APBI in one of its many forms will be a method increasingly available for the modified treatment of selected ESBC.

Morbidity of radiation treatments for breast cancer

Modern radiation treatments for breast cancer are well tolerated and have low rates of acute toxicity and long-term morbidity. Acute effects typically occur during or immediately after treatment and are mostly self-limited. The usual acute effects associated with breast therapy or PMRT include treatment-related fatigue and radiation dermatitis. These effects are usually relatively mild and most women can continue to work and their usual daily routines.

Late effects following treatment are also relatively unusual, particularly for patients treated after breast-conserving surgery for ESBC or DCIS. For these patients, the most common late effect is a change in breast aesthetics. The cosmetic results after lumpectomy and breast irradiation are influenced by technique, patient body habitus, use of systemic therapy, and the extent of surgery. Approximately 70–85% of women treated with breast-conserving surgery and radiation consider their aesthetic outcome (comparing the treated to the untreated breast) as good or excellent.^{300, 301}

The other more common complication from locoregional therapy is lymphedema. Irradiation of the supraclavicular fossa and axillary apex after a level I–II dissection can double the rate of lymphedema from 8–10% (surgery only) to 15–20%. Rates can increase further if level III dissections have been performed and in cases with unresected involved lymph nodes in the infra- or supraclavicular fossa, which necessitate higher radiation doses to this region. Other patient-related factors that contribute to lymphedema include obesity and subsequent injury or infection of the ipsilateral arm.

Breast cancer patients treated with radiotherapy are also at theoretical risk for development of pulmonary toxicity, as standard tangential fields skim a small percentage of ipsilateral lung tissue because of the natural curvature of the thorax and arrangement of the breast in the supine position. It is generally accepted that lung tissue is sensitive to radiation exposure, and even the smallest doses exceed tolerance.³⁰² Therefore, the strategy has generally been to use 3D planning, intensity modulation, and/or prone positioning to minimize the volume of exposed lung to the prescription dose. In the modern era of radiation planning and technique, the development of radiation pneumonitis or consequential clinically significant fibrosis after whole breast irradiation is extraordinarily uncommon.^{300, 303}

Injury to the brachial plexus is of theoretical concern for the treatment of locally advanced breast cancer, where regional nodal irradiation is required. With CFRT, doses to the brachial plexus (typically 4500–5000 cGy) remain well below the theoretical dose threshold that imparts a 5% risk of injury at 5 years (6000–6500 cGy). In cases where patients have gross disease present in the supraclavicular fossa, dose escalation approaching or exceeding this threshold may be necessary, and careful attention to the location and dosimetry of the brachial plexus is important. However, in such cases, the risk of tumor-induced brachial plexopathy by direct invasion far exceeds that of iatrogenic injury.

Cardiovascular morbidity has been the most significant long-term concern associated with breast cancer radiation. It is clear that the early cruder radiation techniques used for breast cancer treatment have been associated with premature cardiac events in long-term survivors, largely the result of unnecessary, and in the past, unquantifiable, dose delivered to underlying cardiovascular structures.³⁰⁴ Modern radiation treatments for breast cancer are associated with less cardiovascular morbidity and mortality than earlier radiation techniques. In the Danish PMRT trials, an electron beam technique was exclusively used in treating the chest wall to minimize dose to the cardiac structures. After a median follow-up of 117 months,

there was no increase in mortality or cardiac-related hospitalizations in the approximately 1500 patients randomized to receive radiation versus the 1500, who were randomized to no radiation.³⁰⁵ A similar morbidity and mortality analysis was performed in Canada, where long-term follow-up of 2128 patients treated with radiation failed to show a difference in cardiovascular morbidity between women with left- or right-sided breast cancer.³⁰⁶ A US report analyzing SEER data found an increase in cardiovascular deaths for irradiated breast cancer patients with left- versus right-sided tumors in the 1970s, but the difference was not found in patients treated in the 1980s and 1990s.³⁰⁷

In summary, there is no true “safe” cardiac radiation dose in the treatment of breast cancer patients, and the risks must be placed in context with the cardiotoxicity associated with current systemic cytotoxic and targeted therapies. Modern radiation treatments should be considered safe and effective. Treatment technique and equipment, prone patient positioning and/or respiratory management when appropriate, and mindfulness on the part of the radiation oncologist are all important to assure minimization of radiation-associated morbidities.

Systemic therapy for early stage breast cancer

Breast cancer is a complex heterogeneous disease with variable clinical presentations and outcomes. After a patient is diagnosed with ESBC, she should receive multidisciplinary care that aims for cure. Unfortunately, 20–30% of women with a diagnosis of ESBC will develop recurrent disease with distant metastases.³⁰⁸

After a patient is diagnosed with ESBC, decisions regarding treatment are influenced by clinicopathologic variables. Clinical factors such as age, menopausal status, size of tumor, and nodal status, as well as pathologic factors such as tumor grade, biomarkers, and proliferation rate are used to determine aggressiveness of a cancer and select treatment options. Tumor biomarkers as determined by IHC and in situ hybridization (ISH) are utilized to stratify breast cancer into three primary types that are prognostic and strongly predict response to specific therapies. The primary types are HR+, HER2+, and TNBCs.

HR+ breast cancers express ERs and PRs for which the current standard assay is IHC. The ER, a ligand-modulated transcription factor, is the primary driver of oncogenesis in HR+ breast cancer through its effects on cellular proliferation. ER and PR bind estrogen with high affinity, leading to conformational changes and entry into the nucleus. This hormone–receptor complex binds to estrogen-specific response elements to activate or repress gene expression. When ER or PR is bound by antiestrogens, growth-promoting genes are blocked. The presence of ER or PR is associated with responsiveness to endocrine therapy.

IHC can be performed on tissue or cytology specimens that are fresh or archived. ER and PR concentration varies for different tumors. The ASCO/College of American Pathologists (CAP) Guideline Recommendations define HR+ as $\geq 1\%$ staining of tumor cells for ER or PR, as patients with carcinoma cells expressing ER or PR as low as 1% have had significant clinical responses to hormone therapy.³⁰⁹ A proportion of 60–80% of breast cancer specimens express ER.

A proportion of 15–20% of breast cancers overexpress HER2, of which approximately 50% are also HR+. The HER2 oncogene encodes a transmembrane glycoprotein receptor with intracellular tyrosine kinase activity. The HER2 receptor is a member of the EGFR family of receptors, which are involved in the activation of signal transduction pathways that regulate growth and differentiation of normal and malignant breast epithelial cells. HER2 overexpression is prognostic and predictive of response to specific chemotherapies and HER2-directed therapies.

The most recent ASCO/CAP guidelines for HER2 testing have recommended that all patients with ESBC or metastatic breast cancer (MBC) have HER2 status assessed by a validated HER2 test.³¹⁰ Expression of HER2 is determined with IHC for the HER2 membrane protein or with ISH [fluorescent in situ hybridization (FISH), chromogenic ISH, or dual in situ hybridization (DISH)] to quantify HER2 gene amplification. FISH can be performed using either a single probe for HER2 or dual probe for HER2 and centromere 17 (CEP17).

A breast cancer is defined as HER2+ by IHC when circumferential membrane staining is 3+ (complete and intense membrane staining in $\geq 10\%$ of tumor cells).³⁰⁸ IHC of 0–1 is HER2 negative (HER2–), while IHC of 2+ is equivocal, and reflex FISH should be performed. A breast cancer is defined as HER2+ by FISH when the ratio of HER2 to CEP17 is >2.0 or <2.0 plus an average HER2 copy number of >6.0 signals/cell. A FISH ratio of <2 and/or an average HER2 copy number <4 signals/cell is negative, while a FISH ratio of <2 and/or an average HER2 copy number of 4.0–6.0 signals/cell is equivocal, and reflex IHC should be performed. Repeat testing should be considered if results seem discordant with other histopathologic findings.

By definition, TNBC lack IHC staining for ER, PR, and HER2 and HER2 amplification by FISH. The ASCO/CAP panel guidelines define HR– as $<1\%$ staining of tumor cells by IHC in the presence of appropriately stained extrinsic and intrinsic controls.³¹¹ The ASCO/CAP guidelines define HER2 negativity as 0–1+ by IHC or FISH nonamplified.³⁰⁸

The annual hazard rates for breast cancer recurrence are highest within the first few years after primary therapy, peaking at approximately 3–5 years and decreasing to a steady state by 7 or 8 years. However, patterns of recurrence vary significantly by breast cancer subtype. Up to 50% of distant recurrences from HR+ ESBC occurs in the first 5 years after diagnosis, but rates of recurrence and/or death from 0.5% to 3% per year extend for another 15 years. In comparison, the ROR of TNBC is highest within the first 3 years of diagnosis, but the magnitude of risk declines rapidly thereafter, with only rare recurrences after 5 years. Even with adjustment for age, race, stage, tumor size, nodal status, race, and treatment, TNBC is associated with a significantly worse OS than HR+ BC (HR 2.72, CI 2.39–3.10, $p < 0.0001$).³⁰⁹ HER2+ ESBC is associated with a more aggressive clinical course with shorter time to relapse and OS than HER2– ESBC. Its natural history dramatically improved with the advent of the HER2-targeted monoclonal antibody trastuzumab, which resulted in a 50% reduction in recurrence rates and an approximately 30% increase in OS. However, the outcome of HER2+ ESBC is also dependent on hormone receptor status, as demonstrated by a reduced response to endocrine-based therapies in HR+/HER2+ ESBC.

Optimal management of ESBC includes a combination of local and systemic therapy. Systemic therapy is used primarily to decrease risk of distant recurrence in patients with invasive disease, but hormone therapy is highly effective in reducing both local recurrence and contralateral new cancers. HR+ disease is treated with one of the several classes of agents, including the SERM tamoxifen, the AIs, and gonadotropin-releasing hormone agonists (GnRHa) to suppress ovarian function in premenopausal women, either with or without chemotherapy. Chemotherapy is the primary systemic treatment for TNBC and is used together with trastuzumab for HER2+ disease.

Targeted biologic therapy is being actively studied in the treatment of ESBC. In general, these agents have demonstrated high efficacy together with standard therapy compared with standard therapy only in the treatment of MBC. Classes of agents include monoclonal antibodies and oral tyrosine kinase inhibitors directed to HER2, cyclin-dependent kinase 4/6 (CDK 4/6) inhibitors or PI3K inhibitors combined with hormone therapies, and immunotherapies that reverse tumor immune tolerance. Details on these trials are

available at <http://www.cancer.gov/about-cancer/treatment/clinical-trials/search>.

Standard treatment recommendations for ESBC are generally applied to specific risk groups, based on biologic subtypes, extent of disease, and patient-related factors. Variable outcomes within these risk groups suggest that different molecular pathways underlie this phenotypic diversity. The rapid evolution in biomedical research and technology over the last two decades has led to an increasing understanding of the molecular pathways that drive cancer growth, affecting both prognosis and response to therapy. Current technologies allow determination of prognosis and help to predict the benefit of chemotherapy in HR+ breast cancer, but unfortunately do not predict which chemotherapy regimen or combination is most effective—leading primarily to overtreatment. New tests facilitate the determination of patients who are at a higher risk for late recurrence. Hopefully, ongoing research will identify combinations of biomarkers or gene signatures that will help to individualize therapy and allow appropriate use of new targeted biologic therapy for the patients who need it most.

The practice of breast oncology is rapidly evolving and oncologists are encouraged to stay informed of such changes through review guidelines and consensus statements provided through national and international organizations. The NCCN Guidelines® provide statements of evidence and consensus with frequent updates and are available at NCCN.org. The St. Gallen International Expert Consensus on the Primary Therapy of Early Breast Cancer has been recently updated and is available at http://www.oncoconferences.ch/mm/mm001/Ann_Oncol-2015-Coates-annonc_mdv221.pdf. The Institute for Quality in the ASCO has created practice guidelines based on review of the best available evidence by expert panels and are available at <http://www.instituteforquality.org/practice-guidelines>.

Prognosis and prediction

There have been multiple attempts to integrate prognostic information into standardized prognostic indices. The University of Nottingham index is based on tumor grade, axillary lymph node involvement, and hormone receptor status.^{312, 313} It has been validated prospectively and confirmed by an independent center, but still has limited applications in the determination of individual prognosis. The Adjuvantonline program (Figure 22) (<https://www.adjuvantonline.com/index.jsp>) is a prognostic index that was in extensive use until the development and widespread use of gene expression assays (see below). This is a free online software that uses patient age, comorbid conditions, tumor size, grade, number of positive axillary nodes, and ER status to calculate the 10-year probability of relapse and death for an individual patient.²³¹ Using this estimated risk level, the program also calculates the absolute benefit the patient would derive from adjuvant tamoxifen, AIs, and various chemotherapy regimens. Investigators from British Columbia recently validated the program, with observed results <2% of those predicted. Unfortunately, Adjuvantonline was developed before routine testing for HER2, and recurrence includes both local and distant risk. For this reason, benefits of chemotherapy in particular may be either amplified or reduced inappropriately.

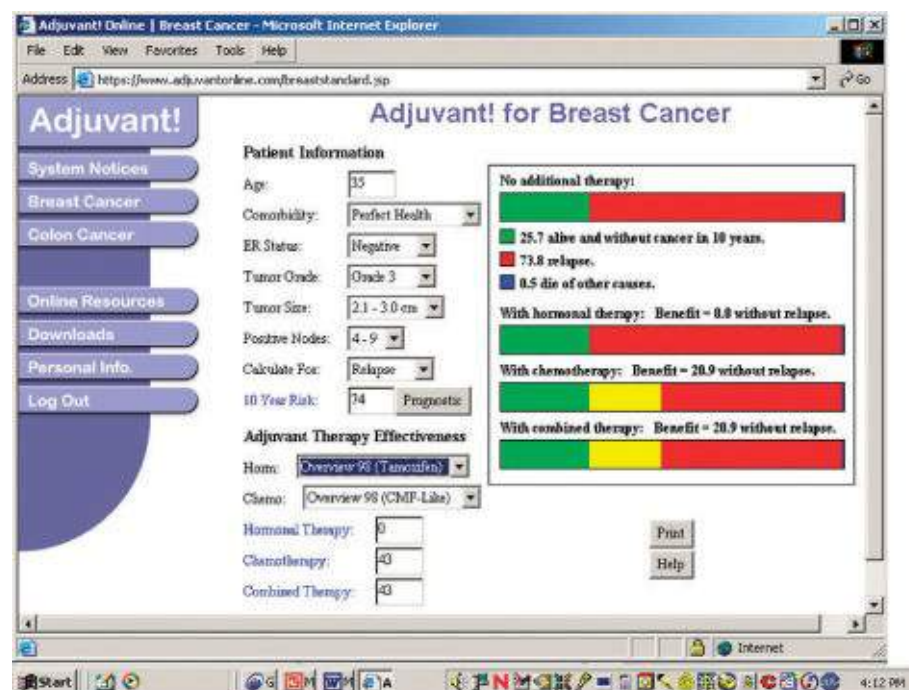

Figure 22 Online prognostic software that predicts 10-year probability of recurrence and mortality, as well as the probability of benefit from various systemic adjuvant treatment options based on individual patient and tumor characteristics.

Intrinsic breast cancer subtypes

Gene expression profiling allows for the simultaneous examination of multiple genetic alterations and the measurement in activity of thousands of genes within a single breast cancer cell, providing a more accurate classification of tumors. In 2000, Perou et al.³¹⁴ used this technology to evaluate 189 breast cancer samples, of which 122 contained expression patterns with significant gene clusters. These clusters were determined to represent four distinct intrinsic breast cancer subtypes: luminal A and B, HER2 enriched, and basal-like. Retrospective studies demonstrated that these subtypes are associated with prognosis and predict treatment outcomes.

The luminal subtypes of breast cancer involve genes associated with the luminal epithelial cells of normal breast tissue and clearly overlap with HR+ breast cancers, the majority (90–95%) of which are of the luminal subtype.³¹⁵ The luminal A subtype, which carries the best prognosis, is found in approximately 40% of breast cancers and is associated with high expression of ER-related genes, but low expression of the HER2 and proliferation-related gene clusters. By contrast, the luminal B subtype is found in about 30–40% of all breast cancers and is associated with reduced expression of several luminal-related genes, low expression of the HER2 gene, and higher expression of the proliferation cluster. Regardless of systemic therapy, luminal B cancers have a worse baseline 5- and 10-year distant recurrence-free survival than luminal A cancers.

The HER2-enriched subtype is associated with high expression of HER2 and proliferation-related genes, and a higher frequency of genomic mutations than other breast cancers.³¹³ Interestingly, some HER2-breast cancers are identified as HER2-enriched.

The basal-like subtype is associated with high expression of proliferation-related gene clusters, such as EGFR, and low expression of ER- and HER2-related genes and is thus generally negative for the ER, PR, and HER2.³¹³ However, the basal-like subtype is not synonymous with TNBC and is associated with the expression of proteins within the basal layer of the breast duct epithelium. Breast cancers with the basal-like subtype have a poor prognosis with an increased risk for relapse within the first 5 years of diagnosis,

but after which the risk rapidly declines. Subsequent studies evaluating variable outcomes with neoadjuvant chemotherapy for TNBC revealed seven additional subtypes: basal-like 1 and 2, immunomodulatory, mesenchymal, mesenchymal stemlike, luminal androgen receptor (AR), and unstable.^{316, 317}

Multigene assays

Several multigene assays that were developed over the last two decades, including Oncotype DX, MammaPrint (MP), Prosigna, the Breast Cancer Index (BCI), and EndoPredict (EP), are commercially available to provide risk assessment for patients with ESBC and in some cases predict benefit of adjuvant therapies. Most importantly, these assays permit rational individualization of treatment by predicting outcome with hormone therapy only for HR+ disease, or alternatively predicting benefit of chemotherapy. The most commonly used assays with the largest supportive data are Oncotype DX and MP.

The Oncotype DX assay, commercially available since 2004, was originally intended as a tool to assess prognosis and predict chemotherapy benefit for women with node-negative, HR+ ESBC, a category of patients for whom the utility of adjuvant chemotherapy is difficult to define when utilizing traditional clinical factors only.^{117, 181} More recently, the assay was validated for use in patients with node-positive disease.¹³⁴ This multigene assay quantifies the expression of 21 genes through a quantitative reverse transcriptase polymerase chain reaction (qRT-PCR) platform applied to a single formalin-fixed paraffin-embedded (FFPE) breast cancer tissue sample.¹¹⁷ The assay is only available through a central laboratory. The 21-gene signature is composed of 16 breast cancer-related genes associated with proliferation, ER regulation, and the HER2 pathway as well as five reference genes for normalization. Expression levels of the 21 genes are applied to an algorithm that calculates the RS, which determines a patient's 10-year ROR after taking 5 years of adjuvant tamoxifen only, as well as her 10-year ROR after adjuvant chemotherapy followed by 5 years of adjuvant tamoxifen. The RS is a continuous variable that ranges from 0 to 100 and falls into one of three categories: low risk (RS <18), intermediate risk (RS 18–30), and high risk (RS >30). Patients with low risk have no benefit from chemotherapy, whereas those with high risk have a significant benefit. The benefit of adjuvant chemotherapy for patients in the intermediate-risk category is less clear and currently under investigation (see below; the TAILORx trial).

The developers of the Oncotype DX assay selected 250 genes from genomic databases and tested their expression on tumor samples from several clinical trials, including the tamoxifen-only arms of NSABP B-14 and NSABP B-20.¹¹⁷ A final panel of 21 genes was selected from these tests and used to calculate the RS of each tumor sample. The initial validation of the prognostic utility of the Oncotype DX assay was performed by evaluating fixed tissue samples from a subset of patients on the tamoxifen-only arm of the NSABP B-14 clinical trial, which included women with HR+ and node-negative ESBC and compared tamoxifen with placebo for 5 years after primary surgery. A total of 668 fixed samples were analyzed and given an RS. The 10-year rate of distant recurrence was split into three groups: 6.8% (95% CI, 4.0–9.6) for low risk (RS <18), 14.3% (95% CI, 8.3–20.3) for intermediate risk (RS 18–30), and 31% (95% CI, 23.6–37.4) for high risk (RS >30). The ROR was significantly lower with the low RS than high RS group ($p < 0.001$).

Several studies have demonstrated the ability of Oncotype DX to predict the benefit of chemotherapy for the different RS groups. Paik et al. measured the RS for a subset ($n = 651$) of tumor samples from NSABP B-20, a clinical trial of postmenopausal women with HR+ node-negative ESBC.¹⁸¹ NSABP B-20 randomized 2363 patients to receive either tamoxifen or adjuvant CMF or MF followed by tamoxifen.³¹⁸ Paik et al. observed a statistically significant interaction between the benefit of chemotherapy and the RS

($p = 0.038$), with a large benefit for patients with a high RS [RR, 0.26; 95% CI, 0.13–0.53] and a mean absolute decrease in 10-year distant recurrence rate of 27.6% (SE, 8.0%). In comparison, minimal benefit from chemotherapy was observed in patients with a low RS (RR, 1.31; 95% CI, 0.46–3.78) and no decrease in 10-year distant recurrence rate (–1.1%; SE, 2.2%).

Albain et al.¹³⁴ performed a retrospective analysis of the association between RS and disease-free survival (DFS) for a subset of postmenopausal women with HR+ node-positive ESBC enrolled in the phase III clinical trial, SWOG-8814, that compared adjuvant tamoxifen versus adjuvant cyclophosphamide, adriamycin, and 5-FU (CAF) followed by tamoxifen. An RS was assessed for 40% of the 927 patients enrolled in the parent trial. The RS was prognostic of DFS in the tamoxifen-only group (HR 2.64, 95% CI 1.33–5.27; $p = 0.006$). Patients with a low RS observed no benefit from CAF (log-rank $p = 0.97$; HR 1.02, 0.54–1.93), while those with a high RS had a statistically significant improvement in DFS (HR 0.59, 95% CI, 0.35–1.01; log-rank $p = 0.033$).

The benefit of adjuvant chemotherapy for patients with node-negative disease with an intermediate-risk Oncotype DX RS is poorly defined and is currently under evaluation in two randomized phase III clinical trials. TAILORx (NCT00310180) evaluates patients with a node-negative HR+ breast cancer with an RS between 12 and 30. The study was initiated in 2006 with a total of 10,273 patients enrolled in it.³¹⁹ Patients with an RS between 11 and 25 ($n = 6897$) were randomized to receive either adjuvant chemotherapy followed by endocrine therapy or endocrine therapy only. Patients with an RS between 26 and 30 were all treated with combined chemotherapy followed by hormone therapy, and those with a score <11 were treated with hormone therapy only. Standard local therapy was recommended. The final data collection was planned to occur in December 2017, but outcome data from the low-risk secondary study group was published in 2015.³²⁰ A total of 1626 patients with a median age of 58 were treated with a median tumor size of 1.5 cm; 59% had intermediate grade histology and a median age of 58. More than half of the patients were treated with an AI (59%). The 5-year invasive disease-free survival (IDFS) rate was 93.8%, and the 5-year distant recurrence-free interval (DRFI) was 99.3% with a 98% OS. Recurrence risk was not significantly affected by age, tumor size, or histologic grade. These data support the clinical utility of gene expression assays in determining breast cancers at very low risk that clearly do not require chemotherapy. The data from the intermediate risk group are eagerly anticipated.

The SWOG Rx for POsitive Node, Endocrine Responsive BC (RxPONDER S1007) clinical trial (NCT01272037) is a prospective study evaluating the noninferiority of endocrine therapy to chemotherapy followed by endocrine therapy in patients with HR+/HER2– node-positive (one to three lymph nodes) breast cancer with an RS of ≤ 25 .³²¹ A total of 4000 patients will be randomized to receive either chemotherapy followed by endocrine therapy or endocrine therapy only. Each patient's adjuvant therapy will be chosen by the treating physician according to standard treatment options. The estimated date of completion of this study is February 2022.

The MP 70-gene breast cancer recurrence assay is intended as a prognostic test for women under 62 years of age with node-negative or positive (one to three lymph nodes), HR+ or HR–, ESBC with a primary tumor no larger than 5 cm.³²² DNA microarray technology is used to measure the mRNA expression levels of 70 specific genes in a breast tumor sample. The test was originally designed for fresh frozen samples but has since been validated for use on FFPE. Expression levels of the 70-genes are used to place patients into low- or high-risk groups. Patients with low-risk are estimated to have a 13% chance of developing metastasis at 10 years without adjuvant therapy compared with high-risk patients associated with a 56% chance.

The assay was developed at the Netherlands Cancer Institute using tumor tissue samples from 78 women

with node-negative breast cancer, who did not receive systemic adjuvant therapy and for whom outcomes were documented.³²³ The entire genome of each of these tumor samples was evaluated with microarray technology to identify genes most associated with recurrence risk. The 70 genes most predictive of recurrence were selected for the MP assay. The assay was later validated retrospectively in its ability to distinguish between low- and high-risk patients with node-negative HR+ breast cancer using several different tissue banks. One study applied the assay to 307 tissue samples from women with HR+ node-negative ESBC, with a significant difference in prognosis between high- and low-risk groups (HR = 2.32).¹⁶⁷ Subsequent data validated the prognostic value of MP in node-positive disease as well.^{324, 325}

The MINDACT trial is a prospective multicenter trial within the Breast International Group (BIG) that is evaluating the MP 70-gene profile in both node-negative and one to three node-positive diseases.¹³³ MINDACT has enrolled 6600 patients, classified as high- and low-risk groups by MP and clinicopathologic risk through Adjuvant!Online. Patients with concordant high risk are offered adjuvant chemotherapy, and those with concordant low risk do not receive chemotherapy.³²⁶ Patients with discordant risk are randomized to receive adjuvant chemotherapy based on either MP or Adjuvant!Online. Patients receiving chemotherapy are also randomized to two different chemotherapy regimens, and those receiving hormone therapy are randomized to two different adjuvant endocrine therapy approaches. The first efficacy results are expected in 2016.

The Prosigna® score is intended to estimate the 10-year risk of distant recurrence for postmenopausal women with HR+ breast cancer, either node-negative (stage I or II) or node-positive (stage II only). The Prosigna score, also known as ROR score, is calculated with a proprietary algorithm that combines a patient's intrinsic breast cancer subtype, as determined by the Predictor Analysis of Microarray 50 (PAM-50), with gross tumor size. PAM-50 is a 50-gene subset derived from the larger gene set used by Perou et al. in 2000 to define the intrinsic breast cancer subtypes. PAM-50 was applied to banked tissue samples to assess prognosis of 761 patients who did not receive any systemic therapies for their ESBC. Results from PAM-50 and associated primary tumor size are used to calculate an ROR score, which is then used to stratify patients with HR+ breast cancer into low-, medium-, and high-recurrence-risk subsets. The selected 50 genes and associated intrinsic subtypes remained significant when evaluated with multivariable analyses that included standard parameters.

Gnant et al.³²⁷ performed an independent, retrospective validation study that demonstrated level 1 evidence of the increased prognostic reliability of the PAM-50-derived ROR score compared with standard clinical predictors. The study cohort included 1478 patient tissue samples from the ABCSG-8 clinical trial, which randomized 3091 women with HR+ ESBC not treated with adjuvant chemotherapy to either 2 years of adjuvant tamoxifen followed by 3 years of adjuvant anastrozole or 5 years of adjuvant tamoxifen. The ROR score added statistically significant prognostic information in comparison to standard clinical predictors ($p < 0.0001$). Samples assigned to the luminal A subgroup had a significantly lower ROR at 10 years than those in the luminal B subgroup.

The BCI, the combination of a two-gene ratio (HOXB13:IL17BR; H/I) and a five-gene (BUB1B, CENPA, NEK2, RACGAP1, and RRM2) molecular grade index (MGI), was developed using a cohort of tamoxifen-treated patients from the randomized prospective Stockholm trial and has been shown to provide an individual risk of distant breast cancer recurrence based on a continuous risk model.^{328, 329} BCI has been shown to significantly predict 0- to 10-year ROR beyond standard clinicopathologic factors and to predict late distant recurrence.³³⁰ A subset analysis of tumor samples from the extended adjuvant hormone therapy MA. 17 trial suggested that H/I could identify a high-risk group in the 5-year tamoxifen group and found that patients with a high H/I score who received letrozole after 5 years had a decreased

probability of distant recurrence.³³¹

EP is an RNA-based multigene score including eight cancer-related and three reference genes that predicts the likelihood of distant recurrence in patients with early-stage, ER-positive, and HER2– breast cancer treated with adjuvant endocrine therapy only.^{332, 333} EP is also combined with nodal status and tumor size into a comprehensive risk score, EPclin.

Hormone therapy for HR+ breast cancer

The role of estrogen in the development and progression of breast cancer was demonstrated over a century ago when a subset of unselected patients with advanced breast cancer were treated with surgical oophorectomy resulting in transient disease control. Throughout the mid-twentieth century, premenopausal women with a history of resected ESBC underwent ovarian ablation through radiation or surgery and were subsequently found to have reduced disease recurrence.³³⁴ Such outcomes led researchers to evaluate systemic endocrine therapies for the treatment of advanced breast cancer as well as for the prevention of disease recurrence in ESBC.

Systemic hormone-based therapy for HR+ ESBC was not available for general use until tamoxifen was approved for postmenopausal women in 1985 and later for premenopausal women in 1990. As a SERM, tamoxifen competitively inhibits estrogen from binding ER, with subsequent antagonist and agonist effects depending on the target tissue. Although incompletely understood, these differential effects are presumptively due to variable interactions with coactivator and corepressor proteins involved in ER-mediated gene regulation.

Tamoxifen was first evaluated as an adjuvant therapy in the Nolvadex Adjuvant Trial Organisation (NATO) clinical trial, which was initiated in 1977 and randomized 1285 women with ESBC to tamoxifen 10 mg bid for 2 years or no further treatment. At a maximum follow-up of 8 years, patients treated with tamoxifen had a 36% reduction in recurrence ($\chi^2 = 17.69$, $p = 0.0001$) and 29% reduction in all-cause risk of death ($\chi^2 = 7.48$, $p = 0.0062$).³³⁵ The initial trials of 5 years of adjuvant tamoxifen demonstrated a small gain in 5-year survival, but a longer follow-up demonstrated that the mortality reduction persisted beyond 5 years with an absolute reduction in mortality three times higher at 15 years after diagnosis. The mortality reductions during years 5–9 and 10–14 were each equivalent to the mortality reduction in years 0–4. A meta-analysis by the EBCTCG published in 1988 included 28 trials evaluating adjuvant tamoxifen and clearly established that tamoxifen reduces 5-year mortality for all patients, but with a greater effect in women ≥ 50 years than those < 50 years.³³⁶ The 2011 EBCTCG meta-analysis of endocrine therapy reported that in the trials of tamoxifen for 5 years versus placebo, at a median follow-up of 13 years, tamoxifen resulted in a significant reduction in breast cancer recurrence at 15 years (RR 0.61, 95% CI 0.57–0.65) and in breast cancer mortality at 15 years (RR 0.70, 95% CI 0.64–0.75).³³⁷ Use of adjuvant tamoxifen for 5 years reduces the annual breast cancer recurrence by almost 40% and death by 31%, independent of age, chemo, LN, and menopausal status. Unfortunately, the ROR does not decrease over time, and over 50% of recurrences and two-thirds of deaths occur over 5 years after diagnosis.

Although of great benefit with regard to the reduction of breast cancer recurrence and OS, tamoxifen is not without troublesome side effects, including some infrequent but serious adverse events (AEs). Antagonistic effects on the central nervous system (CNS) lead to dysfunctional thermoregulation experienced as hot flashes by almost 80% of patients on tamoxifen that is most significant in premenopausal women. Agonistic activity on uterine tissue can facilitate endometrial hyperplasia with a subsequent development of fibroids, polyps, and malignant tumors. The EBCTCG overview analysis of individual patient data from trials of tamoxifen versus placebo demonstrated a 2.4-fold increase in

endometrial cancer, but without an adverse effect on mortality.³³⁸ Patients who were diagnosed with endometrial cancer were almost exclusively >50 years. Long-term follow-up has demonstrated a very small increased incidence of uterine sarcoma that generally presents at an advanced stage, 2–5 years after initiation of tamoxifen therapy. Several pooled analyses have demonstrated an increase in venous thromboembolic events of two- to threefold with tamoxifen, an effect observed primarily seen in women with age ≥ 55 years and higher body mass index. Additional side effects include vaginal discharge, sexual dysfunction, menstrual irregularities, and cataracts.

AIs were initially evaluated in and approved for postmenopausal women with advanced breast cancer and were later studied as an alternative to tamoxifen for adjuvant therapy in postmenopausal women. Aromatase converts androgens to estrogen in peripheral tissues. AIs inhibit this enzymatic activity with a rapid decrease in circulating estrogen. They do not block the secretion of estrogen from ovarian tissue and are therefore not appropriate for premenopausal women with intact ovarian function.

The first and second generations of AI were too toxic for further development, but the third generation of AI—exemestane, anastrozole, and letrozole—was safer and better tolerated. Anastrozole and letrozole are nonsteroidal agents that bind reversibly to aromatase as opposed to exemestane, a steroidal agent that binds irreversibly to aromatase. Side effects and symptoms of AI are discussed below. AIs are associated with an increased risk of osteoporosis, fractures, musculoskeletal symptoms of arthralgias, joint stiffness and bone pain, hot flashes, and sexual dysfunction.

Adjuvant hormonal therapy for postmenopausal women

The development of third-generation AIs challenged and later replaced tamoxifen as the primary adjuvant hormonal therapy in postmenopausal women with HR+ ESBC. Several pivotal phase III clinical trials were initiated in the 1990s to demonstrate the superiority of AIs over tamoxifen for the reduction of their recurrence risk and the improvement of OS of postmenopausal women. Other studies examined the optimal time course of adjuvant hormonal therapy to optimize risk reduction while limiting toxicities. Preclinical data demonstrating tamoxifen resistance in breast cancer cell lines as well as large clinical trials reporting toxicities associated with long-term tamoxifen therapy led investigators to evaluate switching patients to an AI after 2–3 years of adjuvant tamoxifen, known as sequential adjuvant therapy. Extended adjuvant therapy, treatment with tamoxifen for 10 years or tamoxifen for 5 years followed by an AI for 5 years, was explored in an effort to further reduce late recurrence risk in HR+ ESBC.

The Arimidex, Tamoxifen, Alone or in Combination (ATAC) study was the first clinical trial to demonstrate the efficacy of an AI over tamoxifen.^{336, 339, 340} All 9241 randomized participants were postmenopausal and had completed primary treatment with surgery as well as radiation and/or chemotherapy as needed. Patients were not excluded according to hormone receptor status, and 84% were HR+. The three study arms consisted of 5 years of either anastrozole 1 mg daily, tamoxifen 20 mg daily, or a combination of both. The initial analysis, performed with a median follow-up of 33.3 months, demonstrated a 3-year DFS in the anastrozole arm of 89.4% and in the tamoxifen arm of 87.4%, which was statistically significant with an HR of 0.83 (95% CI 0.71–0.96, $p = 0.013$). The combination and tamoxifen arms were similar with an HR of 1.02 (CI 0.89–1.18, $p = 0.8$). Anastrozole was better tolerated with respect to endometrial cancer ($p = 0.02$), vaginal bleeding or discharge ($p < 0.0001$), cerebrovascular events and venous thromboembolic events ($p = 0.0006$ for both), and hot flashes ($p < 0.0001$). However, arthralgias and fractures were significantly less frequent in the tamoxifen than anastrozole arm ($p < 0.0001$ for both). At the 10-year follow-up, anastrozole remained more efficacious in comparison to tamoxifen and the combination arm with regard to DFS (HR 0.91; 95% CI, 0.83–0.99; $p = 0.04$) and time to recurrence.

BIG 1–98 study was a phase III double-blinded clinical trial of postmenopausal women with ESBC that was designed to compare adjuvant monotherapy with letrozole versus tamoxifen for 5 years as well as sequential therapy with letrozole given before or after tamoxifen.³⁴¹ A total of 8010 patients were randomized after surgical treatment to one of the four arms: letrozole 2.5 mg daily for 5 years, tamoxifen 20 mg daily for 5 years, letrozole for 2 years followed by tamoxifen for 3 years, and tamoxifen for 2 years followed by letrozole for 3 years. A protocol amendment in 2005 allowed for crossover from tamoxifen to letrozole because of a significant DFS benefit. At a median follow-up of 8.7 years, letrozole monotherapy was significantly better than tamoxifen monotherapy with regard to DFS and OS, whether assessed with intention to treat or inverse probability of censoring weighting (IPCW), which accounts for selective crossover to letrozole from tamoxifen. At a median follow-up of 8 years, no statistically significant difference was appreciated between the sequential arms.

A meta-analysis published in 2011 reported a cohort of patients ($n = 9856$) from the ATAC and BIG 1–98 trials, who were randomized to receive an AI (anastrozole or letrozole) for 5 years or tamoxifen for 5 years, demonstrating an absolute decrease in recurrence of 2.9% (SE = 0.7%) in those treated with an AI. Recurrences in the AI group were 9.6% compared to 12.6% with tamoxifen ($2p < 0.00001$), with a nonsignificant absolute decrease in breast cancer mortality of 1.1% (SE = 0.0%).

The Intergroup Exemestane Study (IES) randomized 4742 postmenopausal patients with HR+ ESBC who remained disease free after 2–3 years of tamoxifen therapy to either switch to exemestane or remain on tamoxifen for a total of 5 years of adjuvant hormonal therapy.³⁴² At a median follow-up of 30.6 months, a significant improvement in DFS was noted in the exemestane switch arm (unadjusted HR 0.68, 95% CI, 0.56–0.82; $p < 0.001$) with an absolute benefit of 4.7% at 3 years after randomization. At a median follow-up of 91 months, this gain was not lost, but no additional benefit was observed (HR, 0.94; 95% CI, 0.80–1.10; $p = 0.60$).³⁴³ However, an improvement in OS was observed (HR 0.86; 95% CI, 0.75–0.99; $p = 0.04$). Subgroup analyses illustrated a benefit in patients with node-positive or -negative disease and ER+ disease irrespective of PR status. An increase in osteoporosis (9.2% vs 7.2%, $p = 0.01$) and fracture (7% vs 4.9%, $p = 0.003$) was also observed, as expected.

A recent meta-analysis presented by Forbes et al. at ASCO in 2014 including approximately 37,000 women further supported the use of AIs in postmenopausal women.^{344, 345} In trials comparing AI to tamoxifen with a total of 22,533 postmenopausal women with HR+ ESBC, there was a significant reduction in recurrence during years 0–1 (RR 0.66; 95% CI 0.54–0.80) and 2–4 (RR 0.75, 95% CI 0.64–0.88). The meta-analysis also reported on sequential adjuvant therapy. In clinical trials in which women were assigned to sequential tamoxifen followed by an AI versus 5 years of tamoxifen, there was a significant reduction in recurrence (RR 0.84, 95% CI 0.73–0.97) that was lowest during years 2–4 (RR 0.56, 95% CI 0.46–0.67). Furthermore, there were fewer breast cancer-related deaths with sequential adjuvant therapy than tamoxifen only (RR 0.84, 95% CI 0.73–0.97). In trials comparing AI and sequential treatment ($n = 12,799$) using tamoxifen followed by an AI, the recurrence risk was lower for the former than the latter during years 0–1 (RR 0.75, 95% CI 0.75–0.89), but similar during years 2–4 (RR 0.99, 95% CI 0.85–1.15). The similarity during years 2–4 was thought most likely due to the fact that the patients in the sequential group were likely transitioned to AI during that time frame.

Knowing that AIs were more efficacious than tamoxifen in the postmenopausal ESBC setting, clinical trials were developed to evaluate extended AI therapy. MA.17 was a phase III clinical trial that randomized 5187 postmenopausal women with ESBC who previously received 5 years of tamoxifen followed by 5 years of either letrozole or placebo. At a median follow-up of 64 months, a significant benefit in DFS (HR 0.68; 95% CI 0.45–0.61) and OS (HR 0.51, 95% CI 0.42–0.61) was apparent. These results led to the approval of extended adjuvant treatment with tamoxifen followed by letrozole. Patients

who were randomized to placebo were allowed to take letrozole after publication of the trial results and patients were unblinded. Those patients who chose to take letrozole still experienced an increase in DFS, despite a substantial lapse in time between therapies with a median of 2.8 years.

Two large, multinational clinical trials evaluated the extended use of adjuvant tamoxifen and presented similar outcomes. The Adjuvant Tamoxifen: Longer Against Shorter (ATLAS) clinical trial randomized 12,894 patients with ESBC who had completed 5 years of tamoxifen to continue tamoxifen for a total of 10 years or stop at that point of time. More than half of the participants (53%) were known to have ER+ disease, for whom allocation to tamoxifen resulted in a significant benefit with regard to breast cancer recurrence (18% vs 21%, $p = 0.002$) and overall mortality (639 deaths vs 722 deaths, $p = 0.01$).³⁴⁶ The reduction in recurrence became more significant over time with the recurrence rate ratio of 0.9 (95% CI 0.79–1.02) during years 5–9 and 0.75 (95% CI 0.62–0.90) in later years. The cumulative risk of endometrial cancer during years 5–14 was 31% for patients randomized to continue tamoxifen versus 16% for controls with an absolute mortality increase of 0.2%.

The Adjuvant Tamoxifen—To Offer More (aTTom) clinical trial randomized 6953 women with ESBC who had completed >4 years of tamoxifen to either an additional 5 years of tamoxifen or placebo.³⁴⁷ At a median follow-up of 4.2 years, an insignificant reduction in recurrence in the extended therapy arm (RR = 0.94, 95% CI 0.81–1.09, $p = 0.4$). At a median follow-up of 5 years, a significant time-dependent reduction in recurrence was observed with continued tamoxifen (rate ratio 0.99 during years 5–6 [95% CI 0.86–1.15], 0.84 during years 7–9 [95% CI 0.73–0.95], and 0.75 thereafter [95% CI 0.66–0.86]).³⁴⁸ It is important to note that 61% of patients did not have hormone receptor status tested. The rate of endometrial cancer doubled with 10 years of tamoxifen, but with no associated increase in death.

The EBCTCG recently published a patient-level meta-analysis of AI versus tamoxifen in HR+ ESBC that included 31,920 postmenopausal women.³⁴⁹ Recurrence rate ratios in patients treated with 5 years of AI versus 5 years of tamoxifen were significant from years 0–1 (RR 0.64, 95% CI 0.52–0.78) and years 2–4 (RR 0.80, 0.68–0.93), but was no longer significant in the following years. Mortality at 10 years was lower with AI than tamoxifen (RR 0.85, 95% CI 0.75–0.96; $2p = 0.009$). Results of studies comparing 5 years of AI or 5 years of tamoxifen with 2–3 years of tamoxifen followed by AI to year 5 showed a recurrence rate ratio favoring AI only during the time that the treatments differed. However, breast cancer mortality and all-cause mortality were reduced with AI throughout the study, regardless of the similar or different treatment methods. AEs were as expected, with 10-year endometrial cancer incidence increased with tamoxifen in comparison to AI (1.2% vs 0.4%) and with 5-year risk of bone fractures increased more with AI than with tamoxifen (8.2% vs 5.5%). Comparative efficacies of various hormone therapies evaluated in the 2011 and 2015 EBCTCG meta-analyses are provided in [Table 9](#).

Table 9 Comparative efficacy of adjuvant hormonal therapies.^{337, 349}

	Recurrence rate ratio			15-Year recurrence risk difference	15-Year breast cancer mortality rate ratio
	years ^a 0–4	years 5–9	years 10–14		
TAM ^b (5 years) vs observation	0.53 (2p < 0.00001)	0.68 (2p < 0.00001)	0.97	13.2% (RR 0.61 95% CI 0.57–0.65; 2p < 0.00001)	0.70 (p < 0.00001)
	Recurrence rate ratio			10-Year recurrence risk difference	10-Year breast cancer mortality rate ratio
	Years 0–1	Years 2–4	Year 5 and beyond		
AI ^c (5 years) vs TAM (5 years)	0.64 (95% CI 0.52–0.78; p < 0.00001)	0.80 (95% CI 0.68–0.93; p < 0.00001)	NSE ^d (minimal f/u after year 10)	3.6% (95% CI 1.7–5.4)	0.85 (95% CI 0.75–0.96; 2p = 0.009)
AI (5 years) vs TAM (2–3 years) - > AI (to year 5)	0.74 (95% CI 0.62–0.89; 2p = 0.002)	0.99 (95% CI 0.85–1.15)	NSE (minimal f/u after year 7)	NSE (2p = 0.045)	0.89 (95% CI 0.78–1.03; 2p = 0.11)
TAM (2–3 years) - > AI (to year 5) vs TAM (5 years)	NSE (in part due to timing of data collection)	0.56 (95% CI 0.46–0.67; p < 0.0001)	NSE (minimal f/u after year 10)	2.0% (95% CI 0.2–3.8)	0.84 (95% CI 0.72–0.96; 2p = 0.015)

^a Years, years postsurgery.

^b TAM, tamoxifen.

^c Aromatase inhibitor.

^d NSE, no significant effect.

The 2014 ASCO Clinical Practice Guideline Focused Update for adjuvant endocrine therapy recommended that postmenopausal women with HR+ ESBC receive a minimum of 5 years of AI or sequential tamoxifen followed by AI.³⁵⁰ They should be offered a total of 10 years of therapy. The 2015 St. Gallen Consensus on Primary Therapy stated that some postmenopausal women can be treated with 5 years of tamoxifen but that higher risk patients should receive an AI at some point.³⁴⁵ Furthermore, patients with node-positive HR+ ESBC should receive 10 years of endocrine-based therapy, regardless of menopausal status.

Adjuvant hormonal therapy for premenopausal women

The incidence of HR+ breast cancer in premenopausal women has increased in the last two decades, most

likely in the context of diet and lifestyle. Tamoxifen was classified as the standard adjuvant hormonal therapy for premenopausal women with HR+ EBC in 1995. A subsequent EBCTCG meta-analysis in 2001 demonstrated that 5 years of tamoxifen reduced the recurrence rate by 50% and BC-related mortality by 31%, regardless of age.³⁵¹ The role of other therapies, such as ovarian suppression, chemotherapy, or other hormonal therapies such as AIs, remained quite unclear.

INT 0101 (E5188) was a phase III randomized clinical trial of premenopausal with node-positive, HR+ ESBC. Patients were randomized to receive either CAF only, CAF followed by goserelin, or CAF followed by goserelin with tamoxifen.³⁵² The combination of CAF followed by goserelin and tamoxifen was associated with a significant improvement in time to recurrence and DFS compared with the combination of CAF plus goserelin, with a median follow-up of 11.5 years. Retrospectively, benefit was skewed toward women <40 years of age, possibly because they are most likely to regain ovarian function. Unfortunately, the study design did not include a CAF followed by tamoxifen arm, as this sequence was not believed to be of benefit at the time of study design. The inclusion of goserelin was associated with more weight gain, development of diabetes mellitus, and hot flashes.

INT 0101 (E5188) was the first clinical trial to assess the role of LHRH agonists as an adjuvant treatment for premenopausal women. Cuzick et al.³⁵³ performed a meta-analysis of 16 randomized clinical trials evaluating the use of LHRH agonists as adjuvant treatment for premenopausal women with HR+ breast cancer in 2007. Included trials assessed LHRH only, LHRH in combination with tamoxifen, LHRH in combination with chemotherapy, or the combination of LHRH, chemotherapy, and tamoxifen. None of the included trials compared chemotherapy with tamoxifen versus chemotherapy with LHRH. Trials of LHRH only demonstrated a statistically insignificant reduction in RR and death but lacked statistical power. The primary finding was that LHRH plus chemotherapy with or without tamoxifen resulted in a significant benefit in women of ≤40 years of age. Notably, the meta-analysis was underpowered to assess many important questions, such as the role of tamoxifen in premenopausal women and furthermore, none of the chemotherapy regimens were taxane-based and only a few were anthracycline-based.

The Austrian Breast and Colorectal Cancer Study Group 12 (ABCSG-12) clinical trial randomized 1803 women with HR+ ESBC who were receiving a 3-year course of goserelin to receive anastrozole or tamoxifen, with or without zoledronic acid over 3 years.³⁵⁴ At a median follow-up of 48 months, no DFS benefit was seen for women randomized to ovarian suppression plus AI (HR 1.10, 95% CI 0.78–1.53).

The SOFT/TEXT clinical trials have been proved as the most effective adjuvant endocrine therapy for premenopausal women with HR+ ESBC. TEXT and SOFT were phase III randomized clinical trials initiated in 2003 by the International Breast Cancer Study Group (IBCSG) in collaboration with the BIG and the North American Breast Cancer Group.³⁵⁵ The Tamoxifen and Exemestane Trial (TEXT) compared the use of adjuvant tamoxifen plus ovarian suppression and exemestane plus ovarian suppression over a 5-year period. A total of 2672 patients were randomized after surgery and received chemotherapy. By contrast, the Suppression of Ovarian Function Trial (SOFT) involved three arms comparing ovarian suppression plus tamoxifen, ovarian suppression plus exemestane, and tamoxifen only over 5 years. A total of 3066 women were randomized to the above arms after completing surgery and/or chemotherapy and were required to remain premenopausal before trial initiation. More than half of the study participants (53%) received chemotherapy. Bisphosphonates were not allowed in either trial unless patients had osteopenia or osteoporosis.

The original statistical analysis plans for TEXT and SOFT were to compare DFS between treatment groups within each trial separately, but because of fewer events occurring in this relatively low-risk population, trial amendments in 2011 allowed for a combined analysis of the TEXT and SOFT arms

comparing exemestane plus ovarian suppression to tamoxifen plus ovarian suppression. The TEXT/SOFT combined analysis of 4960 patients was reported at a median follow-up of 68 months in July 2014.³⁵⁶ The 5-year DFS in the exemestane plus ovarian suppression arm was 91.1% and in the tamoxifen plus ovarian suppression group was 87.3% with no difference in overall survival. AE rates were similar to those seen in prior studies of postmenopausal women, at 30.6% and 29.4% with exemestane and tamoxifen, respectively. The results suggest that patients with HR+ ESBC with higher-risk disease may achieve a greater reduction in distant recurrence with ovarian suppression plus AI. However, the data are not fully mature and over 50% of expected recurrence events have not yet occurred, suggesting that the current conclusions be accepted with caution.

Analysis of the addition of tamoxifen to ovarian suppression as addressed by SOFT was announced at the San Antonio Breast Cancer Symposium in December 2014. At a median follow-up of 67 months, the 5-year DFS was 86.6% in the ovarian suppression plus tamoxifen arm compared with 84.7% in the tamoxifen-only arm (HR 0.83; 95% CI, 0.66–1.04; $p = 0.10$).³⁵⁷ However, a higher treatment effect with tamoxifen plus ovarian suppression was appreciated in patients who had received chemotherapy (HR 0.78; 95% CI, 0.60–1.02) compared with those who received chemotherapy and tamoxifen only. This effect was also noted in patients who had received chemotherapy followed by exemestane plus ovarian suppression (HR 0.65; 95% CI, 0.49–0.87) compared with chemotherapy followed by tamoxifen only. Results from SOFT and TEXT are provided in [Table 10](#).

Table 10 Summary of results from the TEXT and SOFT clinical trials

TEXT/SOFT primary analysis at a median follow-up of 68 months (n = 4690) ³⁵⁵				
	5-Year DFS	5-Year BC ^a -free survival	5-Year distant BC recurrence-free survival	5-Year overall survival
TAM ^b /ovarian suppression	87.3%	88.8%	92.0%	96.9%
EXE ^c /ovarian suppression	91.1%	92.8%	93.8%	95.9%
	5-Year DFS (HR ^d for recurrence, new cancer, or death)	5-Year BC-free survival (HR for recurrence)	5-Year distant BC recurrence-free survival (HR)	5-Year OS (HR for death)
TAM/ovarian suppression vs EXE/ovarian suppression	0.72 (<i>p</i> < 0.001)	0.66 (<i>p</i> < 0.001)	0.78 (<i>p</i> = 0.02)	Insignificant
SOFT primary analysis at a median follow-up of 67 months (n = 3066) ³⁵⁷				
	5-Year DFS	5-Year BC-free survival	5-Year BC-free survival (chemo ^e)	5-Year overall survival (chemo ^e)
EXE/ovarian suppression	Not reported	90.9%	87.8%	Not reported
TAM/ovarian suppression	86.6%	88.4%	84.8%	94.5%
TAM	84.7%	86.4%	83.6%	90.9%
	5-Year DFS (HR for recurrence, new cancer, or death)	5-Year BC-free survival (HR for recurrence)	5-Year OS (chemo ^e) (HR for death)	
TAM/ovarian suppression vs TAM	0.83 (95% CI 0.66–1.04; <i>p</i> = 0.10)	0.81 (95% CI 0.63–1.03; <i>p</i> = 0.09)	0.64 (95% CI 0.42–0.96)	
Within the subset of SOFT participants <35 years of age (n = 350), 233 were included in the primary analysis, 94% of whom received chemotherapy				
	EXE/ovarian suppression	TAM/ovarian suppression	TAM	
BC-free survival at 5 years	83.4%	78.9%	67.7%	

^a BC, breast cancer.

^b TAM, tamoxifen.

^c EXE, exemestane.

^d HR, hazard ratio.

^e Subset of patients who received chemotherapy.

Comparison of the combined TEXT/SOFT results and ABCSG-12 is difficult given differences in trial design. Only 5% of patients in the ABCSG-12 study received chemotherapy, fewer patients were enrolled, ovarian suppression was given for only 3 years, and the addition of zoledronic acid may have abrogated the effect of AI, resulting in no significant difference between study arms.

The 2014 ASCO Clinical Practice Guideline Focused Update for adjuvant endocrine therapy recommended that premenopausal women with HR+ ESBC receive 5 years of tamoxifen.³⁵⁰ The guidelines state that tamoxifen should be extended to a total of 10 years if a patient remains pre- or perimenopausal after the initial 5-year period. If a woman is postmenopausal after 5 years of tamoxifen, she should be offered continuation of tamoxifen or a switch to an AI for 5 additional years. The 2015 St. Gallen Consensus on Primary Therapy recommends that ovarian suppression plus either tamoxifen or an AI be considered for premenopausal women with high risk of HR+ ESBC.³⁴⁵ High-risk patients were defined as those ≤ 35 years, premenopausal, status postchemotherapy, and with multiple positive nodes.

Adjuvant chemotherapy for HR+/HER2– ESBC

The first demonstration that the natural history of breast cancer could be altered with systemic therapy involved patients who were randomized to undergo radical mastectomy plus 3 days of thiotepa starting at the time of surgery or placebo.³⁵⁸ A significant improvement in 5-year survival for premenopausal women with at least four positive axillary lymph nodes treated with thiotepa in comparison to placebo was reported in 1968, findings that persisted after 10 years of follow-up. A second generation of clinical trials in the 1960s provided further evidence that a disease-free interval could be prolonged with systemic therapy. A clinical trial conducted jointly by the NSABP and the ECOG showed that L-phenylalanine mustard (L-PAM) administered orally for 24 months to patients with node-positive ESBC treated initially with radical mastectomy could prolong the disease-free interval of patients.³⁵⁴ Extended follow-up for more than 20 years showed not only a significant prolongation of DFS but also a significant benefit in the OS of premenopausal patients with the use of this single agent. A similar trend, initially observed in postmenopausal women, was not sustained.

The single-agent regimens examined in the aforementioned early clinical trials showed that systemic chemotherapy could improve outcomes and served as an impetus to design multiple-drug regimens. A third generation of clinical trials from the 1970s introduced regimens that are in use to date. Bonadonna et al. initially reported the Milan Study in 1976, which evaluated the combination of cyclophosphamide 100 mg/m² daily for 14 days, methotrexate 40 mg/m² iv days 1 and 8, and fluorouracil 600 mg/m² iv days 1 and 8 (CMF) given on a 4-week schedule for 12 cycles versus observation after radical mastectomy in women with node-positive ESBC.³⁵⁹ The study showed a significant reduction in treatment failure (5.3% vs 24%; $p < 10^{-6}$) in all subgroups of patients treated with CMF. Two-thirds of patients experienced various toxicities, including nausea, vomiting, anorexia, alopecia, cystitis, and amenorrhea. A median follow-up of 19.4-year results from the Milan trial continued to indicate a benefit in premenopausal, but not postmenopausal women.³⁶⁰ Although CMF was initially reported as less beneficial in postmenopausal women, longer follow-up suggested that older women were more likely to have had dose reductions and that the benefit was similar across age-groups when similar doses were provided.³⁶¹

CMF was broadly used as the primary chemotherapeutic regimen of choice in the 1980s and continues to

serve as reasonable adjuvant chemotherapy for a select group of patients. However, subsequent regimens containing anthracyclines and later taxanes were clearly defined as the standard adjuvant chemotherapy at the beginning of the twenty-first century.

Treatment combining doxorubicin (Adriamycin) and cyclophosphamide (AC) was reported as effective and safe for patients with MBC in 1975.³⁶² A large number of prospective trials evaluating various combinations of the anthracyclines doxorubicin and epirubicin were then conducted to determine optimal combinations as well as treatment frequency and length.

NSABP B-15 was designed to evaluate the benefit of a short course of chemotherapy, AC (doxorubicin 60 mg/m² iv and cyclophosphamide 600 mg/m² iv) given every 3 weeks for four cycles, over the more time-intensive CMF regimen, given every 4 weeks for six cycles.³⁶³ The study randomized 2194 women with node-positive tamoxifen-nonresponsive ESBC treated with primary surgery to either AC or CMF. (Tamoxifen-nonresponsive ESBC was defined as ESBC in all women ≤49 years of age and women 50–59 years with PR disease). With a median follow-up of 3 years, no significant difference in DFS or OS was observed. However, NSABP B-15 suggested that AC was preferable to CMF given its shorter treatment duration. Similar outcomes were noted in NSABP B-16, which included women with tamoxifen-responsive ESBC. Further analysis of existing randomized trials indicated that anthracycline-containing regimens that included three or more drugs (e.g., FAC, CAF, and FEC) had superiority over CMF.

Contemporary adjuvant chemotherapy for HR+/HER2– breast cancer have used taxanes in combination with anthracyclines. Several clinical trials, including CALGB 9344, NSABP B-28, BCIRG 001, and E1199, demonstrated the efficacy of such combinations.

CALGB 9344 had several aims, one of which was to evaluate the addition of paclitaxel to AC.³⁶⁴ A total of 3121 patients with node-positive ESBC were randomized to AC (with varying doses of doxorubicin, described in detail below), with or without four cycles of paclitaxel 175 mg/m² iv every 3 weeks. At a median of 5 years, the DFS for AC only was 65% and for AC plus paclitaxel was 70%, with an HR for recurrence with the addition of paclitaxel of 17%. OS for patients receiving AC only was 77% and for AC plus paclitaxel was 80%, with an HR for death with the addition of paclitaxel of 18%. The addition of paclitaxel resulted in an absolute improvement of DFS and OS at 5 years of 5% and 3%, respectively. These results led to the approval of paclitaxel in sequence with AC as adjuvant chemotherapy for ESBC in 2005.

NSABP-28 opened in 1995 and enrolled a total of 3060 women with node-positive resected operable breast cancer who were then randomized 1 : 1 to receive either four cycles of standard AC followed by four cycles of paclitaxel 225 mg/m² every 3 weeks (AC/T) or four cycles of standard AC only.³⁶⁵ All patients received concurrent tamoxifen. At a median follow-up of 64.6 months, DFS was 76% in the AC/T arm and 72% in the AC only arm with a statistically significant reduction in the RR of disease recurrence (RR 0.83; 95% CI 0.72–0.95; *p* = 0.006). Although the addition of paclitaxel to AC clearly improved DFS, no improvement in OS was appreciated with a 5-year OS of 85% in both groups.

Breast Cancer International Research Group (BCIRG) 001, a phase III clinical trial, was initiated in 1997 and compared six cycles of FAC to six cycles of docetaxel 75 mg/m² iv plus AC (TAC) every 3 weeks.³⁶⁶ A total of 1491 women with node-positive ESBC were randomized to the two arms. At a median follow-up of 55 months, the TAC arm was associated with a reduction in the risk of relapse (HR 0.72, 95% CI 0.59–0.88, *p* = 0.001) and death (HR 0.70, 95% CI 0.53–0.91; *p* = 0.008). Benefits in relapse risk and OS were maintained at a median follow-up of 124 months with HR 0.80 (95% CI 0.68–0.93; log-rank *p* = 0.0043) and HR 0.74 (95% CI 0.61–0.90; log-rank *p* = 0.020), respectively.³⁶⁷ Benefits were independent of the number of positive nodes, hormone receptor status, and HER2 status. BCIRG 001 clearly showed a

role for docetaxel in the adjuvant setting.

The E1199 clinical trial was designed to compare the taxanes paclitaxel and docetaxel, as well as schedules of weekly or every 3 weeks, using a 2×2 factorial design.³⁶⁸ A total of 4950 women with operable, node-positive or high-risk node-negative ESBC were randomized after primary surgery followed by four cycles of AC given every 3 weeks to one of the following arms: (1) paclitaxel 80 mg/m² iv weekly (infused for 1 h) for 12 weeks, (2) paclitaxel 175 mg/m² iv (infused for 3 h) every 3 weeks for four doses, (3) docetaxel 35 mg/m² iv (infused for 1 h) weekly for 12 weeks, or (4) docetaxel 100 mg/m² iv (infused for 1 h) every 3 weeks for four doses. At a median follow-up of 63.8 months, no differences were observed in the primary comparisons between taxane type and schedule. However, the weekly paclitaxel arm was associated with a significant improvement in DFS (HR, 0.79; $p = 0.006$) and OS (HR, 0.76; $p = 0.01$) as a prespecified secondary comparison to paclitaxel given every 3 weeks. These results led the NCCN to recommend weekly paclitaxel followed by AC as a preferred adjuvant regimen for ESBC.³⁶⁹ With a median follow-up of 12.1 years, DFS was still significantly improved, but quantitatively less pronounced in the weekly paclitaxel arm (HR 0.84; $p = 0.011$), whereas OS was only marginally improved (HR 0.87, $p = 0.09$).³⁷⁰ In addition, the arm with docetaxel given every 3 weeks was found to have a significant improvement in DFS (HR 0.79, $p = 0.001$) and a marginal improvement in OS (HR 0.86; $p = 0.054$) compared with every 3-week paclitaxel.

With a clear description that both anthracyclines and taxanes were strongly beneficial for the treatment of ESBC, researchers sought to optimize the benefit of a regimen while concurrently limiting its toxicity by evaluating various doses and intensities. Dose density improved outcomes, but increasing doses of doxorubicin were not more effective.

CALGB 8541 randomized 1572 women with node-positive breast cancer to one of three arms that varied the dose or frequency of cyclophosphamide in CAF.³⁷¹ The arms were cyclophosphamide 400 mg/m² iv plus doxorubicin 40 mg/m² iv every 28 days plus fluorouracil 400 mg/m² iv twice every 28 days for six cycles, cyclophosphamide 600 mg/m² iv plus doxorubicin 60 mg/m² iv every 28 days plus fluorouracil 600 mg/m² iv twice every 28 days for four cycles, and cyclophosphamide 300 mg/m² iv plus doxorubicin 30 mg/m² iv every 28 days plus fluorouracil 300 mg/m² iv twice every 28 days for four cycles. Thus, the first two groups received the same total dose, but with a higher intensity in the second group, while the third group received half the total dose of the other groups, but at the same intensity as the first group. At a median follow-up of 3.4 years, patients treated with a higher or moderate dose intensity had a statistically significantly longer DFS and OS, suggestive of a dose–response effect, and resulting in the selection of cyclophosphamide 600 mg/m² as the standard dose for adjuvant AC in ESBC.

The second aim of CALGB 9344 (described above) was to assess whether increasing doses of doxorubicin provided additional benefit.³⁶⁴ All patients enrolled on the CALGB 9344 received AC with doxorubicin at one of three doses (60, 75, or 90 mg/m² iv) plus standard cyclophosphamide (600 mg/m² iv) every 3 weeks for four cycles, followed by either paclitaxel for four cycles (as described above) or no additional chemotherapy. No benefit was observed with higher doses of doxorubicin as demonstrated by a DFS of 69%, 66%, and 67% for patients who received 60, 75, and 90 mg/m² iv of doxorubicin, respectively.

Preclinical studies revealed that a given dose of chemotherapy kills a certain fraction of cancer cells rather than a specific number. Breast cancers grow with nonexponential Gompertzian kinetics, but regrowth after cytoreduction is in fact more rapid than in exponential models.³⁷² Several researchers hypothesized that more frequent administration of cytotoxic chemotherapy would provide more effective

disease control than increasing doses. An initial limitation to studying this hypothesis was the increased risk of myelosuppression. The development of filgrastim, a recombinant human granulocyte colony-stimulating factor (CSF) that reduces neutropenia, however, allowed for the evaluation of dose-intensified regimens.³⁷³

CALGB 9741 was the pivotal clinical trial that demonstrated that dose density, the administration of chemotherapy with a shortened intertreatment time interval, improved clinical outcomes.³⁷⁴ The study additionally evaluated whether sequential or concurrent administration of chemotherapy agents would provide more benefit, with the hypothesis that higher dose density would be achieved with sequential therapy, which would additionally minimize toxicity. This study enrolled 2005 women with node-positive ESBC to one of four arms: (1) sequential doxorubicin (A) 60 mg/m² iv × four doses followed by paclitaxel (T) 175 mg/m² iv for four doses, followed by cyclophosphamide (C) 600 mg/m² iv for four doses, with all doses given every 3 weeks; (2) sequential ACT as above, with all doses given every 2 weeks with filgrastim; (3) concurrent AC for four cycles every 3 weeks followed by T for four cycles, with all doses given every 3 weeks; and (4) concurrent AC for four cycles followed by T for four cycles, with all doses given every 2 weeks with filgrastim. Drugs were provided with the same dose in all arms. At a median follow-up of 36 months, the dose-dense regimens (every 2 weeks) showed a clear improvement in DFS (risk ratio 0.74; $p = 0.010$) and OS (risk ratio 0.69; $p = 0.013$). The 4-year DFS was 82% for the dose-dense regimens and 75% for the less-dense regimens. No difference was observed between concurrent and sequential schedules. Patients on the dose-dense regimens experienced less-severe neutropenia than other regimens.

With results from CALGB 9741, CALGB 9344, and BCIRG 001, dose-dense AC plus a taxane became the standard of care for node-positive and high-risk node-negative breast cancers. Such regimens are associated with significant toxicity however, with short- and long-term risks. Myelosuppression was initially a more frequent complication that improved with the development of G-CSF. Anthracyclines are associated with increased cardiotoxicity (odds ratio 5.43, 95% CI 2.34–12.62) and is a dose-limiting side effect. Researchers therefore sought less toxic, equally efficacious treatment regimens for women with lower-risk ESBC. US Oncology Research Trial 9735, a phase III clinical trial, randomized 1016 patients with resected operable ESBC to either docetaxel 75 mg/m² iv plus cyclophosphamide 600 mg/m² iv (TC) every 3 weeks for four cycles or standard AC with no prophylactic G-CSF allowed.³⁷⁵ A proportion of 16% of the study participants were ≥65 years of age, a population that was poorly represented in many of the pivotal trials of ESBC. Older women were more likely to have node-positive disease than their younger counterparts. At a median of 5.5 years, 86% of the TC group remained disease-free, in comparison to 80% of the AC group (HR 0.67, 95% CI 0.50–0.94; $p = 0.015$) with no OS benefit appreciated. This benefit was persistent at a median of 7 years of follow-up (HR 0.74, 95% CI 0.50–0.97, $p = 0.033$). In addition, a benefit in OS was recognized with 87% of the TC group alive in comparison to 82% of the AC group (HR 0.69; 95% CI, 0.50–0.97; $p = 0.032$).³⁷⁶ The DFS and OS benefit was independent of age, nodal status, or receptor status. Toxicities varied by regimen, with an increase in myalgias, arthralgias, edema, and febrile neutropenia in the TC group in comparison to an increase in nausea and vomiting in the AC group. Febrile neutropenia was not more frequent in older patients.

CALGB 40101 (Alliance) was designed to evaluate whether single-agent paclitaxel was noninferior to AC in an effort to identify a regimen that provided benefit to women with lower-risk node-positive (one to three lymph nodes) or node-negative ESBC.³⁷⁷ A total of 3871 patients were enrolled and randomized to four arms based on a 2 × 2 factorial design. The arms were standard AC every 3 weeks for four or six cycles and paclitaxel weekly for 12 or 18 weeks. The study accrued slowly, however, and the two longer

duration arms were closed, with further randomization restricted to the two remaining arms. The study was closed early in July 2010 because of failure to achieve the planned accrual target of 4646 patients. At a median follow-up of 6.1 years, HR of 1.26 and 1.27 for DFS and OS, respectively, favored treatment with AC, failing to provide evidence that paclitaxel was noninferior to AC. As expected, more neuropathy was present in the paclitaxel arms, while more hematologic toxicities were observed in the AC arms; paclitaxel was felt overall to be less toxic.

Given the improvement in treatment efficacy for ESBC with combined chemotherapies, such as with AC/T, TAC, and TC, other regimens that were initially evaluated in MBC were evaluated in the adjuvant setting. As of 2015, no additional adjuvant chemotherapy regimens have added benefit to HR+/HER2– ESBC. Preferred and alternative adjuvant (and neoadjuvant) chemotherapy regimens for ESBC are listed in [Table 11](#). Addition of capecitabine or gemcitabine did not improve outcomes.

Table 11 Preferred and alternative neoadjuvant and adjuvant chemotherapy regimens for early-stage breast cancer, by subtype

<i>Preferred neoadjuvant/adjuvant chemotherapy regimens</i>	
HER2– ESBC	Dose-dense doxorubicin + cyclophosphamide (ddAC)/dose-dense paclitaxel (ddT)
	dose-dense doxorubicin + cyclophosphamide (ddAC)/weekly paclitaxel (T)
	docetaxel + cyclophosphamide (TC)
HER2+ ESBC	Doxorubicin + cyclophosphamide (AC)/paclitaxel + trastuzumab (TH) ± pertuzumab
	docetaxel + carboplatin + trastuzumab (TCH) ± pertuzumab
<i>Alternative neoadjuvant/adjuvant chemotherapy regimens</i>	
HER2– ESBC	Dose-dense doxorubicin + cyclophosphamide (ddAC)
	doxorubicin + cyclophosphamide (AC)
	fluorouracil + doxorubicin + cyclophosphamide (FAC)
	fluorouracil + epirubicin + cyclophosphamide (FEC)
	docetaxel + doxorubicin + cyclophosphamide (TAC)
	cyclophosphamide + methotrexate + fluorouracil (CMF)
HER2+ ESBC	Paclitaxel + trastuzumab (TH)
	FEC/taxane + trastuzumab ± pertuzumab
	AC/taxane + trastuzumab ± pertuzumab

Single-agent capecitabine, the prodrug form of 5-fluorouracil, is associated with a response rate up to 30% in patients with MBC. Unlike other chemotherapies, capecitabine is administered orally, which is preferable for many patients. Capecitabine was first evaluated in the setting of ESBC as part of the CALGB 49907 clinical trial.³⁷⁹ The study focused on elderly patients, as it was felt an oral therapy would be better tolerated. CALGB 49907 randomized 633 patients ≥65 years with resected primary operable breast cancer to capecitabine daily for 14 days on a 21-day cycle or to oncologists' choice of CMF or AC. At a median follow-up of 2.4 years, the rates of relapse and death in the capecitabine arm were twice

as high as in the standard therapy arm, with a recurrence HR of 2.09 ($p < 0.001$).

The FINXX clinical trial evaluated the addition of capecitabine to anthracycline/taxane-based therapy.³⁸⁰ Patients were randomized to receive docetaxel with capecitabine for three cycles followed by cyclophosphamide, epirubicin, and capecitabine (TX/CEX) for three cycles or three cycles of docetaxel followed by CEF for three cycles (T/CEF). At a median follow-up of 59 months, no significant difference in recurrence-free survival was demonstrated, with an HR of 0.79 (95% CI, 0.60–1.04; $p = 0.087$).

Given its efficacy in MBC, gemcitabine was evaluated as an adjuvant therapy in combination with an anthracycline and taxane. The tAnGo phase III clinical trial randomized patients with high-risk ESBC to receive either epirubicin 90 mg/m² iv and cyclophosphamide 600 mg/m² iv (EC) every 3 weeks for four cycles followed by gemcitabine 1250 mg/m² iv (days 1 and 8) and paclitaxel 175 mg/m² iv (day 1) (GT) for four cycles every 3 weeks or EC followed by paclitaxel only (EC/T).³⁸¹ A total of 3152 patients were enrolled, of which 55% were ≤ 50 years, 77% were node-positive, 41% were ER+, and 26% were HER2+. A preplanned interim analysis at 30 months was notable for no difference in DFS (HR 1.0, 95% CI 0.8–1.2, $p = 0.96$) or OS (HR = 1.1, 95% CI 0.9–1.4, $p = 0.35$) between the two treatment groups, suggesting no benefit from the addition of gemcitabine.

A clear majority of the 2015 St. Gallen panel members agreed that luminal A-like ESBC was generally less responsive to chemotherapy.³⁴⁵ The panel agreed that luminal B-like ESBC with low-risk scores based on Oncotype DX, MP, and Prosigna should not receive chemotherapy. Relative indications for chemotherapy in luminal-like ESBC were grade 3 histology, ≥ 4 positive LN, high Ki-67, and extensive lymphovascular invasion.

Chemotherapy for HER2+ ESBC

Retrospective analyses of several of the pivotal adjuvant chemotherapy trials revealed that the greatest benefits were observed in subsets of patients with overexpression of HER2. CALGB 8869 was designed to determine whether molecular markers could predict a patient's response to adjuvant chemotherapy in CALGB 8541.³⁸² A total of 442 tumor samples were randomly selected from the CALGB 8541 clinical trial. Patients with tumors that had $\geq 50\%$ overexpression of c-erbB-2 were found to have a significantly longer DFS and OS after receiving the high-dose CAF regimen, and no benefit was seen in those without HER2 overexpression.

As described earlier, CALGB 9344 assessed the effect of escalating doses of doxorubicin as well as the addition of a taxane to anthracycline-based chemotherapy on DFS and OS for women with node-positive ESBC.³⁶⁴ In a retrospective analysis of tumor samples from CALGB 9344, Hayes et al.³⁸³ assessed whether additional benefit was seen in patients with HER2+ ESBC. Approximately 50% of the study participants were randomly selected and their tumor samples were centrally assessed with IHC and/or FISH for HER2 status. As stated elsewhere, no benefit was seen when patients were treated with doses of doxorubicin above 60 mg/m²; consistent with these earlier findings, no benefit was seen with higher doxorubicin dosing in the subset of patients with HER2+ tumors. However, the addition of paclitaxel resulted in a significant benefit for patients with HER2+ disease with an HR for recurrence of 0.59 ($p = 0.01$). Little benefit was appreciated in those patients with HR+/HER2– ESBC.

Hugh et al. assessed prognostic significance and predictive response of tumor subtypes to adjuvant chemotherapy for over 90% of tumor samples from participants in BCIRG 001.³⁸⁴ BCIRG 001, described in detail above, compared TAC with FAC in patients with operable node-positive breast cancer. Tumor subtypes were defined by IHC for ER, PR, HER2, and Ki-67. Patients were subdivided into triple-negative (14.5%), HER2 (8.5%), luminal B (61.1%), and luminal A (15.9%). Three-year DFS p values

were calculated with luminal B as referent. Patients with ER–/PR–/HER2+ observed only a marginally significant benefit in DFS with HR 0.50 (95% CI, 0.29–1.83).

The recognition that a significant benefit was appreciated with anthracycline- and taxane-based chemotherapy in patients with HER2+ ESBC led to the general recommendation that patients with HER2+ breast cancer receive adjuvant chemotherapy.

Trastuzumab-based therapy

The development of anti-HER2 antibody trastuzumab resulted in a dramatic improvement in the outcomes of women with HER2+ breast cancer, with a significant reduction in the development of recurrent breast cancer. Trastuzumab is a humanized monoclonal antibody that suppresses growth, proliferation, and survival of HER2 overexpressing cancer cells. The antibody is targeted against the extracellular region of HER2, preventing dimerization with other HER2 molecules. Scientists have proposed several mechanisms to explain the cellular and molecular activity of trastuzumab. A compelling hypothesis is that trastuzumab activates antibody-dependent cellular cytotoxicity through immunologic targeting of HER2+ tumor cells. In vitro studies have demonstrated that removal of the Fc portion of the trastuzumab antibody destroys trastuzumab activity, while enhancement of the Fc receptor results in increased activity in mouse HER2 enriched tumor models.^{385, 386} An alternative proposal is that after trastuzumab binds HER2, natural killer cells are triggered and facilitate apoptosis. A well-accepted mechanism is that trastuzumab interferes with cell signaling along the MAPK and PI3K/Akt pathways that are involved in cell growth and proliferation.³⁸⁷ Binding of HER2 by trastuzumab prevents HER2 from dimerizing, which is necessary for Akt phosphorylation, blocking tyrosine kinase Src signaling.

Toxicities of trastuzumab

Trastuzumab is generally well tolerated, but cardiac toxicity is a rare but serious adverse effect. Cardiac toxicity was an unexpected finding in the original trastuzumab studies that were conducted in the MBC setting. Cardiac dysfunction due to trastuzumab is defined as a reduction in left ventricular ejection fraction (LVEF) of $\leq 5\%$ with symptoms of congestive heart failure or $\leq 10\%$ in the absence of symptoms.³⁸⁸ A meta-analysis by Seidman et al. of cardiotoxicity in clinical trials of trastuzumab reported that the use of an anthracycline with concurrent trastuzumab resulted in unacceptable cardiotoxicity (27%).³⁸⁹ Cardiotoxicity was less significant in patients who received trastuzumab only (3–7%) or trastuzumab plus paclitaxel (13%). In comparison, 8% of patients receiving anthracyclines without trastuzumab developed cardiotoxicity. Holding of trastuzumab results in reversal of cardiotoxicity in most patients, at which time trastuzumab therapy can be resumed. Optimal monitoring of LVEF in patients on trastuzumab is not well defined, and recommendations vary from every 3 to 6 months.

Historic trials of trastuzumab (B3-1, N9831, BCIRG-006, and HERA)

Trastuzumab was approved as an adjuvant HER2-directed therapy in 2006, in the context of four large clinical trials evaluating over 13,000 women that consistently reported a reduction in 3-year recurrence risk of approximately 50%. Four studies were initiated around 2000 and asked several questions with slight variations in design.

NSABP B-31 enrolled 2030 women with node-positive HER2+ breast cancer who were all to receive standard AC followed by paclitaxel, given either every 3 weeks or weekly.³⁹⁰ Patients were randomized to receive trastuzumab, starting with paclitaxel, for a total of 52 weeks, or to receive paclitaxel only. A second study, North Central Cancer Treatment Group (NCCTG) N9831, enrolled 3506 women, also with

node-positive HER2 ESBC, that had two arms identical to those of NSABP B-31 as well as a third arm that received trastuzumab for 52 weeks, but only after the completion of AC/T (XX). A combined analysis of NSABP B-31 and the first two arms of NCCTG N9831 at a median 2-year follow-up demonstrated a significantly longer DFS in the trastuzumab-containing arms (HR 0.48; 95% CI 0.39–0.59, $p < 0.001$) with an absolute difference in DFS of 12% at 3 years. Trastuzumab arms were associated with a 53% reduction in risk of distant recurrence (95% CI 0.37–0.61, $p < 0.0001$) and a reduction in mortality by one-third, in comparison to the control arms (95% CI 0.48–0.93, $p = 0.015$).

BCIRG006 was a global, multicenter clinical trial that randomized 3222 women to three arms: two arms similar to the NSABP B-31 and NCCTG N9831 studies [standard AC followed by docetaxel with trastuzumab (AC/TH)] and a third, nonanthracycline-containing arm with docetaxel, carboplatin, and trastuzumab (TCH).³⁸⁷ At a median 2-year follow-up, a clear improvement in DFS was appreciated in the trastuzumab-containing arms, with a 51% reduction in risk of relapse in the AC/TH arm ($p < 0.0001$) and a 39% reduction in the risk of relapse ($p = 0.0002$) in the TCH arm. No comparisons of efficacy could be drawn between the AC/TH and TCH arms due to study design. A nonstatistically significant trend toward survival benefit was observed in the trastuzumab-containing arms.

The Herceptin Adjuvant (HERA) phase III clinical trial enrolled 5090 women with HER2+ ESBC who had completed four cycles of adjuvant (or neoadjuvant) chemotherapy and radiation (if indicated) to one of three arms: observation, 1 year of trastuzumab, or 2 years of trastuzumab.³⁹¹ The first interim analysis reported an absolute benefit in DFS of 8.4% at 2 years when comparing 1 year of trastuzumab versus observation. Event-free patients in the observation arm were allowed to cross over to receive trastuzumab.³⁹² Even so, intention-to-treat analysis of 4-year DFS with 1 year of trastuzumab in comparison to observation was significant (78.6% vs 72.2%; HR 0.76; 95% CI 0.66–0.87, $p < 0.0001$). No difference in OS was appreciated. Outcomes associated with 1 years versus 2 years of trastuzumab are discussed below.

NSABP B-31, NCCTG N9831, BCIRG 006, and HERA demonstrated a significant benefit in DFS with the addition of trastuzumab to adjuvant chemotherapy for HER2+ ESBC. The NCCN Guidelines for Breast Cancer that were updated in 2015 state that patients with HER2+ ESBC with a primary tumor >0.5 cm or positive lymph nodes should receive adjuvant chemotherapy with trastuzumab.³⁹⁵ Preferred and alternative adjuvant (and neoadjuvant) chemotherapy regimens for HER2+ ESBC are listed in [Table 11](#). The guidelines state that the benefit of trastuzumab in patients with node-negative T1a (≤ 0.5 cm) or T1b (0.5–1.0 cm) is uncertain and must be carefully weighed with its known toxicities. This question was recently addressed in the APT clinical trial that is described in detail below.

The NCCN Guidelines currently recommend that adjuvant trastuzumab be administered with taxane-based chemotherapy and then as a single agent to complete a total of 1 year (or 52 weeks).³⁹³ This duration was selected arbitrarily in the above clinical trials of trastuzumab. NSABP B-31, NCCTG N9831, and BCIRG 006 only evaluated 1 year of trastuzumab, but HERA evaluated both 1 and 2 years of trastuzumab. At a median follow-up of 8 years, no significant difference was observed in the DFS of patients randomized to 1 or 2 years of trastuzumab (HR 0.99, 95% CI 0.85–1.14, $p = 0.86$).³⁹⁴ Furthermore, grade 3–4 AEs and LVEF dysfunction were more frequent in patients who received trastuzumab for 2 years (20.4% and 7.2%, respectively) than 1 year (16.3% and 4.1%, respectively).

Given the toxicities and costs associated with trastuzumab, researchers investigated whether a shortened course of trastuzumab (9 weeks, 3 months, or 6 months) would be noninferior to the recommended 52-week course. To date, shorter regimens have not proven equivalent in efficacy to the standard 52 weeks of trastuzumab.

The Finland Herceptin (FIN-HER) clinical trial evaluated the efficacy of a short course of trastuzumab to limit cardiotoxicity.³⁹² This phase III clinical trial enrolled 1010 women with node-positive or high-risk node-negative breast cancer to receive either docetaxel for three cycles, followed by FEC, or vinorelbine for three cycles, followed by FEC. A total of 232 participants had HER2+ disease and were additionally randomized to receive or not to receive 9 weeks of trastuzumab during cycles of docetaxel or vinorelbine. The 3-year DFS was improved in the trastuzumab-containing arms (HR for recurrence or death 0.42, 95% CI, 0.21–0.83; $p = 0.01$). No reductions in LVEF or cardiac failure events were observed.

The Protocol for Herceptin as Adjuvant therapy with Reduced Exposure (PHARE) phase III clinical trial enrolled 3384 patients with HER2+ ESBC who had already completed primary surgery, at least four cycles of chemotherapy, and 6 months of trastuzumab.³⁹⁵ Patients were randomized to continue trastuzumab for an additional 6 months (for a total of 12 months) or to discontinue trastuzumab (for a total of 6 months) in an attempt to demonstrate noninferiority. At a median follow-up of 42.5 months, the DFS was 87.8% and 84.9% in the 12- and 6-month arms, respectively, and OS was 95% and 93.1%, thus failing to show noninferiority in the shorter arm.

The Hellenic Oncology Research Group recently reported on a phase III clinical trial that randomized 481 women with node-positive or high-risk node-negative HER2+ ESBC to undergo either 12 or 6 months of trastuzumab in combination with adjuvant chemotherapy.³⁹⁶ In particular, after primary surgery, all patients received dose-dense FEC followed by docetaxel 75 mg/m² every 14 days for four cycles with concurrent trastuzumab, which was then extended for either a total of 12 or 6 months. The 3-year DFS for the 12- and 6-month arms was 95.7% versus 93.3% respectively (HR = 1.57; 95% CI 0.86–2.10; $p = 0.137$), failing to show noninferiority for the 6-month arm.

The Short-HER phase III clinical trial (NCT00629278) compared 3 and 12 months of trastuzumab.³⁹⁷ The study aimed to randomize 2500 women with node-positive or high-risk node-negative HER2+ ESBC to receive four cycles of anthracycline-based chemotherapy, followed by four cycles of taxane-based chemotherapy with concurrent trastuzumab followed by a total of 18 cycles of every 3-week trastuzumab or three cycles of every 3-week docetaxel in combination with trastuzumab, followed by three cycles of FEC with no additional trastuzumab. The study was completed in 2010, but no results have been released as of August 2015.

The Synergism or Long Duration (SOLD) study was a phase III clinical trial (NCT00593697) sponsored by the Finnish Breast Cancer Group to evaluate 9 weeks versus 52 weeks of trastuzumab.³⁹⁸ A total of 2168 women with HER2+ ESBC were randomized to receive either three cycles of every 3-week docetaxel with concurrent trastuzumab (TH) followed by FE75C for three cycles or the same regimen followed by every 3-week trastuzumab for a total of 52 weeks. The study was completed in November 2014, but no results have been released as of August 2015.

The Persephone phase III clinical trial aimed to enroll 4000 patients with HER2+ ESBC to compare 6 months of trastuzumab to the 12-month standard. The study was started in 2007, and 3166 patients had been randomized as of 2014.³⁹⁹ The first planned interim analysis of noninferiority is expected in mid-2016.

The preceding clinical trials demonstrated the importance of HER2-directed therapy with trastuzumab for women with node-positive or high-risk node-negative HER2+ ESBC. Women with small node-negative HER2+ ESBC were not included in these studies, and proper management of such disease is unclear. An NCCN database of 520 patients with HR-/HER2+ ESBC with tumors ≤ 1 cm has reported a median 5-year DFS of 94% (T1bN0), 93% (T1aN0), and 94–96% (T1a-bN0).⁴⁰⁰ The Adjuvant Paclitaxel and Trastuzumab (APT) clinical trial was a single-arm multicenter investigator initiated clinical trial to

develop an efficacious regimen that limited toxicities for patients with small node-negative HER2+ ESBC as such patients are expected to have generally favorable prognosis.⁴⁰¹ All patients received paclitaxel 80 mg/m² iv weekly for 12 weeks and 12 weeks of trastuzumab for 9 additional months. A total of 410 patients were enrolled, with 87.7% completing study treatment. The study demonstrated that a combination of weekly paclitaxel with trastuzumab only was appropriate. The 3-year DFS was 98.7% (95% CI 97.6–99.8), better than historic controls. AEs included 13 patients with one episode of grade 3 neuropathy and 13 patients with asymptomatic declines in ejection fraction from which all but two patients recovered.

Pertuzumab adjuvant and neoadjuvant studies

Pertuzumab, a humanized monoclonal antibody, is a first-in-class HER heterodimer inhibitor that binds to the HER2 dimerization domain and prevents interaction of HER2 with other HER family members. Unlike trastuzumab, which prevents only HER2 homodimerization, pertuzumab inhibits HER2:HER3 binding, which is the most active HER complex.⁴⁰² Pertuzumab was approved by the Food and Drug Administration (FDA) in 2012 for use in patients with MBC based on the results from the CLEOPATRA clinical trial, which demonstrated that the combination of docetaxel, trastuzumab, and pertuzumab was superior to docetaxel plus trastuzumab only. Results from the NeoSphere clinical trial, which evaluated neoadjuvant pertuzumab in combination with docetaxel and trastuzumab, led to its approval in the neoadjuvant setting in 2014. The Adjuvant Pertuzumab and Herceptin INiTiAl TherapY of Breast Cancer (APHINITY) clinical trial (NCT01358877) was designed to determine whether pertuzumab, when given in combination with standard adjuvant chemotherapy and trastuzumab, resulted in an increased efficacy.⁴⁰³ A total of 4810 patients with node-positive HER2+ ESBC were randomized in a double-blind manner to one of two arms in a 1 : 1 ratio. All patients received six to eight cycles of adjuvant chemotherapy with either an anthracycline–taxane or taxane–platin regimen based on investigator's choice. The investigational arm included concurrent trastuzumab and pertuzumab that extended for 1 year, whereas the comparator arm included concurrent trastuzumab and placebo that extended for 1 year. Initial results are expected in 2016.

Pertuzumab is not yet approved in the adjuvant setting. However, the most recent NCCN Guidelines for Breast Cancer state that patients with pathologic stage \geq T2N1, HER2+ ESBC who did not receive a neoadjuvant pertuzumab-containing regimen can receive adjuvant pertuzumab.³⁹⁵

Investigational studies of new adjuvant therapies for HER2+ ESBC

Lapatinib is an oral small-molecule dual tyrosine kinase inhibitor of HER2 and EGFR. Lapatinib was approved in combination with capecitabine for patients with HER2+ MBC who had progressed on trastuzumab.⁴⁰⁴ Although generally well tolerated, lapatinib is associated with mild to moderate diarrhea, rash, and mild, transient increases in liver transaminases. The Tykerb Evaluation After CHemotherapy (TEACH) trial evaluated the efficacy and safety of lapatinib as an adjuvant therapy for patients who had received chemotherapy for HER2 ESBC without trastuzumab.⁴⁰⁵ This multinational, double-blinded phase III clinical trial randomized 3147 patients to receive lapatinib or placebo, to be started at any time after completion of adjuvant chemotherapy. At a median follow-up of 47.4 months in the lapatinib group and 48.3 months in the placebo group, no significant difference in the occurrence of DFS events was appreciated (13% vs. 17%, HR = 0.83, 95% CI 0.70–1.00; p = 0.053). However, central assessment of HER2 status showed that only 79% of the study participants were HER2+ and that the DFS benefit was marginal. The study authors concluded that lapatinib might be an appropriate adjuvant therapy for women with HER2 ESBC who are unable to receive adjuvant trastuzumab.

The Adjuvant Lapatinib and/or Trastuzumab Treatment Optimization (ALTTO) clinical trial randomized 8381 patients with HER2+ ESBC to receive 1 year of lapatinib plus trastuzumab (L + T), 1 year of trastuzumab, and 1 year of lapatinib or trastuzumab only as adjuvant therapy.⁴⁰⁶ ALTTO was a companion study to the NEOALTTO clinical trial (described in neoadjuvant section) that demonstrated a doubling in the pCR rate with L + T in comparison to trastuzumab only.⁴⁰⁷ The initial results of the ALTTO clinical trial were announced at ASCO in 2014. An insignificant improvement was observed in the 4-year DFS with L + T (88%) versus trastuzumab (86%) (HR 0.84, 97.5% CI, 0.70–1.02; $p = 0.048$) and with trastuzumab followed by lapatinib (87%) versus trastuzumab (86%) (HR 0.93, 97.5% CI, 0.76–1.13; noninferiority $p = 0.044$). The initial results from ALTTO were both surprising and disappointing in the context of the NEOALTTO results, leading researchers to question the utility of pCR.

Neratinib is an oral multityrosine kinase inhibitor of HER2, HER4, and EGFR. This novel drug was initially studied in a phase II clinical trial of patients with HER2+ MBC in combination with trastuzumab and paclitaxel, which demonstrated an improvement in progression-free survival (PFS).⁴⁰⁸ Positive results in the metastatic and neoadjuvant setting led to the evaluation of neratinib as an extended adjuvant therapy for HER2+ ESBC. The ExteNET clinical trial was a double-blind, placebo-controlled, phase III clinical trial evaluating the efficacy of 12 months of neratinib following standard chemotherapy with trastuzumab.⁴⁰⁹ The study randomized 2840 patients with HER2+ ESBC who had completed primary surgery and standard adjuvant chemotherapy with trastuzumab to receive neratinib or placebo for 1 year. At a 2-year median follow-up, the neratinib arm was demonstrated to improve DFS in comparison to placebo (93.9% vs. 91.6%; HR 0.67; $p = 0.0046$). The most frequently observed AE in the neratinib arm was diarrhea, with grade 3 diarrhea experienced by 40% of patients.

The ATEMPT phase II clinical trial (NCT01853748) is evaluating the use of single agent ado-trastuzumab emtansine (T-DM1) as an adjuvant therapy with a goal to avoid the toxicity associated with chemotherapy while reducing the risk of disease recurrence, building upon the outcomes from the APT study.⁴⁰¹ T-DM1 is an antibody–drug conjugate linking trastuzumab to the cytotoxic agent DM1. T-DM1 was approved by the FDA as a second-line therapy for HER2+ MBC in 2013 based on results from the EMILIA clinical trial (described in the MBC section). ATEMPT was started in May 2013 with an intention to enroll 500 women with stage I HER2+ breast cancer. Patients are randomized in a 3 : 1 ratio to T-DM1 given every 3 weeks for 51 weeks with weekly paclitaxel given in combination with weekly trastuzumab for 12 cycles followed by 9 months of trastuzumab monotherapy to complete 1 year of trastuzumab therapy. The estimated final data collection for the primary outcome measure of DFS is estimated for May 2017.

Triple-negative breast cancer

No targeted therapies are available for the treatment of TNBC, in contrast to HR+ and HER2+ ESBC that have endocrine- and HER2-based therapies, respectively. For this reason, chemotherapy is the singular adjuvant therapy for patients with TNBC. A majority of the retrospective analyses of tumor subtypes in the pivotal adjuvant chemotherapy trials failed to specify outcomes for TNBC. However, the available analyses have clearly demonstrated significant benefits with taxane-based regimens for TNBC.

The E1199 clinical trial, described in detail above, compared the efficacies of paclitaxel and docetaxel, as well as treatment frequency (3 weeks vs. weekly) in patients with operable, node-positive, or high-risk node-negative ESBC who had already undergone primary surgery followed by four cycles of standard AC.³⁶⁶ An exploratory analysis of the 1025 patients with TNBC at a median follow-up of 12.1 years demonstrated that weekly paclitaxel was associated with a significant improvement in DFS and OS when compared to every 3-week paclitaxel (DFS HR 0.69; $p = 0.001$; OS HR 0.69; $p = 0.019$).³⁶⁸ These

findings showed that patients with TNBC, who are treated with AC followed by weekly paclitaxel, experience a 10% absolute improvement in DFS and OS at 10 years. US Oncology Research Trial 9735, described in detail above, demonstrated that four cycles of TC were superior to four cycles of standard AC with regard to DFS and OS in patients with TNBC.³⁷⁴

Several phase III clinical trials of bevacizumab, a humanized monoclonal antibody against vascular endothelial growth factor (VEGF), suggested some benefit in patients with metastatic TNBC when studied in combination with chemotherapy. The adjuvant bevacizumab-containing therapy in TNBC (BEATRICE) clinical trial randomized 2591 patients with operable primary TNBC to chemotherapy with or without bevacizumab at a dose equivalent to 5 mg/kg weekly for 1 year.⁴¹⁰ TNBC status was centrally confirmed. At a median follow-up of approximately 32 months, the 3-year invasive DFS and OS were similar in both arms.

Several neoadjuvant clinical trials (discussed elsewhere) of platinum agents have demonstrated an improved pCR in patients with BRCA1 ESBC, the majority of which are TNBC. No study specifically evaluating platinum regimens for TNBC in the adjuvant setting has been reported.

Neoadjuvant chemotherapy: sequencing surgery and chemotherapy

Breast cancer treatment historically started with surgical removal followed by chemotherapy, radiation therapy, and hormone therapy, as needed. However, an increasing percentage of breast cancer patients are being treated with chemotherapy before definitive surgery. Preoperative (or neoadjuvant) chemotherapy was initially used in women with inflammatory or inoperable breast tumors in an attempt to render the disease operable. Subsequently, neoadjuvant chemotherapy was investigated as a strategy to permit breast conservation therapy for patients with larger T2 or T3 disease. Even more recently, neoadjuvant chemotherapy has been explored as a treatment option to allow for early evaluation of the effectiveness of systemic therapy and thus provide an opportunity to test promising new agents earlier in the course of the disease. As a result, these treatment philosophies have permitted the majority of breast cancer patients to be eligible for neoadjuvant chemotherapy. [Table 12](#) reviews some of these potential benefits.

Table 12 Potential benefits of using neoadjuvant chemotherapy in breast cancer

Benefits
Improves the ability for patients presenting with inoperable disease or inflammatory breast cancer to undergo surgery
Increases the rate of breast conservation surgery
Improves the cosmetics of breast conservation if more limited surgery can be performed after response to therapy
May allow early identification of resistance, allowing ineffective therapy to stopped earlier
May allow less extensive postsurgical radiation fields
Response to neoadjuvant chemotherapy is prognostic, particularly when minimal or no invasive cancer is found at the time of surgery. Treatment in the neoadjuvant setting is an invaluable research tool to:
Compare the effectiveness of two systemic regimens, or the addition of a targeted agent to standard therapy
Study biological factors that influence chemotherapy sensitivity/resistance
Identify patients at high risk for recurrence despite standard treatment for participation in clinical studies of new agents
Allow early regulatory approval of treatments that have been demonstrated to improve response to standard therapy while waiting for larger adjuvant studies to be completed

Over the years, numerous studies have been conducted to assess the worth of preoperative chemotherapy for primary operable breast cancer. The NSABP B-18, a randomized trial comparing the preoperative and postoperative administration of four cycles of doxorubicin and cyclophosphamide (AC) in patients with operable breast cancer,⁴¹¹ found no difference in DFS and OS in the preoperative chemotherapy group compared with the postoperative adjuvant therapy group. The EORTC completed a confirmatory trial of very similar design, with results quite similar to those obtained in NSABP B-18.³⁶⁵

One unanswered question that arose from B-18 concerned the need for further therapy following initial treatment, and this was addressed in the Aberdeen trial.⁴¹² In this small study, 162 patients received four cycles of doxorubicin, cyclophosphamide, vincristine, and prednisolone (CVAP), and responders were randomized to receive four more cycles of CVAP or four cycles of docetaxel (100 mg/m²) and nonresponders received four cycles of docetaxel. Improvement in response rates was seen in those who received docetaxel and translated into longer relapse-free and OS rates. This study confirmed that improvements in pCR rate are associated with improvement in relapse-free survival (RFS) and OS. The MD Anderson⁴¹³ and NSABP B-27⁴¹⁴ studies both also confirmed that treatment with a noncross-resistant regimen was associated with a trend toward improved RFS and OS compared with those continuing with the doxorubicin regimen.

NSABP B-27 also confirmed that the rate of pCR-predicted RFS and validated the use of pCR as a surrogate marker of long-term benefit from treatment. Therefore, pCR was identified as a useful tool for comparing treatment options.

The response to preoperative chemotherapy became a prognostic marker for DFS and survival. Thus, response to preoperative chemotherapy can be used as an intermediate end point in testing new regimens or the additional effect of new drugs administered after well-established regimens, without having to wait for several years until DFS and survival end points can be compared. With the demonstration that

preoperative chemotherapy is equivalent to postoperative chemotherapy for DFS and survival, new chemotherapeutic regimens can be tested in this setting without fear of putting patients at a disadvantage. As a result, numerous preoperative (or neoadjuvant) treatment studies have followed, which have studied choice of chemotherapy and scheduling consideration. Anthracycline-based regimens concurrently or sequentially including a taxane have shown an increased response rate in the neoadjuvant setting than nontaxane-containing regimens.^{364, 401–412, 415–417}

Neoadjuvant studies have examined chemotherapy, endocrine therapy, and biologic therapy (e.g., HER2-targeted therapy). Studies have shown that certain chemotherapy regimens can benefit specific tumor subtypes.

For patients with TNBC, platinum-based therapies have shown benefit in the metastatic setting; therefore, carboplatin has been studied in combination with NACT and have shown that carboplatin may improve pCR rates.^{418, 419} Carboplatin in combination with a PARP-inhibitor has also shown early promise.⁴²⁰

For patients with HER2+ breast cancer, HER2-directed therapies have been shown to be beneficial in improving pCR rates and longer-term outcomes. The benefit of trastuzumab has been shown in several studies, most notably the NOAH study^{421, 422}, which showed that standard neoadjuvant chemotherapy plus trastuzumab (with the continuation of trastuzumab after surgery) increased pCR [trastuzumab (38%) vs no trastuzumab (19%) ($p = 0.001$)] and EFS rate compared to patients with standard chemotherapy only. The addition of pertuzumab with NACT and trastuzumab showed increased benefit as compared with controls (NACT plus trastuzumab) in both the NeoSphere³⁷⁹ and TRYPHAENA⁴²³ studies. On the basis of these results and the fact that the confirmatory adjuvant trial APHINITY (NCT01358877) had completed accrual, FDA granted accelerated approval to the addition of pertuzumab to chemotherapy and trastuzumab in the neoadjuvant setting. Lapatinib has not met with similar success as pertuzumab, with several studies showing no increase in benefit when substituted for trastuzumab and limited benefit when administered together.^{404, 424, 425} Additional HER2-directed therapies are under study and have shown some initial promise in phase II studies.⁴²⁶

Neoadjuvant studies also have looked at response-adjusted schedules, that is, a set number of cycles of therapy are followed by the same or noncross-resistant therapy based on depending on clinical assessment of response or lack thereof, respectively.⁴²⁷ While these studies have not shown evidence of increased benefit, this study design is an interesting step toward tailoring and individualizing treatment based on early response.

[Table 13](#) summarizes details of several key neoadjuvant chemotherapy studies.

Table 13 Summary of selected neoadjuvant trial results

Breast cancer subtype	Study	Chemotherapy backbone	Comparator	pCR rates (95% confidence intervals)	Su

Studies of endocrine therapy are more limited and have focused predominately on postmenopausal women.⁴³¹ The use of endocrine therapy in postmenopausal women may be equivalent to that of chemotherapy, although the evidence is limited and more studies are needed.^{432, 433} Studies of different endocrine treatments have demonstrated superior efficacy with AIs compared with tamoxifen in clinical trials among postmenopausal women, with improvement in breast conserving surgery, which is related to duration of exposure.^{434–436} Among AIs, there do not appear to be differences in clinical response.⁴³⁷ Ki-67 and a scoring system that takes into account residual tumor as well as proliferation are being studied as a marker for early response or resistance to neoadjuvant hormone therapy.^{438, 439} Current strategies have been evaluating the addition of a number of targeted biologic therapies that have showed improvement in disease control in advanced disease to neoadjuvant hormone therapy with AIs.⁴⁴⁰ These include PI3K and CDK 4/6 inhibitors, among others.⁴⁴¹ The mTOR inhibitor everolimus was first studied in the neoadjuvant setting before being tested in a registration trial in the second-line metastatic setting. It was not possible to identify markers of response and resistance in that initial study, and this goal has proved to be elusive in neoadjuvant endocrine trials.⁴⁴²

There has been a growing interest in studying neoadjuvant endocrine therapy in a broader cohort of HR+ breast cancers in both pre- and postmenopausal women; however, pCR does not appear to be a good surrogate end point of response. Currently, we do not have good early markers of response in HR+ breast cancer. Thus, neoadjuvant therapy can provide the platform to aid in the understanding of the biology of different breast cancers and the response to therapy and help target our effort to improve response and outcome.

Neoadjuvant setting as a registration end point for novel agents

The I-SPY 2 Trial uses an innovative model (an adaptive design that allows you to “learn as you go”) to accelerate the testing and identification of new investigational agents in combination with NACT.⁴⁴³ The trial has demonstrated the ability of multiple companies to collaborate in a trial that uses a common chemotherapy backbone (master trial), where new agents are introduced as amendments. The goal of the study is to promote the testing of new agents with phase I and Ib (in combination with paclitaxel) safety data in the primary disease setting in patients with high risk for early recurrence, to learn for which tumor subtype agents were most effective, and to increase the chance of success of confirmatory phase III trials. Agents “graduate” from the trial if their ability to increase pCR (in comparison to control) for one or more disease subtypes predicts that there will be an 85% likelihood of success in a confirmatory phase III trial. In this way, the most effective agents can be chosen to forward phase III trials, thereby improving 10–30% success rate seen in phase III trials in oncology.⁴⁴⁴ The FDA agreed that the neoadjuvant setting would serve as an opportunity to improve the efficiency of testing novel agents.⁴⁴⁵ The FDA has shown its support of neoadjuvant clinical trials by confirming the evidence base for pCR as a surrogate end point for event-free survival (EFS), conducting a meta-analysis of 12 international trials.⁴⁴⁶ Their main objectives included establishing an association between pCR and EFS and OS to determine if pCR is best correlated with long-term survival in certain subtypes and finally if an increase in frequency in pCR predicts EFS and OS. Their findings established the best definition of pCR. Eradication or absence of tumor in both breast and lymph nodes, ypT0 ypN0 or ypT0/is ypN0 (vs breast only, ypT0/is), was better associated with EFS and OS [(EFS HR: ypT0 ypN0: 0.44; ypT0/is ypN0: 0.48 vs. ypT0/is: 0.60) and (OS HR: ypT0 ypN0 0.36; ypT0/is ypN0: 0.36 vs ypT0/is: OS 0.51)]. They also found that the association between pCR and long-term outcomes was strongest in patients with TNBC (EFS: HR 0.24, 95% CI 0.18–0.33; OS: 0.16, 0.11–0.25) and in those with HER2+/HR– tumors who received trastuzumab (EFS: 0.15, 0.09–0.27; OS: 0.08, 0.03, 0.22).

The FDA then issued guidance on the use of pathologic response as an end point for accelerated approval.⁴⁴⁷ Regular approval of new drugs in ESBC usually requires trials to show clinical benefit in improvement in DFS or OS. The FDA can grant accelerated approval based on a surrogate end point that has been shown to reasonably approximate clinical benefit, and thus the FDA has proposed the use of pCR rate as a surrogate for DFS and OS for HER2+, triple-negative, and more proliferative hormone-positive disease. Importantly, accrual must be completed for the EFS end point (either in the neoadjuvant setting or as a separate adjuvant trial) before accelerated approval can be granted.⁴⁴⁸ If demonstration of an improvement in DFS or OS is not shown in confirmatory trials, the neoadjuvant indication would be removed from the labeling. One randomized trial could support accelerated approval based on the improvement in pCR rate followed by confirmation of the clinical benefit with improvements shown in DFS and OS. The neoadjuvant setting provides a forum to rapidly design and test new treatment strategies and accelerate drug development.

There was concern that the nonconcordant results of the ALTTO⁴⁴⁹ and NeoALTTO⁴⁰⁴ studies would cast doubt on the use of pCR as a surrogate end point. However, the HR of 0.86 observed in ALTTO with lapatinib and trastuzumab was in fact predicted by NeoALTTO, but the number of events was not sufficient to make it statistically significant, AC was given postoperatively rather than preoperatively in NEOALTTO, and the patient population in the ALTTO study was at lower risk (smaller tumors and less node-positive patients) than those in the NEOALTTO study.⁴⁵⁰ These studies also showed the importance of using the same populations for the pCR assessment and EFS assessment, which is the goal of the I-SPY 3 international trial. A new meta-analysis is being planned for the HER2-targeted neoadjuvant studies, once the results are finalized.

Treatment for advanced breast cancer

Role of radiation for recurrent and metastatic breast cancer

The role of palliative radiotherapy is well established in the treatment of symptomatic MBC, but also continues to evolve as a complement to systemic cytotoxic, targeted, and hormonal therapies. Painful bony metastases and simple pathologic fractures of nonweight-bearing bones respond well to short courses of directed radiotherapy. However, local radiotherapy is no substitute for proper orthopedic fixation in highly diseased weight-bearing bones. A phase III randomized trial from RTOG compared single fraction of 800 cGy versus the standard 3000 cGy in 10 fractions found equivalent results for control of bony metastases.⁴⁵¹ Although multiple fraction therapy may be appropriate for complicated bone metastases involving adjacent soft tissue, the single treatment approach minimizes time in treatment and is certainly appropriate in most clinical situations. For patients with widespread osseous disease, modern intravenous pharmaceuticals, such as samarium-153 lexidronam, provide excellent pain relief and improved functionality without the severe and irreversible bone marrow suppression of earlier agents.⁴⁵²

In terms of the treatment of brain metastases, treatment with radiotherapy is quite standard and preferable to surgical treatment in the presence of widespread, poorly controlled systemic metastases. The generally accepted course of palliative whole-brain irradiation for multiple lesions is 3000–3750 cGy in 10–15 fractions, particularly for widespread intracranial disease.⁴⁵³ The optimal therapy for solitary or limited brain metastasis, particularly in patients with well-controlled extracranial disease, is moving away from whole-brain radiation and toward stereotactic radiosurgery (SRS) to avoid neurocognitive toxicity.⁴⁵⁴ In such patients, the toxicity associated with whole-brain treatment may be reserved for those with multiple brain metastases or recurrent metastases after SRS.

For patients with oligometastatic disease (three or fewer sites of gross tumor), there is emerging evidence that focal radiotherapy may be an important supplement to systemic therapy, even in the asymptomatic patient.⁴⁵⁵ A current phase II/III trial is currently evaluating the benefit of adding stereotactic body radiotherapy or surgical resection of limited metastases to standard systemic therapy.⁴⁵⁶ Finally, for patients with locally recurrent disease, even those who have undergone prior radiotherapy, directed radiation and modern reirradiation can be safely integrated with surgery and systemic therapy and are crucial to providing durable local control and improving QOL.^{457, 458}

Systemic therapy for metastatic breast cancer

The incidence of MBC is not formally monitored, but estimates predict that approximately a quarter of all patients diagnosed with ESBC will ultimately develop recurrent disease with distant metastases.⁴⁵⁹ A proportion of 5% of all women diagnosed with breast cancer are found to have de novo MBC, characterized by the presence of distant metastasis at initial diagnosis. In general, recurrences peak 3–5 years after primary therapy for ESBC and then decrease to a steady state by 8 years. Women with HR+ ESBC remain at risk for recurrence for up to 20 years, although 50% of distant recurrences occur within the first 5 years after diagnosis. In comparison, recurrences of TNBC generally occur within the first 3 years with a dramatic reduction in risk thereafter. HER2+ breast cancers historically had a poor clinical outcome and recurred along a timeline similar to TNBC, but as stated in the adjuvant section, HER2-directed therapies have dramatically improved ROR and OS.

As addressed in the adjuvant section of this chapter, clinicopathologic factors—such as age; menopausal status; the size, grade, histology, and biomarker status of a tumor; and nodal status—affect ROR.

However, the frequent development of recurrent disease in patients with small node-negative tumors who completed optimal adjuvant therapy clearly demonstrates that clinicopathologic factors only do not fully explain risk. Regardless of adjuvant therapy, patients with the luminal B intrinsic subtype have worse recurrence-free survival at 5–10 years after diagnosis than those with the luminal A intrinsic subtype.³¹³ Patients with the basal-like subtype have worse outcomes than those with luminal B subtype at 5 years after diagnosis, but these survival curves in fact cross after 10 years.

As with timing of recurrence, the location and extent of metastatic disease are generally associated with specific cancer subtypes. HER2+ breast cancers have a more aggressive biology and tropism for developing visceral and CNS metastasis. TNBC tends to recur locoregionally as well as in the lung or brain, but less commonly in bone.³⁰⁹ HR+ breast cancers typically involve bone and soft tissue and follow an indolent course, but in some cases present more aggressively with visceral involvement.

The median survival of patients with MBC is 2–3 years. Long-term prognosis is determined by tumor biology, growth rate, disease burden, organ localization, duration of treatment response, and resistance or sensitivity to interventions. Most patients with overt distant metastases are presently incurable. However, among those who achieve a complete remission after standard chemotherapy, a few remain progression-free for extended periods of time, occasionally exceeding 10 years. PFS is generally longer for those patients who present with low-volume metastases to the skin, lymph nodes, or bone and shorter for patients with multiple organ involvement, particularly those patients with metastases to the liver, brain, and lung. Survival is longer for patients with HR+ tumors and those who achieve a complete remission with chemotherapy compared with patients with TN or HER2+ tumors and those who fail to respond to systemic treatment.

For the majority of patients with MBC, treatment is strictly palliative, with a goal to delay the progression of disease while concurrently improving QOL through the alleviation of symptoms due to disease and treatment. Patients who are diagnosed with MBC should be informed that their disease is incurable but treatable and encouraged that patients can live with metastatic disease for many years. Given the considerable heterogeneity of MBC, individualized treatment plans should be guided by a multidisciplinary group that includes, but is not limited to medical, surgical, and radiation oncologists, palliative care specialists, psycho-oncologists, specialized oncology nurses, social workers, and patient navigators.⁴⁶⁰

When a patient has symptoms or physical exam findings suspicious for disease recurrence, evaluation should include radiologic evaluation of the chest, abdomen, pelvis, and bones.^{409, 458} This assessment can be achieved with either a CT of the chest, abdomen, and pelvis in combination with a bone scan or PET/CT. Imaging of the brain should not be performed routinely in asymptomatic patients. In addition, laboratory studies should include a complete blood count and a comprehensive metabolic panel. If the serum tumor markers CA 15–3, CA 27.29, and CEA are elevated at baseline, then they can be assessed monthly in combination with physical examination and radiologic imaging to follow treatment response.

On the basis of findings from this baseline assessment, every effort should be made to obtain pathologic confirmation of metastatic disease.^{409, 458} ER, PR, and HER2 must be reassessed on the pathology specimen with high-quality assays, as discordance between primary tumor and metastasis is not uncommon. Discordance occurs in 10–30% of cases in the ER and 20–50% of cases in the PR, while higher concordance is observed in HER2.⁴⁶¹ In the unusual circumstance that tumor tissue cannot be obtained, patient and tumor characteristics are helpful to determine whether a tumor is likely to respond to hormonal manipulation. Older postmenopausal patients with a history of HR+/HER2– ESBC with a disease-free interval exceeding 3 years and small-volume metastatic disease located predominantly in

soft tissue and/or bone are more likely to respond to endocrine therapy than patients with opposite characteristics. In the case of an indolent clinical course, a negative ER assay should prompt a repeat assay to ensure a false-negative result does not preclude potentially beneficial endocrine therapy.

A clear association exists between the use of treatment guidelines and improvement in survival. Several guidelines exist for the management of MBC. Guidelines developed at the Second International Consensus Conference for Advanced Breast Cancer (ABC2) in Lisbon, Portugal, in November 2013 were a joint effort between the European School of Oncology (ESO) and the European Society for Medical Oncology (ESMO).⁴⁵⁸ ASCO's Clinical Practice Guidelines provide evidence-based recommendations that are developed by a multidisciplinary group of experts using a systematic review of phase III trials as well as clinical experience. Several ASCO Clinical Practice Guidelines exist for MBC and can be found at <http://www.institutequality.org/practice-guidelines>.^{462–465}

Systemic therapies for HR+/HER2– MBC

Most patients with a new diagnosis of HR+/HER2– MBC are initially treated with endocrine-based therapy. Chemotherapy should be reserved for those patients with threatened or existing end-organ dysfunction, for whom a rapid reduction in tumor burden is essential. Only a few clinical trials have compared endocrine-based therapy with chemotherapy in patients with HR+/HER2– MBC. A Cochrane meta-analysis published in 2003 evaluated 10 relevant studies and reported that although chemotherapy resulted in a more rapid response rate (RR 1.25; 95% CI, 1.01–1.54; $p = 0.04$), no difference in OS was observed (HR 0.94; 95% CI, 0.79–1.12; $p = 0.5$).⁴⁶⁶ The included trials were conducted several decades ago, evaluated variable hormone therapies, and failed to adequately assess QOL. Given the goals of treatment, most guidelines recommend that patients with HR+/HER2– MBC are initially treated with hormone therapy, except with rapid progression.^{409, 458}

Endocrine-based treatment options for patients with HR+/HER2– MBC include tamoxifen, the non-steroidal aromatase inhibitors (NSAIs) anastrozole and letrozole, the steroidal AI exemestane, and fulvestrant, as well as less-commonly used therapies such as megestrol acetate and estradiol. When choosing treatments, one must consider prior endocrine therapy in the adjuvant setting and the amount of time that elapsed between adjuvant therapy and recurrence. Side effect profiles and logistics associated with drug administration should also be considered on an individualized basis.

Approximately 50% of patients will respond to treatment with first-line hormone-based therapy. Patients who completed adjuvant hormonal therapy and achieved a long disease-free interval are likely to respond to first-line hormonal therapy. The time to maximal response with endocrine therapy can be quite prolonged, and treatment should not be abandoned prematurely. Patients should be continued on a therapeutic trial of a specific hormone therapy for at least 6–12 weeks in the absence of progressive disease before switching to other therapies. Patients without clinical response or with progressive disease after two sequential lines of hormone therapy should transition to chemotherapy. Patients who respond to hormone therapy often can continue on several sequential hormone therapy lines until either no further lines are available or upon development of visceral crisis.

Virtually all patients with HR+/HER2– MBC will eventually develop secondary resistance to hormone therapy. Over the last decade, molecularly targeted drugs have been developed in combination with first- and second-line hormone therapies to overcome or prevent hormone resistance. Several of these combinations have resulted in improved PFS, further delaying transition to chemotherapy.

Endocrine-based therapies for premenopausal HR+/HER2– MBC

Premenopausal women with MBC were historically treated with bilateral oophorectomies, suppressing serum estrogen to postmenopausal levels. The LHRH agonists goserelin and leuprolide became available for use in MBC in the 1980s, providing similar clinical benefits without surgical intervention.⁴⁶⁷ Tamoxifen was not initially studied as a single agent for premenopausal breast cancer, but rather in combination with LHRH agonists. Klijn et al.⁴⁶⁸ published a meta-analysis in 2001 that reviewed four phase II clinical trials evaluating LHRH agonists with or without tamoxifen with a total of 506 women with MBC. The combination arms resulted in increased RR, PFS, and OS in comparison to LHRH agonists only. No published trials have compared tamoxifen with or without LHRH agonists.

Both the ABC2 consensus guidelines and the NCCN Guidelines recommend ovarian suppression or ablation in combination with endocrine-based therapy as the first treatment for premenopausal women with HR+/HER2– MBC.^{409, 458} The initial endocrine-based therapy should be tamoxifen, unless metastases developed within 12 months of adjuvant tamoxifen. If tamoxifen resistance is proven or after a patient progresses on first-line tamoxifen with or without an LHRH agonist, then the same treatment sequences recommended for postmenopausal women can be followed, but with continued use of LHRH agonist.

Endocrine-based therapies for postmenopausal HR+/HER2– MBC

Tamoxifen was approved for use in postmenopausal women with MBC in 1977 and remained the primary therapy for HR+ MBC for over two decades. Early clinical trials compared tamoxifen with available hormonal therapies, such as diethylstilbestrol, ethinyl estradiol, megestrol acetate, and fluoxymesterone. Tamoxifen was found in many cases to have response rates as high as 50% in patients with HR+ MBC and more tolerable side effects.⁴⁶⁹

Several multicenter phase III clinical trials published in 2000 and 2001 demonstrated that third-generation nonsteroidal AI were either superior or equivalent to tamoxifen as the first-line therapy for postmenopausal women with MBC.^{470–472} The largest was a phase III study that randomized 907 postmenopausal women with HR+ (or hormone receptor status unknown) MBC to either letrozole 2.5 mg daily or tamoxifen 20 mg daily.⁴⁶⁹ Patients on the letrozole arm experienced a higher clinical benefit rate (CBR) (49% vs 38%; $p = 0.001$) and a significantly longer TTP (41 weeks vs 26 weeks; HR 0.70; 95% CI, 0.60–0.82; $p = 0.001$) than those patients on the tamoxifen arm. A meta-analysis by Mauri et al.⁴⁷³ in 2006 evaluated trials comparing AI with tamoxifen and other hormonal therapies and demonstrated a statistically significant survival benefit from third-generation AI in the first-line setting (11% relative hazard reduction; 95% CI, 1–19%; $p = 0.03$). The side effects and toxicities associated with tamoxifen and AI are discussed in the adjuvant hormonal therapy section. Incomplete cross-resistance exists between steroidal and nonsteroidal AI.⁴⁷⁴ Studies have clearly demonstrated that patients who progress on one AI can reach a clinically meaningful benefit with an agent from the other class.^{475, 476}

Fulvestrant is a first-in-class pure ER antagonist that competitively inhibits binding of ER by estradiol, leading to accelerated degradation of ER and inhibition of estrogen signaling through the ER.⁴⁷⁷ In comparison to the estrogenic effects of tamoxifen, fulvestrant has fewer noxious side effects and adverse toxicities. On the basis of phase III clinical trial results demonstrating similar response rates and time to progression (TTP) as anastrozole, fulvestrant was approved by the FDA in 2002 to be administered as a monthly intramuscular injection. Initial approval was based on a dose of fulvestrant 250 mg intramuscularly (IM) monthly, but the subsequent COMparisoN of Faslodex In Recurrent or Metastatic breast cancer (CONFIRM) trial, as described below, demonstrated that fulvestrant 500 mg IM monthly with a loading dose was superior.⁴⁷⁸

North American Trial 0021 was a phase III, double-blind, double-dummy clinical trial that randomized 400 postmenopausal women with HR+ MBC to receive fulvestrant 250 mg IM monthly or anastrozole 1 mg daily.^{481, 479} Approximately 96% of patients had received tamoxifen as adjuvant or metastatic therapy. At a median follow-up of 16.8 months, no statistically significant differences were appreciated in TTP (HR 0.92; 95% CI, 0.74–1.15; $p = 0.42$), CBR, overall response (OR), or AEs.

The randomized, double-blind, double-dummy, phase III clinical Evaluation of Faslodex versus Exemestane Clinical Trial (EFFECT) compared fulvestrant with exemestane in women with HR+ MBC who had progressed or recurred after treatment with a nonsteroidal AI.⁴⁸⁰ A proportion of 60% of the 693 women enrolled in this study had received at least two prior endocrine therapies. Fulvestrant was given with a loading dose of 500 mg IM on day 0, followed by 250 mg on days 14 and 28 and 250 mg every 4 weeks thereafter, whereas exemestane was administered orally at 25 mg daily. Similar to Trial 0021, no statistically significant difference was appreciated. The median TTP was 3.7 months in both groups (HR 0.963; 95% CI, 0.819–1.133; $p = 0.6531$). ORR (7.4% vs 6.7%; $p = 0.736$) and CBR (32.2% vs 31.5%; $p = 0.853$) were similar between fulvestrant and exemestane, respectively. Both treatments were well tolerated in a meaningful proportion of patients.

The phase III CONFIRM trial was designed to determine whether a higher dosing regimen of fulvestrant would increase treatment efficacy, as suggested by preclinical and clinical phase II results.⁴⁷⁶ A total of 736 postmenopausal women with HR+ MBC were randomized to receive fulvestrant 500 mg IM (on days 0, 14, 28, and every 28 days thereafter) or 250 mg IM (every 28 days). All participants had prior antiestrogen or AI treatment in either the adjuvant or metastatic setting. A prolonged PFS (HR 0.80; 95% CI, 0.68–0.94; $p = 0.006$) was demonstrated with fulvestrant 500 mg IM versus 250 mg IM. AEs such as injection site pain, nausea, and bone pain occurred with similar incidence and severity between the two groups. These results led to the FDA approval of fulvestrant 500 mg IM in September 2010.

The Fulvestrant first-line Study comparing endocrine Treatments (FIRST) was a phase II open-label clinical trial that randomized 205 women with HR+ MBC to fulvestrant 500 mg IM (on days 0, 14, 28, and every 28 days thereafter) or anastrozole 1 mg daily.⁴⁷⁷ Patients had not received endocrine therapy for advanced disease, and <30% received adjuvant endocrine therapy that had been completed >12 months before randomization. Follow-up analysis after 79.5% of patients had discontinued treatment showed a median TTP of 23.4 months on the fulvestrant arm compared with 13.1 months on the anastrozole arm (HR 0.66; 95% CI, 0.47–0.92; $p = 0.01$).⁴⁸² Recently, Robertson et al. have reported a significant benefit in median OS for fulvestrant 500 mg versus anastrozole (HR 0.70; 95% CI, 0.50–0.98; $p = 0.041$), with a median difference of 5.7 months between the two arms⁴⁸³

The phase III SoFEA clinical trial evaluated the role of combination endocrine therapy in postmenopausal women with HR+ MBC who had progressed or recurred on an NSAI.⁴⁸⁴ A total of 723 women were randomized to receive fulvestrant plus anastrozole, fulvestrant with placebo, or exemestane with placebo. No difference in PFS was appreciated in the fulvestrant plus anastrozole arm versus the fulvestrant plus placebo arm, or the exemestane arm versus the fulvestrant plus placebo arm. However, the study used a suboptimal fulvestrant dose of 250 mg IM.

Additional endocrine-based therapies exist for patients who progress on hormone therapies, but have a low-tumor burden with minimal symptoms or are poor candidates for chemotherapy, such as ethinyl estradiol and megestrol acetate. Preclinical studies have demonstrated that HR+ breast cancer cells undergo estradiol-induced apoptosis after prolonged estrogen deprivation. A phase II clinical trial by Ellis et al. randomized 66 women with HR+ MBC who had progressed on AI to receive estradiol 30 mg daily or 6 mg.⁴⁸⁵ A CBR of approximately 30% was demonstrated in both arms, but fewer serious AEs

were observed in the low-dose arm. Megestrol acetate is a progestational agent with activity in HR+ MBC. Early studies demonstrated a response rate of 25% and median PFS of 15 months to megestrol acetate 40 mg four times daily in MBC.⁴⁸⁶ The benefit of megestrol acetate after treatment with an AI has not been assessed. Notable side effects include weight gain, fluid retention, vaginal bleeding, venous thromboembolic disease, and poor QOL.

Active endocrine-based therapy trials

Several ongoing clinical trials have been evaluating the optimal sequence of standard hormone therapies as well as new antiestrogens. Positive safety and efficacy results from the phase II FIRST study led to the design of the Fulvestrant and AnastrozoLe COmpared in hormonal therapy Naïve advanced breast cancer (FALCON) clinical trial (NCT01602380).⁴⁸⁷ This randomized, double-blind, multicenter phase III clinical trial enrolled 450 postmenopausal women with HR+ locally advanced or MBC who did not undergo prior endocrine-based therapy in the adjuvant or metastatic setting. Patients are randomized to receive fulvestrant 500 mg IM (on day 1, 14, and 28, followed by every 28 days thereafter) or anastrozole 1 mg daily. A press release in mid-2016 stated that the FALCON trial had met its primary endpoint of improved PFS with fulvestrant compared to anastrozole. Results will be presented in the fall of 2016.

Other studies evaluating endocrine-based therapies are focused on novel hormone agents, such as ER-degrading agents, androgen antagonists, and AR inhibitors. Details on these trials are available at <http://www.cancer.gov/about-cancer/treatment/clinical-trials/search>.

Endocrine-based therapy in combination with targeted drugs

Hormone-based therapy is an effective and generally well-tolerated treatment option to control disease while delaying the transition to chemotherapy in patients with HR+/HER2– MBC. Unfortunately, all patients will ultimately develop disease that is resistant to endocrine-based therapies. Patients who relapse within the first 2 years of starting adjuvant endocrine therapy, within 12 months of completing adjuvant endocrine therapy, or progress <6 months after starting endocrine therapy for MBC have secondary or acquired resistance.⁴⁵⁸ Molecular mechanisms involved in the acquisition of primary and secondary resistance are complex. Preclinical studies have recognized the presence of adaptive cross talk between the ER and various growth factor receptor and intracellular signaling pathways. Putative mechanisms that allow breast cancer cells to escape the inhibitory effects of hormone-based therapy include mutations in the ER gene (ESR), enhanced signaling through upregulation of growth factor pathways, induction of estrogen-independent growth, hypersensitivity to low estrogen concentrations, and cyclin D1 overexpression. An improvement in the understanding of mechanisms of hormone resistance through preclinical models led to the development of clinical trials that aim to delay or revert endocrine resistance by combining traditional hormone-based therapy with drugs that selectively target tumor biology. [Table 14](#) lists many of the investigational therapeutics, their mechanism of action and molecular target, and breast cancer subtype of interest.

Table 14 Investigational drugs, associated molecular targets, and breast cancer subtypes of interest in ongoing clinical trials

Molecular targets	Investigational drug	Mechanism(s) of action	Breast cancer subtypes under investigation and if tested as single agent or in combination
Fibroblast growth factor	Lucitanib	FGF receptor inhibitor; VEGF receptor inhibitor;	Any subtypes with FGFR mutation (single agent)

(FGF) pathway		PDGF receptor inhibitor	
Insulin-like growth factor (IGF) pathway	Cixutumumab (IMC-A12)	Anti-IGF-1 receptor monoclonal antibody	Any subtype (with temsirolimus) HER2+ (with cytotoxic agent and lapatinib)
JAK/STAT pathway	Ruxolitinib (INCB-18424)	JAK1/2 inhibitor	HER2+ (with trastuzumab) HER2– (with cytotoxic agents) Any subtype (with cytotoxic agents)
MAPK pathway	Selumetinib (AZD6244, ARRY-142886)	MEK inhibitor	HR+ (with EBT ^a)
PI3K/Akt/mTOR pathway	Alpelisib (BYL719) Taselisib (GDC-0032)	Alpha-specific PI3K inhibitor	HR+/HER2– (with EBT) HER2+ (with HER2-directed therapies) TNBC (with enzalutamide)
	Buparlisib (BKM120) Pictilisib (GDC-0941)	Pan-class 1 PI3K inhibitor	HR+/HER2– (with EBT; ribociclib; with cytotoxic agent) TNBC (with cytotoxic agent)
	MK-2206 Triciribine (BML-EI332) AZD5363	Akt inhibitor	Any subtype (with cytotoxic agent) HR+/HER2– (with EBT)
	Temsirolimus	mTOR inhibitor	HR+/HER2– (with EBT) TNBC (with cytotoxic agent; bevacizumab)
	Sapanisertib (MLN0128)	mTORC1/2 inhibitor	HR+/HER2– (with EBT)
Cyclin-dependent kinases (CDK)	Abemaciclib (LY2835219) Dinaciclib (SCH727965) Ribociclib (LEE-001)	CDK 4/6 inhibitor	HR+/HER2– (with EBT)
Colony-stimulating factor (CSF)-1 receptor	PLX3397	CSF-1R inhibitor; KIT inhibitor	TNBC (with cytotoxic agent)
Glycoprotein NMB (gpNMB)	Glembatumumab vedotin (CDX-011)	Anti-gpNMB antibody–drug conjugate	TNBC (single agent)
Heat shock protein 90 (HSP90)	Ganetespib (STA-9090)	HSP90 inhibitor (a novel small molecule inhibitor)	HR+/HER2– (with cytotoxic agent) Any subtype (single agent)
HER2	Neratinib (HKI-	Dual HER2/EGFR tyrosine	HER2+ (single agent)

	272)	kinase inhibitor	HER2+ (with cytotoxic agent) HER2+ (with trastuzumab) HER2 equivocal (with cytotoxic agent)
	Margetuximab	Fc-optimized anti-HER2 monoclonal antibody	HER2+ (single agent; with cytotoxic agent)
	MM-302	HER2-targeted liposomal doxorubicin (a novel antibody–drug conjugate)	HER2+ (single agent)
	ONT-380 (ARRY-380)	HER2-specific inhibitor (a novel small molecule inhibitor)	HER2+ (single agent)
HER3	Patritumab (U3-1287)	Anti-HER3 monoclonal antibody (a novel agent)	HER2+ (with cytotoxic agent; with trastuzumab)
Histone deacetylase (HDAC)	Entinostat Vorinostat Panobinostat	HDAC inhibitor	HR+/HER2– (with EBT; with immunotherapy) HER2+ (with cytotoxic agent; with trastuzumab) All subtypes (single agent)
PARP	Olaparib Veliparib (ABT-888)	PARP1/2 inhibitor	TNBC (single agent; with cytotoxic agent)
	Talazoparib (BMN-673)	PARP1/2 inhibitor, PARP1/2 trapper	gBRCA (single agent)
PD-1 and PD-L1	Pembrolizumab (MK-3475)	Anti-PD-1 monoclonal antibody	TN (with cytotoxic agents) HR+/HER2– (with HDAC inhibitor; with EBT)
	Atezolizumab (MPDL3280A)	Anti-PD-L1 monoclonal antibody	TNBC (single agent) HER2+ (with cytotoxic agent; with trastuzumab)
SRC	Dasatinib	SRC inhibitor	HER2+ (with trastuzumab and cytotoxic agents)
Steroid hormones	Bazedoxifene	Selective estrogen receptor modifier	HR+ (with CDK 4/6 inhibitor)
	Enobosarm (GTx-024)	Selective androgen receptor modifier	TN/AR+ (single agent) ER+/AR+ (single agent)
	Bicalutamide	Antiandrogen	HR+ or HR–/AR+ (with CDK 4/6 inhibitor)
	Enzalutamide	Androgen receptor inhibitor	HR+/HER2– (with EBT) TNBC (single agent; with PI3K inhibitor)

^a EBT, endocrine-based therapy.

Endocrine-based therapy and antiangiogenic agents

Angiogenesis plays a well-defined role in the development of breast cancer. Preclinical studies suggest that VEGF, which is secreted by HR+ breast cancer cells, drives tumor proliferation through neoangiogenesis. Elevated levels of VEGF are associated with early recurrence and hormone therapy resistance. The Letrozole/Fulvestrant and Avastin (LEA) study was the first phase III clinical trial evaluating the combination of hormone therapy with the anti-VEGF monoclonal antibody bevacizumab as a first-line therapy for patients with HR+/HER2– MBC.⁴⁸⁸ The study randomized 380 patients to receive endocrine therapy (either letrozole or fulvestrant) in combination with bevacizumab 15 mg/kg iv every 3 weeks or endocrine therapy only. Approximately one-half of the study participants received endocrine therapy in the adjuvant setting, of which only 20% received an AI. At a median follow-up of 23.7 months, the median PFS was 19.3 months in the bevacizumab-containing arm and 14.4 months in the control arm (HR 0.83; 95% CI, 0.65–1.06; $p = 1.26$). Time to treatment failure and OS were similar in both arms, whereas toxicities were more significant in the bevacizumab-containing arm.

Initial results from CALGB 40503 (Alliance), a large phase III clinical trial evaluating the combination of first-line letrozole with bevacizumab in patients with HR+ MBC, were reported by Dickler et al. at ASCO 2015.⁴⁸⁹ At a median follow-up of 39 months, 258 PFS events had been observed, with a median PFS of 20 months in the combination arm in comparison to 16 months in the letrozole-only arm (HR 0.74; 95% CI, 0.58–0.95; $p = 0.016$). ORR ($p = 0.004$) and CBR ($p = 0.005$) were significant in the bevacizumab-containing arm, but no difference in OS was appreciated. A significant increase in toxicity was appreciated in the combination arm with 50% of those patients reporting high-grade AEs in comparison to only 14% of patients on the control arm.

Endocrine-based therapy and PI3K/Akt/mTOR pathway inhibitors

The PI3K/Akt/mTOR pathway has critical roles in cellular proliferation, metabolism, and survival. Hyperactivation of the PI3K/Akt/mTOR pathway leads to increased downstream signaling with ligand-independent activation of the ER. The PI3K/Akt/mTOR pathway is frequently dysregulated in approximately 50% of HR+ MBC, and inappropriate upregulation is associated with poor outcomes and resistance to hormonal therapies. Preclinical studies of mTOR inhibitors in combination with endocrine therapy demonstrated synergistic inhibition of HR+ breast cancer cell lines. The addition of the mTOR inhibitor everolimus to second-line hormone therapy with exemestane for patients with MBC more than doubled PFS with a numerical but nonsignificant improvement in OS, leading to regulatory approval of everolimus in this setting.⁴⁸⁸ Toxicity was significantly increased, including stomatitis.⁴⁸⁹ Ongoing trials are evaluating the use of everolimus as well as other inhibitors of the PI3K pathway in various disease settings. Inhibitors of the alpha-specific subunit of PI3K have already provided encouraging early results, with different and possibly more favorable toxicity outcomes.

The Breast Cancer Outcomes with Everolimus (BOLERO-2) clinical trial was a double-blinded, randomized, phase III study that evaluated the addition of everolimus, an mTOR inhibitor, to exemestane in women with HR+/HER2– MBC who had progressed on an NSAI.⁴⁹⁰ At a median follow-up of 18 months, the median PFS was 7.8 months in the everolimus plus exemestane arm in comparison to only 3.2 months in the placebo plus exemestane arm, respectively.⁴⁹¹ These significant PFS results were the basis for the FDA approval of everolimus in combination with exemestane in patients who had progressed on NSAI. A final analysis at 39 months showed a 4-month benefit in OS (HR 0.89; 95% CI, 0.73–1.10; $p = 0.14$) that was insignificant.⁴⁹² Everolimus is associated with many class-specific AEs that are dose-limiting and can cause significant morbidity, including stomatitis, rash, and noninfectious pneumonitis.

Several ongoing studies have been evaluating everolimus in the neoadjuvant, adjuvant, and metastatic settings. Details on these trials are available at <http://www.cancer.gov/about-cancer/treatment/clinical-trials/search>.

HORIZON was a randomized, placebo-controlled phase III clinical trial that randomized 1112 postmenopausal women with HR+ MBC to receive the mTOR inhibitor temsirolimus 30 mg daily (5 days every 2 weeks) plus letrozole 2.5 mg daily or placebo plus letrozole in the first-line setting.⁴⁹³ Approximately 60% of these patients did not receive endocrine-based therapy in the adjuvant setting. No improvement in PFS was seen in the overall patient population (HR 0.90; 95% CI, 0.76–1.07; $p = 0.25$) or among those patients who received prior adjuvant endocrine-based therapy (HR 0.84; 95% CI, 0.66–1.08; $p = 0.17$). Discrepancies between the BOLERO-2 and HORIZON results are in part attributed to variations in pharmacokinetics, dosing schedules, and study populations.

Endocrine-based therapy and CDK 4/6 inhibitors

CDK are a class of serine/threonine kinases with a key role in the regulation of cell replication and division. CDK 4/6 forms a complex with cyclin D to inactivate the retinoblastoma protein (Rb), permitting activation of gene transcription. Dysregulation of CDK can lead to excessive cell proliferation, complicated by tumor growth and resistance. Preclinical studies have demonstrated that inhibitors of CDK 4/6 induce cell growth arrest and apoptosis of breast cancer cell lines and that a synergistic effect occurs when ER+ breast cancer cells are exposed to CDK 4/6 inhibitors plus endocrine-based therapies.⁴⁹⁴ CDK 4/6 inhibitors are a novel class of small-molecule therapeutics that are administered orally. Their primary toxicity is a self-limited, uncomplicated neutropenia. Several CDK 4/6 inhibitors are actively investigated in clinical trials with promising outcomes.

Palbociclib is an oral CDK 4/6 inhibitor with promising results in both phase II and III settings. In the first-line setting, a phase II trial showed doubling in PFS with the addition of palbociclib to letrozole, without an improvement in OS.⁴⁹⁵ These data led to accelerated FDA approval of palbociclib in combination with letrozole as first-line therapy for metastatic HR+ breast cancer, with final approval dependent on results from a phase III trial, which should be available in 2016. In the second-line setting, the addition of palbociclib to fulvestrant also more than doubled PFS, and OS data are immature.⁴⁹⁶ The primary toxicity from palbociclib is self-limited, uncomplicated neutropenia.

PALOMA-1/TRIO-18 was an international, randomized, open-label, phase II clinical trial evaluating the addition of palbociclib, a CDK 4/6 inhibitor, to letrozole in the first-line setting of HR+/HER2– MBC.⁴⁹³ A total of 165 postmenopausal women were randomized to palbociclib 125 mg, taken once daily for 21 days of a 28-day cycle, plus letrozole 2.5 mg daily or to letrozole only. Approximately 50% of patients had de novo MBC and therefore no prior treatment. The median PFS for the letrozole-only arm was 10.2 months, while the palbociclib-containing arm was 20.2 months (HR 0.488; 95% CI, 0.319–0.748; one-sided $p = 0.0004$). The study was not powered to assess OS. Grade 3–4 neutropenia was present in 54% of patients on the palbociclib-containing arm versus only 1% of patients on the letrozole-only arm. No cases of febrile neutropenia or neutropenia-related infections occurred during the study. These results published in February 2015 led to the accelerated approval by the FDA of palbociclib in combination with letrozole for the initial hormone-based treatment of HR+/HER2– MBC.⁴⁹⁷

The PALOMA-2 phase III clinical trial is an ongoing, confirmatory study with a similar design to PALOMA-1 (ClinicalTrials.gov identifier NCT 0201740427). Over 650 patients were randomized with a 3 : 1 ratio to palbociclib plus letrozole or placebo plus letrozole. Initial results are expected in 2016.

PALOMA-3 was a phase III clinical trial evaluating the combination of fulvestrant with palbociclib in

patients with HR+/HER2- MBC who had progressed or relapsed on prior hormonal therapy.⁴⁹⁴ A total of 521 patients were randomized in a 2 : 1 ratio to palbociclib plus fulvestrant or placebo plus fulvestrant. The study allowed for enrollment of premenopausal women on ovarian suppression with goserelin. The median PFS was 9.2 months in the palbociclib-containing arm in comparison to 3.8 months in the placebo arm (HR for progression or death 0.42; 95% CI, 0.32–0.56; $p < 0.001$).

Palbociclib has been the only approved CDK4/6 inhibitor to date, but ongoing clinical trials are investigating the CDK 4/6 inhibitors ribociclib and abemaciclib in the metastatic as well as neoadjuvant and adjuvant settings.

Ribociclib and abemaciclib

MONALEESA-1 is a randomized phase II clinical trial evaluating the biologic activity of ribociclib (LEE-001), a CDK 4/6 inhibitor, in the neoadjuvant setting (ClinicalTrials.gov identifier NCT01919229). The study is completed and initial results are expected in 2016. MONALEESA-2 is a double-blinded, placebo-controlled, phase III clinical trial evaluating the combination of letrozole 2.5 mg daily and ribociclib 600 mg daily (taken once daily for 3 weeks followed by 1 week off in 4-week cycles) in an estimated 500 patients with HR+/HER2- MBC who have received no prior therapy for advanced disease (ClinicalTrials.gov identifier NCT01958021). A press release in mid-2016 announced that MONALEESA-2 had met its efficacy endpoint. Data is expected later in 2016.

Abemaciclib (LY2835219) is a CDK 4/6 inhibitor with less hematologic, but more gastrointestinal toxicity than other class members. MONARCH-1 is a phase II clinical trial evaluating single-agent abemaciclib (LY2835219) in patients with HR+/HER2- recurrent, locally advanced, or MBC who have progressed on both hormone therapy and chemotherapy in the metastatic setting (ClinicalTrials.gov identifier NCT02102490). Data was presented by Dickler et al. at the ASCO meeting in 2016, demonstrating an overall response rate of 19.7%, with a clinical benefit rate of 42.4%. MONARCH-3 is a randomized, double-blinded phase III clinical trial enrolling an estimated 450 postmenopausal women with HR+/HER2- MBC to receive an NSAI plus abemaciclib or NSAI plus placebo in the first-line setting (ClinicalTrials.gov identifier NCT02246621). Final data collection for PFS is expected in June 2017. A phase II study evaluating the efficacy and safety of abemaciclib in patients with HR+/HER2- breast cancer involving brain metastases is also ongoing (ClinicalTrials.gov identifier NCT02308020).

Endocrine-based therapy and androgen receptor inhibitors

Expression of the AR is quite variable across breast cancer subtypes, with approximately 84–95% of HR+ breast cancers also expressing AR, in comparison to only 10–43% in HR- breast cancers.⁴⁹⁸ Preclinical data suggest that the AR is involved in the development of resistance to AI. A multicenter, double-blinded, phase II clinical trial that randomized 247 patients with HR+/HER2- MBC to exemestane plus enzalutamide 160 mg daily or placebo is ongoing (ClinicalTrials.gov identifier NCT02007512).

Endocrine-based therapy and PI3K inhibitors

Several ongoing phase II and III clinical trials are evaluating oral PI3K inhibitors, such as the class I pan-PI3K inhibitor buparlisib (BKM120) and the alpha-selective PI3K inhibitors alpelisib (BYL719) and taselisib, as first- and second-line therapies for MBC. BELLE-2 was a randomized, double-blinded, placebo-controlled, phase III clinical trial evaluating the combination of fulvestrant 500 mg IM (on days 0, 14, 28, and every 28 days thereafter) with buparlisib 100 mg daily in postmenopausal women with

HR+/HER2- MBC who have progressed on an AI (ClinicalTrials.gov identifier NCT01610284). Data was presented by Baselga et al. at the San Antonio Breast Cancer meetings in 2015, demonstrating a minimal benefit in PFS and significant toxicity. Interestingly, circulating cell free DNA was evaluated in a small subset of patients, and demonstrated a greater benefit in patients with demonstrated mutations in PIK3CA. This interesting hypothesis generating data is encouraging, but the little benefit in PFS and toxicity make it highly unlikely that further development of buparlisib will be pursued. BELLE-3 is the only ongoing trial with buparlisib, a randomized, placebo-controlled phase III clinical trial evaluating the combination of fulvestrant 500 mg IM (on days 0, 14, 28, and every 28 days thereafter) with buparlisib 100 mg daily in postmenopausal women with HR+/HER2- MBC who have progressed on an mTOR inhibitor in combination with endocrine therapy (ClinicalTrials.gov identifier NCT01633060). This study will help determine whether an alternative drug targeting the PI3K/Akt/mTOR pathway is beneficial after progression on an mTOR inhibitor.

Although the results of buparlisib were discouraging, two PIK3CA alpha targeted agents are in phase III trials, based on encouraging data from earlier phase studies. Both trials are comparing fulvestrant with placebo or with the targeted agent in postmenopausal women with HR+ HER2- MBC. SOLAR-1 is evaluating alpelisib (NCT02437318), and SANDPIPER is evaluating taselisib (NCT02340221).

The combination of endocrine therapy and PI3K inhibitors is also under investigation in the neoadjuvant setting. NEO-BELLE, a randomized, double-blinded phase II clinical trial in post-menopausal women with HR+ HER2- ESBC comparing the combination of letrozole 2.5 mg daily with the alpha specific PI3K inhibitor (alpelisib) or letrozole plus placebo, (ClinicalTrials.gov identifier NCT01923168). Patients randomized to the experimental arm will receive alpelisib 300 mg daily. Treatment will continue for 24 weeks, unless unacceptable toxicity or progression occurs, at which time the patients will undergo surgery. The trial originally included buparlisib; following the disappointing results of BELLE-2, this arm was discontinued.

Many ongoing studies are evaluating drugs that target the PI3K/Akt/mTOR pathway in ESBC and MBC. Details on these trials are available at <http://www.cancer.gov/about-cancer/treatment/clinical-trials/search>.

Endocrine-based therapy and HDAC inhibitors

Preclinical models of entinostat, a novel inhibitor of class 1 histone deacetylases (HDAC), demonstrated restoration of hormone sensitivity through downregulation of growth factor signaling pathways, normalization of ER levels, and increases in aromatase level.⁴⁹⁹ ENCORE301 was a randomized phase II clinical trial that randomized 130 postmenopausal women with HR+/HER2- MBC who had progressed on an NSAI to receive exemestane 25 mg daily plus entinostat 5 mg po weekly or exemestane plus placebo.⁵⁰⁰ Intention to treat analysis showed an improved PFS in the entinostat-containing arm with a PFS of 4.3 months versus 2.3 months in the control arm (HR 0.73; 95% CI, 0.50–1.07; one-sided $p = 0.055$). Median OS was evaluated as an exploratory end point and notably improved in the entinostat-containing arm (28.1 months) in comparison to the control arm (19.8 months) (HR 0.59; 95% CI, 0.36–0.97; $p = 0.036$). These results led to the designation of entinostat as a breakthrough therapy by the FDA in 2013. E2112, a phase III clinical trial that compares exemestane with or without entinostat, aims to enroll 600 patients with HR+/HER2- MBC (ClinicalTrials.gov identifier NCT02115282).

The pan-HDAC inhibitor vorinostat is currently under investigation with the immune checkpoint inhibitor pembrolizumab to assess the response of hormone therapy-resistant MBC to epigenetic immune priming. Pembrolizumab is discussed in detail below. This phase II clinical trial aims to enroll 58 patients with

HR+ MBC with prior hormone therapy in the metastatic setting to receive tamoxifen 20 mg daily, vorinostat 400 mg daily (5 days on, 2 days off weekly, on a 21-day cycle), and pembrolizumab 200 mg iv every 3 weeks (ClinicalTrials.gov identifier NCT02395627). Patients are randomized to start pembrolizumab at the start of either cycle 2 or cycle 4.

Guidelines and recommendations for treatment of HR+/HER2– MBC

The ABC2 consensus guidelines state that the preferred first-line endocrine therapy for postmenopausal women with HR+/HER2– MBC is either an AI or tamoxifen, depending on type and duration of adjuvant therapy.⁴⁵⁸ Fulvestrant high dose is also included as a first-line option. Second, the guidelines state that patients with HR+/HER2– MBC who experience disease progression after treatment with an NSAI should be considered for treatment with everolimus plus exemestane. The NCCN Guidelines are in agreement with these statements from the ABC2.⁴⁰⁹

Chemotherapy for MBC

Decisions regarding the use of chemotherapy in MBC depend in large part on the subtype of a patient's disease. Chemotherapy is the only treatment available for metastatic TNBC and is generally combined with HER2-targeting agents in HER2+ MBC. As stated earlier, chemotherapy for HR+/HER2– MBC should be reserved for the rapid management of visceral crisis, de novo hormone resistance, or when patients develop irreversible resistance to endocrine-based therapies. [Table 15](#) includes commonly used single-agent and combination chemotherapy regimens used in MBC.

Table 15 Commonly used single-agent and combination chemotherapy regimens for HER2– and HER2+ metastatic breast cancer

HER2– MBC	Single agent	Paclitaxel (weekly)
		Docetaxel (every 3 weeks)
		Nab-paclitaxel
		Doxorubicin
		Pegylated liposomal doxorubicin
		Epirubicin
		Capecitabine
		Eribulin
		Ixabepilone
		Vinorelbine
		Gemcitabine
		Carboplatin
		Cisplatin
	Combination	Docetaxel + capecitabine
		Gemcitabine + paclitaxel (or docetaxel)
		Gemcitabine + carboplatin (or cisplatin)
HER2+ MBC	Paclitaxel (or docetaxel) + trastuzumab + pertuzumab	
	T-DM1	
	Lapatinib + capecitabine	
	Paclitaxel + trastuzumab	
	Vinorelbine + trastuzumab

Chemotherapy can be administered as a single agent or as a more intensive regimen of two or more drugs in combination. Historically, combination regimens were selected over single-agent chemotherapy as the increased RR and TTP associated with combined regimens were presumed to improve OS as well. A meta-analysis by Carrick et al. in 2009 reviewed 43 trials of chemotherapy for MBC, involving 9742 patients to assess outcomes associated with single-agent versus combination chemotherapy.⁵⁰¹ A proportion of 55% of trial participants included in this meta-analysis received first-line therapy. Combination regimens were not only superior with regard to RR, PFS, and OS (HR for OS 0.88; 95% CI, 0.83–0.94; $p < 0.0001$) but also were associated with a statistically significant increase in toxicity. A subsequent meta-analysis by Dear et al.⁵⁰² in 2013 evaluated 12 trials, including nine different treatment comparisons, to evaluate benefits of combination chemotherapy versus sequential use of the same agents. The meta-analysis demonstrated no difference in OS (HR 1.04; 95% CI, 0.93–1.15; $p = 0.45$) between combination and sequential chemotherapy. However, combination chemotherapy was associated with

increased tumor response (RR 1.16; 95% CI 1.06–1.28; $p = 0.001$) and decreased risk of progression (HR 1.11; 95% CI 0.99–1.25; $p = 0.08$) in comparison to sequential single-agent chemotherapy.

Maintenance chemotherapy is the continuation of a treatment beyond the achievement of best response. In 2011, Gennari et al. reported a meta-analysis of randomized clinical trials comparing first-line therapies given over a prespecified duration or continued as maintenance therapy.⁵⁰³ This meta-analysis included 11 trials with 2269 patients and showed that maintenance chemotherapy was associated with an improved OS (HR 0.91; 95% CI 0.84–0.99; $p = 0.046$) and PFS (HR 0.64; 95% CI 0.55–0.76; $p < 0.001$). The role of maintenance chemotherapy was more recently assessed in a multicenter phase III clinical trial in South Korea.⁵⁰⁴ A total of 324 patients with MBC were enrolled and received six cycles of paclitaxel plus gemcitabine in the first-line setting. The 231 patients who achieved disease control were then randomized to the maintenance paclitaxel plus gemcitabine arm or observation off any treatment. Median PFS was significantly longer in the maintenance arm than in the observation arm (7.5 months vs 3.8 months, respectively; $p = 0.026$). In addition, median OS was significantly longer in the maintenance arm than in the observation arm (32.3 months vs 23.5 months, respectively; $p = 0.047$). Not surprisingly, maintenance chemotherapy was associated with increased myelosuppression and neuropathy. The study included patients with metastatic TNBC and HR+ MBC. Patients with HR+ MBC on the observation arm did not receive maintenance hormone therapy, and only 20% had received any prior endocrine therapy. Subset analyses demonstrated that the PFS benefit was primarily seen in those patients with the TN subtype. Maintenance endocrine therapy after achieving best response with induction chemotherapy has not been studied in clinical trials, but is a reasonable option.⁴⁵⁸

A majority of patients will respond to first-line therapies. No clinical trials have demonstrated an improvement in OS using a specific chemotherapy in comparison to another in the first-line setting for MBC. In general, anthracyclines and taxanes are considered as the most effective classes of chemotherapy for breast cancer and are commonly used therapies in the first-line setting. However, treatment choice should be individualized, with consideration of prior adjuvant chemotherapy regimens, timing of relapse, total lifetime anthracycline exposure, and comorbidities.

Single-agent chemotherapy

The taxanes paclitaxel and docetaxel, compounds that stabilize microtubules and thereby induce cell cycle arrest, are among the most effective and best tolerated chemotherapies for the treatment of breast cancer. The FDA originally approved single-agent paclitaxel in 1994 at a dose of 175 mg/m² iv every 3 weeks, given as a 1- to 3-h infusion. CALGB 9840 was a phase III clinical trial that randomized 585 patients with MBC to receive paclitaxel at either 80 mg/m² iv given 3 weeks a month or paclitaxel 175 mg/m² iv given every 3 weeks as first- or second-line chemotherapy.⁵⁰⁵ A combined analysis, which included an additional 158 patients treated with every 3-week paclitaxel 175 mg/m² on the CALGB 9342 study, demonstrated a significant improvement in OS of 24 months on the weekly arm in comparison to 12 months on the every 3-week arm (HR = 1.28; $p = 0.0092$). RR (42% vs 29%) and median TTP (9 months vs 5 months) were also significantly increased. Grade 3 neuropathy was more common on the weekly than every 3-week arm (24% vs 12%; $p = 0.0003$), whereas higher rates of myelosuppression and infectious complications were noted on the every 3-week arm.

Docetaxel is generally administered at a dose of 75–100 mg/m² every 3 weeks as a 1-h infusion. Several small phase II and III clinical trials have compared weekly docetaxel at 35–40 mg/m² with every 3-week docetaxel between 75 and 100 mg/m² iv, and a meta-analysis by Mauri et al. in 2010 demonstrated no significant difference in ORR, PFS, or OS between these docetaxel schedules.^{506–509} However, the

weekly schedule resulted in less myelosuppression and neuropathy, but more frequent nail changes and epiphora.

A phase III clinical trial has compared docetaxel 100 mg/m² iv every 3 weeks with paclitaxel 175 mg/m² iv every 3 weeks in patients with MBC who had progressed on anthracycline-containing therapy. Of the 372 patients randomized, those on the docetaxel arm experienced a longer TTP than those on the paclitaxel arm (5.7 months vs 3.6 months; HR 1.64; 95% CI, 1.33–2.02; $p < 0.0001$) as well as longer OS (15.4 months vs 12.7 months; HR 1.41; 95% CI, 1.15–1.73; $p = 0.03$).⁵¹⁰ However, the preferred regimens of weekly paclitaxel and every 3-week docetaxel have not been compared in a head-to-head trial. Docetaxel and paclitaxel are not completely cross-resistant and many patients derive clinical benefit from treatment with one taxane after developing resistance to the other.^{511, 512}

Nanoparticle albumin-bound paclitaxel (nab-paclitaxel) was developed to avoid the infusion reactions associated with the solvents used with paclitaxel and docetaxel, Cremophor EL and Polysorbate 80, respectively. The FDA approved nab-paclitaxel in 2005 based on its superior efficacy in comparison to every 3-week paclitaxel in a phase III clinical trial.⁵¹³ In particular, 454 women with MBC were randomized to receive nab-paclitaxel 260 mg/m² iv every 3 weeks or paclitaxel 175 mg/m² every 3 weeks. Approximately 40% of study participants had not received prior chemotherapy in the metastatic setting. Patients on the nab-paclitaxel arm had significantly higher ORR (33% vs 19%; $p = 0.001$) and longer TTP (23.0 weeks vs 16.9 weeks; HR 0.75; $p = 0.006$) than those on the paclitaxel arm. Grade 4 neutropenia was less common on the nab-paclitaxel arm than the paclitaxel arm (9% vs 22%; $p < 0.001$), while grade 3 sensory neuropathy was more common on the nab-paclitaxel than the paclitaxel arm (10% vs 2%; $p < 0.001$), but most episodes resolved with treatment interruption and dose reduction. No corticosteroids or antihistamines were used on the nab-paclitaxel arm and no hypersensitivity reactions occurred. No study has compared weekly nab-paclitaxel with the preferred weekly paclitaxel regimen.

A phase II randomized clinical trial compared several schedules of nab-paclitaxel and every 3-week docetaxel.⁵¹⁴ In this study, 300 patients with treatment naïve MBC were randomized to nab-paclitaxel 300 mg/m² iv every 3 weeks, 100 mg/m² the first 3 of every 4 weeks, 150 mg/m² the first 3 of every 4 weeks, or docetaxel 100 mg/m² every 3 weeks. The nab-paclitaxel arm at 150 mg/m², the first 3 of every 4 weeks, was associated with the highest RR, PFS, and OS.⁵¹⁵ Rates of peripheral neuropathy due to nab-paclitaxel are fairly similar to paclitaxel and docetaxel, but rates of neutropenia are lower.

Anthracyclines are a reasonable first-line chemotherapy for MBC, but evaluation of a patient's cardiac risk factors and lifetime anthracycline exposure (doxorubicin 450–550 mg/m² and epirubicin 900 mg/m²) is critically important to reduce risk of cardiotoxicity. Doxorubicin is typically given as 60–75 mg/m² every 3 weeks or 20 mg/m² weekly. Epirubicin can be given as 75–100 mg/m² every 3 weeks or 20–30 mg/m² weekly. Pegylated liposomal doxorubicin (PLD) is an enhanced form of doxorubicin that is encapsulated in liposomes to minimize adverse effects, while maintaining treatment efficacy. Several phase III clinical trials comparing PLD and doxorubicin have demonstrated equivalent efficacy with a significantly lower risk of cardiotoxicity, allowing for anthracycline-based retreatment in the metastatic setting.^{516–518} PLD is also associated with less alopecia and nausea, but more hand-foot syndrome and mucositis.

A randomized controlled trial of first-line doxorubicin versus paclitaxel every 3 weeks, with crossover allowed at progression, found a higher RR and PFS with first-line doxorubicin, but no statistically significant difference in OS.⁵¹⁹ Doxorubicin resulted in more toxicity, but better control of cancer-related symptoms. By contrast, the single-agent arms of doxorubicin and paclitaxel every 3 weeks in the E1193

clinical trial showed equivalent RR, time to treatment failure, OS, and QOL.⁵²⁰ A meta-analysis of three clinical trials, including 919 patients who were randomized to single-agent anthracycline versus every 3-week taxane, demonstrated similar RR (33% and 38%, respectively; $p = 0.08$) and OS (HR 1.01; 95% CI, 0.88–1.16; $p = 0.90$), but an increase in PFS with anthracyclines (HR 1.19; 95% CI, 1.04–1.36; $p = 0.011$).⁵²¹ No clinical trials have compared anthracyclines with weekly paclitaxel in the first-line setting.

Capecitabine is an orally administered third-generation fluoropyrimidine carbamate that is preferentially converted in tumor tissue to its active metabolite 5-fluorouracil by thymidine phosphorylase, thus allowing for more selective cytotoxicity with fewer toxic side effects. Several phase II clinical trials have demonstrated that single-agent capecitabine has activity in patients with MBC with prior exposure to anthracyclines and taxanes with RR of 15–29% and OS of 10.1–15.2 months.^{522–525} The FDA approved capecitabine for use in patients with MBC in 1998, as a single agent in patients with MBC refractory to anthracycline and taxanes, and in combination with docetaxel in 2001, as described below. Both the FDA approval and the capecitabine package insert recommend capecitabine starting dose of 1250 mg/m² twice daily for 2 weeks followed by a 7-day rest period. However, lower starting doses of 1000 mg/m² twice daily for 2 weeks, followed by a 1-week rest period are associated with similar efficacy, but less palmar-plantar erythrodysesthesia and diarrhea.⁵²⁶

Eribulin, a novel synthetic inhibitor of tubulin polymerization, was approved for use in patients with MBC who had received two prior chemotherapies in the metastatic setting by the FDA in 2010 in the context of significant results from the EMBRACE study, a phase III clinical trial of heavily pretreated patients with MBC.⁵²⁷ In this open-label study, 762 patients were randomized in a 2 : 1 ratio to receive eribulin 1.4 mg/m² iv on days 1 and 8 of a 21-day cycle or physician's choice chemotherapy. Median OS was significantly improved in the eribulin arm (13.1 months; 95% CI, 11.8–14.3) in comparison to the physician's choice arm (10.6 months; 95% CI, 9.3–12.5; HR 0.81, 95% CI, 0.66–0.99; $p = 0.041$). Peripheral neuropathy led to the discontinuation of eribulin in 5% of patients.

The effects of eribulin and capecitabine on both OS and PFS were compared in a phase III clinical trial in an attempt to identify a standard therapy for use in patients with MBC that had progressed on both anthracycline- and taxane-based therapies.⁵²⁸ A total of 1102 women with MBC were randomized to receive eribulin or capecitabine as their first-, second- or third-line chemotherapy. Eribulin was not superior to capecitabine with regard to OS (15.9 months vs 14.5 months; HR 0.88; 95% CI, 0.77–1.00; $p = 0.56$) or PFS (4.1 months vs 4.2 months; HR 1.08; 95% CI, 0.93–1.25; $p = 0.30$). No difference in objective RR was observed with 11.0% for eribulin and 11.5% for capecitabine. QOL scores were also similar, with a majority of AEs of grades 1 or 2.

Ixabepilone is an epothilone, a novel class of antimicrotubule agents developed to overcome taxane and anthracycline resistance. Phase II studies of ixabepilone 40 mg/m² iv every 3 weeks in heavily pretreated patients with MBC demonstrated objective RR of approximately 12% and stable disease in 40–50% of participants.^{529, 530} Transient peripheral neuropathy, myelosuppression, alopecia, and fatigue were common toxicities in these studies. Its approval by the FDA in 2007 was based on a phase III clinical trial evaluating the combination of ixabepilone and capecitabine, but labeling allows for monotherapy. Ixabepilone is currently only available in the United States.

The semisynthetic vinca alkaloid vinorelbine has been evaluated extensively for the treatment of MBC and used in clinical practice for several decades, but has never gained regulatory approval by the FDA. Phase II clinical trials of single-agent vinorelbine dosed at 30 mg/m² on days 1 and 8 of a 21-day cycle have demonstrated RR of 40–50% in the first line and 20–35% in second line for patients with MBC.⁵³¹

⁵³² Vinorelbine is well tolerated with myelosuppression as the main side effect.

Some chemotherapy treatments used in MBC are approved as single agents, but more commonly used in combinations, as described below. Gemcitabine is a pyrimidine antimetabolite that inhibits DNA synthesis through a unique mechanism of action. It has been studied as a first-, second-, and third-line treatment for patients with MBC with average RRs of 37%, 26%, and 13%, respectively.^{533–535} Given its limited toxicity as well as unique mechanism of action, it is often combined with other chemotherapy treatment methods, such as taxanes and platinum. In 2004, the U.S. FDA approved gemcitabine in combination with paclitaxel for use in patients with MBC who had progressed on prior anthracycline treatment. Cisplatin and carboplatin are DNA cross-linking agents with similar activity in previously untreated MBC, with objective response rates between 8% and 35%.^{536–538}

The preferred single-agent chemotherapies for recurrent MBC according to the NCCN Guidelines are doxorubicin, PLD, paclitaxel, capecitabine, gemcitabine, vinorelbine, and eribulin.⁴⁰⁹

Combination chemotherapy regimen

Several regimens of combination chemotherapy are available for when a more rapid tumor response is needed to improve cancer-associated symptoms or in the context of a life-threatening visceral crisis. However, such regimens are generally more toxic and their use should be carefully assessed/weighed. Some combination regimens approved for use in the adjuvant or neoadjuvant setting have also been demonstrated as effective in the metastatic setting, such as an anthracycline plus cyclophosphamide with or without fluorouracil, and CMF. Non-anthracycline-containing taxane-based regimens include paclitaxel or docetaxel combined with gemcitabine, docetaxel plus capecitabine, and paclitaxel plus either cisplatin or carboplatin. Available combination regimens for patients who progress on both anthracyclines and taxanes include gemcitabine plus carboplatin. Suggested combination regimens are found within the NCCN Guidelines for Breast Cancer, which are available at NCCN.org.^{395, 409}

The phase III Intergroup E1193 randomized clinical trial compared single-agent doxorubicin, single-agent paclitaxel, and doxorubicin plus paclitaxel, with allowance for crossover between single-agent arms after progression, in patients with MBC.⁵¹⁸ Response rates and TTP were statistically superior in the combination arm at 47% and 8 months, respectively, than in either of the two single-agent arms (36% and 5.8 months with doxorubicin; 34% and 6.0 months with paclitaxel). However, no benefit in OS was observed in the combination arm in comparison to sequential single-agent therapy. Global QOL measurements were similar in all arms.

Combination chemotherapy regimens typically are based on preclinical evidence of synergy between two agents with distinct mechanisms. Taxanes enhance the activity of capecitabine through the upregulation of thymidine phosphorylase, and early phase I studies clearly demonstrated synergy between docetaxel and capecitabine. A phase III clinical trial reported by O'Shaughnessy et al.⁵³⁹ in 2002 randomized 511 patients with anthracycline-resistant MBC to receive capecitabine 1250 mg/m² po twice daily on days 1–14 plus docetaxel 75 mg/m² iv on day 1 of a 21-day cycle or docetaxel 100 mg/m² iv every 21 days. The combination arm was associated with a significant increase in ORR (42% vs 30%; $p = 0.006$), median TTP (6.1 months vs 4.2 months; HR 0.652; 95% CI, 0.545–0.780; $p = 0.001$), and OS (14.5 months vs 11.5 months; HR 0.75; 95% CI, 0.634–0.947; $p = 0.0126$). This clinical trial was the first to demonstrate improved OS with a docetaxel-containing combination. However, more patients in the combination arm than the single-agent arm (20% vs 7%) received sequential single-agent docetaxel after completion of the study, complicating interpretation of OS.

A phase III clinical trial that randomized 170 patients to receive gemcitabine 1000 mg/m² iv on days 1 and 8 of a 21-day cycle plus docetaxel 75 mg/m² iv on day 8 or docetaxel 175 mg/m² iv every 3 weeks demonstrated an increase in TTP with the combination arm (HR 0.77; 95% CI, 0.59–1.01; log-rank = 0.06), but no difference in RR or OS.⁵⁴⁰ However, few patients enrolled in this study received second- or third-line treatment. A global phase III clinical trial randomized 529 patients with MBC who had received an anthracycline in the adjuvant setting to receive gemcitabine 1250 mg/m² iv on days 1 and 8 plus paclitaxel 175 mg/m² iv on day 1 every 21 days or paclitaxel only.⁵⁴¹ TTP was longer (6.14 months vs 3.98 months; log-rank $p = 0.0002$) and RR was increased (41.4% vs 26.2%; $p = 0.0002$) in the combination arm in comparison to paclitaxel only. However, the trial did not use the optimal weekly schedule of paclitaxel. These results led to the FDA approval of gemcitabine in combination with paclitaxel as a first-line treatment for patients with MBC in 2004. A phase III clinical trial evaluated gemcitabine plus paclitaxel or docetaxel with every 3-week or weekly schedules.⁵⁴² In this study of 240 patients, similar TTP and OS were demonstrated between the various arms. Similar ORRs were observed with the different taxanes, but weekly schedules were favored over every 3-week schedules. The combinations of docetaxel with either gemcitabine or capecitabine have been compared in several phase III clinical trials. A pooled analysis of these studies has shown no difference in OS, PFS, or ORR.⁵⁴³

Preclinical studies have demonstrated synergy between gemcitabine and platinum agents, and subsequent clinical trials demonstrated that this combination has moderate activity in patients with prior exposure to anthracyclines and taxanes. A multicenter phase II clinical trial that treated 39 patients with heavily pretreated MBC with gemcitabine 1000 mg/m² iv on days 1 and 8 and carboplatin AUC 4 on day 1 every 3 weeks reported an ORR of 31% (95% CI, 17–48%) and a median TTP of 5.3 months (95% CI, 2.6–6.7 months).⁵⁴⁴ A multicenter phase II clinical trial that treated 33 patients with heavily pretreated MBC with gemcitabine 1000 mg/m² iv and cisplatin 30 mg/m² iv on days 1 and 8 of a 21-day cycle reported an ORR of 25.8% (95% CI, 17–48%) and a median TTP of 4 months (95% CI, 2.15–5.85 months).⁵⁴⁵

Antiangiogenic agents plus chemotherapy in MBC

As mentioned in the adjuvant section, neoangiogenesis plays an important role in the development of breast cancer, and several antiangiogenic agents have been evaluated in the metastatic setting. The FDA approved the monoclonal antibody bevacizumab in combination with chemotherapy for the first-line treatment of MBC in 2008. This approval was based on results from the phase III E2100 clinical trial that randomized 722 patients with MBC to weekly paclitaxel with or without bevacizumab (10 mg/kg iv every 2 weeks).⁵⁴⁶ The bevacizumab-containing arm was associated with a significant benefit in PFS (11.8 months) in comparison to the control arm (5.9 months; HR 0.6), but with no difference in OS ($p = 0.16$). Subsequent phase III studies of bevacizumab in combination with first-line chemotherapy demonstrated a less-significant PFS improvement and no effect on OS, leading to withdrawal of the FDA approval of bevacizumab for MBC in 2011.

The phase III AVastin And DOcetaxel (AVADO) clinical trial randomized 736 patients with MBC to docetaxel 100 mg/m² iv plus bevacizumab at 7.5 or 15 mg/kg iv or docetaxel plus placebo every 3 weeks.⁵⁴⁷ At a median follow-up of 25 months, PFS was superior in both bevacizumab-containing arms, most notably with a PFS of 10.1 months in the bevacizumab (15 mg/kg)-containing arm in comparison to 8.2 months in the control arm. The phase III RIBBON-1 clinical trial randomized 1237 patients with HER2– MBC to investigator's choice first-line chemotherapy with or without bevacizumab 15 mg/kg, and found a statistically significant improvement in median PFS when bevacizumab was given in combination with capecitabine, taxanes, or anthracyclines. A meta-analysis of E2100, AVADO, and RIBBON-1,

published in 2012 by Rossari et al.,⁵⁴⁸ demonstrated a significant improvement in 1-year OS in bevacizumab containing arms, but no difference in median OS (HR 0.97; 95% CI, 0.86–1.08, $p = 0.056$). Many additional phase II and III clinical trials have evaluated the addition of bevacizumab to first-, second-, and subsequent-line chemotherapies. The phase III RIBBON-2 clinical trial evaluated the combination of bevacizumab with investigator's choice second-line chemotherapy, and found a statistically significant improvement in median PFS from 5.1 to 7.2 months with the addition of bevacizumab to either capecitabine, taxanes, gemcitabine, or vinorelbine.⁵⁴⁹ Similar to other studies, no significant effect on OS was appreciated. In addition to the absence of a survival benefit, bevacizumab in combination with chemotherapy is associated with an increased risk of grade 3–4 hypertension (4.4%), thromboembolic disease (3.2%) proteinuria (1.7%), and hemorrhage (1.4%).⁵⁵⁰ The ongoing global, double-blinded, phase III MERiDiAN clinical trial is evaluating first-line weekly paclitaxel with or without bevacizumab in patients with HER2– MBC.⁵⁵¹ The study will assess PFS in all patients as well as the subgroup of patients with high-baseline VEGF-A concentrations as a predictive marker of treatment benefit.

Other types of antiangiogenic agents have been evaluated for the treatment of MBC. Sunitinib, a small molecule multitargeted TKI that inhibits the VEGF receptor, was studied in combination with capecitabine in a phase III clinical trial of patients with anthracycline- and taxane-resistant MBC.⁵⁵² The study randomized 442 patients with up to two prior regimens for MBC to capecitabine 2000 mg/m² with or without sunitinib 37.5 mg po daily. ORR, PFS, and OS were similar between the two arms.

Ramucirumab, a humanized monoclonal antibody against VEGF receptor-2, was studied in combination with docetaxel in the phase III ROSE/TRIO-12 clinical trial.⁵⁵³ This double-blinded study randomized 1144 patients with HER2– MBC to receive first-line docetaxel 75 mg iv with ramucirumab 10 mg/kg iv or placebo every 3 weeks. No statistically significant difference in median PFS (HR 0.88; $p = 0.077$) or OS (HR 1.01; $p = 0.915$) was detected, while toxicities such as fatigue, hypertension, hand-foot syndrome, and stomatitis were significantly higher in the ramucirumab-containing arm. No antiangiogenic agents are approved for the treatment of MBC as of 2015, but many remain under evaluation and can be found at www.clinicaltrials.gov.

Systemic therapies for HER2+ MBC

In the absence of HER2-targeted therapy, patients with HER2+ breast cancer experience shortened OS because of aggressive tumor behavior.⁵⁵⁴ The approval of trastuzumab in combination with paclitaxel for the first-line treatment of HER2+ MBC in 1998, and later for ESBC in 2006, dramatically improved outcomes for these patients. Unfortunately, 15% of patients with HER2+ ESBC will develop incurable metastatic disease after completing 1 year of adjuvant trastuzumab, and 30–50% of patients treated with trastuzumab in the metastatic setting will progress within 1 year. The development and FDA approval of three additional HER2-directed therapies, lapatinib, pertuzumab, and T-DM1, has further improved the survival of patients with HER2+ MBC. Many novel HER2-directed therapies are currently under evaluation and described below.

Pivotal trials of trastuzumab in HER2+ MBC

The early clinical trials of trastuzumab in patients with HER2+ MBC evaluated first- and second-line trastuzumab monotherapy and trastuzumab in combination with chemotherapy. A single-arm study of first-line trastuzumab monotherapy in 114 women with HER2+ MBC showed an RR of 26% and CBR of 38%.⁵⁵⁵ In comparison, a study of trastuzumab monotherapy in 222 patients with HER2+ MBC and

progression after one or two chemotherapy regimens resulted in an ORR of 15% and median duration of response of 9.1 months.⁵⁵⁶

The FDA approval of trastuzumab was based on the pivotal phase III trial by Slamon et al., which randomized 469 women with HER2+ MBC to standard chemotherapy (an anthracycline plus cyclophosphamide, or paclitaxel) plus trastuzumab versus chemotherapy only in the first-line setting.⁵⁵⁷ Trastuzumab was given with a loading dose of 4 mg/kg iv followed by 2 mg/kg iv weekly. The addition of trastuzumab to chemotherapy was associated with a longer TTP (7.4 months vs 4.6 months; $p < 0.001$), higher ORR (50% vs 32%; $p < 0.001$), longer duration of response (9.1 months vs 6.1 months; $p < 0.001$), and longer OS (25.1 months vs 20.3 months; $p = 0.046$) in comparison to chemotherapy only. The primary toxicity associated with trastuzumab was a reduction in LVEF, which was most prominent in patients receiving the combination of anthracycline and cyclophosphamide plus trastuzumab (27%), in comparison to paclitaxel plus trastuzumab (13%), anthracycline and cyclophosphamide only (8%), or paclitaxel only (1%). This increased toxicity led to the general recommendation that anthracyclines not be combined with trastuzumab in the metastatic setting.^{409, 464}

Several other phase II and III clinical trials of single-agent chemotherapy plus trastuzumab in the first-line setting have been performed. In a multinational phase II clinical trial that was reported by Marty et al. in 2005, 186 patients with HER2+ MBC were randomized to docetaxel 100 mg/m² iv every 3 weeks with or without trastuzumab until disease progression.⁵⁵⁸ The addition of trastuzumab to docetaxel was associated with an increased median TTP (11.7 months vs 6.1 months; $p = 0.0001$), ORR (61% vs 34%, $p = 0.0002$), and OS (31.2 months vs 22.7 months; $p = 0.0325$) in comparison to the control arm. Patients in the control arm who crossed over to single-agent trastuzumab at the time of progression had an OS similar to those on the docetaxel plus trastuzumab arm (30.3 months vs 31.2 months, respectively), clearly demonstrating the effectiveness of trastuzumab in the second-line setting.

Several single-arm phase II clinical trials reported ORRs of 63–78% with the combination of vinorelbine plus trastuzumab in patients with HER2+ MBC, a regimen that is generally well tolerated with primary AEs of neutropenia and neuropathy.^{559–561} Essentially all other studies combining trastuzumab with chemotherapy have demonstrated safety and efficacy, although the majority are single-arm trials. In many countries, the combination of trastuzumab with chemotherapy has become the standard of care for patients with HER2+ MBC, regardless of the type of chemotherapy used and its efficacy.⁵⁶²

Preclinical studies demonstrated synergy between platinum agents, taxanes, and trastuzumab, and subsequent clinical trials attempted to further improve clinical benefit by combining these drugs.⁵⁶³ A multicenter phase III clinical trial randomized 196 women with HER2+ MBC and without prior treatment in the metastatic setting to six cycles of trastuzumab and paclitaxel 175 mg/m² iv every 3 weeks with or without carboplatin AUC 6 iv, followed by weekly maintenance trastuzumab.⁵⁶⁴ Patients in the carboplatin-containing arm were found to have increased ORR (52% vs 36%; $p = 0.04$) and PFS (10.7 months vs 7.1 months; HR 0.66; 95% CI, 0.59–0.73; $p = 0.03$), as well as increased grade 4 neutropenia. A prespecified subset analysis of patients with HER2+ IHC 3+ (in comparison to 2+) demonstrated an even higher ORR (57% vs 36%; $p = 0.03$) and PFS (13.8 months vs 7.6 months; HR 0.55; 95% CI, 0.46–0.64; $p = 0.005$). No improvement in OS was observed.

BCIRG 007 was a multicenter phase III clinical trial that evaluated the addition of carboplatin to docetaxel and trastuzumab in the first-line setting.⁵⁶⁵ A total of 263 women with untreated HER2+ MBC were randomized to eight cycles of trastuzumab plus docetaxel 100 mg/m² iv every 3 weeks, or trastuzumab, carboplatin AUC 6 iv and docetaxel 75 mg/m² iv every 3 weeks, with maintenance trastuzumab thereafter. In comparison to the above study by Robert et al., no significant differences were

appreciated in TTP, RR, OS, or toxicity. The lack of any benefit with the addition of carboplatin was thought in part because of use of a higher dose of docetaxel in the control arm. The addition of carboplatin to a taxane and trastuzumab has not become a standard first- or second-line regimen, due in large part to the development of additional HER2-directed agents, which have resulted in improved PFS and OS, as described below.

Few studies have compared trastuzumab monotherapy with trastuzumab plus chemotherapy. A phase III study of first-line trastuzumab and docetaxel versus trastuzumab monotherapy, followed by trastuzumab plus docetaxel at the time of progression resulted in a significant improvement in median PFS (HR 4.24; $p < 0.01$) and OS (HR 2.72; $p = 0.04$) with upfront combination therapy.⁵⁶⁶ A majority of the 112 patients in this study had visceral metastases and multiple metastatic sites. A similar phase II study in 101 patients compared first-line docetaxel plus trastuzumab with single-agent trastuzumab, followed by single-agent docetaxel upon progression.⁵⁶⁷ The two arms had similar PFS, but there was an improved RR and a statistically insignificant improvement in OS with the combination. This trial design does not reflect the current clinical practice of continuing trastuzumab together with chemotherapy after progression, the use of which was confirmed to improve outcome in the German Breast Group (GBG) 26 / BIG 03–05 study clinical trial, as designed below.

Before the FDA approvals of lapatinib and T-DM1, the optimal second-line therapy for patients who had progressed on first-line taxane plus trastuzumab was unknown. Some researchers theorized that progression was due to chemotherapy resistance, and that trastuzumab should therefore be continued at the time of progression.^{568, 569} The GBG 26/BIG 03-05 study was a phase III clinical trial that randomized patients with HER2+ MBC who had progressed on first-line taxane plus trastuzumab to receive second-line capecitabine plus continued trastuzumab versus capecitabine only.⁵⁷⁰ GBG 26/BIG 03-05 closed early after accruing only a third of its target, in part due to the approval of lapatinib with capecitabine for the second-line setting. Despite this, continuation of trastuzumab with capecitabine rather than capecitabine only was associated with a statistically significant improvement in ORR (48.1% vs 27.0%; $p = 0.0115$) and TTP (8.2 months vs 5.6 months, $p = 0.0338$), although the numerical improvement in OS was not significant (24.9 months vs 20.6 months, $p = 0.73$) as the study was underpowered. Other attempts were made to study the continuation of trastuzumab after progression, but GBG 26/BIG 03-05 is the only prospective study to demonstrate its effectiveness.

Trastuzumab is either given with a loading dose of 4 mg/kg iv followed by 2 mg/kg iv weekly or with a loading dose of 8 mg/kg iv followed by 6 mg/kg iv every 3 weeks.⁴⁰⁹ A subcutaneous formulation of trastuzumab was recently developed as a cost-effective alternative to the standard iv formulation.⁵⁷¹ The enHANced treatment with NeoAdjuvant Herceptin (HannaH), multinational, open-label, randomized phase III clinical trial has recently demonstrated that trastuzumab 600 mg subcutaneous (sc) every 3 weeks was noninferior to standard intravenous trastuzumab in the neoadjuvant setting with regard to pCR.⁵⁷² Participants on the subcutaneous arm suffered more frequent infections. The fixed-dose sc formulation of trastuzumab has been recently approved in the European Union as a patient-preferred alternative because of shorter administration times and less discomfort. An ongoing phase III clinical trial, Preference for Herceptin SC or IV Administration (PrefHER), evaluates both patient and physician preference as well as cost savings associated with the subcutaneous formulation (ClinicalTrials.gov Identifier, NCT01401166).

Beyond trastuzumab: additional HER2-directed therapies

Approximately 30–50% of patients with trastuzumab-naïve HER2+ MBC do not achieve an objective

response to trastuzumab plus chemotherapy in the first-line setting, and subsequently experience shorter TTP (7–17 months) and OS (22–38 months).^{557, 560} Furthermore, acquired resistance to trastuzumab ultimately develops in all patients. Proposed mechanisms for de novo and acquired trastuzumab resistance include intrinsic molecular changes to HER2, upregulation of parallel compensatory signaling pathways, defects in antibody-dependent cellular cytotoxicity, and alterations in apoptosis.^{573, 574} An intense interest in the development of alternative approaches to block downstream effects of the HER2 pathway has led to significant improvements in outcomes, as outlined below.

Lapatinib for HER2+ breast cancer

Lapatinib is an oral, small-molecule TKI that targets the intracellular kinase domain of HER2 and is active against trastuzumab-resistant HER2-overexpressing breast cancer cells. The FDA approved lapatinib in combination with capecitabine in 2007 in the context of a phase III clinical trial of patients who had progressed on regimens containing a taxane plus trastuzumab. A total of 324 patients with HER2+ MBC were randomized to lapatinib 1250 mg po daily plus capecitabine 2500 mg/m² po daily (days 1–14 of a 21-day cycle) or capecitabine only.⁴⁰² A significant improvement in independently assessed PFS was observed on the lapatinib-containing arm in comparison to the control arm (8.4 months vs 4.4 months; HR 0.49; 95% CI, 0.34–0.71; $p < 0.001$). The final analysis demonstrated a survival advantage in the lapatinib-containing arm in comparison to the capecitabine arm (75.0 weeks vs 64.7 weeks).⁵⁷⁵ No case of reduced LVEF or cardiomyopathy was observed. Diarrhea (60% vs 39%; $p \leq 0.001$) was more common in the combination arm than in the control arm, but most cases were grade 1 or 2, and rates of grade 3 diarrhea were similar (12% vs 11%). Fewer cases of CNS metastasis were observed in the lapatinib-containing arm (4 patients vs 11 patients), but this finding was not statistically significant.⁴⁰² From 2007 to 2012, lapatinib plus capecitabine was considered an appropriate second-line therapy for HER2+ MBC after progression on a taxane plus trastuzumab therapy.⁵⁷⁶

Preclinical studies have demonstrated synergy as well as lack of cross-resistance between lapatinib and trastuzumab. EGF104900 was a phase II clinical trial that randomized 296 patients with heavily pretreated HER2+ MBC to lapatinib plus trastuzumab or lapatinib only.⁵⁷⁷ Participants had received a median of three prior trastuzumab-containing regimens. The combination of lapatinib plus trastuzumab was superior to lapatinib only with regard to PFS (HR 0.74; 95% CI, 0.58–0.94, $p = 0.011$), CBR, and OS (14.5 months vs 9.5 months; HR 0.74; 95% CI, 0.57–0.97; $p = 0.026$).⁵⁷⁸ Rates of diarrhea were higher in the combination arm (60% vs 48%; $p = 0.03$) than in the lapatinib arm, but rates of grade 3 diarrhea were the same (7%).

NCIC CTG MA.31 was an international, open-label phase III clinical trial that randomized 652 women with treatment naïve HER2+ MBC to receive 24 weeks of a taxane in combination with either lapatinib or trastuzumab, followed by the same HER2-directed monotherapy.⁵⁷⁹ The combination of lapatinib and a taxane was inferior with regard to both PFS (9.1 months vs 13.6 months; $p < 0.001$) and OS in comparison to trastuzumab and a taxane, providing clear evidence that trastuzumab is superior to lapatinib in the first-line setting.

HER2+ breast cancers exercise a tropism for the CNS. Unfortunately, trastuzumab cannot cross the blood–brain barrier. An estimated 10–15% of patients with HER2+ MBC develop brain metastasis after treatment with trastuzumab despite control of systemic disease. This high frequency of CNS metastases is likely due to multiple factors, but the extension of life through systemic control afforded by trastuzumab likely increases the likelihood that CNS metastases will become clinically apparent. As stated earlier, Geyer et al. reported a statistically insignificant trend of fewer cases of CNS metastasis with the

combination of lapatinib plus capecitabine versus capecitabine only.⁴⁰² Several investigations have subsequently evaluated the ability of lapatinib to prevent or treat CNS metastasis.

Patients treated with single-agent lapatinib after receiving radiotherapy for progressive brain metastases achieved ORR of only 6%, but in combination with capecitabine ORR were more pronounced at 21–31.8%.^{580–582} The phase II LANDSCAPE clinical trial treated patients with HER2+ untreated brain metastases with lapatinib plus capecitabine, and showed a CNS ORR of 65.9%, TTP of 5.5 months, and OS of 17.0 months.⁵⁸³

CEREBEL was a multicenter, open-label, phase III clinical trial designed to evaluate the effect of lapatinib plus capecitabine on the development of CNS metastasis as first site of progression.⁵⁸⁴ A total of 540 patients with HER2+ MBC were randomized to lapatinib 1250 mg/mg daily plus capecitabine 2000 mg/m² twice a day (days 1–14 of a 21-day cycle) or every 3-week trastuzumab plus capecitabine 2500 mg/m² twice a day (days 1–14 of a 21-day cycle). The study was terminated early because of the absence of difference in the incidence of CNS metastases as first site of relapse with 3% on the lapatinib-containing arm and 5% on the trastuzumab-containing arm. Furthermore, patients on the trastuzumab-containing arm exhibited higher PFS (HR 1.30; 95% CI, 1.04–1.64) and OS (HR 1.34; 95% CI, 0.95–1.64).

Pertuzumab for HER2+ MBC

Pertuzumab, as described in the adjuvant section, is a humanized monoclonal antibody that prevents HER2 dimerization by binding a different epitope than trastuzumab.^{585, 586} The combination of pertuzumab and trastuzumab leads to a more comprehensive blockade of the HER2 signaling pathway, and strongly enhances antitumor activity in comparison to single-agent activity in preclinical studies.⁵⁸⁷ A phase II clinical trial compared single-agent pertuzumab with the combination of pertuzumab and trastuzumab in patients with HER2+ MBC who had progressed on trastuzumab plus chemotherapy.⁵⁸⁸ While pertuzumab only had minimal antitumor activity, the combination therapy resulted in a CBR of 50%, ORR of 24.2%, and PFS of 5.5 months with minimal additional toxicity.

The Clinical Evaluation of Pertuzumab and Trastuzumab (CLEOPATRA) study was an international, multicenter, clinical trial that led to the FDA approval of pertuzumab in combination with docetaxel and trastuzumab in 2012.⁵⁸⁹ The study randomized 808 patients with HER2+ MBC and no prior treatment in the metastatic setting to receive trastuzumab plus docetaxel 75 mg/m² iv with either pertuzumab or placebo every 3 weeks. Pertuzumab was given with a loading dose of 840 mg followed by 420 mg every 3 weeks. Trastuzumab plus either pertuzumab or placebo were continued after discontinuation of chemotherapy in responding patients until tumor progression or death. Less than 50% of the participants had received treatment in the adjuvant setting and approximately 10% had received adjuvant trastuzumab.

The CLEOPATRA study demonstrated that the addition of pertuzumab led to a 6.3-month improvement in investigator-assessed PFS (18.7 months vs 12.4 months; HR 0.68; 95% CI, 0.51–0.75; $p < 0.001$) and 15.7-month improvement in OS (56.5 months vs 40.8 months; HR 0.68; 95% CI, 0.58–0.80; $p < 0.001$) in comparison to the control arm.⁵⁹⁰ The ORR was 80.2% in the pertuzumab group and 69.3% in the control group.⁵⁹¹ The median number of docetaxel cycles per patient was eight in both the control group (1–41 cycles) and pertuzumab group (1–35 cycles). The addition of pertuzumab did not lead to increased rates of cardiac dysfunction, but was associated with more frequent diarrhea (66.8% vs 46.3%) and rash (33.7% vs 24.2%) than those in the control arm.

The incidence of CNS metastasis as first site of disease progression was similar between the pertuzumab

and control groups (13.7% vs 12.66%).⁵⁸⁹ However, the median time to development of CNS metastasis was prolonged in the pertuzumab group (15.0 months) compared with the control group (11.9 months; HR 0.58; 95% CI, 0.39–0.85; $p = 0.0049$). OS in patients with CNS metastases as the first site of disease progression was associated with a statistically insignificant trend in favor of the pertuzumab group (34.4 months vs 26.4 months).

Several predictive biomarkers were appreciated in the CLEOPATRA clinical trial. Elevated serum HER2 protein levels, serum HER2 and HER3 mRNA levels, and low-serum HER2 extracellular domain (sHER2) were associated with a significantly better prognosis ($p < 0.05$).⁵⁹² Patients with wild-type PIK3CA had a longer median PFS than those with mutant PIK3A in both the control (13.8 months vs 8.6 months) and pertuzumab groups (21.8 months vs 12.5 months).

Several ongoing clinical trials have been evaluating combinations of trastuzumab and pertuzumab with various chemotherapies in the settings of both ESBC and MBC. Details on these trials are available at <http://www.cancer.gov/about-cancer/treatment/clinical-trials/search>.

T-DM1 for HER2+ MBC

The novel antibody drug conjugate T-DM1 allows for intracellular delivery of the highly potent antimicrotubule cytotoxic agent emtansine directly to HER2+ breast cancer cells. T-DM1 was discussed in the adjuvant section, but originally investigated in the metastatic setting. In 2013, the FDA approved T-DM1 for use in patients with HER2+ MBC who had progressed after a trastuzumab-containing taxane regimen in the metastatic setting. The approval of T-DM1 was based on the EMILIA study, an international, multicenter, open-label phase III clinical trial that randomized 991 patients with HER2+ MBC to T-DM1 or lapatinib plus capecitabine, the standard option at that time for patients who had progressed on trastuzumab-based therapy.⁵⁹³ Enrolled patients had progressed on trastuzumab and a taxane. T-DM1 resulted in a significantly improved median PFS (9.6 months vs 6.4 months; HR 0.65; 95% CI, 0.55–0.75; $p < 0.001$) and median OS (30.9 months vs 25.1 months; HR 0.68; 95% CI 0.55–0.85; $p < 0.001$) in comparison to lapatinib plus capecitabine. Furthermore, T-DM1 was better tolerated with lower overall toxicity. The most common grade 3–4 AEs with T-DM1 were thrombocytopenia (12.9%) and elevated transaminases (2.9–4.3%).

Additional evidence for the efficacy of T-DM1 was shown in TH3RESA, an international, randomized, open-label phase III clinical trial that evaluated T-DM1 in patients with HER2+ MBC who had progressed on two or more HER2-targeted regimens.⁵⁹⁴ Participants of this study were heavily pretreated, with approximately 50% having four previous lines of chemotherapy for MBC. A total of 602 patients were randomized in a 2 : 1 ratio to T-DM1 or physician's treatment of choice. Treatment with T-DM1 was associated with a 2.9-month increase in median PFS over the control arm (6.2 months vs 3.3 months; HR 0.528; $p < 0.001$), as well as an increase in interim median (HR 0.552; $p = 0.0034$, efficacy stopping boundary not crossed). Safety results were similar to those in EMILIA.

The phase III MARIANNE clinical trial compared the use of single-agent T-DM1, T-DM1 plus pertuzumab, and trastuzumab with chemotherapy in the first-line setting for HER2+ MBC.^{595, 596} The study was designed before the approval of pertuzumab plus trastuzumab in combination with docetaxel and therefore did not include the current first-line standard of care for HER2+ MBC. Approximately 31% of the enrolled patients had received neoadjuvant or adjuvant HER2-directed therapy, while 37% were treatment naive in the context of de novo HER2+ MBC. Initial results were presented at ASCO 2015, and although the TDM-1-containing arms were noninferior in PFS (HR 0.91; 97.5% CI, 0.73–1.13; $p = 0.31$) in comparison to trastuzumab plus chemotherapy, they failed to demonstrate superiority in PFS.

Treatment recommendations for HER2+ MBC

The optimal sequence of all known HER2-directed therapies is unknown. The available chemotherapy regimens in combination with HER2-directed therapies for HER2+ MBC are listed in [Table 15](#). Results of CLEOPATRA, EMILIA, and TH3RESA were used to generate the most recent guidelines published by ABC2, ASCO, and NCCN.^{409, 458, 464} In general, the combination of trastuzumab, pertuzumab, and a taxane is the preferred first-line treatment option for HER2+ MBC. A common and appropriate clinical practice is to discontinue the taxane, while continuing the biologic therapy after completion of eight cycles of this first-line regimen. T-DM1 is the preferred second-line treatment (in comparison to lapatinib plus capecitabine), and is also preferred for a later cycle (in comparison to treatment of physician's choice) if not provided in the second-line setting. Use of pertuzumab beyond its combination with trastuzumab and chemotherapy in the first line is not supported; however, if a patient has not received pertuzumab, it can be used beyond the first-line.

Almost 50% of patients with HER2+ breast cancer also have HR+ disease, which is associated with biologic characteristics that confer a relative resistance to endocrine therapy in comparison to HR –/HER2+ disease. Patients with HR+/HER2+ disease are generally classified as the luminal B intrinsic subtype group.³¹³ Preclinical and clinical trials have demonstrated that resistance to hormone-based therapies in part can be overcome by HER2-directed therapy, suggesting a cross talk between the ER and HER2 pathways. Patients with nonvisceral, indolent disease, and comorbidities that limit chemotherapy options are appropriate candidates for combined hormone therapy and HER2-targeted agent.⁴⁵⁸

The phase III Trastuzumab and Anastrozole Directed Against ER+ HER2+ Mammary Carcinoma (TAnDEM) clinical trial randomized 207 postmenopausal women with HR+/HER2+ MBC to anastrozole with or without trastuzumab.⁵⁹⁷ Patients on the trastuzumab-containing arm were found to have a significant improvement in PFS in comparison to the anastrozole arm (4.8 months vs 2.4 months; HR 0.63; 95% CI, 0.47–0.84; $p = 0.0016$), but no difference in OS. The international, open-label, phase III eLEcTRA clinical trial randomized postmenopausal women with HR+/HER2+ MBC to letrozole only or letrozole plus trastuzumab in the first-line setting.⁵⁹⁸ The study closed early after enrolling only 57 out of a planned 370 patients because of poor accrual. The median TTP was shorter in the letrozole arm than in the combination arm (3.3 months vs 14.1 months (HR 0.67; $p = 0.23$), with a reduced CBR (39% vs 65%; odds ratio; 95% CI, 1.01–8.84). Although not statistically significant, these findings are similar to those in the TAnDEM clinical trial. Although chemotherapy in combination with HER2-targeting agents is generally selected for most patients with HR+/HER2+ MBC, those patients who receive endocrine therapy over chemotherapy should receive it in combination with HER2-targeting agents given the PFS benefit showed in the TAnDEM clinical trial.⁴⁵⁸

Somatic mutations of HER2 in HER2– breast cancer

Cancer genome sequencing studies have demonstrated the presence of HER2 somatic mutations in patients with HER2– breast cancer. A study by Bose et al. evaluated 25 such patients and identified 13 activating mutations that presumptively drive oncogenic transformation.⁵⁹⁹ Breast cancer cells bearing these activating mutations treated with neratinib were potently inhibited. An ongoing multicenter phase II clinical trial has been currently evaluating the use of neratinib in patients with solid tumors and HER2 somatic mutations (ClinicalTrials.gov Identifier NCT01953926). A second, ongoing phase II clinical trial evaluates the use of neratinib with or without fulvestrant in patients with HER2– MBC and HER2 somatic mutations (ClinicalTrials.gov Identifier NCT01670877).

HER2-directed therapy in combination with targeted drugs

As described earlier, bevacizumab has been evaluated in combination with hormone therapy to reverse hormone resistance in HR+ MBC and also in combination with chemotherapy, but remains unapproved for breast cancer in the United States. VEGF is upregulated in HER2-overexpressing breast cancer cells, and antiangiogenic agents are also of great interest in HER2+ MBC. The combination of bevacizumab, trastuzumab, and capecitabine was associated with an ORR of 73% and PFS of 14.4 months in a small, phase II clinical trial. The phase III AVEREL clinical trial randomized 424 patients with HER2+ MBC to docetaxel plus trastuzumab with or without bevacizumab in the first-line setting.⁶⁰⁰ An independent assessment demonstrated a statistically insignificant clinical benefit with the addition of bevacizumab, with PFS in the control arm versus bevacizumab-containing arm (13.9 months vs 16.5 months; HR 0.0162) that failed to meet the protocol-specified primary end point. No unexpected AE occurred with the combination of trastuzumab and bevacizumab. Interestingly, higher concentrations of plasma VEGF-A were associated with poorer outcome, but also a larger bevacizumab treatment effect.

Trastuzumab resistance is associated with loss of the tumor suppressor gene PTEN, alterations in the PI3K pathway, and increased activation of mTOR.^{601, 602} Several phase III clinical trials have investigated the use of the mTOR inhibitor everolimus in combination with chemotherapy for HER2+ MBC, but failed to demonstrate a benefit. In the BOLERO-3 clinical trial, 569 women with HER2+ MBC were randomized to receive everolimus 5 mg/daily or placebo, with all participants receiving weekly vinorelbine plus trastuzumab.⁶⁰³ Patients who recurred during or within 12 months of adjuvant trastuzumab or progressed during or within 4 weeks of trastuzumab in the MBC setting were considered trastuzumab-resistant. PFS was modestly prolonged at 7 months in the everolimus arm compared with 5.78 months in the control arm (HR 0.78; 95% CI, 0.65–0.95; $p = 0.0067$), and OS has not yet been reported. Subgroup analyses demonstrated more benefit from everolimus in patients <65 years and with nonvisceral HR–/HER2+ MBC. As experienced in other trials and in clinical practice, everolimus was associated with significant toxicity. An exploratory analysis of archived tumor tissue showed significant benefit derived from the addition of everolimus in patients with a low PTEN concentration than in those with a high PTEN concentration (HR 0.40; 95% CI, 0.20–0.82; p -interaction = 0.01), and in patients with a high pS6 concentration than in those with low pS6 concentration (HR 0.48; 95% CI, 0.24–0.96; p -interaction = 0.04). PIK3CA mutations did not seem to predict benefit (HR 0.65; 95% CI, 0.21–1.45; p -interaction = 0.32).

Everolimus was also evaluated as a first-line treatment for HER2+ MBC in the phase III BOLERO-1 clinical trial that randomized 719 treatment naïve patients in a 2 : 1 ratio to paclitaxel plus trastuzumab with either everolimus 10 mg daily or placebo.⁶⁰⁴ Initial results were presented at SABCS 2014 by Hurvitz et al., which showed no improvement in PFS (14.95 months vs 14.49 months; HR 0.89, 95% CI, 0.73–1.08; $p = 0.1166$). The PFS of participants with HR–/HER2+ on the everolimus-containing arm was notable, but it failed to meet prespecified significance as designated by protocol. The safety profile was similar to that reported in BOLERO-3 and other everolimus-based trials. With the combined data from BOLERO-3 and -1, everolimus does not play any therapeutic role in the treatment of HER2+ MBC.

Novel targeted agents in HER2+ MBC

MM-302 is a pegylated liposomal antibody–drug conjugate that delivers doxorubicin particularly to HER2+ breast cancer cells and thereby limits exposure of healthy tissues to chemotherapy. A phase I clinical trial demonstrated both the safety and antitumor activity of MM-302 in combination with trastuzumab in HER2+ MBC.⁶⁰⁵ HERMIONE is an ongoing, international, multicenter, open-label,

randomized phase II clinical trial that evaluates the effectiveness of MM-302 30 mg/m² iv every 3 weeks plus trastuzumab in comparison to physician's choice of chemotherapy (e.g., vinorelbine, capecitabine, or gemcitabine) plus trastuzumab in patients with anthracycline naïve HER2+ MBC that have progressed on pertuzumab and T-DM1 (ClinicalTrials.gov identifier NCT02213744).⁶⁰⁶ Margetuximab is a chimeric monoclonal antibody similar to trastuzumab with an Fc fragment engineered to promote increased binding to CD16A and subsequently preserve the antiproliferative effects of trastuzumab. Preclinical studies demonstrated superiority of margetuximab over trastuzumab, and a phase I trial revealed that margetuximab was well tolerated. An active phase II trial evaluates margetuximab in patients with MBC with HER2 equivocal by IHC and negative by FISH (ClinicalTrials.gov Identifier NCT01838021). A planned phase III clinical trial SOPHIA aims to randomize 528 patients with HER2+ MBC who have progressed on trastuzumab, pertuzumab, and T-DM1 to receive chemotherapy with either margetuximab or trastuzumab (ClinicalTrials.gov Identifier NCT02492711). These and other investigational HER2-directed drugs are presented in [Table 14](#).

ONT-380, previously known as ARRY-380, is an orally active, reversible, and selective small molecule HER2 inhibitor. There are two ongoing phase Ib trials with ONT-380 in patients with HER2+ MBC. The first trial is designed to evaluate ONT-380 in combination with T-DM1 in patients previously treated with a taxane and trastuzumab (ClinicalTrials.gov Identifier NCT01983501). The second trial is designed to evaluate ONT-380 in combination with capecitabine and/or trastuzumab in patients previously treated with trastuzumab and T-DM1 (ClinicalTrials.gov Identifier NCT02025192). Interim analyses of both studies demonstrated that ONT-380 was well tolerated and provided clinical benefit.^{607, 608}

Many small-molecule TKI have been evaluated in the setting of MBC. Neratinib, a potent irreversible TKI of HER1, 2, and 4 described in the adjuvant section, overcame trastuzumab resistance in HER2+ breast cancer cells in preclinical studies. A phase I clinical trial evaluated neratinib in combination with weekly paclitaxel and trastuzumab in patients with HER2+ MBC previously treated with HER2-directed therapy and a taxane demonstrated an ORR of 38%, CBR of 52%, and PFS of 3.7 months.⁴⁰⁵ A phase II clinical trial failed to demonstrate superiority of neratinib monotherapy over lapatinib plus capecitabine in patients with HER2+ MBC, who were treated with at least two prior trastuzumab-containing regimens.⁶⁰⁹ A multinational, open-label, phase I/II clinical trial evaluated the safety and efficacy of neratinib in combination with capecitabine in patients with trastuzumab-pretreated HER2+ MBC.⁶¹⁰ The ORR was 64% in lapatinib-naïve patients and 57% in patients with prior lapatinib exposure, and median PFS was 40.3 and 35.9 weeks, respectively. The most common toxicities were diarrhea (88%) and hand-foot syndrome (48%). In the ongoing phase II NEfERTT clinical trial, 479 patients with HER2+ MBC were randomized to first-line paclitaxel with either neratinib or trastuzumab (ClinicalTrials.gov Identifier NCT00915018). A press release in November 2014 reported similar PFS between the two treatment arms, but fewer brain metastases in those treated with neratinib versus trastuzumab (7.4% vs 15.6%; $p = 0.006$).⁶¹¹ Toxicity was increased with neratinib, with grade 3 diarrhea experienced in 30% and 4% of patients receiving neratinib and trastuzumab, respectively. The NEfERTT clinical trial did not use prophylactic antidiarrheal therapy, and several trials have reported a marked reduction in diarrhea with the use of prophylaxis. The ongoing phase III NALA study aims to randomize 600 patients with HER2+ MBC who have progressed on ≥ 2 HER2-directed regimens in the metastatic setting to neratinib plus capecitabine versus lapatinib plus capecitabine (ClinicalTrials.gov Identifier NCT01808573).

A phase I clinical trial evaluates the combination of the alpha-selective PI3K inhibitor alpelisib (BYL719) in combination with T-DM1 in patients with HER2+ MBC, who have progressed on prior trastuzumab- and taxane-based treatment (ClinicalTrials.gov identifier NCT02038010). A phase Ib clinical trial currently evaluates the PI3K inhibitor taselisib (GDC-0032) in combination with several

currently approved HER2-directed therapies (ClinicalTrials.gov identifier NCT02390427). A class I pan-PI3K inhibitor pilaralisib (SAR245408) will be combined with trastuzumab and paclitaxel in a phase I/II clinical trial of patients with trastuzumab refractory HER2+ MBC.⁶¹²

Systemic therapies for triple-negative MBC

Chemotherapy remains the mainstay of treatment for all stages of TNBC. As described in the neoadjuvant section, TNBC is quite sensitive to anthracyclines and taxanes. Several clinical trials evaluating the addition of carboplatin to standard chemotherapy in the neoadjuvant setting have showed pCR rates of 22–53% in TNBC.^{416, 613} Long-term outcomes of PFS and OS are not yet available, however, and platinum agents are not yet the standard of care for early-stage TNBC.

Platinum agents have also been evaluated in the setting of metastatic TNBC, with initial results from the first phase III clinical trial comparing first-line carboplatin to docetaxel reported at SABCS 2014.⁶¹⁴ The multicenter TNT study randomized 376 women with untreated metastatic TNBC to carboplatin AUC 6 iv every 3 weeks or docetaxel 100 mg/m² iv every 3 weeks with an option for crossover at the time of progression. At a median follow-up of 11 months, the ORR and PFS rates were similar in both groups. A prespecified subgroup analysis of the 43 trial participants with germline BRCA1/2 mutations demonstrated a statistically significant increase in ORR in the carboplatin arm compared with the docetaxel arm (68% vs 33%; $p = 0.03$).

Primary tumor samples from participants in the TNT study were analyzed for homologous recombination deficiency (HRD) with an HRD Assay developed by Myriad Genetics.⁶¹⁵ Patients with germline or somatic BRCA mutations tended to have high HRD scores. No significant difference in PFS or OS was observed between the two treatment arms in patients with high HRD scores, or in those with low HRD scores.

Approximately 75% and 50% of BRCA1/2-associated breast cancers, respectively, are triple-negative. BRCA1/2 are tumor suppressor genes with products that play key roles in the repair of double-stranded DNA breaks through homologous recombination. When the remaining wild-type BRCA allele in a tumor precursor cell is lost in patients with a germline BRCA1/2 mutation, genomic instability ensues because of reduced efficiency of HR. This impaired DNA repair mechanism is thought to confer increased sensitivity to platinum agent, as shown in the TNT trial.

Poly(adenosine diphosphate-ribose) polymerase (PARP) recognizes and repairs single-stranded DNA breaks through base excision repair. PARP inhibitors prevent the repair of single-stranded DNA and are highly selective for BRCA-mutant tumor cells. While a single mutated gene product may be compatible with cell viability, additional mutations in related genes are more likely to lead to cell death. This concept of synthetic lethality is a critical genetic concept that has directed the evaluation of PARP inhibitors for the treatment of BRCA-associated and BRCA-like TNBC.

Proof of the activity of PARP in BRCA-associated cancers was demonstrated in an international, multicenter, phase II clinical trial that treated 54 women with BRCA-associated MBC and at least one prior chemotherapy regimen with single-agent olaparib.⁶¹⁶ An RR of 41% and median PFS of 5.7 months were achieved when participants received olaparib 400 mg twice daily. A phase I clinical trial currently evaluates the combinations of olaparib with either buparlisib (BKM120, a novel class I pan-PI3K inhibitor) or alpelisib (BYL719, a novel alpha-selective PI3K inhibitor), in patients with TN MBC (ClinicalTrials.gov Identifier NCT01623349).

Several other PARP inhibitors are under investigation as monotherapy or in combination with other

targeted therapies or chemotherapy, including veliparib (ABT-888), talazoparib (BMN-673), iniparib, niraparib, and rucaparib. A phase 1 dose escalation study of the PARP inhibitor veliparib (ABT-888) in combination with carboplatin in patients with metastatic TNBC or a germline BRCA1/2 mutation in HER2– MBC is ongoing (ClinicalTrials.gov Identifier NCT01251874). A phase III clinical trial of carboplatin and paclitaxel in combination with veliparib (ABT-888) or placebo in patients with BRCA-associated HER2– MBC is ongoing (ClinicalTrials.gov Identifier NCT02163694). The study aims to enroll 270 patients with an estimated primary completion date of January 2017.

Preclinical studies of talazoparib have demonstrated that this PARP inhibitor has much higher potency than other class members.⁶¹³ The phase II ABRAZO clinical trial evaluates talazoparib in patients with BRCA1/2 mutations and MBC who have either progressed more than 8 weeks after their last platinum agent dose or who have received more than two regimens in the metastatic setting, but no platinum agents (ClinicalTrials.gov identifier NCT020234916). The international, multicenter, phase III EMBRACA clinical trial evaluates single-agent talazoparib in patients with germline BRCA mutations and locally advanced or MBC.⁶¹⁷ A planned 429 patients with no more than two prior chemotherapy regimens in the metastatic setting will be randomized 2 : 1 to talazoparib 1.0 mg daily in 21-day cycles or physician's choice treatment (capecitabine, eribulin, gemcitabine, or vinorelbine) with a primary end point of PFS. Talazoparib Beyond BRCA (TBB) is a single-arm phase II clinical trial evaluating talazoparib in patients with metastatic TNBC who are BRCA1/2 wild-type, but with a HRD as determined by the HRD assay developed by Myriad® (ClinicalTrials.gov identifier NCT02401347).

Recent clinical trials in metastatic TNBC

Approximately 10–32% of TNBC express the AR, and agents that block AR signaling are under active investigation in the setting of MBC.³¹⁴ Monotherapy with the nonsteroidal antiandrogen bicalutamide was evaluated in a phase II clinical trial of patients with AR positive (AR+)/HR– MBC.⁶¹⁸ Out of 424 patients with HR– MBC screened, 12% were deemed to have AR+ tumors with >10% AR+ by IHC. The 6-month CBR was 19% (95% CI, 7–39) and median PFS was 12 weeks (95% CI, 11–22), clearly demonstrating proof of principle. Traina et al. reported the results of an open-label phase II clinical trial evaluating single-agent enzalutamide, a potent AR inhibitor, in patients with AR+ metastatic TNBC at ASCO 2015.⁶¹⁹ Out of 404 patients screened for AR positivity by IHC, 79% had AR > 0% and 55% had AR ≥ 10% by IHC. A total of 118 patients were treated with enzalutamide 160 mg daily. Gene profiling was used to develop an androgen-related gene signature, and patients with the signature had a superior median PFS (32 weeks) to those without the signature (9 weeks). An ongoing phase Ib/II clinical trial is evaluating the effect of the PI3K inhibitor taselisib (GDC-0032) in combination with enzalutamide in patients with metastatic AR+ TNBC (ClinicalTrials.gov identifier NCT02457910). These and other investigational agents are listed in [Table 14](#).

The reversal of immune tolerance in MBC through immunotherapy has attracted research attention recently. Immune tolerance to tumor cells can occur through engagement of tumor surface ligands, such as programmed cell death ligand 1 (PD-L1), with inhibitory receptors of anti-tumor T-cells, such as programmed cell death protein 1 (PD-1) and B7.^{620, 621} PD-L1 is expressed in approximately 20% of TNBC, significantly higher than in other types of breast cancer.⁶²² Preclinical studies of monoclonal antibodies against PD-L1 and PD-1 have demonstrated restoration of tumor-specific T-cell immunity, particularly in the metastatic TNBC setting. Initial results of two phase 1b expansion studies of anti-PD-1 and anti-PD-L1 antibodies were reported at SABCS 2014. Single-agent treatment with the highly selective anti-PD-1 antibody pembrolizumab (MK-3475) was evaluated in 32 heavily pretreated women with TN MBC, 58% of whom expressed PD-L1.⁶²³ Disease stabilization was appreciated in 25.9% of

patients, and disease response in 18.5%. The anti-PD-L1 antibody atezolizumab (MPDL3280A) was evaluated in 21 patients with heavily pretreated, PD-L1-positive metastatic TNBC, of whom 19% had an ORR, including two complete responses and two partial responses. The 24-week PFS was 27% (95% CI, 7–47).⁶²⁴

Many novel agents are under investigation in the setting of metastatic TNBC, including macrophage inhibitors, biologics, and FGFR inhibitors ([Table 14](#)). PLX3397 is a novel oral tyrosine kinase inhibitor that potently inhibits CSF-1 receptor kinase, which plays a key role in the regulation of tumor-associated macrophages. A phase Ib/II clinical trial of PLX3397 in combination with eribulin in patients with metastatic TNBC is ongoing (ClinicalTrials.gov Identifier NCT01596751). CDX-011 (glembatumumab vedotin) is an antibody–drug conjugate that binds to glycoprotein (gp) NMB. The phase II METRIC clinical trial aims to randomize 300 patients with gpNMB overexpressing TNBC to CDX-011 or capecitabine to assess the safety and efficacy of CDX-011 (ClinicalTrials.gov Identifier NCT01997333). Approximately 25% of breast cancers have aberrant FGF signaling.⁶²⁵ Lucitanib is a novel oral inhibitor of fibroblast FGF receptors 1 and 2 and VEGFR1-3 with activity against breast cancer cells in preclinical studies. Lucitanib monotherapy in patients with FGF-aberrant MBC was associated with an ORR of 50% in a phase I clinical trial. A dose-finding phase II clinical trial with a similar design is currently underway in patients with FGF-aberrant MBC, including those with TNBC.⁶²⁶

Management of CNS metastasis in MBC

Overall, CNS metastases occur in a small percentage of patients with MBC, but in metastatic TNBC and HER2+ MBC, the incidence is significant at 30–45%.^{627–630} The management of parenchymal brain metastases often involves a coordinated effort between neurosurgeons, radiation oncologists, and medical oncologists. Patients with a single or limited number of potentially resectable brain metastases should be treated with surgery or radiosurgery. Leptomeningeal carcinomatosis is a overwhelming complication of MBC and often heralds the final stages of a patient's cancer. Treatment for leptomeningeal carcinomatosis may include intrathecal chemotherapy, radiation, and supportive care. As stated earlier, the incidence of brain metastases in patients with HER2+ BC treated with trastuzumab has increased over the last two decades. This trend is most likely due to an overall improvement in OS in patients treated with trastuzumab, and the failure of trastuzumab to penetrate the CNS.⁶⁵¹ As stated earlier, lapatinib showed a statistically insignificant trend toward decreased development of CNS metastases as the first site of progression.⁴⁰² Lapatinib, neratinib, and other therapies targeted toward CNS metastases are under evaluation.

Liver-targeted therapy in MBC

No prospective randomized clinical trial data, including PFS and OS, exist for the focal management of liver lesions. However, many locoregional techniques exist. Local therapy of liver metastases should only be attempted in highly selected patients after a thorough discussion with a multidisciplinary tumor board.⁴⁵⁸

Bone-targeted therapies in MBC

Bone is the most common site of metastasis with up to 80% of patients with MBC developing osseous metastases during their clinical course. Osseous metastases are the most frequent source of morbidity and disability related to breast cancer with complications of pain, fracture, spinal cord compression, and hypercalcemia. Bone-targeted agents are an important aspect of systemic management alongside

antineoplastic therapy, whereas localized treatment with radiation or surgery can be used for more acute management of impending or active fractures. Orthopedic assessment of metastatic lesions in major weight-bearing sites (e.g., hips, femora, humera, and shoulders) is recommended to prevent pathological fractures that would lead to disability or death. Radiotherapy to painful sites of bone metastasis or impending fracture sites in weight-bearing bones is commonly used in association with systemic treatments.

Bone-modifying therapy should start at the first evidence of osteolytic bone metastases. Bisphosphonates are effective inhibitors of osteoclast activation. In several phase III clinical trials, the bisphosphonate zoledronic acid was found to reduce the risk of a skeletal-related event (SRE), mean time to SRE, and annual skeletal morbidity in comparison to pamidronate as well as placebo.^{631, 632} In a large phase III trial, denosumab significantly delayed time to first and subsequent SRE compared with zoledronic acid; there were no differences in OS, DFS, and serious AEs.⁶³³ Denosumab causes more hypocalcemia and is more costly but is associated with a quicker administration time, fewer acute-phase reactions, and fewer renal side effects. The two classes of agents appear to have similar rates of osteonecrosis of the jaw.

Special topics

Contralateral prophylactic mastectomy

Patients with unilateral breast cancer treated with mastectomy often consider undergoing contralateral prophylactic mastectomy to decrease the risk of contralateral breast cancer. Several large institutional and geographic studies of patients with unilateral breast cancer treated with mastectomy in the United States have demonstrated an increase in contralateral prophylactic mastectomy over the past two decades.^{374, 634–636} This has not been associated with a decrease in breast cancer mortality. However, in patients who have a high risk of developing contralateral breast cancer, such as those with BRCA1/2 mutations, contralateral prophylactic mastectomy has improved long-term survival and is cost-effective.^{637–639} Younger age and family history have been associated with higher risks of contralateral breast cancer, and there are emerging data that this may be due to polygenic causes.⁶⁴⁰

Factors that have been associated with the pursuit of contralateral prophylactic mastectomy include patient age <50 years, Caucasian race, a family history of breast cancer, BRCA mutation testing, invasive lobular histology, preoperative MRI, breast reconstruction, and treatment at an NCI-designated cancer center.^{634, 641–643} Together with the increase in contralateral prophylactic mastectomy over the past 15 years, mastectomy techniques that spare the nipple–areola complex (NAC) skin, such as nipple-sparing mastectomy (NSM) and TSSM that require immediate breast reconstruction, have been increasingly used^{229, 644–648}

Many studies have demonstrated an increased risk of contralateral breast cancer in patients with BRCA1/2 mutations, and contralateral prophylactic mastectomy improves long-term survival in these patients.^{637, 638, 642, 649, 650} In a study comparing BRCA1/2-negative families and BRCA1/2-positive families, the 25-year risk of contralateral breast cancer was 44.1% for BRCA1 mutations, 33.5% for BRCA2 mutations, and 17.2% for no mutations identified.⁶⁵¹

A recent study evaluating the pursuit of contralateral prophylactic mastectomy in patients with access to TSSM and immediate breast reconstruction showed an increasing percentage of patients who underwent contralateral prophylactic mastectomy between 2006 and 2013, which is consistent with prior reports.^{374, 634, 635, 642} In this study, 50% of patients underwent contralateral prophylactic mastectomy: 45% of patients without known deleterious mutations and 100% with deleterious mutations. These proportions

are significantly higher than that previously reported.^{374, 635, 642} This is likely due to the inherent selection biases of having patients who were mostly Caucasian, relatively young, and treated at an NCI-designated cancer center with access to surgeons who performed TSSM with immediate breast reconstruction.^{642, 643}

The range of patients who test negative for genetic mutations but still undergo contralateral prophylactic mastectomy (in women who elect mastectomy) is 27–58%.^{642, 652, 653} Within this group, there is an increasing trend of contralateral prophylactic mastectomy related to younger patient age, younger age of relatives diagnosed with breast or ovarian cancer, and increasing number of family members with breast or ovarian cancer. Previous studies have reported that increasing number of relatives with breast cancer is correlated with an increasing risk of contralateral prophylactic mastectomy in BRCA1/2-positive families.⁶⁵⁴ In patients from BRCA1/2-negative families, the 25-year risk of contralateral breast cancer was 28.4% for those who were younger than 40 years at their first breast cancer diagnosis, which approaches 33.5% observed in patients with BRCA2 mutations.⁶⁴⁹ These findings suggest that patients diagnosed at younger ages or with strong family histories may perceive an increased risk of contralateral breast cancer that could not be measured. There is evidence that a polygenic risk score may assess inherited risk of contralateral breast cancer and identify patients who have risks of contralateral breast cancer equivalent to BRCA carriers.⁶⁴⁰ The choice of contralateral prophylactic mastectomy is made more frequently in patients with risk factors for contralateral breast cancer and in those with tumors of lower pathologic stages⁶⁵¹ suggests that women with tumors of higher pathologic stage may be concerned about the higher risk of ipsilateral recurrence compared with the development of contralateral breast cancer. Examination of the pathology of prophylactic mastectomy specimens shows that only 2.2–4.7% of them exhibited pathologic abnormalities, including DCIS, LCIS, and mucinous carcinoma.^{651, 655, 656}

However, women should know that additional contralateral prophylactic mastectomy procedures may lead to a small but increased risk of postoperative complications in patients. Contralateral prophylactic mastectomy was associated with double the risk of superficial nipple necrosis and implant exposure. It was also associated with increased risks of wound breakdown and infections requiring oral antibiotics, but these RR estimates were <2. Contralateral prophylactic mastectomy was not associated with an increased risk of implant loss in patients who had implant-based reconstruction. These results are consistent with other studies which have found that contralateral prophylactic mastectomy increases complications by 1.5–2.1 times compared with unilateral mastectomy.^{657–660}

Several studies have demonstrated that patients who feel the benefits of reducing the risk of contralateral breast cancer, decreased screening, and better aesthetic results after reconstruction may outweigh the increased risk of postoperative complications with contralateral prophylactic mastectomy, even in the absence of any data that it will reduce mortality. Those who chose contralateral prophylactic mastectomy have expressed a subjective fear of developing cancer, have a family history of breast cancer, and/or wish to maintain or improve breast cosmesis.^{661–665} Their subjective sense of vulnerability may be much higher than their actual risk of contralateral breast cancer.⁶⁶⁶ Some European authors have suggested that an increased fear of cancer and the acceptability of plastic surgery have contributed to the rising use of contralateral prophylactic mastectomy in the United States.⁶⁶⁷ A patient-reported outcome study showed that those who underwent contralateral prophylactic mastectomy had higher satisfaction with their breasts and overall reconstructive outcomes than those who did not have contralateral prophylactic mastectomy.⁶⁶⁸

Management of isolated locoregional recurrence

If an isolated chest wall or regional lymph node recurrence is detected, biopsy confirmation and surgical

resection are recommended. If not irradiated earlier, radiotherapy to the chest wall and involved regional lymph node-bearing area is indicated, and hormone therapy should be used for HR+ disease. An open-label trial (the CALOR trial) randomized patients with surgically resected locoregional recurrence with or without chemotherapy.⁴⁵⁵ Patients with HR+ disease received adjuvant endocrine therapy, and radiation was required for microscopically involved surgical margins. The trial included only 162 patients, but at a median follow-up of 4.9 years, DFS events were significantly less frequent in those receiving chemotherapy compared with those who did not (28% vs 44%). Chemotherapy was significantly more effective in those with HR– disease, but the numbers are too small to draw a definitive conclusion.

On the basis of these data, patients with locoregional recurrence should receive available treatments based on disease subtype and prior therapy, including radiation therapy, hormone therapy, and chemotherapy.

Breast cancer in pregnancy

Approximately 1–2% of women with breast cancer are pregnant at the time of diagnosis, at an average age of 35 years. Nonpregnant breast cancer patients with an equivalent stage of disease as a pregnant patient have similar prognoses. Unfortunately, diagnosis is often delayed in pregnant patients because of physical examination changes associated with pregnancy, and their prognosis is often worse due to a higher stage at diagnosis.⁶⁶⁹

In general, radiographic assessments should be performed only when results would modify disease management.⁶⁷⁰ Ultrasound is often the initial imaging study performed in a pregnant woman.⁶⁷¹ Mammography is not contraindicated and radiation exposure to the fetus is minimal, but abdominal shielding is recommended. Sensitivity of a mammogram in a pregnant or lactating patient is reduced, however, because of increased breast density in pregnancy. MRI with contrast is contraindicated as no data exist with regard to the effect of gadolinium on the fetus.⁶⁷²

Treatment recommendations for the management of breast cancer in pregnancy must be based on detailed discussions between the patient's surgeon, medical oncologist, and obstetrician. Furthermore, a patient's belief and value system must be considered. Treatment options for women who develop breast cancer during their pregnancy are similar to those options available to nonpregnant patients. However, the timing and sequence of treatment depends on the trimester of pregnancy at diagnosis as well as whether the disease is locally advanced or not.⁶⁷⁰ Although rarely warranted, pregnancy termination should be considered, particularly when diagnosed in the first trimester. If diagnosis of a low-risk breast cancer occurs late in pregnancy, it is generally appropriate to delay treatment until after delivery. Mastectomy is appropriate at any point during pregnancy with minimal risk to the fetus, whereas radiation therapy is clearly contraindicated and delayed until after delivery.^{673–675}

Chemotherapy can cause teratogenesis and must be avoided in the first trimester. A single prospective and several retrospective clinical trials have evaluated the use of chemotherapy in pregnancy, and a consensus is that doxorubicin-based therapy is appropriate in the second and third trimesters with minimal maternal, fetal, or neonatal toxicity.^{676–679} A retrospective study in 2012 demonstrated no significant differences in birth weight, gestational anomalies, or neutropenia in patients receiving every 3-week doxorubicin and cyclophosphamide (AC) or dose-dense AC with pegfilgrastim,⁶⁸⁰ and other studies have demonstrated similar findings. Insufficient data exist to support the use of other chemotherapies or biologics, whereas tamoxifen is clearly associated with miscarriage and congenital malformations.

Male breast cancer

The most common presenting symptoms of male breast cancer include breast mass, bloody nipple discharge, nipple retraction, axillary mass, and local or distant pain. Male patients often present with more advanced disease because of the lack of awareness of the diagnosis. Evaluation and diagnosis are similar to that performed in women. Most men with early-stage disease are treated with simple mastectomy and SLND, and those with locally advanced disease should first be offered neoadjuvant therapy. Adjuvant radiation follows the same practice patterns as those for women.

Because of the rarity of breast cancer in men, no randomized clinical trial of systemic therapy specific to men with breast cancer has been performed. Adjuvant therapy options for male breast cancer are similar to those for women. A retrospective study by Giordano et al. in 2005 reported the outcomes of 156 men with breast cancer treated at a single institution.⁶⁸¹ A total of 135 men had ESBC and 85% of the study population had HR+ disease. OS was significantly higher in those who received hormone-based therapy (HR 0.45, 0.01). Tamoxifen is preferred over AI. A retrospective analysis of hormonal therapy in 257 men with ESBC demonstrated a higher risk of death with AI over tamoxifen (HR 1.55, 95% CI 1.13–2.13, $p = 0.007$). Poor adherence to tamoxifen is common in men and clearly associated with worse 10-year rates of DFS (42% vs 80%, $p = 0.007$) and OS (50% vs 80%, $p = 0.008$) in comparison to high adherence.⁶⁸²

Retrospective studies have demonstrated a response rate of up to 80% in male patients with HR+ breast cancer. Experience with other hormone-based therapies as well as newer targeted therapies is quite limited. In general, chemotherapy has similar efficacy in men as women with MBC.

Inflammatory breast cancer

IBC is an aggressive, locally advanced form of breast cancer that constitutes up to 2% of newly diagnosed breast cancers in the United States. The prognosis of patients with IBC is poor and before the advent of systemic chemotherapy, the 5-year survival rate after optimal locoregional therapy was <5%.⁶⁸³ Although multidisciplinary approaches have improved outcomes, a population-based study using SEER data from 2004 to 2007 demonstrated that patients with IBC have a 43% increased risk of death from breast cancer than locally advanced non-IBC (HR 1.43; 95% CI 1.10–1.86, $p = 0.008$).⁶⁸⁴

IBC is a clinical diagnosis characterized by a physical examination notable for erythema and edema (peau d'orange) involving at least one-third of the skin of the breast and present for no longer than 6 months.⁶⁸⁵ Dermal lymphatic involvement is not necessary to support the diagnosis, and a core biopsy of the breast generally provided a definitive diagnosis. A palpable underlying mass is frequently absent, and IBC is often mistaken as mastitis and treated with antibiotics.

The standard approach to IBC is neoadjuvant chemotherapy, and the use of regimens containing both anthracyclines and taxanes is recommended.^{409, 683} Patients with HER2+ IBC should be administered neoadjuvant regimens identical to their HER2+ non-IBC counterparts. Most cases of IBC respond dramatically to chemotherapy, and >90% of patients are generally rendered free of locoregional disease. Locoregional treatment after neoadjuvant chemotherapy should include both mastectomy and radiation therapy. Some centers have used breast-conserving surgery after a complete response to neoadjuvant chemotherapy, but this practice pattern is not recommended by international consensus committees. Furthermore, SSM is contraindicated in IBC.⁶⁸³

Treatment of the elderly

The fastest growing segment of the US population is that aged ≥ 65 years. At present, this group represents 12% of the population, but 50% of breast cancers occur in this group. As life expectancy of US women is 80 years, and as our elders are healthier even today, the life expectancy of most breast cancer patients exceeds 10 years. Few studies have been carried out to clearly define the management of elderly women with breast cancer.^{686, 687} The definition of “elderly” may be based on chronologic age, physiologic age, or life expectancy. Increasingly, therapeutic decisions in this group are made based on comorbid conditions that usually limit life expectancy to a much greater extent than breast cancer. Treatment methods should not vary between different age-group patients. The presence of important comorbid conditions changes life expectancy and hence the expected benefits from all our interventions for breast cancer. The standard treatment for elderly patients with ESBC should be lumpectomy, SLNB, and radiotherapy, with adjuvant systemic treatment defined based on prognostic factors, ER, PR, and HER2. Increasingly, molecular profiles that predict tumor behavior will aid us in tailoring treatment. Results of a recent study on the impact of MP on women >60 years of age at intermediate risk by Adjuvant!Online provided additional information not predicted by clinical data only.⁶⁸⁸ In the future, we will describe the use of molecular tests to define a population of patients where we can test the impact of less intervention.

At present, the use of AIs or tamoxifen has become standard therapy for the management of women with HR+ tumors, regardless of age. Endocrine therapy is not indicated for patients with HR– tumors. It should be noted that in CALGB 9343, women over 70 years of age with ER-positive tumors treated with tamoxifen or tamoxifen plus radiation were much more likely to die of other disease. At 8 years, death from breast cancer was 3% and death from other causes was 21%.

When the risk of breast cancer is sufficiently high to provide chemotherapy and the benefits of this treatment exceed risks, full-dose chemotherapy should be given to elderly patients.⁶⁸⁹ The use of less than full-dose chemotherapy will usually be ineffective, at the cost of unnecessary toxicity. In a CALGB study, however, women who received doxorubicin in a CAF regimen at a dose of 30 mg/m^2 four times every 4 week did as well as those who received 60 mg/m^2 four times or 40 mg/m^2 six times if their HER2/neu assay was negative. Prospective validation of these results is needed. Recently, there has been interest in devising protocols to evaluate new drugs that may be less toxic in such patients. A phase III clinical trial compared single-agent oral capecitabine with classical CMF or AC in the adjuvant treatment of patients >65 years of age. Capecitabine was clearly inferior to the standard regimens in DFS, and standard chemotherapy was well tolerated.⁶⁹⁰

Symptom management and survivorship

The ACS estimated that there were more than 3 million breast cancer survivors as of 2014.¹ Approximately 72% of breast cancer survivors (>2 million women) are aged ≥ 60 years; fewer than 10% are <50 . Understanding the issues facing both young and old survivors is critical to supporting QOL and appropriate risk reduction and monitoring.

Standard posttreatment follow-up care for survivors of ESBC should include surveillance for cancer recurrence or new primary breast cancers and prevention of secondary cancers. Patients should be assessed for late psychosocial and physical affects and provided with interventions for the consequences of treatment, such as new medical problems, symptoms, and psychological distress. Finally, both primary care providers and cancer specialists should jointly manage the coordination of survivorship care.

During the first 3 years after completion of combined modality therapy for primary breast cancer, patients should be visited every 3–6 months with a careful history and complete physical examination at each

visit.⁴⁰⁹ For the subsequent 2 years, patients should be visited every 6–12 months and annually thereafter. Patients who have undergone breast-conserving surgery should undergo a mammogram 6 months after completion of radiation therapy, 1 year after the initial mammogram, and annually thereafter. Imaging studies should be performed only if warranted by symptoms or physical findings. Complete blood counts, comprehensive metabolic panels, tumor markers, and imaging are not recommended outside of symptoms or physical findings, as early detection of MBC provides no advantage to OS. Active areas of research include monitoring of circulating cell-free DNA as an early marker of disease recurrence.

The transition from provider-intense cancer treatment to a posttreatment program with less-frequent visits can be difficult for many patients, particularly in resource-poor, low- and middle-income settings. Patients should be educated with regard to recognizing signs and symptoms of disease recurrence, management of short- and long-term physical and psychosocial symptoms, and the importance of healthy lifestyle modifications to maintain a healthy weight through physical activity.^{692, 693} At this time, the general recommendation is that cancer survivors achieve 150 min of moderate-intensity activity a week. Additional survivorship concerns include fertility, fatigue and depression, cognitive dysfunction, pain, lymphedema, sexual dysfunction, sleep disorders, bone health, cardiac toxicity, and healthy lifestyle choices. Some of these issues are reviewed in detail in the NCCN Guidelines for Survivorship Version 1.2016.⁶⁹¹

Obesity and diabetes in breast cancer

Patterson et al.⁶⁹² evaluated the effect of comorbid medical conditions on breast cancer outcomes for 2542 women with ESBC followed for a median of 7.3 years. Most notably, patients with diabetes had over twice the ROR (HR 2.1, 95% CI 1.3–3.4) and mortality (HR 2.5, 95% CI 1.4–4.4). A meta-analysis by Sparano et al. in 2012 demonstrated that obesity was associated with inferior DFS (HR 1.24, 95% CI 1.06–1.46, $p = 0.0008$) and OS (HR 1.37; 95% CI 1.13–1.67; $p = 0.002$) in patients with HR+ breast cancer, but not other subtypes.⁶⁹⁴

Several clinical trials have evaluated various interventions for weight loss and nutrition in an effort to improve outcome. The WINS study was a phase III clinical trial initiated in 1994 that randomized 2437 women with ESBC in a 60 : 40 ratio to receive a low-fat eating plan guided by registered dietitians versus observation. Long-term analysis was presented at SABCS 2014.⁴² At a median follow-up of 5 years, patients in the intervention arm achieved reductions of 9.2% in fat calories and 6 pounds in weight. Recurrence was 24% lower in the intervention arm over a mean of 60 months of follow-up. The maximum benefit from the intervention was observed in women with HR– ESBC who achieved a 54% decrease in mortality, whereas no benefit was appreciated in women with HR+ ESBC. However, the Women's Healthy Eating and Living (WHEL) randomized clinical trial, which compared a low-fat diet high in vegetables and fruits with observation in 3088 women, showed no effect on breast cancer events or mortality at 7.3 years of follow-up.⁶⁹⁵

Fertility management

Women of reproductive age constitute 15% of invasive breast cancer worldwide.⁴⁵⁹ These women often experience premature ovarian failure or infertility after receiving chemotherapy, which can damage ovarian reserve.⁶⁹⁶ The ASCO Clinical Practice Guidelines for fertility preservation for patients with cancer recommend that fertility preservation be discussed with all patients of reproductive age before initiation of therapy, if infertility is a potential risk.⁶⁹⁷ Patients who are ambivalent or desire fertility preservation should be referred to reproductive specialists. Embryo and oocyte cryopreservation are the

only established methods of fertility preservation. Emerging data suggest that the risk of ovarian failure might be reduced with the use of goserelin during adjuvant chemotherapy in patients with HR– ESBC.⁶⁹⁸

The Prevention of Early Menopause Study (POEMS)/S0230 clinical trial was a phase III clinical trial that assessed the development of ovarian failure in premenopausal women with HR– ESBC who were treated with chemotherapy plus goserelin.⁶⁹⁸ Unfortunately, the study failed to reach its target enrollment of 416 patients because of early closure for loss of funding. A total of 257 women were randomized to standard cyclophosphamide-containing chemotherapy with or without goserelin. Results of the study were available for only 218 women at a median follow-up of 4.1 years. Ovarian failure occurred in 8% of the patients in the goserelin arm, in comparison to 22% in the control arm (odds ratio, 0.30; 95% CI, 0.9–0.97; two-sided $p = 0.04$). The rate of pregnancy was higher in women in the goserelin arm than the control arm (21% vs 11%, $p = 0.03$). The authors concluded that although data were missing, goserelin, when administered in combination with chemotherapy in women with HR– ESBC, appeared to reduce the risk of early menopause as well as improve maintenance of fertility.

As premenopausal patients with HR+ ESBC undergo adjuvant endocrine therapies for several years, they have delayed childbirth. Such patients often consider oocyte or embryo cryopreservation before the initiation of therapy but are theoretically at increased risk of accelerated tumor growth because of ovarian stimulation and increasing estrogen levels. Oktay et al.⁶⁹⁶ have recently described an ovarian stimulation protocol for patients with HR+ ESBC that uses letrozole in combination with follicle-stimulating hormone to limit the increase of estrogen levels. In the study, 131 women with ESBC underwent ovarian stimulation with concurrent letrozole 5 mg/day before chemotherapy and cryopreservation. The live birth per embryo transfer rate in the study population was 51.5%, similar to the US national mean for women without cancer.

Alopecia

Hair loss due to chemotherapy is emotionally traumatic for many women with breast cancer and is often ranked as the most feared side effect of treatment. Devices to facilitate scalp cooling and prevent chemotherapy-induced alopecia have been studied and widely used throughout Europe and Canada for decades, with recent studies in the United States demonstrating efficacy with common chemotherapy regimens for ESBC. The Dutch Scalp Cooling Registry of almost 1500 women who underwent scalp cooling during chemotherapy reported efficacy in 50% of patients and no cases of scalp metastasis at 5 years of follow-up.⁶⁹⁹ Several small clinical trials over the last few years using newer systems such as the Penguin cold cap, the DigniCap, and PAXMAN Orbis scalp cooler have reported higher degrees of efficacy with reports of $\leq 25\%$ hair loss in 65–75% of users. Ongoing clinical trials in the United States have continued to evaluate the safety and efficacy of these systems (NCT01831024, NCT01986140).

Lymphedema

Lymphedema of the arm is characterized by regional swelling because of accumulation of protein-rich fluid within body tissues, leading to disfigurement and decreased mobility and function.⁷⁰⁰ It affects approximately 21% of breast cancer survivors with variable incidence depending on the type of surgery. In addition to decreased functionality, patients experience paresthesias, pain, and psychologic distress, resulting in a reduced QOL. Early physiotherapy, including manual lymph drainage, massage of scar tissue, and shoulder exercises, starting within days of surgery results in a lower incidence of lymphedema. Treatment options for lymphedema include physical therapy to optimize range of motion, progressive resistance training with compression garments, weight loss, and properly fitted compression

garments.⁶⁹¹ Patients should be referred to a lymphedema specialist when available. Operative therapies are considered a last option and remain under investigation.

Hot flashes

A proportion of 65–80% of ESBC survivors develop hot flashes that may occur with chemotherapy-induced ovarian suppression or antiestrogen therapies. Several randomized controlled trials have demonstrated that pharmacologic intervention with either venlafaxine, gabapentin, or clonidine (SSRI) reduced the frequency of hot flashes more effectively than placebo.⁷⁰¹ The effectiveness of nonpharmacologic interventions including acupuncture and cognitive behavioral therapy is less clear, in part due to methodologic issues regarding sham interventions.

Bone health

Estrogen deprivation results in bone resorption with rapid bone loss. Women treated with AIs are therefore at increased risk of bone density loss and subsequent adverse skeletal events. Patients on AIs should undergo a fracture risk assessment with a dual-energy X-ray absorptiometry (DEXA) scan as well as review of clinical factors such as age, prior fracture history, low body mass index, and tobacco and alcohol use. Bone density should be repeated every 1–2 years. In addition, patients should be encouraged to take calcium and vitamin D. Patients who develop osteopenia or osteoporosis while on AI therapy should be considered for either a bisphosphonate or denosumab.

Adjuvant bisphosphonate therapy to reduce the risk of distant recurrence in women with ESBC has been evaluated for several decades with variable results. A meta-analysis of individual patient data from randomized studies of adjuvant bisphosphonate therapy has been recently published by the EBCTCG.⁷⁰² A total of 18,766 women were enrolled in trials of bisphosphonate therapy for 2–5 years. The reduction in bone recurrence was significant (HR 0.83, 95% CI 0.87–1.01; $2p = 0.004$). A clear reduction in recurrence, distant recurrence, bone recurrence, and breast cancer mortality was observed in postmenopausal patients.

Chapter 109

Malignant melanoma

Justin M. Ko, MD, MBA, FAAD ■ Susan M. Swetter, MD ■ Jonathan S. Zager, MD ■ Vernon K. Sondak, MD ■ Scott E. Woodman, MD, PhD ■ Kim A. Margolin, MD

Overview

Melanoma comprises a wide variety of malignant cell types arising from the skin, the mucous membranes, and the pigmented cells of the eye. While these tumors are all classified as melanoma and share a common molecular biology of pigmentation and biological resemblance to cells of neural crest origin, important distinctions in other molecular characteristics and patterns of exposure to ultraviolet light as a carcinogen determine their clinical natural history, including the response to therapeutic interventions. While the majority of melanomas are diagnosed at an early stage and curable with minimal surgery, melanoma has the potential for early and widespread dissemination via lymphatic and hematogenous routes. Surgery remains the mainstay of therapy for primary, regional, and many cases of single- or oligo-metastatic disease, but systemic therapies have dramatically improved the prognosis for metastatic melanoma, particularly immunotherapies that enhance existing cellular immunity. The rapid discovery of new molecular targets, immunotherapy combinations (including the use of radiotherapy), and understanding of the mechanisms of therapeutic resistance are likely to lead to even greater improvements in the prognosis for patients with melanoma in the near future.

Dermatologic principles in melanoma

Epidemiology and etiology

Melanoma incidence and mortality rates continue to rise worldwide, driven by increased ultraviolet (UV) light exposure (both natural and artificial sources) and differences in prognosis according to age and sex. In the United States, 76,380 new cases of invasive cutaneous melanoma will be diagnosed and approximately 10,130 deaths will occur in 2016.¹ Incidence has been increasing steadily for the past 30 years, and since 2004, Caucasians have experienced an increase in incidence by 3% each year, faster than that of nearly all cancers.² Western states with increased ultraviolet radiation (UVR) have a greater incidence.³ Incidence rates are rising more than twofold among young women (ages 15–39) and increasing even more sharply among middle-aged and older men.^{3, 4}

The increase in melanoma incidence has been attributed to factors including increased intermittent UVR exposure in fair-skinned populations, higher rates of skin biopsies and screening resulting in the detection of thinner, more favorable lesions, and potential changes in the histologic interpretation of early evolving lesions from atypical melanocytic hyperplasia or severely dysplasia to melanoma *in situ*.^{5, 6} However, continued increases in the incidence rates of thicker tumors, including steep rises among individuals of lower socioeconomic status, points to a true increase in potentially fatal cases and lack of screening as a critical factor accounting for recent melanoma incidence trends.⁷

Risk factors

Environmental factors

The risk of developing melanoma is related to acute, intense, and intermittent exposure to UV light, but the relationship between UV exposure and melanomagenesis is not straightforward. Melanomas frequently occur in locations often covered by clothing, and indoor workers have been shown to have a higher incidence of melanoma on sun-exposed sites, observations that provide support for the notion that melanomas arise through different molecular pathways.^{8,9} Melanoma incidence rates on sun-exposed and less exposed body areas also have different age peaks,¹⁰ around 55 years for melanomas on intermittently exposed sites such as the trunk and proximal extremities, which probably reflects a period of vulnerability to UV radiation early in life and a latency to full melanomagenesis followed by a decline in the incidence of melanomas attributable to those mechanisms.¹¹ Conversely, melanomas on chronically exposed sites such as the face and distal extremities continue to rise with age. Signature DNA mutations induced by UV are found commonly in driver mutations identified in melanoma¹² but not as often as in nonmelanoma skin cancers that are more directly related to chronic sun exposure, so alternate sources of mutagenesis are likely. Nevertheless, a randomized study in Australia showed that consistent daily application of both UVA- and UVB-filtering broad-spectrum sunscreen (compared with discretionary or nonuse) resulted in a decreased incidence of melanoma.¹³ Indoor tanning is now proven to be a major contributor to the increasing incidence of cutaneous melanoma among young women, with greater melanoma risk proportional to measures of tanning practices, including increasing years, hours, and sessions of indoor tanning.^{14,15} Alarming, 76% of melanomas in fair-skinned participants were attributed to tanning bed use at young ages. A strong association of tanning bed use with recreational drugs,¹⁶ suggesting a common genetically mediated addiction, is consistent with animal studies showing sunlight-seeking behaviors mediated by opioid-related substances through endorphin receptors.¹⁷

Host factors

Although the process by which normal melanocytes transform into melanoma cells is not entirely understood, it is believed to involve progressive genetic mutations that alter cell proliferation, differentiation, and death and impact cellular susceptibility to the carcinogenic effects of UVR.

Melanoma is largely a disease of individuals of fair complexion, including those with red or blond hair and fair skin, who burn easily or have a history of severe sunburn, or who are unable to tan.¹⁸ Caucasians with an increased number of nevi or a tendency to freckle are also at increased risk for developing melanoma.¹⁹ The risk of cutaneous melanoma in the presence of increased numbers of common/typical nevi, large nevi, and/or clinically atypical nevi (CAN) on the body was confirmed in a pooled analysis of melanocytic nevus phenotype, even at different latitudes.²⁰ Both prior personal history and family history are important risk factors for the development of melanoma.²¹ Solid-organ transplant populations are at far greater risk of squamous cell carcinomas and also develop more melanomas compared to the general population.²²

Genetic predisposition and familial melanoma

The majority of melanomas appear to be sporadic, with only 5–10% of cases attributable to an identified familial predisposition.²³ Familial melanoma is characterized by an increased risk of developing melanoma, a higher incidence of multiple primary melanomas, and typically an earlier age at onset.²⁴ Specific genetic alterations have been implicated in the pathogenesis of familial melanoma. Mutations at

the CDKN2A locus on chromosome 9p21, which codes for the tumor suppressor p16 and p14/ARF, account for about one-third of familial cases. Additional melanoma risk occurs in CDKN2A mutation carriers who express variants of the melanocortin receptor gene MCR1, which is associated with red hair, fair skin, and freckling. As mutations of either of these genes are present in only a subset of familial melanoma kindreds, other melanoma susceptibility genes likely exist. Formal recommendations for p16 mutation testing have been proposed in patients with a personal or family history of 3 or more invasive melanomas or cancer “events,” defined as 2 invasive melanomas and 1 pancreatic cancer in the patient or family members, or vice versa, which conveys a >20% risk of carriage.²⁵ However, owing to the low frequency of mutations even among high-risk individuals and the lack of implications for dermatologic surveillance, genetic testing other than for research purposes is generally not recommended.

Atypical mole syndrome/phenotype

The presence of numerous CAN, also termed “dysplastic nevi,” is the most important clinical risk factor for melanoma. Compared with the general population, patients with CAN have a 2- to 15-fold elevated risk of developing melanoma, and risk increases with the number of CAN and/or personal or family history of melanoma.²⁶ An atypical mole phenotype is characterized by numerous (>50–100) common nevi along with multiple (generally >5), large (>6–8 mm) nevi with color variegation, border irregularity, and asymmetric shape. Melanomas seldom arise in association with pre-existing atypical nevi, and over 70% of melanomas in patients with any type of melanocytic nevus (common, atypical, or congenital) are believed to develop de novo, although CAN with severe histologic dysplasia may more often be true melanoma precursors.²⁷ Melanomas associated with atypical/dysplastic nevi are generally thin superficial spreading type, possibly due to increased skin surveillance in affected individuals.

Congenital melanocytic nevi (CMN)

Congenital melanocytic nevi (CMN) are evident in 1–6% of neonates and uncommonly transform into melanoma.²⁸ Patients with “large or giant” congenital nevi (lesions >20 cm in diameter in an adult, >6 cm on the body of an infant, or >9 cm on the head of an infant) have a less than 5% lifetime risk of developing a melanoma^{29–32} with about half arising during the first few years of life.³³ The risk of melanoma arising within small-sized (<1.5 cm) and medium-sized CMN is low and virtually nonexistent before puberty.³⁴ Management of CMN hinges on many variables including ease of monitoring and potential psychosocial benefits and harms of surgical procedures.

Melanoma risk assessment

Several risk assessment tools have been used to target individuals at high risk for melanoma, in particular Caucasian men over 65 and individuals of lower socioeconomic status—two groups with the highest melanoma mortality.

Current risk assessment tools are derived from a large case–control study of 718 non-Hispanic white patients and 945 controls that involved inspection of the back for suspicious moles and asked two questions about complexion and history of sun exposure.³⁵ Mild freckling and light complexion were demonstrated as risk factors for both men and women. In addition, >17 small moles and ≥2 large moles in men or ≥12 small moles on the backs of women were also significant risk factors. These data led to the Melanoma Risk Assessment Tool, which is available from the National Cancer Institute (<http://www.cancer.gov/melanomarisktool/>). The tool calculates absolute risk of melanoma over the next 5 years up to age 70.

Prognostic factors

A number of clinical factors affect patient prognosis including age, gender, and anatomic location of the primary tumor. In general, men, older age individuals, and those with melanoma on the head and neck tend to fare worse. A population-based study in France during 2004–2008 showed that male patients had thicker and more frequently ulcerated tumors. Older patients had thicker and more advanced melanomas, with more frequent head and neck location.³⁶

While newer concepts in the taxonomy of melanoma suggest distinct molecular, genetic, anatomic, and UV-exposure-linked characteristics, growth kinetics of certain histological subtypes also appear to play a role in prognosis. The rapidly growing nodular subtype of melanoma tends to elude early detection based on clinical characteristics alone. Nodular melanoma (NM) comprises <15% of subtyped melanoma cases in the United States and Australia, but accounts for a disproportionate number of thicker tumors (>2 mm) and melanoma deaths compared with other histologic subtypes.

Newer molecular techniques such as gene expression profiling may soon assist in identifying thin melanomas with more aggressive behavior.³⁷

Clinical presentation

Cutaneous melanoma can occur anywhere but is most common on the lower extremities and back in women and on the trunk in men. From a clinical standpoint, a new or changing “mole” or skin lesion is the most-common warning sign for melanoma. The so-called “ABCDEs” of early diagnosis pioneered by Rigel et al.³⁸ are an easy mnemonic to improve recognition of the classic early signs of melanoma ([Table 1](#)). To simplify further, Weinstock³⁹ succinctly focused the message by emphasizing that the most important warning sign is a new or changing skin lesion. The "ugly duckling" warning sign refers to a pigmented or clinically amelanotic lesion that looks different from the rest, which may be of value to identify melanomas that lack the classic ABCD criteria (e.g., nodular, amelanotic, or desmoplastic subtypes).^{40, 41}

Table 1 ABCDEs: clinical features of melanoma

A	Asymmetry—the two halves of the lesion do not match each other
B	Border irregularity—may appear ragged, notched or scalloped
C	Color variation—color is not uniform or lesion may be many colors displaying shades of tan, brown, or black. White, reddish, or blue-gray discoloration is of particular concern
D	Diameter—usually >6 mm (roughly the diameter of a pencil eraser) although melanomas may be smaller in size; any growth in a nevus warrants an evaluation
E	Evolving lesion—changes in size or color; critical for nodular or amelanotic melanoma, which may not exhibit the ABCD criteria above

As histologic features of a primary melanoma are critical for melanoma staging and prognostication, proper initial biopsy of a suspicious lesion is paramount. An excisional biopsy with narrow clinical margins (1–3 mm) of normal-appearing skin around the pigmented lesion is preferred when possible to provide accurate diagnosis and histologic microstaging. An important exception to this rule is the lentigo maligna (LM) subtype of melanoma *in situ*, in which the risk of misdiagnosis is high if small or partial biopsy specimens are taken. The best diagnostic biopsy technique in this case is often a broad shave biopsy that extends into at least the papillary dermis, provides the opportunity to exclude microinvasive

melanoma, and allows for optimal histopathologic interpretation of the tumor.

Pathologic features

With the exception of NM, the growth patterns of the other clinicopathologic subtypes are characterized by a preceding *in situ* (radial growth) phase that lacks the biologic potential to metastasize and may last from months to years before dermal invasion (vertical growth) occurs.

Dermal invasion confers metastatic potential, although the greatest risk occurs in the setting of a vertical growth (tumorigenic) phase.⁴² Immunohistochemical staining for lineage [S-100, human melanoma black 45 (HMB-45), melan-A/Mart-1] or proliferation markers (Ki67) may be helpful in some cases for histologic differentiation from melanoma simulators such as melanocytic nevi, Spitz nevi, cellular blue nevus, clear cell sarcoma, or malignant peripheral nerve sheath tumor.⁴³ A study of melanoma biomarker expression in melanocytic tumor progression examined differential expression of melanoma biomarkers between nevi, primary melanoma, and metastases.⁴⁴ Approaches combining Ki67/Anti-MART-1 (Melan-A) and HMB-45/MITF immunostains have also been shown to hold promise in the diagnosis of melanoma.⁴⁵

A pathology report for melanoma should include cytomorphology and architecture, along with tumor thickness (Breslow depth), presence of ulceration, dermal mitotic rate (measured as number per mm²), and microsatellites and lymphovascular invasion, if present. Anatomic level of invasion (Clark's level) has less prognostic significance and is now considered optional in pathology reporting.

Atypical melanocytic lesions in children and adolescents in particular may be difficult to distinguish from true melanoma, including atypical Spitz tumors and Spitz or melanocytic tumors of uncertain malignant potential (STUMPs or MelTUMPs, respectively). As such, molecular techniques such as comparative genomic hybridization (GGH) and fluorescence *in situ* hybridization (FISH) have been utilized to assist in the determination of malignant versus benign behavior.^{46–49} Newer gene expression profiling techniques may be of further value of molecular testing for challenging atypical melanocytic neoplasms and to aid in prognosis and risk stratification,^{50–53} and some of these findings may yield prognostic data sufficiently robust to support their inclusion in future melanoma staging systems.

Clinicopathologic subtypes

The four major classical “histogenetic” subtypes of primary cutaneous melanoma are based on histopathologic findings, anatomic site, and degree of sun damage. These include superficial spreading melanoma, NM, lentigo maligna melanoma (LMM), and acral lentiginous melanoma. In addition, there are other rarer variants (<5% of melanomas), which include (1) desmoplastic/neurotropic melanoma, (2) mucosal (lentiginous) melanoma,⁵³ (3) blue nevus-like melanoma, (4) melanoma arising in a giant/large congenital nevus, and (5) melanoma of soft parts (clear cell sarcoma).

Superficial spreading melanoma

Superficial spreading melanoma accounts for nearly 70% of cutaneous melanoma, commonly displays the ABCDE signs, and is the most-common subtype in individuals aged 30–50 years, as well as those with atypical/dysplastic nevi. It is most common on the trunk in men and women and on the legs in women.

Nodular melanoma

NM is the next most-common melanoma subtype, and occurs in 15–30% of patients, most commonly on the legs and trunk in men and women. It typically presents as a dark brown-to-black papule or dome-shaped nodule with rapid growth over weeks to month, which may ulcerate and bleed with minor trauma. This subtype is responsible for most thick melanomas at diagnosis.^{54, 55}

Lentigo maligna melanoma

LMM incidence is rising in the United States.⁵⁶ It is typically located on chronically sun-damaged skin (head, neck, and arms) of fair-skinned older individuals (average age 65 years), slowly growing over years to decades. The *in situ* precursor lesion termed LM is typically a longstanding large >1–3 cm flat (macular) lesion, demonstrating pigmentation ranging from dark brown to black, although white or hypopigmented areas are common within LM. Dermal invasion denoting progression to LMM is characterized by the development of raised brown-black nodules within the *in situ* lesion.

Acral melanoma

Acral melanoma is the least-common subtype of melanoma in white persons (2–8% of melanoma cases), although the most-common subtype of melanoma in darker-complexioned individuals (i.e., African American, Asian, and Hispanic persons), representing 29–72% of melanoma cases in these populations. Because of delays in diagnosis, it may be associated with a worse prognosis.^{57, 58} Acral lentiginous melanoma occurs on the palms, soles, or beneath the nail plate (subungual melanoma), which may manifest as diffuse nail discoloration or a longitudinal pigmented band (melanonychia striata) within the finger or toenail. Pigment spread to the proximal or lateral nail folds is termed the Hutchinson sign, which is a hallmark for subungual melanoma.

Less-common subtypes

Desmoplastic melanoma is a less common but important melanoma subtype, given its predilection for older age individuals, clinical features similar to nonmelanoma (keratinocytic) skin cancer, and potential indication for adjuvant radiation therapy following wide excision (depending on tumor thickness, perineural invasion, and margin status). Amelanotic melanoma (<5% of melanomas) can occur with any subtype and often mimics basal cell or squamous cell carcinoma, dermatofibroma, or a ruptured hair follicle. It occurs most commonly in the setting of the nodular or desmoplastic subtype or melanoma metastasis to the skin, presumably because of the inability of these poorly differentiated cancer cells to synthesize melanin pigment.

Genetics and molecular pathology

Significant complexity exists in the clinical and histopathological presentation, cells of origin (epithelium associated versus nonepithelium associated), causative relationship to UV radiation, age of onset, somatic mutations, and germline genetic predisposition. Melanoma is not a homogeneous disease but instead is composed of biologically distinct subtypes, the phenotype of which is driven by underlying genetic alterations.⁵⁹

One growth factor pathway that has garnered considerable attention as related to melanoma is the RAS–RAF–MAPK–ERK (mitogen-associated protein kinase, MAPK) signaling cascade. A unique mutation at position 1799 of the gene for the serine–threonine kinase BRAF in the MAPK pathway—occurring in about half of cutaneous melanomas—results in a substitution of glutamine (about 75–80% of cases) or

lysine for valine (most of the remaining cases) at position 600 which confers constitutive activity, resulting in hyperproliferation and resistance to apoptosis among cells driven by this oncogenic mutation.⁶⁰ The biology of melanoma in cells dependent on a BRAF mutation is also impacted by coexisting mutations or other alterations of gene expression in linked pathways, particularly the PTEN/AKT/PI3K/mTOR pathway that is critical in the control of metabolic sensors and the cancer/microenvironment nutrient balance. Activating mutations of NRAS, as well as less-common oncogenes such as c-kit (covered in greater detail below), result in downstream activation of both of these pathways.

Most BRAF-mutated melanomas arise in intermittently sun-exposed skin, while melanomas from chronically sun-exposed areas have a lower incidence of BRAF mutations and occasionally carry a mutation or amplification of c-KIT, a receptor tyrosine kinase that^{61, 62} may be altered in about 15–20% of acral and mucosal melanomas.^{61–63} Activation of c-kit results in the stimulation of both the MAPK and PI3K–AKT pathways, producing both proliferative and survival advantages.⁶⁴

The observation that *BRAF* mutations noted in benign melanocytic nevi⁶⁵ typically arising by early adolescence occurred with the same frequency as in non-CSD melanoma led Bastian and colleagues to propose that patients with acquired nevi and non-CSD melanomas may have a particular susceptibility for developing *BRAF*-mutated melanocytic neoplasms at relatively low doses of UV radiation. This concept was supported in subsequent studies that demonstrated a germline variation in the melanocortin receptor 1 (MC1R) to significantly contribute to this susceptibility.^{66, 67} More specifically, variants of MC1R were shown to strongly increase the risk for non-CSD melanomas with *BRAF* mutation.

None of the oncogenes or tumor suppressor genes identified in melanoma are thought to be solely responsible for melanoma pathogenesis, and some appear to be mutually exclusive due to overlapping downstream functions. For instance, NRAS, as mentioned above, activates Raf kinases in response to growth factor receptor activation and harbors activating mutations in 15–20% of melanomas, but almost never occurs with a BRAF mutation.⁶⁷ The loss of the p16 tumor suppressor is a relatively frequent event in melanoma, and there is significant overlap with BRAF mutation.⁶⁸ PTEN mutations and deletion have been described in a minority of melanomas and appear to coincide with BRAF mutation ([Figure 1](#)).⁶⁹

Surgical management of melanoma

Management of primary cutaneous melanoma

Surgery remains the mainstay of treatment for primary cutaneous melanoma, and the specific recommendations have not changed significantly over the last decade. Primary melanoma is treated by wide excision with a defined margin of adjacent normal-appearing skin. The margin of resection is dependent on the Breslow depth of the tumor and the site of the primary. Margin widths are measured

from the biopsy scar or residual pigment at the time of surgery; it is not expected to equate to a histopathologic measurement on the resection specimen. A histologically negative margin, however, is always the goal in excising the primary tumor. Current recommendations for width of the excision in invasive melanoma ([Table 2](#)) are supported by randomized trials, summarized in [Table 3](#).^{71–74} For melanoma *in situ*, the recommended margin is 0.5–1 cm.⁷⁵ For invasive melanomas ≤1 mm in depth, 1 cm margins are recommended and are associated with low rates of local recurrence. For melanomas between 1 and 2 mm, 1–2 cm margins are recommended, taking into consideration cosmetic or functional outcome. For melanomas >2 mm, 2 cm margins are recommended, whenever feasible.⁷⁵ A meta-analysis found that margins >2 cm are unnecessary even for thick primaries, and margins should not be <1 cm for any invasive melanoma.⁷⁶

Table 2 Recommended margins of wide excision for cutaneous melanoma based on primary tumor thickness and location

Breslow thickness	Primary site	Recommended excision margin (cm)
Melanoma <i>in situ</i>	Anywhere on the skin	0.5–1
0.01–1.00 mm	Anywhere on the skin	1
1.01–2.00 mm	Head/neck, distal extremity ^a	1
	Trunk or proximal extremity ^b	2
>2.00 mm	Head/neck, distal extremity ^a	1
	Trunk or proximal extremity	2

^a Subungual primary tumors may require distal digital amputation.

^b If a skin graft would be required to reconstruct the excision defect, it is acceptable to take a 1 cm excision margin.

Note: Local anatomic constraints and specific patient factors may justify minor deviations from the standard margin recommendations.

Table 3 Summary of ASCO-SSO recommendations for sentinel lymph node biopsy in melanoma

- SLNB is recommended for patients with cutaneous melanomas with Breslow thickness of 1 to 4 mm at any anatomic site;
- SLNB may be recommended for staging purposes and to facilitate regional disease control for patients with melanomas that are >4 mm in Breslow thickness;
- There is insufficient evidence to support routine SLNB for patients with melanomas that are <1 mm in Breslow thickness, although it may be considered in selected high-risk patients;
- Completion lymph node dissection is recommended for all patients with a positive SLNB.

SLNB, sentinel lymph node biopsy. Adapted from Wong et al, 2012.⁸⁵

Management of the regional lymph nodes

The role of sentinel lymph node biopsy

The presence of occult tumor deposits within clinically negative lymph nodes (defined by the AJCC

staging system as “microscopic” disease) is a key predictor of outcome in clinical stage I and II melanoma,⁷⁷ and evidence suggests even tiny nodal micrometastases have clinical relevance.^{78, 79} Melanoma micrometastases in the regional lymph nodes cannot reliably be detected by any imaging modality including PET–CT^{80, 81} or ultrasonography.^{82, 83} Sentinel lymph node biopsy (SLNB) can identify micrometastases with low morbidity.⁸⁴ In 2012, an evidence-based assessment of the indications for SLNB in melanoma was issued jointly by ASCO and the Society of Surgical Oncology (SSO) ([Table 4](#)).⁸⁵

Table 4 Summary of selected final results of the Multicenter Selective Lymphadenectomy Trial 1 (MSLT-1)

	Result	Comment
Feasibility	At least one sentinel node was identified in 99.5% of patients undergoing SLNB	SLNB highly feasible in a worldwide experience
Yield and false-negative rate	The sentinel node was positive in 19% of patients with melanomas ≥ 1.2 mm: 16% for melanomas 1.2–3.5 mm and 33% for melanomas >3.5 mm Nodal recurrence occurred in 5.9% of patients with a negative sentinel node: 4.8% for melanomas 1.2–3.5 mm and 10.3% for melanomas >3.5 mm	SLNB is an effective staging procedure with an acceptable false-negative rate
Prognostic significance	A positive sentinel node was associated with ~ 2.5 -fold increases in disease recurrence and death from melanoma for melanomas 1.2–3.5 mm; 10-year melanoma-specific survival was 85% for patients with a negative sentinel node versus 62% for patients with a positive sentinel node	Sentinel node status is the strongest known prognostic indicator in clinically node-negative intermediate-thickness melanoma
Survival impact of SLNB	There was a nonsignificant 3% increase in 10-year melanoma-specific survival for intermediate-thickness melanoma patients randomized to SLNB versus observation	SLNB does not significantly affect survival for all patients subjected to the procedure
Relapse-free survival impact	Patients randomized to SLNB had a statistically significant improvement in relapse-free survival compared to observation	SLNB significantly reduces melanoma recurrence for intermediate and thick melanomas, mostly by decreasing subsequent nodal relapse
Impact on node-positive patients	Patients with intermediate-thickness melanoma and positive nodes who were randomized to SLNB (with completion lymphadenectomy) had statistically significantly improved distant metastasis-free survival and melanoma-specific survival compared to observation arm patients who failed clinically in the regional nodal basin; there were no significant differences for patients with thick melanomas and positive nodes between the SLNB and observation arms	Early treatment of intermediate-thickness node-positive melanoma by radical lymphadenectomy improves outcomes significantly; patients with thick node-positive melanomas may be at such high risk of distant disease that timing of lymphadenectomy loses importance

SLNB, sentinel lymph node biopsy.

Adapted from Sondak and Gibney 2014.⁷⁰ Original data from Morton.

The panel found that the strongest evidence supported SLNB for patients with intermediate-thickness melanomas, based on interim results from the prospective randomized Multicenter Selective Lymphadenectomy Trial I (MSLT-1).⁷⁷ Key ASCO–SSO SLNB recommendations are summarized in [Table 3](#). The mature results of MSLT-1 ([Table 5](#))⁸⁶ and retrospective institutional series^{89–92} also support

SLNB for patients with clinically node-negative thick melanomas (>4 mm). Controversy remains regarding the use of sentinel node biopsy in patients with thin melanomas (<1 mm), which were not adequately assessed in the MSLT-1 study nor included in the prospective but nonrandomized Sunbelt Melanoma Trial.^{93–95}

Table 5 High-risk features for selecting T1 melanomas for sentinel lymph node biopsy

High-risk criterion	Impact on likelihood of finding a positive node	Comment
Thickness 0.76–0.99 mm	In a registry series of 1250 patients with melanomas ≤ 1 mm selected by a wide variety of criteria to undergo SLNB, metastases were detected in 6.3% of 891 melanomas ≥ 0.76 mm but in only 2.5% of 359 melanomas ≤ 0.75 mm. No metastases were detected in sentinel nodes from patients with melanomas < 0.5 mm. ⁸⁷ In a large contemporary single-institution experience from a center where SLNB was routinely offered to patients with melanoma ≥ 0.76 mm without requiring any other high-risk feature to be present, 8.4% of patients had a positive sentinel node ⁸⁶	Most patients with thin melanomas and a positive sentinel node are found in this upper end of the T1 thickness spectrum; very few unselected patients with melanomas < 0.76 mm are at sufficient risk of nodal metastasis to justify SLNB
Ulceration	18.3% of patients in a registry series ⁸⁷ and 23.5% of patients in a single-institution series ⁸⁸ who had ulcerated T1 melanomas had a positive sentinel node	Relatively rare finding in T1 melanomas (present in $< 10\%$ of cases) but perhaps the highest risk factor for sentinel node positivity in thin melanoma
Mitotic count	Mitotic count $\geq 1/\text{mm}^2$ was not predictive of nodal metastases in a registry series ⁸⁷ but was predictive in a single-institution series ⁸⁸	Presence of even one dermal mitosis in a T1 melanoma upstages the tumor from T1a to T1b in the current AJCC staging system. It remains unclear whether the presence of dermal mitoses is sufficient to justify SLNB, especially in melanomas < 0.76 mm
Patient age	—	Younger patients have a higher risk of positive sentinel nodes across all tumor thickness categories as well as more years at risk for nodal recurrence
Clark level	Clark level was a significant predictor of sentinel node status in a registry series ⁸⁷ but not in a single-institution series ⁸⁸	Clark level IV melanomas are more likely to be at the thicker end (≥ 0.76 – 1.00 mm) of T1 where most nodal metastases are encountered. The value of SLNB for Clark IV melanomas < 0.76 mm has not been demonstrated

Today, the majority of newly diagnosed cutaneous melanomas are T1 lesions (≤ 1 mm in thickness), with a low overall risk of nodal metastasis or death from melanoma.⁹⁶ Recommending sentinel node biopsy for all patients with T1 melanomas is not cost-effective.⁹⁵ ASCO–SSO recommends that SLNB for thin melanoma be considered in selected cases with “high-risk” features ([Table 6](#)).⁸⁵

Table 6 Summary of follow-up guidelines for patients with completely resected melanoma from various national and international organizations. These guidelines have not been prospectively validated and hence should only be considered as recommendations

Stage	Physical examination	Imaging
Stage I	Every 3–12 months \times 5 years with annual follow-up beyond 5 years as clinically indicated	No imaging needed unless clinically indicated
Stage II	Every 3–6 months \times 2 years, then every 3–12 months for an additional 3 years with annual follow-up beyond 5 years as clinically indicated ^a	Cross-sectional body imaging considered for higher risk patients: CT and/or PET/CT, to screen for recurrent disease. Consider brain MRI annually ^b
Stage III–IV	Every 3–6 months \times 2 years, then every 3–12 months for an additional 3 years with annual follow-up beyond 5 years as clinically indicated ^c	Cross-sectional body imaging should be considered for higher risk patients: CT and/or PET/CT, to screen for recurrent disease. Consider brain MRI annually ^b

^a Consider more frequent and longer follow-up in high-risk stage II patients with thick and/or ulcerated primary tumors.

^b Ultrasonography can be considered to evaluate regional nodal basins.

^c Consider more frequent and longer follow-up in high-risk stage IIIb/c patients.

Abbreviations: CT, computed tomography; CXR, chest X-ray; PET/CT; positron emission tomography/computed tomography.

Adapted from Fields and Coit 2011.¹⁴⁵

On the basis of the large retrospectively collected registry data, SLNB seems well justified for many patients with melanomas 0.76–1.00 mm, but not for the majority of patients with melanomas <0.76 mm in thickness.⁹⁶ In addition, patient age, preference, and comorbidities need to be considered in the decision regarding SNLB.

A few other clinical situations pertaining to the use of SLNB deserve mention. Desmoplastic melanomas in general appear to have a lower risk of nodal metastases,^{97, 98} and some authors advocate abandoning SLNB in this histologic type.⁹⁹ In recent series, the risk of nodal metastases has been shown to be high enough to justify routine consideration of SLNB in all patients with desmoplastic melanomas ≥ 1 mm in thickness.⁹⁹ Pediatric melanoma patients have a higher incidence of nodal metastases, yet an apparent better overall prognosis compared to adults, and the role of SLNB in these patients remains controversial, especially for the so-called atypical melanocytic proliferations of childhood.^{100–103}

Completion lymphadenectomy for sentinel node-positive disease

NCCN guidelines,⁷⁵ strongly supported by decades of clinical experience, call for routine performance of a therapeutic lymphadenectomy in all melanoma patients with clinically positive nodes and no

radiographic evidence of distant metastases. The routine use of completion lymphadenectomy after a positive SLNB is more controversial,¹⁰⁴ although it is recommended by the ASCO/SSO guidelines as standard of care in the absence of clinical trial participation.⁸⁵ The MSLT-1 trial showed that outcomes for patients with intermediate-thickness melanoma undergoing completion lymphadenectomy were superior to those for patients who recurred in the nodal basin,⁸⁶ but by the nature of the trial, the contribution of the completion lymphadenectomy over and above removal of the sentinel node could not be assessed. Nonsentinel nodes are only found to have tumor involvement in a minority of cases,¹⁰⁷ and at least some sentinel node-positive patients do well for an extended period of time even without undergoing completion lymphadenectomy.⁸⁶ The morbidity of lymphadenectomy, especially severe lymphedema, has been shown to be less for completion lymphadenectomy after a positive SLNB than for therapeutic lymphadenectomy after nodal recurrence.¹⁰⁹ A prospective randomized trial comparing ultrasound surveillance of the lymph node basin to immediate completion lymphadenectomy for sentinel node-positive patients, MSLT-2, recently completed accrual with results pending (clinicaltrials.gov NCT00297895).

Radical lymphadenectomy for macroscopic nodal disease

In contrast to the situation for SLNB identified microscopic disease, a therapeutic radical lymph node dissection is virtually always indicated for clinically evident, resectable nodal metastasis; systemic therapy and/or radiation is not an adequate substitute for surgical treatment of the clinically positive nodal basin.⁷⁵

Management of in-transit and locoregional recurrent melanoma

Wide excision is indicated for biopsy-proven local, satellite, or in-transit recurrence in the absence of distant disease. Full radiographic staging (with PET/CT or CT and brain MRI or CT) should be performed before curative-intent excision of the recurrent tumor.

Intra-arterial regional perfusion therapies

Hyperthermic isolated limb perfusion (HILP) and isolated limb infusion (ILI) are methods by which an extremity with unresectable locally recurrent or in-transit metastatic melanoma is isolated from systemic circulation and high-dose chemotherapy administered intra-arterially with limited systemic exposure. HILP is performed by directly dissecting and cannulating the major vessels of the extremity and circulating chemotherapy via a cardiopulmonary bypass machine, which allows increased temperature and an oxygenated perfusate. HILP can achieve concentrations within the limb 15–25 times higher than would be tolerated systemically, with limb temperatures reaching 39–41°C. By virtue of the increased concentration and the potential synergistic effects of hyperthermia, drugs such as melphalan, with little or no activity if administered systemically, become highly effective regional agents.^{110, 111} Response rates in the range of 80–90% with complete response (CR) rates as high as 60–70% have been reported.^{111–114} Melphalan is the most-common agent used in the United States, while melphalan plus tumor necrosis factor alpha (TNF- α) is often used in Europe.¹¹⁵ The value of TNF- α has not been clearly demonstrated, as a large multicenter randomized trial found no statistically significant differences in either overall or CR rates or survival and the addition of TNF- α was associated with significantly higher regional toxicity.¹¹⁴

Isolation of the limb during HILP substantially minimizes the risk of systemic toxicity from the high-dose chemotherapy; however, significant morbidity may still occur. The most-common morbidity is

lymphedema and has been reported to occur in 12–36% of patients. Severe regional toxicities including compartment syndrome in up to 5% of cases as well as limb loss in up to 3.3% of cases have been described.^{115, 116}

ILI is the less-invasive counterpart to HILP and is a low-flow infusion conducted in a mildly hyperthermic, acidotic, and hypoxic environment. Catheters are percutaneously placed into the artery and vein of the uninvolved limb and advanced into the vessels of the involved limb proximal to the extent of disease, avoiding the need for open surgical cannulation with its attendant morbidity. The chemotherapy is manually circulated for 30 min.¹¹⁷ Regional CR rates after ILI are in the range of 23–44% with partial response (PR) rates in the range of 27–56%.^{117, 118} Although these results are lower than reported after HILP, the two techniques have not been prospectively compared in a head-to-head manner in a clinical trial setting. In a recent retrospective comparison of HILP and ILI (ILI = 94, ILP = 109), the overall response rate was 53% for ILI versus 80% for ILP ($p > 0.001$). Median overall survival (OS) was 46 months for ILI versus 40 months for ILP ($p = 0.31$). There were no differences in age, sex, or N stage between groups; however, BOD was higher for the ILI group (high BOD 58 vs. 44%, $p = 0.04$).¹¹⁹ Importantly, ILI can be readily repeated if necessary and appears to have less regional toxicities than HILP (erythema and edema of the skin are among the most-common side effects with tissue loss seen <1% of the time) and virtually no systemic toxicities.^{116–119}

There is some debate regarding whether ILI or HILP should be employed first in the treatment of in-transit melanoma, and this decision is based in part on the presence of nodes requiring node dissection or a high burden of disease in the limb, both of which might be better addressed with HILP, although the data are lacking to support this theory. In view of the relative morbidities and effectiveness, HILP is usually reserved as a salvage procedure for patients who progress rapidly after ILI without any evidence of distant metastasis. Repeat ILI can be attempted in patients who had a good initial response to ILI but eventually progressed.

Intralesional and topical therapies

Intralesional therapy in melanoma has several advantages over regional or systemic therapy. Local drug administration allows for delivery of an increased concentration of the agent and reduced regional and systemic exposure, potentially increasing efficacy and lowering toxicity. Moreover, alterations in the tumor microenvironment can be immunogenic and induce local immune responses that result in the “bystander effect,” where uninjected distant lesions exhibit a response, as has been reported with multiple different types of intralesional therapies.

Bacille Calmette-Guérin (BCG) was one of the first intralesional therapies used for in-transit metastases. In that initial landmark series, 90% of injected cutaneous lesions regressed and 17% of patients also had regression of uninjected lesions. Some patients remained disease free for years after completion of the BCG injections.¹²⁰ Interleukin-2 (IL-2) has also been used for intralesional injection in melanoma; the toxicity profile of IL-2 appears to be better than that of BCG. There is a risk of local reactions, and flu-like symptoms following injections are very common (85%).¹²¹ Intralesional treatment with IL-2 is relatively expensive. PV-10 is a 10% solution of rose bengal, a water-soluble xanthine dye used for decades as an intravenous diagnostic agent for assessing hepatic function and topically by ophthalmologists, making it a potentially low-cost treatment that has shown efficacy when “repurposed” for intralesional administration.¹²² Responses have been reported in patients refractory to previous systemic ipilimumab, anti-PD1 and vemurafenib, with evidence of bystander effects in uninjected lesions.¹²³

Talimogene laherparepvec (TVEC, previously known as OncoVEX), is a genetically modified oncolytic herpes virus incorporating the coding sequence for human granulocyte-macrophage colony-stimulating factor (GM-CSF). Oncolytic viruses are designed to selectively replicate in tumors, thereby infecting and destroying cancer cells and inducing immune responses that target the cancer cell. Expression of the GM-CSF gene (GM-CSF) in tumor cells is expected to recruit and activate antigen-presenting cells and immune effectors that mediate potent antitumor T cell cytotoxicity. Tumor destruction in this fashion may also induce T cells capable of circulating and exerting antitumor effects in nearby and distant uninjected metastases. The phase III OPTiM study included 436 patients randomized in a 2 : 1 manner to intralesional TVEC or subcutaneous GM-CSF alone, respectively. There was a 26.4% objective response rate for TVEC compared to a 5.7% for GM-CSF ($p < 0.001$). There was a statistically significant increase in the primary endpoint of durable response rate (DRR), defined as a partial or CR lasting for 6 months or more. DRR was 16.3% for TVEC and 2.1% for GM-CSF ($p < 0.001$). Overall survival results also favored TVEC, although without statistical significance.¹²⁶ This promising form of viral-mediated immune gene therapy is now being tested in combination with immune checkpoint blockers and other immunomodulatory interventions, and other oncolytic viruses with or without transgenes are also under investigation for melanoma and other malignancies.¹²⁴

Imiquimod and diphencyprone (DPCP) are topically applied, rather than injected intralesionally. This approach is particularly appealing for patients with multiple small cutaneous nodules. Topical application of imiquimod, with or without additional agents such as topical 5-fluorouracil, resulted in regression of up to 90% of treated superficial lesions.^{125, 126} DPCP is a contact sensitizer that induces contact hypersensitivity; in a cohort of 50 patients treated with DPCP, 23 patients (46%) achieved a CR and an additional 19 patients (38%) showed a PR. The side effect profile of DPCP is tolerable, with skin reactions such as blistering and irritation being the most-common side effects.¹²⁷

Radiation therapy

In patients with in-transit or regional recurrence, radiation may offer a benefit. Treatment protocols are not well defined but the potential for symptom control makes radiation an option for selected patients with unresectable locoregional melanoma¹²⁸ and is now under active investigation as an immunomodulator, detailed later in this chapter.

Surgical metastasectomy for stage IV melanoma

Patients with isolated, resectable distant metastatic melanoma are candidates for surgical management aimed at removing all known sites of disease. Identifying which patients will benefit from metastasectomy requires good clinical judgment and a thorough preoperative staging that includes PET–CT of the body and MRI of the brain to rule out occult sites of metastasis.¹²⁹

There has been only one prospective (albeit nonrandomized) trial evaluating surgery for patients with stage IV melanoma, the S9430 trial conducted by the Southwest Oncology Group.¹³⁰ Patients with stage IV melanoma were enrolled as soon as the determination of potential resectability was made, before actually undergoing surgery. This allowed the investigators to estimate resectability rate and define relapse-free and overall survival after complete resection. Among the 77 study patients, 3 patients had no evidence of melanoma in the resected specimen (the suspected metastatic deposit was either a second primary malignancy or a benign finding) and 2 patients had only stage III disease. An additional 8 patients were not able to have all disease resected. Therefore, 64 patients (88.9%) were in fact resected to a disease-free state. After a median follow-up of 5 years, all but 6 (9.4%) had recurred, with a median relapse-free survival (RFS) of approximately 5 months. Median overall survival was 21 months with an

estimated 12-month survival of 75% and survival at 4 years was 31%.¹³⁰ Although small, this prospectively derived and with otherwise unselected patients, the resectability and survival rates reported in S9430 are the most representative data available for comparing surgical and nonsurgical approaches to stage IV melanoma. It is possible that using the more sensitive current imaging methods to find patients with resectable single or oligometastases would lead to more favorable outcomes if the study were done now. However, new systemic therapy approaches to metastatic melanoma are becoming so effective that a reconsideration of the role of surgery in front-line management may be appropriate, and of great importance is the investigation of the potential for neo-adjuvant therapies from among the molecularly targeted agents and the new immunotherapies, particularly PD-1 blocking agents that work relatively quickly and may render a formerly unresectable lesion more amenable to surgery.

The role of adjuvant therapy for stage II and III disease

Immunotherapy

Immunotherapy has been the adjuvant treatment approach evaluated most extensively in melanoma, and the most extensively evaluated adjuvant immunotherapy has been interferon- α (IFN- α), in a variety of doses, schedules, and formulations. High-dose IFN- α is a 1-year adjuvant therapy regimen involving two components: a 1-month “induction” phase administering 20 million units of IFN- α 2b/m² of body surface area intravenously 5 days per week for 4 weeks, followed by an 11-month “maintenance” phase administering 10 million units/m² subcutaneously three times a week. Three randomized trials have demonstrated that high-dose IFN- α is associated with improved RFS, and two trials showed improved OS as well.^{131, 132} In the United States, high-dose IFN- α is approved for use in the adjuvant therapy of thick, node-negative and node-positive melanoma. To date, no studies of high-dose IFN- α have defined subsets of patients that clearly respond better or worse to treatment. The relative importance of the induction and maintenance phases has not been adequately defined, but it does appear that the 4-week induction phase alone is inadequate.¹³³

Adjuvant IFN- α regimens involving lower doses of IFN- α (3–10 million units administered three times a week not adjusted for body surface area and without the initial intravenous component) have also been tested. Low-dose IFN- α is approved for adjuvant use in some European countries and has been advocated for use in intermediate-thickness, node-negative melanoma as well.¹³⁴ In the absence of direct comparisons between high- and low-dose IFN- α regimens, meta-analyses have been performed to assess the overall and comparative efficacy of adjuvant IFN- α therapy. Meta-analysis results clearly support that IFN- α therapy delays recurrence, with an overall RFS improvement of 17% (hazard ratio for recurrence 0.83) in the latest analysis, but do not identify clear differences between high- and low-dose regimens in efficacy. Meta-analysis results also show a statistically significant improvement in OS for adjuvant IFN- α , with a 9% (hazard ratio for survival 0.91) improvement seen.¹³⁵

Pegylated IFN- α was approved in the United States as an alternative adjuvant treatment for stage III melanoma in 2011, based on the results of a single randomized trial.¹³⁶ This trial demonstrated a statistically significant improvement in RFS, in keeping with trials of standard IFN- α , but did not show an OS benefit. An interesting observation was made, however, that the subset of patients with sentinel node-positive melanoma from an ulcerated primary showed a dramatic survival benefit (41% improvement) when treated with pegylated IFN- α . Although some other IFN- α trials have seen a similar benefit in this subset,^{137, 138} this is best considered an unproven but provocative finding pending definitive replication. Pegylated IFN- α has not been directly compared to high-dose IFN- α , but appears to have fewer serious

side effects with pharmacologic properties that might make it a more favorable agent for the maintenance phase. Unlike high-dose IFN- α , pegylated IFN- α is intended to be given subcutaneously for 5 years (3 mcg/kg/week), and the 1-month intravenously administered induction phase is replaced with a 2-month long subcutaneously administered induction phase at a higher dose (6 mcg/kg/week).

Other adjuvant systemic therapies under investigation

The availability of new agents with documented survival benefits in unresectable metastatic melanoma has spurred trials of these agents in the adjuvant setting. It remains to be seen if these agents will be equally or more effective than available IFN- α regimens, and how the toxicities of these new drugs will be tolerated by patients who are disease free and possibly cured at the time of treatment. Nonetheless, it is likely that the advances in understanding melanoma biology and the regulators of the antitumor immune response that have profoundly changed treatment for stage IV melanoma will eventually translate into new, more effective and hopefully less toxic approaches to the prevention of recurrence by adjuvant therapy.

A multiagent biochemotherapy regimen consisting of IFN- α , IL-2, dacarbazine, vinblastine, and cisplatin was compared to high-dose IFN- α in a randomized trial showing a statistically significant RFS advantage but no difference in OS.¹³⁹ Although this is the first randomized trial to ever show a statistically significant advantage over high-dose IFN- α , the toxicity of this regimen limits its use, and the lack of an OS advantage argues against this becoming a new standard for the adjuvant treatment of melanoma.

Ipilimumab has been shown to improve survival in stage IV melanoma (detailed later in this chapter), with less toxicity than is associated with biochemotherapy, making it a logical candidate to evaluate in the adjuvant setting. Preliminary data from a randomized trial comparing ipilimumab at 10 mg/kg (a dose higher than that approved for use in the treatment of unresectable metastatic melanoma) to placebo showed statistically significantly improved RFS relapse for the ipilimumab arm.¹⁴⁰ Unfortunately, the toxicity of the regimen was unexpectedly severe. Data regarding the impact of this adjuvant ipilimumab regimen on OS are pending. Importantly, the relative impact of adjuvant ipilimumab over that provided by IFN- α is currently unknown. Given the toxicity encountered with adjuvant ipilimumab at 10 mg/kg, there is also a need to assess the risk–benefit ratio relative to the standard 3 mg/kg ipilimumab dose. A randomized trial has been conducted to evaluate ipilimumab at 10 and 3 mg/kg compared to high-dose IFN- α (E1609, NCT01274338). This trial has completed accrual and results are eagerly awaited. The safety and tolerability of anti-PD1 antibodies appear to be superior to both IFN- α and ipilimumab, making these antibodies ideal candidates for evaluation as adjuvant therapy. The results of completed but not yet mature randomized trials of ipilimumab versus nivolumab (Checkmate 238, NCT 02833906) and of pembrolizumab versus placebo (EORTC Keynote 054, NCT 02362594) will likely define future adjuvant systemic therapy recommendations.

Additional trials investigating the activity of adjuvant BRAF inhibitors alone or in combination with MEK inhibitors have completed accrual and await outcome data. Legitimate concerns have been raised about the tolerability of these agents in the adjuvant setting, particularly considering the potential for rapid development of resistance and for secondary malignancies to arise in patients taking these agents, and their routine use is not recommended in the adjuvant setting.¹⁴¹

Adjuvant radiation to the resected nodal basin

Criteria for identifying patients at high risk of regional recurrence in the resected nodal basin after radical lymphadenectomy include multiple (≥ 4) or matted tumor-involved lymph nodes, the presence of

extranodal extension of tumor in at least one node, and large size (≥ 3 cm) of any one lymph node. In a prospective trial, 217 eligible patients possessing at least one of these criteria were randomized to observation or postoperative nodal basin irradiation after lymphadenectomy.¹⁰⁸ After a median follow-up of 40 months, nodal basin relapse occurred in 34 of 108 patients (31.5%) in the observation arm, confirming the high risk of regional recurrence in these patients. Nodal basin relapse was significantly reduced in the adjuvant radiotherapy group compared with the observation group, but no differences were noted for RFS when all sites of relapse were included or for OS.¹⁰⁸ This confirmed the ability of postoperative radiation to significantly decrease recurrence within the nodal basin in patients at high risk of such recurrence, and radiation should be considered for selected high-risk cases. It will also be important to study the interaction of adjuvant locoregional radiotherapy with immune checkpoint blockade in the adjuvant therapy of high-risk melanoma.

Surveillance for high-risk melanoma patients

A variety of algorithms have been proposed regarding the frequency and nature of the follow-up evaluation of melanoma patients after surgical treatment.^{142–144} To date, no studies have documented that surveillance of patients after surgical treatment of melanoma with any imaging or laboratory studies (including chest X-rays, PET/CT, or MRI scans) are cost-effective. One study evaluating the results of follow-up after surgery in stage melanoma III patients found that half of all recurrences were detected by patients, and that “neither more intense nor more frequent follow-up is associated with discovery of resectable first relapses.”¹⁴² While most proposed follow-up algorithms involve more frequent follow-up in the initial years after surgery, the conditional probability of recurrence of stage I and II melanoma is actually fairly constant over the first decade after surgery.¹⁴⁴ Education is key and should be focused on both the patient and family as well as the primary care physicians, dermatologists, and surgeons alike, and melanoma centers may want to train and even “certify” providers in their catchment area. Patients should be willing to return to the melanoma center for evaluation of suspected recurrence, because properly diagnosing recurrence (e.g., documenting nodal recurrence by needle aspiration cytology instead of open biopsy) is important to successful treatment. Importantly, we need to individualize the follow-up, identifying which patients are best suited to have the bulk of their surveillance outside the melanoma center and which ones should return more frequently.

[Table 6](#) summarizes the follow-up guideline for patients with completely resected melanoma from various national and international organizations. These guidelines have not been prospectively validated and hence should only be considered as recommendations. (Adapted from Fields and Coit.¹⁴²)

Uveal melanoma and rare melanomas of the eye

Uveal melanoma (UM) is the most-common primary intraocular cancer of the eye in adults and represents 5% of all melanomas. The term “UM” is used for melanomas that arise within the uveal tract (i.e., iris, ciliary body, or choroid), while the broader term “ocular” melanoma includes such sites as conjunctiva and eyelid, which behave like cutaneous melanoma. UMs are further designated as anterior (iris) or posterior (ciliary body and/or choroid) chamber tumors. Anterior chamber UM is rarer (<10% of UMs) and tends not to metastasize, whereas approximately half of patients diagnosed with posterior chamber UM will develop metastases.

Local therapy for UM employs radioactive plaque, proton therapy, or enucleation of the primary UM tumor. In a randomized study comparing ¹²⁵I plaque brachytherapy with enucleation, 85% of patients receiving radiation retained their eye, and 37% had visual acuity over 20/200 in the irradiated eye 5

years after therapy. No survival difference was seen between the radioactive plaque and enucleation groups.¹⁴⁵ Thus, a radiotherapeutic approach has become the strategy of choice for primary UM treatment, with enucleation reserved for the remaining <10% of cases in which radiotherapy is not possible (e.g., bulky disease, technically difficult tumor location, patient preference). Because most patients do not undergo enucleation, fine-needle aspiration techniques are now often used to obtain the pathologic and molecular diagnostic information that is critical to prognosis.

UM metastases are hematogenous, because the uveal tract does not appear to contain clear lymphatic channels with draining lymph nodes. The liver is ultimately involved in 95% of metastatic UM cases and is the sole site of metastatic UM in approximately 50% of patients. The most common other sites of metastatic UM are lung (24%), bone (16%), and skin (11%). Unlike cutaneous melanoma, UM infrequently metastasizes to lymph nodes or brain. The clinical course of patients with UM is highly dependent on disease progression in the liver. The median survival after diagnosis of patients with liver metastases is approximately 4–6 months with a 1-year survival of approximately 10–15%. Patients with metastases limited to extrahepatic sites have a median survival of approximately 19–28 months with a 1-year survival of approximately 76%. Thus, hepatic- versus extrahepatic-only disease may represent distinct biological entities.¹⁴⁶

Approximately 90% of UM harbor activating, mutually exclusive, recurrent mutations in the g-protein alpha q (*GNAQ*) or 11 (*GNAI1*) subunit genes. Nearly all *GNAQ/11* gene mutations localize to a hotspot in exon 5 (Q209), although a small number localize to exon 4 (R183). *GNAQ/11* gene mutations are early tumorigenic events that are insufficient to initiate metastatic disease, but some of the downstream pathways in UM resulting from additional molecular aberrations, such as protein kinase C and others, may be targetable with investigational agents in development.¹⁴⁷ Additional recurrent missense mutations in *SF3B1* (altering the R625 amino acid position in most cases) or *EIF1AX* (exons 1 or 2) genes occur in equal proportion in approximately 40% of UM tumors and are essentially mutually exclusive with each other. Truncating and nontruncating mutations are observed in the nuclear ubiquitin carboxy-terminal hydrolase *BAP1* gene located on chromosome 3p21.1. Genetic aberrations in *BAP1* tend to co-occur with monosomy 3, resulting in the loss of heterozygosity of *BAP1*. Both *BAP1* gene mutations and monosomy 3 tend not to co-occur with *SF3B1* or *EIF1AX* gene mutations, and the former are associated with a high risk of developing metastatic UM.¹⁴⁸ Consistent with *BAP1* mutations leading to loss of tumor suppression, there have been multiple reports of germline *BAP1* mutations within families that result in a high incidence of UM.¹⁴⁹ Another recurrent chromosomal aberration observed in UM is 8q copy number gain (often with 8p loss), which tends to accompany monosomy 3 and is associated with a shorter time to relapse. Conversely, 6p copy number gain (often with 6q loss) is usually present in tumors that lack monosomy 3 or 8q copy number gain and is associated with a low risk of metastasis. Less-frequent chromosomal aberrations, such as 1p and/or 16q loss, have also been described. With the exception of *BAP1*, the identification of specific genes that correlate functionally with these chromosomal aberrations is less clear.¹⁵⁰

Multiple anatomic, histologic, and molecular features within primary tumors are associated with poor prognosis: (1) location in ciliary body (poorer) > choroid iris (rarely metastasize); (2) greater tumor size; (3) extrascleral invasion; (4) epithelioid > spindle cell histology; (5) higher mitotic rate; (6) presence of monosomy 3 ± chr 8q gain; and (7) class 2 class 1b class 1a gene expression profile (a 15-gene expression profile that accurately predicts outcome and does not require chromosomal analysis). However, the strongest risk factors for metastasis are copy number profile (e.g., presence of monosomy 3/chr 8q gain) and/or a class 1b/2 gene expression profile.^{151, 152}

Metastatic UM has proven essentially recalcitrant to traditional chemo- and immunotherapeutic approaches. Given the current inability to therapeutically target the aforementioned molecular aberrations characteristic of UM, there has been a major focus on targeting the “effector” molecules associated with these genetic alterations. The most successful systemic approach to date has been to target the MEK–MAPK pathway that is clearly activated by *GNAQ/11* mutations. A phase II randomized clinical trial showed that treatment of metastatic UM patients with single-agent selumetinib (a small molecule MEK inhibitor) resulted in tumor regression in 50% and RECIST responses in 15% of cases. A significant difference in median progression-free survival following treatment with selumetinib (15.9 weeks) compared to dacarbazine (7 weeks) was shown, although without an improvement in overall survival.¹⁵³ Targetable effectors of mutant *BAP1*/monosomy 3 are still under investigation. Retrospective analyses of metastatic UM patients from multiple centers treated with ipilimumab suggest that long-term tumor response was observed in a subset (~5%), as well as prolonged stable disease (SD) in a slightly larger subset of advanced disease patients.¹⁵⁴ More recently, therapy of metastatic uveal melanoma with antibodies blocking PD-1 or PD-L1 was reported from a multi-institution retrospective series and also showed very low activity,¹⁵⁵ further evidence that the successful therapy of this melanoma variant requires strategies that focus on its unique molecular biology and targets in its immune tumor microenvironment.

For patients with liver-only or -dominant metastatic UM, multiple therapies specifically directed at the liver have been explored: isolated or percutaneous hepatic perfusion of chemotherapy, transarterial chemoembolization (TACE), radioembolization or cryoembolization, or selective internal radiation therapy (SIRT). Liver-directed therapy studies tend to have low patient numbers, but when taken in aggregate, suggest relatively high tumor response, prolonged time-to-progression, and/or survival in the population of patients upon whom they have been employed. Nine studies (totaling 209 patients) using TACE (mostly cisplatin-based) reveal a 2% CR, 24% PR, and 33% SD rate when taken in aggregate. Eight pooled studies (totaling 277 patients) show hepatic intra-arterial chemotherapy (mostly employing either a fotemustine or melphalan-based regimen) to have a 9% CR, 22% PR, and 29% SD rate to this approach. Finally, four studies (totaling 59 patients) treated with hepatic arterial perfusion reveal an 8% CR, 44% PR, and 10% SD rate (reviewed in Ref. 156).

There may be a role for surgical resection of metastatic UM if there is a relatively stable and safely resectable solitary lesion(s). In a study in which 61 patients had surgical resection in addition to chemotherapy, a 22-month median overall survival was observed among patients who could undergo resection with curative intent compared to 10 months among those who could not. Variations in patient referral and selection criteria are important factors in all of these outcomes, which must be validated by performing well-controlled prospective randomized trials.

With one of the most predictive sets of molecular markers of metastatic risk, the relatively recent identification of clear genetic drivers within primary UM tumors, and a wide spectrum of clinically relevant approaches (molecular inhibitors, immunotherapies, radiation and surgery) now available, there is tremendous excitement that truly effective therapies for UM in both the adjuvant and advanced settings are within practical reach.

Melanoma of the conjunctival surface of the eye is rare and may complicate primary acquired melanosis. Recent reports demonstrating the presence of typical activating BRAF mutations in 29% and NRAS mutations in 18% of a cohort of 78 conjunctival melanomas provide further evidence of the close relationship of melanomas in this site to cutaneous melanomas, with case reports of clinical responses to vemurafenib that corroborate the importance of BRAF as an oncogenic driver in conjunctival melanoma.^{157, 158}

Biology and therapy of advanced melanoma

The diagnosis of metastatic melanoma may be triggered by new symptoms or signs in a patient with a history of melanoma (about half of the presentations) or a new but asymptomatic finding on radiographic surveillance scans, based on guidelines and practice that take into account the initial stage, time-dependent risk of relapse, and likelihood that intervention will change the natural history of the disease. Skin and soft tissue are more common sites of initial metastatic disease than visceral sites, and a minority of patients have widespread metastatic disease secondary to hematogenous spread, such as is common with mucosal melanomas.

Uncommonly, advanced melanoma may present as a solitary or multiple metastases—even in the central nervous system—without a known history or evidence of a concurrent new primary melanoma. It has been postulated that immune-mediated control or regression of a missed primary controlled by a local immune response explains this phenomenon, which also has a slightly more favorable prognosis than matched cases with a known primary.¹⁵⁹ Melanoma spreads widely and spares few organs or sites, with a particular affinity for the brain, where it is often the immediate or major contributing cause of death due to bleeding and edema. Other sites of melanoma metastasis that are rare for other cancers include the small and large intestine and even the heart. Characteristics of primary melanoma that pose increased propensity to specific sites of metastasis are under investigation. For example, the CCL25 and CCR9 chemokine: chemokine receptor interaction has been reported in intestinal metastases¹⁶⁰ and increased activity of the phosphatase and tensin homolog (PTEN)-related pathway is associated with a higher rate of eventual metastasis to the brain (reviewed in Ref. 161). Many other molecular alterations, most recently the expression of a variant CD44v6 molecule, a receptor for hyaluronic acid that is highly expressed by brain,¹⁶² have been reported to impact the risk and/or the biological behavior of established brain metastases (reviewed in Ref. 163).

Molecularly targeted therapy for melanoma

Metastatic melanoma is divided into three substages based on modest differences in the survival curves for M1a, limited to skin and soft tissue; M1b, involving lung with/without skin/soft tissue; and M1c, metastatic to any visceral organ and/or with elevation of the serum lactate dehydrogenase (LDH) above the institutional upper limit of normal.⁹⁴ The differences among these subsets are being eclipsed by a rapid growth in understanding of the molecular basis of different melanomas such as detailed by Bastian's group.⁶¹ However, except for notable examples such as the melanomas that carry actionable oncogenic driver mutations (BRAF, c-kit, NRAS) and UM, which is routinely excluded from most clinical trials of immunotherapy, clinical trials for advanced melanoma have included unselected patients, with prestratification in some instances for known prognostic variables such as the LDH and the performance status.

Melanoma, together with lung cancer, has the highest frequency of mutations per cell among all human malignancies, which is largely attributable to frequent C → T transitions resulting from solar UV exposure.¹² A few mutations result in “driver” oncogenes (such as activating BRAF v600^E or v600^K mutations or NRAS mutations at G12, G13 or Q61) and/or important “passenger” alterations that collaborate to varying degrees in oncogenesis (such as PTEN loss of function, which occurs in at least 20–30% of melanomas, often in association with BRAF mutations,¹⁶⁴ and many others such as TP53 and p16INK4a and p14ARF¹²). Simultaneous mutation of BRAF and NRAS is rarely found in primary melanomas untreated with BRAF inhibitors. The importance of the PTEN pathway and its downstream mediators of a wide variety of proliferative, metabolic and antiapoptotic functions is illustrated by a large

number of mechanisms for pathway activation, including hypermethylation of the PTEN promoter and rare mutations of AKT or PI3kinase isoforms (reviewed in Ref. 165).

The molecular drivers currently targetable by therapeutic agents approved for melanoma are limited to BRAF-activating mutations, which are tested by either pcr-based or gene sequencing methods¹⁶⁶ for the mutations encoding BRAF v600^E or one of the less-common activating mutations at residue 600 of the BRAF serine–threonine kinase. BRAF v600^E has a change from valine to glutamic acid (V→E) and accounts for approximately 75% of cases, while the next most common is valine to lysine (V→K) in about 17%. Other amino acid substitutions account for the small number of remaining cases.¹⁶⁷ Tumors carrying V600^K are associated with more advanced age, chronic sun damage, and a somewhat less favorable outcome even with BRAF inhibition.¹⁶⁸ There are many assays available for next generation genomic sequencing that detect additional alterations with therapeutic implications, for example, activating c-kit mutations in about 20% of mucosal and 15% of acral melanomas with occasional responsiveness to imatinib^{170–172} and related tyrosine kinase inhibitors, and NRAS mutations, which have shown responsiveness to MEK and cyclin-dependent kinase (CDK) 4/6 inhibitors although not as sensitive as BRAF-mutated melanoma¹⁷² These assays are also valuable for discovery of new mechanisms of resistance, especially when performed sequentially on biopsies before and during therapy. Also of interest is the recent observation of BRAF gene fusions with several other molecular species in Spitzoid nevi that provide unique targets for several agents already in testing.¹⁷³

Disease regression occurs in the majority of patients treated with single-agent BRAF or MEK inhibitors ([Table 7](#)) and can be improved with the combination of inhibitors, which have shown survival benefit over single-agent BRAF inhibition. As some of the toxicities of BRAF inhibitors occur via paradoxically-enhanced signaling from upstream pathways that also activate MEK,¹⁷⁴ these effects are less prominent during combined therapy; furthermore, the secondary low-grade cutaneous proliferations (keratoacanthoma and squamous cancers) attributed to mutant HRAS activation upstream of MEK¹⁷⁵ are also reduced during combination therapy. Such combinations also yield higher response rates and additional disease regression, as shown on the “waterfall” plots of maximum regression in individual subjects. Longer progression-free and overall survival has also been reported with these combinations over BRAF inhibition alone.^{176–179} Toxicities of single-agent therapy with either BRAF or MEK inhibitors are generally tolerable but may require dose reduction, brief drug holiday, or a switch in agent(s). They are briefly summarized in [Table 7](#), but further management guidelines are available from recent experience^{181, 182} and will undoubtedly emerge with more experience, particularly since the regulatory approval of these agents has led to their more widespread use.

Acquired resistance to single MAPK inhibitors occurs after a median of 6 months and somewhat later (median 8–11 months) with combined MAPK inhibitors ([Table 7](#)), although a fraction of patients may enjoy prolonged control.¹⁸³ The mechanisms of resistance as well as protection against resistance are becoming evident from the many clinical trials that provide tissue for analysis before therapy and during therapy or at the time of progression. Reactivation of MEK signaling occurs in most cases of acquired resistance to MAPK inhibition, via alterations in BRAF (gene amplification or truncation mutations); secondary mutations in NRAS with the downstream consequence of increased CRAF heterodimerization with blocked mutant BRAF to reactivate downstream signaling; rare MEK mutations or related (COT1) activation; and several receptor kinase alterations ([Figure 2](#)) that also activate the PI3kinase/AKT pathway.^{182, 183} An earlier-onset form of therapy resistance, termed “adaptive” by Kugel and Aplin, involves shifts in metabolic or receptor tyrosine kinase signaling that confer growth advantage or resistance to apoptosis and may also be targetable with small molecule inhibitors or antibodies but have been less extensively studied than acquired mechanisms.¹⁸⁴ Therapeutic trials to delay or prevent the emergence of resistance will be critical, as established resistance is difficult to overcome with any form of targeted therapy. For example, the activity of combination MEK plus BRAF inhibitor after BRAF inhibition fails is modest (only 15% response, PFS <4 months¹⁸⁵), and current efforts are focused on preventing or delaying resistance by improving front-line therapy and molecular typing. The use of intermittent dosing, based on strong preclinical data¹⁸⁸ and clinical anecdotes, is also under investigation (clinicaltrials.gov NCT02196181).

Figure 2 Multiple molecular pathways, such as the RAF/MEK/MAPK and PI3K/AKT pathways, have been found to support melanoma proliferation and survival. Understanding these pathways will enable the development of targeted therapies for melanoma.

The choice between immunotherapy and targeted agents for the first-line therapy of patients whose melanoma carries a BRAF activating mutation remains unclear, as the kinetics of benefit are so different. MAPK inhibitors work quickly and relieve symptoms within days to weeks, while immunotherapy responses may require weeks to months, particularly ipilimumab, which has shown several patterns of response, including both delayed responses after objective progression as well as the appearance of new lesions before an overall objective response.¹⁸⁹ Until the completion of planned drug-sequencing trials (see below) to answer this question, it is generally recommended that patients with a BRAF-mutated melanoma and rapidly growing, symptomatic or very high tumor burden be treated first with combination MAPK inhibitors. This critical question is being tested in a large U.S. cooperative group trial (NCT02224781). Patients with advanced melanoma carrying an activating BRAF mutation are randomized to initial therapy with dabrafenib plus trametinib versus ipilimumab plus nivolumab. Upon progression, patients are crossed over to the opposite treatment. The trial results will define the optimal initial therapy and sequence among these patients, as well as important predictors (which may range from simple clinical tests such as serum LDH to complex immunologic parameters in blood or tumor) of benefit from each regimen. Additional unresolved questions include whether and how to continue targeted agents in patients requiring palliative radiotherapy (which can interact to enhance skin and liver toxicities) or surgery for single sites of symptomatic progression during disease control in other sites.

Immunotherapy for advanced melanoma

Interleukin-2 and other cytokines

IL-2 is an immunomodulatory cytokine with pleiotropic effects on immune effectors that has activity against melanoma when given at high pharmacologic doses. Most recent data show a 15–25% rate of objective response and an RFS plateau of 20%.¹⁹⁰ To date, clinical criteria for safety and the availability of an expert team to administer high-dose IL-2 and the associated supportive care are used to select patients for this form of treatment; although many dose and schedule alterations and the addition of a variety of toxicity modulators have been studied, no modification of the original regimen has improved its unfavorable therapeutic index. The toxicities of high-dose IL-2 result from a generalized capillary leak syndrome mediated by small molecule vasoactive agents such as nitric oxide and a reversible systemic inflammatory response syndrome with multiorgan dysfunction that may also be attributed to the effects of IL-2-induced inflammatory mediators such as tumor necrosis factor and interferon- γ . Studies are now underway to identify immunologic or genetic predictors of benefit (clinicaltrials.gov NCT01288963) that will potentially complement those under investigation for selection of other immunotherapies (detailed below) as single agents or, more likely, in combination or carefully sequenced strategies. Other trials test the activity of regimens that combine or sequence IL-2 with immune checkpoint blockers as well as the potential role for newer cytokines, particularly those that stimulate cytotoxic T cells but, unlike IL-2, do not also stimulate regulatory T cells or activation-induced cell death. The importance of collecting blood and tumor tissue before and, whenever possible, during therapy for the elucidation of biomarkers of response and resistance (and possibly of toxicity) has emerged as a critical element likely to lead to better selection criteria for first and subsequent therapies.

Immune checkpoint inhibitors in advanced melanoma

Ipilimumab is a fully human antibody to CTLA4, a molecule that provides an “immune checkpoint” on activated effector T cells by engaging with the ligand B7.1 on tumors or on dendritic cells and removing it from the activating receptor CD28. In the presence of anti-CTLA4, activation is restored, and a pre-existing but ineffective immune response against tumors is enhanced. CTLA4 blockade also promotes homing of effector T cells to tumor and elimination of Treg cells.^{190, 191} When used at the approved dose of 3 mg/kg \times 4 doses at 3-week intervals, ipilimumab provides objective response in 10–15% of patients, with less than partial regressions or disease stabilization in another 10–15%.¹⁹² The survival appears to plateau after 2.5 years at about 20%, so these patients may be cured by a durable and effective immune response (reviewed in Ref. 193). Likely as a result of additional mechanisms of action, the patterns of response to CTLA4 blockade may be atypical and delayed, making it more difficult to know when to switch a patient to second-line therapy upon the appearance of progression. However, with the advent of new checkpoint blocking agents particularly antibodies that block the PD-L1/PD-1 interaction (see below and [Table 8](#), Refs), practical recommendations for the use of single-agent ipilimumab are evolving rapidly. For melanoma and some other malignancies, the role of combined or optimally-sequenced CTLA4 and PD-1 or PD-L1 blockade are now the most critical clinical questions. Remaining questions include the survival benefit and safety/tolerability use of adjuvant ipilimumab (covered earlier in this chapter) and the therapeutic index of higher doses and more prolonged dosing schedules of CTLA4 blockade as well as novel combinations with other immunomodulatory agents (see [Figure 3](#)). For example, the addition of GM-CSF (daily for 2 weeks of every 3) to a 10 mg/kg dose of ipilimumab, given every 3 weeks \times 4 and then every 12 weeks, was recently shown to both enhance survival and reduce ipilimumab's toxicities,¹⁹² an intriguing result that warrants further study for both advanced disease and in the adjuvant setting. Although the BRAF mutation has been associated with a higher likelihood of relapse and slightly more aggressive metastatic disease,¹⁹⁹ it does not appear to impact the activity of ipilimumab in melanoma.²⁰⁰

Hypofractionated or other schemes of radiation may also overcome resistance to ipilimumab and other immunomodulatory therapies via multiple mechanisms that include enhanced antigen and MHC expression, reduction of suppressive cells and molecules, and induction of inflammatory substances that promote dendritic cell function, which in turn enhances tumor antigen-specific responses, and many clinical trials have been initiated to study these effects in melanoma and other tumors.^{201–203} Important interactions among these modalities are shown in [Figure 3](#).

Ipilimumab's toxicities are immune-based and include pruritus, rash, fatigue, and diarrhea (about 1/3 to half of patients), while colitis requiring intervention is less common (7–10%) but can cause bleeding and even bowel perforation (<1%). Hypophysitis may result in adrenal, thyroid, and reproductive hormone insufficiency requiring replacement hormone therapy and sometimes a brief course of therapeutic

glucocorticosteroid for local inflammation, especially if vision is compromised by compression of the optic chiasm by the inflamed pituitary. Immune-related hepatitis and rare cases of other organ involvement such as neuropathy have been reported. The first line of therapy for most immune-related adverse events is generally a brief course of therapeutic glucocorticoids followed, if necessary, by anti-tumor necrosis factor antibody (for rare cases of steroid-resistant hepatitis, mycophenolate mofetil is preferred) (reviewed in Ref. 204). While an association between autoimmune reactions and tumor regression has been reported for CTLA4 antibody therapy,²⁰⁵ and the generation during therapy of a higher circulating lymphocyte count has also correlated with therapeutic benefit, these associations are imperfect and do not provide insight into *pretreatment* biomarkers that can be used to foresee the likelihood or either benefit or toxicity. However, a recent report details the presence in pretreatment melanoma biopsies of common exomic mutation sequences creating immunogenic MHC class I-binding tumor neoepitopes from the tumors of patients who benefited from CTLA4 blockade.²⁰⁶ This report, along with others that demonstrate benefit associated with antigen-specific immune responses to melanoma in patients benefiting from ipilimumab,²⁰⁷ lends support to the concept that immune checkpoint inhibition exploits existing antitumor immune responses, which in many cases are now believed to be tumor-specific mutations, presumably derived from the damage induced by carcinogens of known importance in tumorigenesis.²⁰⁸ Thus, combinations with other immunomodulators that provide costimulation, reduce negative signaling in the tumor microenvironment, or enhance the functions of antigen-presenting cells are under investigation. Insights from further study of pre- and posttreatment tumor and circulating cells and their gene expression and patterns of activation may also lead to better selection criteria for initial therapy in individual patients.

PD-1 (for programmed death), has two important ligands, PD-L1 (expressed on a wide variety of cells and variably inducible in tumors, generally by cytokines produced by infiltrating lymphocytes) and PD-L2 (predominantly expressed on hematopoietic cells). Ligand engagement of PD-1 triggers negative signaling in effector T cells, rendering them unresponsive to further antigen stimulation and eventually apoptotic, a cascade that, in the case of tumor expressing PD-L1, may be one mechanism of tumor resistance to immune control. This may be of particular importance in “adaptive resistance,” a term used to describe the induction of PD-L1 on tumor cells by γ -interferon produced by infiltrating CD8 lymphocytes, which may set the stage for effective immunotherapy by PD-1 or PD-L1 blocking antibodies.^{209–211} Such antibodies, fully human or extensively humanized, have recently been studied in patients with advanced melanoma and several other malignancies, and the results of these studies, which showed objective responses in about 25–30% of patients previously treated with ipilimumab and, if BRAF mutant, with a BRAF inhibitor, led to the approvals of pembrolizumab and nivolumab in late 2014 for advanced pretreated melanoma. However, the randomized trial that demonstrated a dramatic progression-free and overall survival benefit of nivolumab over dacarbazine (hazard ratio for death 0.42, 1-year survival 73% vs 42%) in the first randomized study for patients with untreated BRAF wild-type melanoma¹⁹⁴ ([Figure 4](#)), quickly led to the routine use of these antibodies in the first-line setting, even for patients with BRAF mutant melanoma.

Figure 4 PFS, nivolumab plus ipilimumab versus either single agent. (a) Kaplan–Meier curves for progression-free survival in the intention-to-treat population. The median progression-free survival was 6.9 months (95% CI, 4.3 to 9.5) in the nivolumab group, 11.5 months (95% CI, 8.9 to 16.7) in the nivolumab-plus-ipilimumab group, and 2.9 months (95% CI, 2.8 to 3.4) in the ipilimumab group. Significantly longer PFS was observed for nivolumab plus ipilimumab than for ipilimumab (hazard ratio for death or disease progression, 0.42; 99.5% CI, 0.31 to 0.57; $P < 0.001$) and for nivolumab versus ipilimumab (hazard ratio, 0.57; 99.5% CI, 0.43 to 0.76; $P < 0.001$). (b) PFS for patients with PD-L1-positive tumors, and (c) PFS for patients with PD-L1-negative tumors. Source Larkin et al 2015.¹⁹⁶ Reproduced with permission of the New England Journal of Medicine.

The toxicity data for PD-1 blocking antibodies have demonstrated the expected superior therapeutic ratio over single-agent ipilimumab, which has lower benefit and higher immune-related side effects (data summarized in [Table 8](#)). Most toxicities affect the same tissues targeted by ipilimumab's immune-related adverse effects but appear to be less frequent and severe; unique toxicities such as pneumonitis, nephritis, and neuritis have been reported in occasional patients on PD-1 axis blockade, and rare case reports describe other unusual events likely to represent loss of immune tolerance resulting from this form of checkpoint blockade. However, also shown in [Table 8](#), while the combination of CTLA4 and PD-1 blockade has shown higher response rates and progression-free survival over single-agent ipilimumab (further detailed below), the toxicities of the combination are much more frequent, of higher grade, and include events not reported previously for either agent alone. The advantage of combined blockade over PD-1 blockade alone is also under intense investigation, as the retrospective subset analyses of this ground-breaking study suggested that for high PD-L1-expressing tumors, the benefits of single agent nivolumab are comparable to those of combined therapy, while for tumors without PD-L1 expression, the optimal therapy may require both agents. It has been postulated that blocking PD-L1 rather than PD-1 would leave intact the immune tolerance dependent on PD-L2:PD-1 interactions. Two PD-L1 antibodies currently under investigation in melanoma and other malignancies (Atezolizumab and Durvalumab) have demonstrated preliminary activity and may be combinable with other agents of interest in melanoma, including bevacizumab (antivascular endothelial factor, which has immunopotentiating properties), MAPK inhibitors, and other immunomodulatory agents that costimulate cytotoxic cells or inhibit local suppressive cells or molecules in the tumor microenvironment.

Combination therapy with concurrent ipilimumab and nivolumab showed particularly dramatic antitumor effects confirmed in a phase III study comparing the combination with each of the single agents in untreated advanced melanoma.¹⁹⁷ Several recent reports have described potential biomarkers of benefit from PD-1/PD-L1 antibodies in both melanoma and non-small-cell lung cancer, including the expression of PD-L1 on tumor and/or stromal cells, the presence of a brisk CD8 lymphocyte infiltrate, and oligoclonality of the T-cell receptors among the tumor-infiltrating CD8 cells in melanoma,^{215, 216} and the explosion of clinical settings in which these agents are now undergoing evaluation is certain to reveal additional insight into predictive factors and mechanisms of activity and failure. Other checkpoint blocking antibodies and related immunomodulatory agents also hold promise in melanoma, including agonistic antibodies that costimulate T cells through ligands associated with activation (agonistic anti-CD137, anti-OX40, anti-CD40, anti-CD27) and dendritic cells (Toll receptor ligands and tumor vaccines antigens bound to dendritic cell-targeting antibodies). Other strategies include the inhibition of other immunosuppressive signals in the tumor microenvironment, such as indoleamine dioxygenase or signaling receptors on suppressive tumor-associated macrophages.

Sequential or simultaneous administration of molecularly targeted and immunotherapeutic agents

The data from retrospective series suggested that patients with BRAF-mutated melanoma who started with targeted therapy and then received ipilimumab at the time of progression had more unfavorable outcomes than patients who started with immunotherapy and crossed over to targeted therapy at the time of treatment failure.^{217, 218} While this outcome may have resulted from a true treatment-sequence effect, it may also reflect the assignment of patients with more aggressive disease to targeted therapy first, and patients with less aggressive tumor to immunotherapy first. An ongoing randomized clinical trial to test this question of optimal sequence, comparing the two combination regimens with the highest reported activity in melanoma (detailed below) as first-line therapy with a crossover to the alternative therapy at progression, will answer this critical question of the optimal first-line therapy and sequence of therapies for these patients, who comprise approximately half of those with advanced melanoma arising in common cutaneous sites (clinicaltrials.gov NCT 02224781). Concurrent therapy with MAPK inhibitors while initial combination therapy with vemurafenib and ipilimumab proved excessively toxic,²¹⁹ many other combinations of molecularly targeted therapy with immunotherapy are under investigation, based in part on promising data supporting the importance of BRAF mutation in resistance to immunotherapy and its inhibition in promoting immune response (reviewed in Ref. 220).

Cytotoxic agents and combinations with immunotherapy for advanced melanoma

Until the advent of high-dose IL-2, therapy for metastatic melanoma was of very limited benefit, with low rates of objective response to single-agent cytotoxic therapies and limited response durations for both IL-2 and cytotoxic agents or combinations. The standard and only FDA-approved drug was dacarbazine, with response rates in the 10–12% range, and an oral equivalent of this drug, temozolomide, has often been used with similar outcomes but better tolerance.²²¹ Although expectations were high for temozolomide as treatment for patients with brain metastases due to its central nervous system penetration and its widespread use in primary brain tumors, the low activity of dacarbazine and temozolomide in melanoma tempered enthusiasm, and it is now used predominantly for patients who have failed or cannot tolerate the other agents detailed above. Alternative multiagent regimens have been more toxic and without proven benefit despite reports of higher response rates, particularly to “biochemotherapy” combinations with at least 3 cytotoxic agents and 2 immunotherapies, usually IL-2 and IFN- α .²²² Nanoparticle-albumin-bound paclitaxel or unmodified paclitaxel as a single agent or in combination with carboplatin are cytotoxic regimens with modest activity against melanoma but have not demonstrated survival benefit in prospective trials.²²³

Melanoma metastatic to the brain

Melanoma has the highest propensity of any adult solid tumor to spread hematogenously to the brain, and due to its vascular nature and its high growth rate in many cases, it poses serious threats to the survival and well-being of patients. Surgical resection may be required for diagnosis and is often necessary for immediate relief of the complications of edema, bleeding, and rapidly progressive neurologic deficits. The impact of whole-brain radiation given in standard or alternative dose and fractionation schedules has been minimal and cannot be distinguished from the benefits of simply treating patients with glucocorticosteroids.²²⁴ Stereotactic radiotherapies (SRS) have the most favorable outcomes despite the lack of randomized, controlled comparisons,²²⁵ with the maximum size and number of lesions amenable to

treatment varying by center and type of modality (gamma-knife or cyberknife). Whole-brain radiotherapy is of limited palliative benefit and may be offered to patients with numerous lesions or failure of prior therapy, including systemic agents, which are increasingly showing activity against melanoma brain metastases (molecularly targeted agents²²⁶ and ipilimumab²²⁷). Ongoing investigations test double MAPK inhibition for melanoma metastatic to the brain, including preoperative therapy of resectable disease to allow post-therapy analysis of responding and nonresponding metastases (clinicaltrials.gov NCT01978236). Despite the lack of direct penetrance of the intact BBB by these therapies,²²⁸ their level of activity against melanoma brain metastases is in the range reported outside of the central nervous system, probably due to several factors, including the loss of BBB integrity resulting from tumor growth and inflammation as well as, in the case of immunotherapies, peripherally activated lymphocytes that gain access and migrate to the melanoma metastasis in the CNS.^{229, 230} Further understanding of the process of brain metastasis for the prevention and selection of optimal therapies will depend on factors that include the molecular characteristics of the primary site as well as changes occurring as melanoma cells experience other metastatic niches before the brain. Investigation of earlier-stage disease has provided limited and heterogeneous insights, but recent reports suggest the importance of the PTEN/AKT/PI3 kinase pathway either intrinsically or via signals from nearby astrocytes.¹⁶³ It will be important to study the effects of other checkpoint inhibitors such as PD-1 and PD-L1 antibodies in patients with melanoma metastatic to the brain, and such studies are ongoing (clinicaltrials.gov NCT02085070 and NCT02320058).

Tumor-infiltrating lymphocyte (TIL) therapy in melanoma

The ability to isolate, expand, and infuse large numbers of autologous tumor-derived cytotoxic T lymphocytes, usually derived from dissected fragments of excised tumor and expansion of predominantly CD8 lymphocytes in IL-2-containing medium into patients with advanced melanoma, has been under investigation for over 20 years and appears to be improving. Using regimens that include lymphodepleting high-dose chemotherapy and, in some cases, total body irradiation to provide homeostatic cytokines and high-dose IL-2 to stimulate *in vivo* expansion and survival of antitumor effector cells, response rates in the range of 50% with durable complete remissions in 20% of patients have been reported among patients experiencing adequate TIL (tumor-infiltrating lymphocyte) growth and able to complete the entire course of therapy.²³¹ Further manipulations have included pretreatment with BRAF inhibitors, “young” TIL cells, and immune checkpoint blockers, and it is likely that the need for HDIL-2 in these regimens will be replaced by more tolerable factors to expand and maintain the infused cytotoxic cell product. Recent observations regarding the immunobiology of TIL cells in melanoma are consistent with the findings detailed earlier for effective melanoma immunotherapy with PD-1 checkpoint blockade, including the presence of multiple immune checkpoints (PD-1, LAG3, TIM3) and costimulatory molecules (4-1BB, ICOS) on CD8 effector T cells and oligoclonality of T-cell receptor beta gene sequences on CD8 cells with antigen specificity for tumor-specific mutations.²³²

The recent advent of multiple new targeted agents and immune checkpoint inhibitors will provide ample opportunities to study the role of TIL cell therapies both for patients who fail to achieve durable benefit from the former agents and as part of multicomponent strategies for optimal therapy of advanced melanoma. While advanced melanoma will continue to be a lethal disease for a fraction of patients, the rapid emergence of highly active molecularly targeted therapies and immunotherapies with mechanisms of action and resistance that are more successfully probed and manipulated promise to counter the threat of this constellation of diseases and to continue to lead the way in new therapeutic discoveries.

Summary

Melanoma is rising in incidence and mortality in a pattern reflecting exposure to ultraviolet light (both natural and artificial) and other carcinogens that have not been fully elucidated. Familial risk factors include rare mutations of cyclin kinase genes and more common polymorphisms of genes such as the melanocortin receptor that control pigmentation of the skin and hair. Other risk factors include large numbers of moles or atypical nevi. Among the clinicopathologic subtypes, nodular melanoma has the most unfavorable prognosis owing to more rapid growth, the absence of an initial noninvasive radial growth phase, and a propensity to be nonpigmented, resulting in thicker tumors at diagnosis. Surgical excision guidelines include the need for adequate margins around the primary site to reduce the probability of local relapse; sentinel node biopsies guided by lymphoscintigraphic- and lymphatic-tracking dyes at the time of wide local excision; and completion lymph node dissection for patients with one or more involved sentinel nodes. Imaging guidelines are often tailored to the calculated risk of relapse using the 2009 AJCC staging system based on Breslow thickness, ulceration, mitotic rate, and number and size of nodal metastases. Metastasis occurs via predominantly hematogenous spread for uveal and mucosal melanoma and some cutaneous melanomas, while lymphatic spread is also common with cutaneous melanomas. Surgical management of metastatic melanoma depends on the number and location of metastases but can be associated with prolonged relapse-free survival. Metastatic melanoma is divided by prognosis into skin/soft tissue only, lung, and visceral metastasis and/or elevation of serum lactate dehydrogenase. Metastasis to the brain is more common in melanoma than any other malignancy and carries the most unfavorable prognosis, although improvements have resulted from stereotactic radiosurgery, and new molecularly targeted therapies as well as immunotherapies have shown activity against brain metastases. Melanoma is an immunogenic tumor that has been successfully treated with high-dose interleukin-2, *ex vivo* expanded tumor-infiltrating lymphocytes, and antibodies that block the CTLA4 and PD-1/PD-L1 immune checkpoints. Combinations with radiation therapy have also shown promise through multiple modulations of suppressive factors in the tumor immune microenvironment. Molecularly targeted agents, particularly those that inhibit sequential steps in the mitogen-activated protein kinase pathway in melanomas carrying an oncogenic activating mutation of BRAF, have also improved survival, and new agents to prevent or overcome resistance as well as to target other molecular drivers are under investigation. The challenge of brain metastases, likely originating from cells with molecular features predisposing them to traffic to and thrive in the brain, is still an important cause of melanoma death despite some responsiveness to targeted and immunotherapies and remains under intense investigation.

Chapter 110

Other skin cancers

William G. Stebbins, MD ■ Eric A. Millican, MD ■ Victor A. Neel, MD, PhD

Overview

Several more common types of nonmelanoma skin cancer are presented with attention to etiology and current treatment options.

The skin is a heterogeneous organ, consisting of elements of ectodermal, endodermal, and mesodermal origin. Such a diverse group of tissues gives rise to a wide variety of benign and malignant tumors. Many of these tumors are rare and will not be discussed in this chapter. [Table 1](#) lists the more common premalignant and malignant tumors, which we discuss in detail. These are tumors relevant to the oncologist because they have the capacity to metastasize and cause serious medical harm. We also touch on several tumor syndromes that may present with unusual benign skin tumors that, if recognized, should prompt the clinician to conduct a detailed search for an internal malignancy. Melanoma, Kaposi sarcoma, the malignant histiocytoses, and the cutaneous lymphomas are discussed elsewhere in this book.

Table 1 Common premalignant and malignant neoplasms of the skin

	Premalignant	Malignant
Epidermis	Actinic keratosis Arsenical keratosis HPV-induced premalignant papules (epidermodysplasia verruciformis, bowenoid papulosis) Mucosal leukoplakia	Keratoacanthoma Basal cell carcinoma Merkel cell carcinoma Squamous cell carcinoma
Dermal		Dermatofibrosarcoma protuberans
		Malignant fibrous histiocytoma
		Angiosarcoma
Appendageal	Nevus sebaceous	Sebaceous carcinoma
		Extramammary Paget disease
Benign cutaneous tumors associated with cancer syndromes		
Trichilemmomas → Cowden disease (breast/visceral tumors)		
Sebaceous tumors → Muir–Torre syndrome (GI/GU tumors)		
Mucosal neuromas → MEN type IIB (thyroid carcinoma/pheochromocytoma)		

Abbreviations: GI, gastrointestinal; GU, genitourinary; HPV, human papillomavirus; MEN, multiple endocrine neoplasia.

The incidence of nonmelanoma skin cancer (NMSC), which includes squamous cell carcinoma (SCC) and

basal cell carcinoma (BCC), is increasing ([Table 2](#)). In the United States, approximately 480,000 persons were diagnosed with NMSC in 1983,¹ over 1 million in 2008,² and an estimated >3.5 million in 2014.³ The ratio of BCC to SCC among whites in the United States, Australia, and the United Kingdom is about 4:1.^{1, 4, 5} Together, these two tumors account for approximately 90% of all skin cancers. In recent years, the role of the sun in the causation of these common skin tumors has received much attention.⁶

Table 2 Nonmelanoma skin cancer statistics (U.S. 2014)

	BCC and SCC	Merkel cell carcinoma
Magnitude of the problem (yearly)	>3,500,000 new patients	1000-1500 new patients
Severity of the problem (yearly)	2% deaths from SCC	300-500 deaths
	Disfigurement	Incidence increasing
	Disability

Ultraviolet radiation in the pathogenesis of skin cancers

In the past several decades, research on the relationship between the sun and skin cancer has escalated principally because of fear of the consequences of increased ultraviolet B (UVB) radiation on the earth's surface as a result of ozone depletion in the stratosphere. There is now general consensus over the role of sunlight in the etiology of NMSC.^{7, 8} Chuang and colleagues⁹ reported a 45-fold increase in NMSC in the Japanese population in Kauai, Hawaii, as compared with the Japanese population in Japan. Another study showed the incidence of SCC, but not BCC, in a group of Caucasian fishermen in Maryland correlated directly with the amount of sun exposure.¹⁰ A population-based study on nearly 12,000 patients also demonstrated the close correlation between chronic cumulative sun exposure and SCC.¹¹ Geographically, the incidence of skin cancer in whites increases toward the equator, further supporting the role of sunlight in carcinogenesis.

UVB imprints a unique signature on the DNA it damages. Cellular attempts to repair this damage can lead to CC>TT mutations or C → T transitions. UVA can also induce these mutations, though likely indirectly through the creation of reactive oxygen species.^{12, 13} In the precursors of SCC (known as actinic keratoses), inactivating mutations of the tumor suppressor *P53* harbor these UV-induced errors.¹⁴ Because *P53* is involved in the transcriptional regulation of DNA repair genes, cell-cycle control genes, and the induction of cell death, damage to this important regulator by UV irradiation is one mechanism that allows for the overgrowth of damaged cells.

In addition to natural sun exposure, indoor tanning is increasingly recognized as carcinogenic. According to a meta-analysis, patients who reported ever using a tanning bed had a 67% increased risk of developing SCC and a 29% increase risk of BCC.¹⁵ Two independent case–control studies also found a greater than 60% increase in the risk of early-onset (younger than age 50) BCC.^{16, 17} Overall, more than 419,000 cases of skin cancer in the United States are attributable to indoor tanning annually.¹⁸ These and other similar findings led the International Agency for Research on Cancer to classify UV tanning devices as Group 1 carcinogens.¹⁹ More recently, the United States FDA reclassified tanning devices as class II (moderate-to-high risk) devices, and several states have passed legislation limiting their use among minor children. UVB and UVA (320–400 nm) also have direct and indirect effects on the cutaneous immune system, lowering cell-mediated immunity, and inducing T-suppressor cell production.²⁰ Loss of local

immunity is thought to be another factor influencing carcinogenesis.

Tumors arising from the epidermis

Actinic keratosis

Definition

Actinic keratosis, also known as solar keratosis, is a very common lesion occurring in susceptible persons as a result of prolonged and repeated solar exposures. The action of ultraviolet radiation results in damage to the keratinocytes and produces single or multiple, discrete, dry lesions with adherent scale. These premalignant lesions may, in time, progress to SCCs.

Epidemiology

Actinic keratosis affects predominantly the sun-exposed areas of fair-skinned people. The incidence in elderly whites may approach 100% in some populations.¹ Actinic keratosis may appear at a much younger age (under 30 years) in individuals with an outdoor occupation, such as farmers, ranchers, and sailors, or an outdoor lifestyle. The lesions are more common in transplant recipients²¹ and albinos.²² It is rare in darker-skinned individuals, and almost never affects blacks, East Indians, or other Asians.

Clinical features

The onset of actinic keratosis is typically insidious and therefore often passes unnoticed for some time. The characteristic lesion is rough and gritty to palpation, similar to the feel of coarse sandpaper. Lesions are usually skin-colored or yellow brown, often with a reddish tinge, and round-to-oval, often <1 cm in diameter. They may be flat to papular, as in the hypertrophic variety of actinic keratosis ([Figure 1](#)). There may be single or multiple scattered discrete lesions, typically limited to sun-exposed areas. A pigmented variant, named spreading pigmented actinic keratosis, is a brown, slowly growing, slightly scaly lesion that tends to appear on the face and may be larger than 1.5 cm in diameter, making it difficult to distinguish from lentigo maligna.

Figure 1 Actinic keratosis. Multiple discrete lesions on the scalp. These lesions are “gritty” to palpation. The largest lesion in the center of the picture represents the hypertrophic variant. This must be differentiated from a squamous cell carcinoma in situ.

Diagnosis

The diagnosis of actinic keratosis is usually based on clinical examination alone. The hypertrophic variant may sometimes be confused with early SCC. Suchniak and colleagues²³ demonstrated histologically the presence of *in situ* or invasive SCCs in 50% of lesions diagnosed clinically as hypertrophic actinic keratoses.

Treatment

Flat actinic keratosis lesions are most easily treated with cryotherapy.²⁴ Brief applications of liquid nitrogen with a cotton tipped swab or spray gun will suffice in the majority of cases. Retreatment may be necessary for more stubborn lesions. It is not necessary to freeze to the point of blistering. Curettage and electrodesiccation of the lesions are equally effective, but carry a slightly greater risk of scarring and dyspigmentation. The hypertrophic lesions are best evaluated by biopsy to rule out invasive SCC.

Where large areas of skin are involved, 5-fluorouracil preparations may be applied twice a day to the affected areas for up to 4 weeks. This results in a brisk reaction in the treated areas, ranging from redness, soreness, and weeping, to shallow ulceration and crusting ([Figure 2](#)), which gradually subsides after discontinuation of the cytotoxic cream. Newer formulations containing 0.5% 5-fluorouracil used once daily for 4 weeks may cause less skin irritation.²⁵

Figure 2 Actinic keratosis. Extensive actinic keratosis on the face. Note that the right half has been used as control and the left half of the forehead and the nose were treated with 5% 5-fluorouracil cream for 14 days.

Multiple additional topical approaches are available. 5% imiquimod cream has been used twice weekly for 16 weeks for nonhypertrophic, actinic keratoses of the face/scalp in immunocompetent individuals.

Side effects include redness, itch and/or burning, and hypopigmentation at the local site. Imiquimod works via upregulation of inflammatory cytokines through stimulation of toll-like receptor 7 (TLR7). Topical 3% diclofenac gel has been reported to be efficacious for actinic keratoses.²⁶ The product is used twice daily for 60–90 days. The frequency of complete response seems lower than with 5-fluorouracil or imiquimod, and skin irritation can result from treatment. The FDA recently approved another topical medication, ingenol mebutate, which works via induction of direct cell death as well as nonspecific inflammation. This medication has demonstrated comparable results to other topically applied therapies with the advantage of a being administered over a shorter 2–3 day course.²⁷

Lastly, photodynamic therapy (PDT) employs a topically applied photosensitizer, aminolevulinic acid, which is preferentially absorbed by the premalignant cells and photoactivated upon exposure to blue or red light. PDT results in clearance of up to 90% of actinic keratoses in patients with extensive actinic keratoses of the face and scalp.²⁸ Stinging of the treated skin occurs during light exposure. A sunburn-like reaction follows therapy.

Course and prognosis

The lesions of actinic keratosis may disappear spontaneously, but, in general, they persist if not treated. There is modest lifetime risk (<10%) of an individual actinic keratosis transforming into SCC. Marks and colleagues²⁹ reported that 60% of SCCs arise from preexisting solar keratoses.

Keratoacanthoma

Definition

Keratoacanthoma is a common, rapidly growing low-grade tumor that may involute spontaneously, even if untreated. It is believed to originate from the hair follicles.

Epidemiology

Few studies have been done on the incidence of keratoacanthoma.³⁰ Chuang and colleagues³¹ reported an incidence rate of 103.6 per 100,000, based on the small population in Kauai, Hawaii. It is most common between the ages of 60 and 65 years and is rare in persons younger than the age of 20 years. In contrast to SCC and BCC, there is no increase in frequency in old age. It is uncommon in blacks or Japanese, and is approximately two to three times more common in males. The majority of patients have a solitary lesion.

Sun exposure and exposure to chemical carcinogens such as tar are thought to be etiologic factors. The possibility of a viral etiology is still being debated. The presence of HPV has been demonstrated by DNA hybridization and polymerase chain reaction (PCR) studies.³² The possibility of a genetic defect has also been proposed because these tumors are more common in patients with the Muir–Torre syndrome than in the general population.

Clinical features

Keratoacanthomas characteristically arise on hair-bearing skin. The most common areas are the central parts of the face: cheeks, nose, ears, lips, eyelids, and forehead, as well as the dorsa of the hands, wrists, and forearms. The trunk and scalp are uncommon sites. Typically, the lesion presents as a solitary, rapidly growing, firm, dome-shaped, flesh-colored to slightly pink lesion with a plug of keratin in the central crater ([Figure 3](#)). The evolving lesion typically grows rapidly for 2–4 weeks to a size of up to 2 cm in diameter. The mature lesion involutes spontaneously after a few months, leaving a scar. The complete

cycle of growth to spontaneous resolution takes 4–6 months.³³ Multiple or recurrent lesions may occur, particularly in cases associated with tar exposure. Multiple lesions associated with defects in cell-mediated immunity and with multiple internal malignant neoplasms and sebaceous adenomas, as part of Muir–Torre syndrome, have been noted. There is no evidence that the solitary type is associated with internal malignancy.

Figure 3 Keratoacanthoma. A pink, dome-shaped lesion with a central core of keratin. This rapidly growing lesion is located on the mid-forehead. Source: Courtesy of P.L. McCarthy, MD.

Diagnosis

The main differential diagnosis is to distinguish keratoacanthoma from SCC. The rapid evolution and spontaneous involution, the characteristic dome shape with a central plug of keratin, and the relatively young age of the patient are all clues to the diagnosis. In most cases, a wedge biopsy is essential to exclude an invasive SCC.

Treatment

Keratoacanthomas may resolve spontaneously. Surgical excision of the lesion will produce better cosmetic results and provide tissue for histopathologic diagnosis. Radiotherapy³⁴ has been used successfully in lesions that cannot be distinguished from SCCs, as well as the so-called giant aggressive keratoacanthomas.^{35, 36} The dosage used, 4000–6000 cGy, is the same as the tumoricidal dosage used for SCCs. A biopsy of the lesion to rule out SCC prior to treatment may be prudent.

Course and prognosis

Keratoacanthoma is a low-grade tumor that carries a very good prognosis. Reports of malignant transformation or metastasizing lesions are probably misdiagnosed SCCs.

Squamous cell carcinoma

Definition

SCC is a malignant tumor arising from epidermal or appendageal keratinocytes or from squamous mucosal epithelium. There is often a history of damage by exogenous agents acting as carcinogens, such as sunlight, ionizing radiation, local irritants, or arsenic. The tumor cells have a tendency toward keratin formation. Variants include Bowen disease, an *in situ* SCC; verrucous carcinoma, a low grade SCC with

a clinicopathologically distinct warty appearance; Buschke–Loewenstein tumor, the subset of verrucous carcinoma found on the genitals; oral florid papillomatosis, which involves the oral cavity; and epithelioma cuniculatum which involves the plantar surface.

Epidemiology

The incidence of cutaneous SCC varies greatly for different parts of the world, different races, and different life habits and occupations. The incidence was reported as 41.4 cases per 100,000 in 1983,¹ and is increasing.² Over the past three decades, SCC incidence has increased over 200% in the United states, and >700,000 cases are diagnosed annually.³⁷

As previously mentioned, mutations in the *P53* tumor-suppressor gene have been found in a number of SCCs.³⁸ Phototherapy patients who received broadband UVB or psoralen plus ultraviolet A (PUVA) for the treatment of skin diseases, such as psoriasis or mycosis fungoides (cutaneous T-cell lymphoma), are also at increased risk.^{39, 40} The incidence of SCC is much higher in immunosuppressed patients, and these patients should be followed very carefully. Many dermatology departments now have dedicated clinics for immunosuppressed and transplant patients.⁴¹ Depending on the dose of immunosuppressive drugs and previous sun exposure, transplant patients have up to a 65-fold increased risk of developing SCC.⁴² The SCC to BCC ratio also reverses from 0.25 to 1 in the general population to 1.5-3 to 1 in transplant patients. Tumors in such patients tend to behave more aggressively.^{39, 43}

Verrucous carcinoma of the skin is a rare tumor, with more than 100 reported cases.⁴⁴ Approximately 80–90% of patients are male, with a mean age of 52–60 years. The Buschke–Loewenstein tumor is a verrucous carcinoma of the anogenital mucosa. Penile Buschke–Loewenstein tumor is the most common, with an incidence between 5% and 24% of all penile cancers. Vaginal, cervical, perianal, and perirectal Buschke–Loewenstein tumors are less common than penile ones. The etiology of these tumors is linked to HPV, particularly to HPV serotypes 6 and 11.⁴⁴

The incidence of Bowen disease has not been extensively investigated. The incidence has been reported as 14 per 100,000 population in Rochester, Minnesota,⁴⁵ and 142 per 100,000 population in Kauai, Hawaii.⁴⁶

Progress has been made in the identification of heritable risk factors in NMSC.⁴⁷ Polymorphisms of the melanocortin-1 receptor, which are linked to an increased risk of melanoma, segregate with patients at an elevated risk for both SCC and BCC.

Clinical features

SCC often arises in skin that is damaged or has been subjected to chronic irritation. Thus, the skin adjacent to the carcinoma may show evidence of solar damage, such as actinic keratoses, wrinkling, dryness, telangiectasias, and irregular pigmentation. Alternatively, there may be features of radiodermatitis from previous radiation therapy,⁴⁸ a sinus tract associated with an underlying osteomyelitis, or scarring from a burn (“Marjolin ulcer”).⁴⁹ Chronic venous ulcers of the lower extremities are also associated with increased risks of developing SCC.⁵⁰ Chronic ulcers that show features of proliferation beyond the expected granulation process should raise the suspicion of malignant transformation.

SCC usually evolves faster than BCC, but not as rapidly as keratoacanthoma. The earliest lesion, the intraepidermal SCC or carcinoma *in situ*, typically appears as a scaly, erythematous plaque on sun-exposed areas, often with a sharply demarcated but irregular outline ([Figure 4](#)). Bowen disease is

clinically identical to SCC *in situ*. Bowen disease on the glans penis is also known as erythroplasia of Queyrat.

Figure 4 Squamous cell carcinoma (SCC) arising in SCC *in situ*. A nodule of invasive SCC on the lower leg arising within the well-demarcated, erythematous scaly plaque of SCC *in situ*.

Invasive SCC ([Figure 5](#)) almost always arises from a preexisting premalignant lesion or an *in situ* carcinoma, although *de novo* SCC has been reported.⁵¹ The lesion is typically an erythematous, indurated papule, plaque, or nodule, which may be polygonal, oval, round, or verrucous in shape ([Figures 6](#) and [7](#)). The tumor tends to increase both in elevation and diameter with time. A hallmark of SCC is its firmness on palpation. The late lesion is often eroded, crusted, and ulcerated with an indurated margin. The ulcer is often covered with a purulent exudate and bleeds easily ([Figure 7](#)). Early ulceration is often a marker for anaplastic lesions. Regional lymphadenopathy may be present either as a response to infection of the ulcer or from metastases. The latter tend to be rubbery and more irregular, and may be fixed to adjacent tissues.

Figure 5 Invasive squamous cell carcinoma. Erythematous, hyperkeratotic nodule on the forehead resembling a keratoacanthoma (see Fig. 112–3). An incisional or excisional biopsy is necessary to distinguish the two lesions.

Figure 6 Invasive squamous cell carcinoma. A hyperkeratotic, crusty plaque on the forearm. Note the evidence of sun damage in the surrounding skin: wrinkling, bruising, and a lackluster appearance.

Figure 7 Invasive squamous cell carcinoma. An ulcerated lesion on the glans penis with an indurated margin. The ulcer typically bleeds easily.

Verrucous carcinoma of the skin is most commonly found on the soles of men.⁴⁴ Typically, it presents as a slowly enlarging cauliflower-like mass. It is locally aggressive and may grow to a significant size. The ball of the foot is involved in more than 50% of cases. Other locations include the face, buttocks, oral cavity, trunk, and extremities. The bulk of the tumor is soft and may be foul-smelling. If left untreated, the tumor will eventually penetrate the underlying soft tissue and bone. However, metastasis is rare.

The Buschke–Loewenstein tumor most commonly affects the penile glans and prepuce of uncircumcised males, presenting as a cauliflower-like, fungating, foul-smelling tumor on the coronal sulcus. In women, it may be present on the vagina, cervix, or vulva. The Buschke–Loewenstein tumor has a tendency to infiltrate deeply, causing destruction of underlying tissues.

SCC of the lip may arise from an area of leukoplakia or actinic cheilitis, and almost always occurs on the lower lip. This tumor is typically much more aggressive than those on glabrous skin and has a higher rate of metastasis.

Carcinomas arising in longstanding radiation dermatitis tend to be histologically anaplastic and extremely aggressive, with a high rate of metastasis.⁵²

Treatment

The choice of treatment modality depends on the degree of differentiation of the tumor and the presence or

absence of metastasis. The size, shape, location of the tumor, and the predisposing factors should also be considered. In the case of a localized, well-differentiated tumor with no evidence of metastasis, the goal should be complete eradication of the lesion. In the presence of lymph node metastases or unresectable tumors, palliative treatment may be considered. The variety of modalities available for consideration include electrodesiccation and curettage (ED&C), excisional surgery, Mohs surgery, cryosurgery, electrosurgery, and radiation therapy.^{34, 53–55}

Electrodesiccation and curettage

ED&C is an option for SCC *in situ*, particularly on the trunk. The primary drawback is the lack of histologic confirmation of clear tumor margins, but in properly chosen patients the recurrence rate is similar to excisional surgery.⁵⁶ Invasive SCC and tumors with high-risk features have a higher risk of recurrence, however, and the preferred treatment for these tumors would allow for proper margin assessment. The larger, circular scar left from the ED&C procedure is also a deterrent for some patients.

Excisional surgery

Surgical excision with primary closure or repair with skin graft or flap is the treatment of choice for relatively small lesions with distinct borders. There should be an adequate margin of clearance of 3–5 mm to minimize the risk of recurrence. Brodland and Zitelli⁵⁷ reported that margins of 4 mm were required to achieve a 95% tumor clearance rate. For invasive or large tumors (>2 cm in diameter), or tumors on high-risk areas such as the scalp, ears, nose, eyelids, or lips, Mohs micrographic surgery is the preferred approach.

Prophylactic lymph node dissection is not recommended because of the relatively low rate of metastasis. Sentinel lymph node biopsy is an emerging approach for high-risk tumors, though the specific indications remain undefined. Tumors that have metastasized to regional lymph nodes are best treated with excision, lymph node dissection, and chemoradiation.

Mohs surgery

Mohs micrographic surgery is a technique wherein a single physician excises the tumor and performs a histologic examination of 100% of the surgical margin. This technique has the lowest local recurrence rate of all treatment modalities while also allowing maximum conservation of surrounding healthy tissue, allowing for an optimal cosmetic result.⁵⁷ It is the treatment of choice for tumors on cosmetically or functionally sensitive areas, as well as for recurrent tumors. It is also indicated for immunocompromised patients, tumors in previously irradiated skin, or tumors with high-risk features including poor differentiation, breslow depth ≥ 2 mm, diameter ≥ 2 cm, or perineural invasion. Appropriate use criteria for Mohs surgery have been published.^{57, 58}

Cryosurgery

Treatment of SCC by freezing with liquid nitrogen is best restricted to the carcinoma *in situ* on areas that are not cosmetically sensitive. This modality has the advantage of simplicity with a high cure rate when employed in the proper situation.^{54, 59}

Radiation therapy

Radiation therapy is an option for patients who cannot tolerate other more invasive treatment modalities. The treatment schedule is determined by the treatment modality, size, depth, and location of the tumor and

the particular time-dose-fractionation schedule used. A fractionated dose provides the best cure rate and the lowest risk of adverse events, but fractionation schedules vary from 5 to 30 fractions.³⁴ Most radiation for skin cancers in the United States is delivered using electron beam or superficial X-ray therapies with a dose between 4000 and 6000 cGy. The reported 5-year control rates for these approaches are 89% and 68% for primary and recurrent SCC, respectively.⁶⁰ While reasonable, these are significantly below the 5-year cure rates for excisions or Mohs micrographic surgery. More recently, high-dose rate electronic brachytherapy has become a popular treatment approach, but 5-year control data is lacking.⁶¹ Postoperative radiation therapy can also be considered as an adjuvant treatment for certain high-risk tumors including those with perineural invasion or other high risk features (see AJCC high-risk features in the following).

Patient and tumor site selection are critical for all radiation therapy. Good cosmetic results can be obtained for carefully selected small lesions of the nose, lip, eyelid, and canthus, though these may deteriorate with time. Lesions on the dorsum of the hand and those over bony and cartilaginous structures should not be treated with radiation because of the risk of radiation necrosis. Lesions in younger patients should be approached with caution given the risk of tumors arising secondary to the treatment. Tumors that do arise in areas of chronic radiation dermatitis should not be treated with further radiation.

Chemotherapy

The use of oral acitretin has decreased the incidence of SCC when given as a chemopreventive agent. The benefit from such long-term use has to be weighed against the toxicity, which includes hypertriglyceridemia, arthralgias, mucocutaneous xerosis, and alopecia. In organ transplant recipients, where the risk of developing skin cancer and risk of death from SCC is increased, chronic use of retinoids may be justified.⁶²

Course and prognosis

The risk factors correlated with local recurrence and metastatic rates include treatment modality, prior treatment, location, size, depth, histologic differentiation, histologic evidence of perineural involvement, precipitating factors other than ultraviolet light, and host immunosuppression. SCC in skin carries an overall metastatic rate of 3–6%.⁶³ Those arising from sun-damaged skin typically have a low risk for metastasis whereas those arising from chronic osteomyelitic sinus tracts, irradiated areas, and burn scars have a much higher metastatic rate (31%, 20%, and 18%, respectively). Carcinoma on the lower lip, although mostly sun induced, has a metastatic incidence of about 15%. Tumor arising in areas such as the glans penis (see [Figure 7](#)), the vulva, and the oral mucosa also have a high rate of metastasis. It is estimated that as many as 8,800 patients died of SCC in 2012.³⁷

The seventh edition of the American Joint Committee on Cancer (AJCC) staging system for SCC was released in 2010, and includes high-risk features of tumor diameter ≥ 2 cm, tumor thickness > 2 mm or Clark level $\geq IV$, poor differentiation, perineural invasion, invasion into cranial bone, and anatomic location on the ear or lip.⁶⁴ Although this is an improvement over the sixth edition staging system, some have proposed alternative staging systems that may more accurately stratify high-risk tumors into different prognostic groups.⁶⁵

With proper treatment, the overall 5-year remission rate is 90%, including SCC of the lip.⁶³ Frankel and colleagues⁶⁶ recommended follow-ups at least every 3 months for a year after treatment of SCC, and semiannually thereafter for up to 4 years.

Basal cell carcinoma

Definition

BCC is a malignant tumor that very rarely metastasizes. It is composed of cells that arise from the epidermis and the appendages which resemble the basal layer of the epidermis and is associated with a characteristic stroma. It tends to grow slowly and invade locally over many years. Eventually it can ulcerate, hence its archaic name “rodent ulcer.”

Epidemiology

BCCs account for more than 75% of NMSC diagnosed in the United States each year.^{67, 68} Incidence varies from 422 per 100,000 general population in Kauai, Hawaii,³⁰ to 146 per 100,000 in Rochester, Minnesota.⁶⁹ BCC is the most common form of skin cancer in whites,¹ and is rare in darkly pigmented people. It most frequently occurs in persons older than 40 years of age. The frequency is slightly higher in males. Other risk factors include geographic locations with high solar intensity, exposures to inorganic trivalent arsenic, ionizing radiation, and immunosuppression. Phototherapy patients receiving UVB or PUVA for treatment of certain dermatoses, such as psoriasis or mycosis fungoides, are also at increased risk.³⁹ Recent studies suggest a correlation between BCCs and exposures to sunlight in early life and intense intermittent (recreational) sun exposures.^{70, 71} This is contrary to the previous belief that BCCs result from cumulative lifetime sunlight exposures. Genetic studies show that loss-of-function mutations in the tumor-suppressor gene patched, or gain-of-function mutations in the smoothened gene, lead to the formation of sporadic basal cell tumors.^{72, 73} Germline mutations in these genes lead to Gorlin or basal cell nevus syndrome.

Clinical features

BCC is characteristically slow-growing over months to years. It is usually asymptomatic unless ulceration occurs, and then there is bleeding. It most frequently occurs on sun-exposed areas such as the face and upper trunk, and is not seen on the palms and soles.

Early lesions are round-to-oval papules or nodules, firm to palpation, often with an umbilicated center that may be ulcerated. The color is pink to red and often has a translucent or pearly quality ([Figure 8](#)). If left untreated, the lesion enlarges slowly and is destructive to neighboring structures by direct invasion. Longstanding lesions are ulcerated as a rule ([Figure 9](#)). The surrounding skin often shows telangiectasias and other evidence of solar damage, such as actinic keratoses, atrophy, wrinkling, dryness, and irregular pigmentation. Some BCCs are pigmented and may exhibit a bluish hue.⁷⁴ These may be confused with malignant melanoma ([Figure 10](#)). The so-called superficial-type BCC usually presents on the trunk as an irregular, atrophic plaque with a slightly raised border and can be mistaken for psoriasis or dermatophytic infection ([Figure 11](#)). Infiltrative-type BCCs can be difficult to detect. They are often ivory-white, and may resemble morphea and are therefore called morphea-form BCCs. This type of lesion usually occurs on the face and has a more aggressive behavior.⁷⁵

Figure 8 Basal cell carcinoma. A pearly nodule with an umbilicated, ulcerated center and telangiectasia.

Figure 9 Basal cell carcinoma. Note the erosive nature of such a long-standing lesion.

Figure 10 Pigmented basal cell carcinoma. A pink, irregular plaque with dark-blue to black pigmentation at the center that mimics a superficial spreading melanoma. The shiny quality is one clue to the diagnosis.

Figure 11 Superficial basal cell carcinoma. A large, 5-cm lesion on the abdomen. The pearly, string-like border is the clue to the clinical diagnosis.

Treatment

The choice of therapy depends on the type and size of the lesion, the location, the general condition of the patient, the cosmetic considerations, and, not least, the experience and skill of the operator.⁶⁷ Morphea-form BCCs usually have indistinct borders clinically and may result in underestimation of the extent of the tumor. Lesions situated in the nasolabial crease, around the eye, and behind the ear also tend to undermine deeply and extend far beyond the clinical border ([Figure 12](#)). Lesions that ulcerate early tend to be more aggressive. Knowledge of the behavior of the different clinical and pathologic types of BCC is essential in determining the choice of therapy. Treatment of BCCs should be aimed at a cure in the first instance. Under-treatment will result in recurrence and deep invasion.

(a)

(b)

Figure 12 (a) Basal cell carcinoma. The lesion is quite limited clinically. (b) Same patient after treatment with Mohs surgery, illustrating the cryptic extension far beyond the clinically evident border.

Electrodesiccation and curettage

ED&C can be a reasonable option for small (<1 cm) tumors in low-risk areas that lack high aggressive histologic features. In carefully selected patients, the recurrence rate is similar to excision, but in less appropriate lesions the recurrence rate can exceed 20%.⁷⁶ Primary drawbacks include the lack of histologic confirmation and the appearance of a round, hypopigmented scar.

Surgical excision

Surgical excision of the tumor with 4 mm margins followed by primary closure produces good cosmetic results and allows the surgical margins to be examined by the pathologist to confirm adequate margins.⁷⁷ Tumor present at the lateral excision margins will result in marginal recurrences, which tend to present early and may be reexcised with relative ease. Inadequate deep margins result in recurrences which tend to present late, together with invasion of deep structures. For lesions without aggressive histologic features on the trunk or extremity the recurrence rate is less than 5%.⁷⁷

Mohs surgery

Mohs micrographic surgery offers the lowest recurrence rate of all treatment options while allowing maximum conservation of healthy surrounding tissue (see [Figure 12](#)). According to the appropriate use criteria published in 2012, Mohs surgery is indicated for tumors with aggressive histologic features including morpheaform, infiltrative, metatypical, and micronodular patterns. It is also indicated for nearly all recurrent tumors, lesions on the head, neck, genitals, pretibial legs, hands, and feet as well as nodular tumors >2 cm on the trunk.⁵⁸ Advantages include complete margin assessment of the tumor and maximal tissue preservation. Disadvantages include cost and, in some areas, limited availability of trained Mohs surgeons.⁷⁸

Radiation therapy

Treatment with ionizing radiation is an option in selected patient populations, in particular, elderly or fragile patients who cannot tolerate invasive procedures. Electron beam and superficial X-ray therapies yield 5-year control rates of 95% and 86% in primary and recurrent BCCs.⁶⁰ Electron beam brachytherapy has been used with early success in BCC, but large studies and 5-year data are lacking.⁶¹ Lesions >5 cm have higher recurrence rates than smaller tumors.⁷⁹ The treatment schedule is chosen according to the type, location, size, and depth of the tumor, the total dose of radiation, and the number of fractions that will be given. Atrophy, necrosis, and scarring may be kept to a minimum when the total dose, typically in the range of 4000–6000 cGy, is divided into several smaller fractions over several weeks. Hypo-fractionated schedules with 5–8 treatments have been suggested, particularly with high-dose rate brachytherapy, to minimize patient inconvenience. However, these may have more adverse events and poorer cosmesis compared to traditional 20–30 fraction regimens.⁸⁰

Chemotherapy

Topical applications of 5% 5-fluorouracil cream to the tumor twice a day for several weeks is best suited only for small, superficial tumors in elderly patients who cannot tolerate other more aggressive forms of treatment. The rate of recurrence, however, is considerably higher. Intralesional 5-fluorouracil has also been tried in nodular lesions.^{81, 82} Five percent imiquimod cream five times per week for 6 weeks has been shown to be effective therapy for the majority of biopsy-proven superficial BCCs in immunocompetent individuals. Lesions >2.0 cm or lesions not located on trunk, neck, or extremities (other than hands and feet) are excluded in the FDA indications.

In 2012 the FDA approved vismodegib for metastatic or “locally advanced” BCC. Vismodegib inhibits the transmembrane protein smoothened, blocking the hedgehog signaling cascade. In the pivotal phase 2, nonrandomized trial, 30% of patients with metastatic disease and 43% of patients with locally advanced (inoperable) disease showed at least a partial response. The median response duration was 7.6 months.⁸³ Adverse events are almost universal, and they include muscle spasm, dysgeusia, alopecia, diarrhea, and

Course and prognosis

BCCs are slow growing as a rule. However, if left untreated, they may reach a large size, with consequent extensive tissue destruction. In a comprehensive review of recurrence rates for primary BCCs, the results are highly comparable for the various treatment modalities.⁷⁸ Most studies reported a 95% or higher cure rate.^{76, 85} A lower 5-year recurrence rate has been reported with Mohs surgery than with other commonly used modalities. Metastasis, although rare, may occur, particularly in large or recurrent lesions.⁸⁶ In such cases, the prognosis is usually poor, with a 1-year survival rate of less than 20%, and a 5-year survival rate of approximately 10%. In general, the 5-year occurrence rate of new BCCs developing in patients with a previous BCC may be as high as 45%.⁸⁷

Merkel cell carcinoma

Definition

The Merkel cell was first described by Merkel in 1875. It is a nondendritic, nonkeratinocytic epithelial clear cell normally found in the epidermis and dermis of mammals and humans. Merkel cell carcinoma (MCC) was first described by Toker in 1972, and is thought to arise from the cutaneous Merkel cell. It is a high-grade malignant tumor, with a high rate of local recurrence and metastasis. Mortality of 33% at 3 years exceeds that seen in cutaneous melanoma.

Epidemiology

MCC is a relatively uncommon neoplasm. Data from SEER show a 3-fold increase in incidence from 1996 to 2001, which had quadrupled by 2006 (0.15–0.6 per 100,000 annually).^{88, 89} This is partially because of improved diagnostic accuracy with the advent of targeted immunostains such as cytokeratin 20 (CK20). Approximately 1500 cases of MCC were diagnosed in 2007 and it is believed that this incidence has remained fairly consistent in recent years. The median age at diagnosis is 69 years, and 90% of patients are older than 50 years. There is a slight male predominance. Higher rates of MCC are seen in patients with HIV, CLL, or solid organ transplantation. A previously unknown polyoma virus was recently identified in 80% of MCC tumors.⁹⁰

Clinical features

The most common sites of involvement are head and neck (49%), extremities (38%), with the lower extremities more frequently involved than the upper extremities, and trunk (13%), mainly lower back and buttocks. The lesions present as papules or nodules, pink to red to violet, often with overlying telangiectasia. Typically, the tumors are <2 cm in size. MCC can be suspected based on the mnemonic AEIOU (asymptomatic/lack of tenderness, expanding rapidly, immune suppression, older than 50 years, UV-exposed site on a person with fair skin).⁸⁸ CK20 immunostaining (perinuclear dot pattern) has greatly assisted diagnosis of MCC.

Treatment

Wide local excision is the standard treatment modality.⁹¹ Alternatively, local excision with margin control by frozen-section histology (Mohs surgery) may be of value.⁹² Studies have shown that sentinel lymph node biopsy is predictive of nodal involvement.⁹³ Postoperative adjuvant radiation therapy remains

controversial in patients with a negative sentinel node biopsy. However, it has been shown to improve local and regional control in patients with positive sentinel nodes, and is strongly recommended in patients with bulky regional disease and multiple metastatic lymph nodes.⁸⁹ It also may be beneficial for either local recurrences or for local control after node dissection.⁹⁴ Chemotherapy regimens have not been shown to extend life.

Course and prognosis

Overall mortality by 3 years is approximately 33% for patients with MCC. Outcome is based on primary tumor size and stage of disease. Sentinel node biopsy is of value in identifying patients with disease in the nodes (stage III). In 2010, The AJCC instituted a 4-stage classification for MCC (stage I—tumor < 2cm; stage II—tumor ≥ 2 cm; stage III—regional nodal metastases; stage IV—distant metastases).⁸⁹ Immunosuppressed patients have a higher mortality than immunocompetent patients.⁹⁵

Tumors arising from dermis

Dermatofibrosarcoma protuberans

Definition

Dermatofibrosarcoma protuberans (DFSP) is a locally malignant, slow-growing tumor originating in the dermis. The tumor cells resemble fibroblasts with various degrees of atypia.

Epidemiology

DFSP is an uncommon tumor that typically presents during early to mid-adult life, and rarely in children. Males are affected 4 times as often as females. It may be more common in blacks than in whites. Associations with arsenic exposure, burn or surgical scar, acanthosis nigricans, and rapid growth during pregnancy have been reported.

Clinical features

DFSP is most commonly situated on the trunk and proximal extremities. It typically presents as a solitary, slow-growing nodule with multiple palpable surface irregularities.⁹⁶ The early lesion may resemble a dermatofibroma, keloid scar, or SCC (see [Figure 13](#)). The lesion is firm to palpation and varies from flesh color to reddish to yellow. The center may be ulcerated. The tumor can achieve an enormous size with multiple satellite nodules, if untreated. The characteristic irregular surface on a firm, plaque-like base may suggest the diagnosis. A biopsy will provide confirmation. The average size at the time of surgery is approximately 5 cm.

Figure 13 Dermatofibrosarcoma protuberans on the back of the neck. Firm papule resembling a dermatofibroma. Source: Courtesy of R.A. Johnson, MD.

Recently, DFSPs were shown to harbor chromosomal translocations that fuse the collagen type I alpha gene with the gene for platelet-derived growth factor B.⁹⁷ The presence of this specific t(17;22) translocation permits the diagnosis of DFSP in equivocal cases.

Treatment

DFSP has a high recurrence rate after conventional surgical excision, with a range of 30–50%.⁹⁸ Lateral surgical margins of at least 3 cm excised through the deep fascia are the current recommendation for conventional excision. In one large series, this yielded a recurrence rate of approximately 10%. Because of the potential for deforming surgical defects, Mohs surgery, which permits microscopic control of the excision margins, is the treatment of choice. This allows the subclinical margins to be mapped at the time of surgery, and, consequently, the surgical margins more precisely determined. Prophylactic lymph node dissection is not recommended because of the low initial risk of metastasis. Recently, the receptor tyrosine kinase inhibitor imatinib has been used with success in treating multiply recurrent and metastatic cases of DFSP.⁹⁹

Course and prognosis

In a review of 136 cases of DFSP treated with Mohs surgery, a local recurrence rate of 6.6% was determined, although smaller studies have shown fewer recurrences.¹⁰⁰ The experience of the Mohs surgeon is critical in preventing tumor recurrence. Historically, late recurrences are frequent, thus long-term follow-up is recommended.

Cutaneous angiosarcoma

Definition

Angiosarcoma (AS) is an aggressive malignancy of endothelial cells, arising in the setting of chronic lymphedema, chronic radiation dermatitis or on the face and scalp of the elderly patients.

Epidemiology

Cutaneous AS affects elderly men more often than women. Sun does not appear to be an important factor because the tumor often appears under cover of hair.¹⁰¹ AS developing in areas of chronic lymphedema (so-called Stewart–Treves syndrome) is an infrequent complication of mastectomy, axillary node

dissection for melanoma, lymphedema secondary to filarial infection and chronic idiopathic lymphedema. Unfortunately, up to 0.5% of women undergoing mastectomy and lymph node dissection develop AS within 1–30 years. Radiation-induced AS is a rare iatrogenic complication of radiation that develops in or near the irradiated site. The incubation period may be up to 40 years in some cases.

Clinical features

In all three presentations, the clinical features can be similar. Bruise-like macules, papules, and nodules develop and tend to enlarge quickly. Ulceration can occur in advanced lesions. On the face, facial edema can be the presenting sign. In all cases, the lesions extend beyond the clinical borders.

Treatment

Treatment for AS is not promising. One problem is that by the time a diagnosis is made the tumors have spread several centimeters beyond the clinically appreciated borders. AS of the face and scalp is rarely less than 10 cm in diameter at presentation. Wide surgical resection followed by radiotherapy is the mainstay of treatment. In a study of 24 patients with AS of the face and scalp, local control was obtained in 57%. However, of those patients, 47% developed distant metastases.¹⁰² In surgically unresectable tumors, radiation therapy and adjuvant chemotherapy with intralesional recombinant interleukin-2 and interferon- α -2b¹⁰³ or liposomal doxorubicin¹⁰⁴ may extend the life of some patients. Targeted biologic therapies such as imatinib mesylate and bevacizumab are also being investigated.¹⁰⁵

Course and prognosis

Survival at 5 years is approximately 12%.¹⁰¹

Tumors arising from appendages

Sebaceous carcinoma

Definition

Frequently arising on the eyelid, sebaceous carcinoma is a malignant adnexal neoplasm.

Epidemiology

Sebaceous carcinoma is the second most frequent malignancy of the eyelid next to BCC.

Clinical features

Misdiagnosis of sebaceous carcinoma is frequent. The tumor usually appears as a painless, flesh-colored papule, or nodule on the upper or lower eyelid where it is easily dismissed as a chalazion or chronic blepharitis. Ulceration is often the feature that stimulates clinical suspicion and biopsy. Focal loss of eyelashes and a yellowish hue are other diagnostic clues. Sebaceous tumors are frequently associated with the Muir–Torre syndrome, as described later in this chapter.

Treatment

In a recent evidence-based review on the management of eyelid malignancies, Mohs micrographic surgery and excision with frozen-section control were shown to be superior to other modalities, including radiation therapy.¹⁰⁶

Course and prognosis

A study of 18 patients with sebaceous carcinoma treated with the Mohs technique reported an 11% recurrence rate after an average follow-up of 37 months.¹⁰⁷ One patient had metastatic disease (5.6%). This compared favorably to other published rates of recurrence and metastasis, which had been as high as 30% and 22%, respectively.

Extramammary Paget disease

Definition

Extramammary Paget disease (EMPD) is a neoplasm of apocrine glands that clinically resembles Paget disease of the breast, but occurs in areas rich in apocrine glands, including the perineum and axilla.

Epidemiology

More frequent in women and whites, EMPD usually strikes after the fifth decade.

Clinical features

EMPD is a scaly, sharply margined plaque, most commonly found in the vulva. Because itching and burning are common symptoms, it is often mistaken for intertrigo or flexural eczema, and the diagnosis is delayed. Progressive enlargement of the plaque in the face of topical steroid or antifungal medications is a diagnostic clue.

Treatment

Evaluation to identify the presence of underlying malignancy is crucial. Surgical excision is the treatment of choice for primary EMPD. Although conventional surgery can yield a recurrence rate of more than 40%, microscopically controlled excision (Mohs surgery) appears to yield at least as good results while sparing tissue loss. High-dose (4000 cGy) radiotherapy produced local regression in one small study. Ablative carbon dioxide laser treatment is palliative, as recurrence rates are very high. More recently, topical imiquimod 5% cream has been used with some success as either monotherapy or in combination with other treatments.¹⁰⁸

Course and prognosis

When EMPD is associated with an adenocarcinoma, the prognosis is poor. However, even primary EMPD can eventually ulcerate and become locally invasive and spread to lymph nodes, with depth of invasion >1 mm being an important prognostic factor. Even after wide excision, local recurrence still approaches 25%.

Benign cutaneous tumors associated with cancer syndromes

Trichilemmoma (in Cowden disease)

Definition

Trichilemmoma is a tumor that exhibits features of outer root sheath differentiation of hair. In Cowden disease, multiple trichilemmomas are associated with multiple hamartomatous neoplasms of ectodermal, mesodermal, and endodermal origin, the most important include fibrocystic disease and carcinoma of the

breast, adenoma and follicular adenocarcinoma of the thyroid, gastrointestinal polyps, and lipomas.¹⁰⁹

Figure 14 Cowden disease. Multiple trichilemmomas on the upper lip. Similar papules are present on the mucosal surface of the lower lip.

Figure 15 Cowden disease. Translucent keratotic papules on the palmar surface. Source: Courtesy of R.A. Johnson, MD.

Epidemiology

Cowden disease is a rare autosomal dominant condition with variable expressivity. Fewer than 100 cases are reported to date. Male patients slightly exceed females among all the cases reported. All reported patients are white, except for one Japanese and two black patients. The age span is between 4 and 75 years, with the median age being 39 years.

Clinical features

In Cowden disease, trichilemmomas present as small lichenoid, skin-colored to yellow-tan papules with a smooth surface. They are concentrated on the face, especially around the orifices and the ears. Similar papules may appear on the extremities, including palmoplantar surfaces, and the oral cavity, particularly on the gingiva and the tongue ([Figures 14](#) and [15](#)). The presentation of these papules usually precedes the appearance of breast cancer and, therefore, can serve as a marker of associated cancer.

Genetics

Germ line mutations in the protein tyrosine phosphatase *PTEN* have been linked to multiple families with Cowden disease.¹¹⁰

Treatment

Therapies are directed toward achieving good cosmetic appearance and treatment of the various associated benign and malignant tumors, as indicated. In view of the high incidence of breast cancer in female patients, which may be as high as 50%, frequent breast examination and mammography are indicated.

Sebaceous adenoma (in Muir–Torre syndrome)

Definition

Sebaceous adenoma is a rare, benign tumor consisting of incompletely differentiated sebaceous lobules within the dermis. In Muir–Torre syndrome, multiple sebaceous adenomas, carcinomas and keratoacanthomas are associated with multiple visceral malignant neoplasms, most commonly carcinoma of the colon and carcinoma of the ampulla of Vater. These sebaceous tumors are rare enough that the presence of a single lesion in an otherwise healthy patient warrants an investigation for internal neoplasms.

Epidemiology

Solitary sebaceous adenoma is a rare tumor that occurs in elderly patients of both sexes. The multiple type, associated with Muir–Torre syndrome, is familial, with more than 50% of reported patients having an immediate family member with a history of internal cancer, most frequently of the colon.¹¹¹

Clinical features

Sebaceous adenoma typically appears as a firm, flesh-colored to waxy-yellow papule or pedunculated lesion, usually less than 1 cm in size. The surface may be smooth or verrucous. Older lesions may be plaque-like or ulcerated. It is usually located on the face or scalp and is usually slow growing.

Genetics

The DNA mismatch repair gene *HMSH2* has been identified as one of the genes disturbed in Muir–Torre syndrome.¹¹² Mismatch repair gene immunohistochemistry (IHC) of sebaceous neoplasms can be helpful as part of the workup of patients with suspected Muir–Torre syndrome, although sensitivity and specificity are fairly poor when used as a screening tool.¹¹³

Treatment

The treatment of choice is surgical excision. The tumor is also radiosensitive.

Multiple mucosal neuromas (multiple endocrine neoplasia 2B, MEN2B)

Definition

Mucosal neuromas present as small, discrete and coalescing, painless nodules, usually involving the lips, and sometimes studding the margins of the tongue. The association of multiple mucosal neuromas, medullary thyroid carcinoma and pheochromocytoma has been established as a familial syndrome.

Epidemiology

Discrete mucosal neuromas are common and often result from direct trauma, as in the typical bite neuroma. More than 150 cases of multiple neuromas associated with endocrine tumors have been described in the literature.¹¹⁴

Clinical features

In MEN2B, diffusely enlarged lips are an early feature. Diffuse and symmetric fleshy papules and nodules occur on the tongue by the end of first decade. Any mucosal surface may be involved. Patients often develop a Marfanoid habitus. Most importantly, medullary thyroid carcinoma may develop in early adulthood. These tumors produce calcitonin and can stimulate parathyroid hyperplasia. Pheochromocytomas are frequently present as well.

Genetics

In all cases studied to date, mutation in the protooncogene *RET*, a receptor tyrosine kinase, has been uncovered.¹¹⁵

Course and prognosis

Medullary thyroid carcinoma is often the cause of death. Routine screening for this tumor with ultrasonography and by measuring serum calcitonin levels is useful, but current recommendations suggest prophylactic thyroidectomy in cases where a *RET* mutation is documented.¹¹⁶

Metastatic tumors to the skin

Cutaneous metastases of internal cancers are uncommon. In a report of 7316 non-melanoma cancer patients,¹¹⁷ only 1% of patients had cutaneous metastases at the time of diagnosis. In a study of 2298 patients reported as having died of visceral carcinoma, only 2.7% had evidence of cutaneous metastases.¹¹⁸ In a more recent retrospective study of 4020 patients with metastatic carcinomas and melanoma, 10% had cutaneous metastases. In general, the incidence of the various cancers metastatic to the skin correlates well with the incidence of the particular primary tumor.¹¹⁹

The spectrum of metastatic tumors differs slightly between the two sexes.¹¹⁹ In one study, the most common primary sources of metastatic carcinoma to the skin in males were malignant melanoma (32%), lung (12%), large intestine (11%), carcinoma of the oral cavity (9%) and larynx (5.5%), and kidney (5%). In females, breast is by far the most common source (70%), followed by melanoma (12%), and ovary (3%), and large intestine, lung, and oral cavity, each accounting for 1.3–2.3% of the cases.¹¹⁹ In females, the incidence of lung carcinoma has increased dramatically in recent years, resulting in a corresponding

rise in the incidence of cutaneous metastatic lung carcinoma deposits. Other carcinomas that metastasize to the skin include thyroid, pancreas, liver, gallbladder, urinary bladder, endometrium, prostate, and testis. However, these are quite rare.

Typically, metastatic cancer presents as multiple, firm, nonulcerated nodules. When solitary, they may be misdiagnosed as primary skin tumors. Inflammatory skin metastases mimicking cellulitis may occur in 10% of metastases from breast cancer. The most common sites for skin metastases are chest and abdomen, followed by head and neck; metastasis to the extremities is rare. Metastases in the scalp can be associated with alopecia (“alopecia neoplastica”). Dissemination may be via the bloodstream or via the lymphatics. Carcinomas of the breast and of the oral cavity tend to spread through the lymphatics, whereas others tend to spread hematogenously. Lymphatic dissemination may explain the observation that skin metastases tend to be close to the site of the primary tumor: chest in lung carcinoma, abdominal wall in gastrointestinal tumors, and lower back in renal cell carcinoma.

The prognosis for patients with cutaneous metastases is generally poor. In Lookingbill and colleagues,¹¹⁹ the average time from diagnosis of skin metastases to death for the various primary tumors varies from 1 to 34 months. The variability in prognosis may be the result of advances in cancer therapy during the past decades. Some patients with metastatic melanoma to skin as the sole site of metastasis may have prolonged disease-free survival.

Chapter 111

Bone tumors

Timothy A. Damron, MD, FACS

Overview

Bone tumors are uncommon lesions that affect all ages of patients and may involve any bone in the body. Bone lesions may be benign neoplasms or reactive lesions, primary bone sarcomas, metastatic carcinomas to bone, myeloma, or lymphoma. The benign bone lesions, which predominate in children and young adults, may behave in an inactive, active, or aggressive fashion, and the latter may simulate malignancy. Primary bone sarcomas have a bimodal distribution, whereas metastatic disease, myeloma, and lymphoma of bone predominate in adults. Despite the broad spectrum of bone tumors, each individual entity has a distinct clinical and radiographic presentation, with a predilection for specific locations, which lends itself to narrowing the differential diagnosis and selecting appropriate management.

Bone sarcomas account for less than 0.2% of all cancers. During 2014, approximately 3020 new cases of primary bone sarcomas were diagnosed, and approximately 1460 deaths occurred. The three most common bone sarcomas are osteosarcoma, chondrosarcoma, and Ewing sarcoma. However, the most common primary malignancy of bone is myeloma, and the most common cancer that involves bone is metastatic carcinoma.

The pathologic classification of bone tumors continues to evolve. To a large extent, classification continues to be according to the cell of origin or tissue type. Primary bone tumors may derive from cartilage cells, bone cells, and vascular cells, among others, but for some tumors, the cell of origin is unknown. The most widely accepted pathologic classification system to date is that of the World Health Organization.

Introduction

As a group, bone tumors are uncommon lesions arising from a wide array of cells, affecting all ages of patients, and involving any bone in the body. They include benign lesions, primary bone sarcomas, metastatic carcinomas to bone, myeloma, and lymphoma. The benign bone lesions may behave in an inactive, active, or aggressive fashion. Despite the broad spectrum of bone tumors, each individual entity has a distinct clinical and radiographic presentation, with a predilection for specific locations, which lends itself to narrowing the differential diagnosis and selecting appropriate management.

Bone sarcomas account for less than 0.2% of all cancers.¹ During 2014, approximately 3020 new cases of primary bone sarcomas were diagnosed, and approximately 1460 deaths occurred. The three most common bone sarcomas are osteosarcoma (45%), chondrosarcoma (36%), and Ewing sarcoma (18%).² However, the most common primary malignancy of bone is myeloma, and the most common cancer that involves bone is metastatic carcinoma. Malignancies of bone as a group are only the tip of the iceberg, as the vast majority of bone lesions are benign.

The pathologic classification of bone tumors continues to evolve. To a large extent, classification continues to be according to the cell of origin or tissue type. Primary bone tumors may derive from cartilage cells such as chondrocytes (enchondromas, periosteal chondromas, chondroblastomas, chondromyxoid fibromas, chondrosarcomas), bone cells such as osteoblasts and osteocytes (osteoma, osteoid osteoma, osteoblastoma, osteosarcoma), and vascular cells (hemangioma and angiosarcoma), among others, but for some tumors, the cell of origin is unknown. The most widely accepted pathologic classification system to date is that of the World Health Organization (WHO), and their terminology is used to a large degree in this chapter, although some tumors, such as benign fibrous tumors, are grouped differently.³ The WHO classification of bone tumors has been updated since the last publication of this text ([Table 1](#)).

Table 1 Classification of bone tumors by 4th edition of WHO classification on bone and soft-tissue tumors.³

<i>Chondrogenic tumors</i>
Osteochondroma
Chondromas: enchondroma, periosteal chondroma
Chondromyxoid fibroma
Osteochondromyxoma
Subungual exostosis and bizarre parosteal osteochondromatous proliferation
Synovial chondromatosis
Chondroblastoma
Chondrosarcoma (grades I–III) including primary and secondary variants and periosteal chondrosarcoma
Dedifferentiated chondrosarcoma
Mesenchymal chondrosarcoma
Clear cell chondrosarcoma
<i>Osteogenic tumors</i>
Osteoma
Osteoid osteoma
Osteoblastoma
Low-grade central osteosarcoma
Conventional osteosarcoma
Telangiectatic osteosarcoma
Small cell osteosarcoma
Parosteal osteosarcoma
Periosteal osteosarcoma
High-grade surface osteosarcoma
<i>Fibrogenic tumors</i>
Desmoplastic fibroma of bone
Fibrosarcoma of bone

<i>Fibrohistiocytic tumors</i>
Nonossifying fibroma and benign fibrous histiocyoma of bone
<i>Ewing sarcoma</i>
<i>Hematopoietic neoplasms</i>
Plasma cell myeloma
Solitary plasmacytoma of bone
Primary non-Hodgkin lymphoma of bone
<i>Osteoclastic giant cell-rich tumors</i>
Giant cell lesion of the small bones
Giant cell tumor of bone
<i>Notochordal tumors</i>
Benign notochordal cell tumor
Chordoma
<i>Vascular tumors</i>
Hemangioma
Epithelioid hemangioma
Epithelioid hemangioendothelioma
Angiosarcoma
<i>Myogenic, lipogenic, and epithelial tumors</i>
Leiomyosarcoma
Lipoma
Liposarcoma
Adamantinoma
<i>Tumors of undefined neoplastic nature</i>
Aneurysmal bone cyst
Simple bone cyst
Fibrous dysplasia
Osteofibrous dysplasia
Langerhans cell histiocytosis
Erdheim–Chester disease
Chondromesenchymal hamartoma
Rosai–Dorfman disease

The introductory sections of this chapter deal with the pretreatment phase (evaluation, staging, and biopsy), the middle sections with surgical treatment (surgical margins through reconstructive options), radiation therapy, and medical management, and the final sections with the specific benign and malignant bone tumors as well as congenital syndromes related to bone tumors.

Evaluation

Crucial information about bone lesions is derived from the history, physical examination, and radiographic features. The goal of evaluation of any bone lesion is to arrive at a narrow differential diagnosis which will guide subsequent action. In some cases, a specific diagnosis may be determined, and, depending upon the diagnosis, the action may include observation (e.g., nonossifying fibroma, enchondroma), biopsy confirmation (e.g., aneurysmal bone cyst (ABC), chondroblastoma, giant cell tumor, osteosarcoma), irrigation/debridement (e.g., osteomyelitis), aspiration/injection (e.g., unicameral bone cyst), radiofrequency ablation (RFA) (e.g., osteoid osteoma), excision (e.g., osteochondroma), or prophylactic stabilization (e.g., established metastatic carcinoma, myeloma). In other cases, the lesion may only be categorized according to a general category of biologic behavior: latent, active, or aggressive. Latent bone tumors may be observed. Active lesions often require biopsy and curettage with or without grafting. Aggressive bone tumors almost always require biopsy confirmation prior to treatment and include both benign aggressive lesions (e.g., ABC, chondroblastoma, and giant cell tumor of bone) and malignancies (e.g., primary bone sarcomas, metastatic carcinoma, myeloma, lymphoma).

Important historical features are the patient's age and the means by which the lesion was discovered. Age divisions are particularly helpful when the patient is less than 5 years old, where metastatic neuroblastoma has its peak occurrence and sarcomas are rare, and when the patient is older than 40, where the differential diagnosis, in order of decreasing frequency, includes metastatic carcinoma, myeloma, lymphoma, and primary bone sarcomas such as chondrosarcoma, secondary osteosarcoma, malignant fibrous histiocytoma of bone, and fibrosarcoma.

The means of discovery of a bone lesion is variable. Bone lesions discovered incidentally during evaluation for other reasons are usually latent lesions that require nothing further than observation. In adult patients, the most common lesion discovered incidentally is an enchondroma; in pediatric patients, it is a nonossifying fibroma. Painless bony masses are usually osteochondromas, but other surface bone lesions may present in this fashion. The broadest category is the painful bone lesion, and this includes a wide variety of active and aggressive bone lesions. Pathologic fractures may be divided into those preceded by pain, which are usually associated with active or aggressive bone tumors, and those not preceded by pain, which are more commonly latent lesions. Pathologic fractures preceded by pain should usually be biopsied, whereas those not preceded by pain may often be observed at least until the fracture heals, although exceptions exist.

Plain radiographs are standard for the radiologic evaluation of any bone tumor. These should be evaluated for location (epiphyseal, metaphyseal, diaphyseal, surface, or intracortical), lesional border characteristics (type 1 (geographic), type 2 (moth eaten), or type 3 (permeative)), bone response to the lesion (periosteal reaction), and matrix mineralization pattern (cartilaginous, osseous, ground glass) when present ([Table 2](#)). Classification of the type 1 border can be broken down into three specific subtypes.⁵ Type 1A is characterized by a thick, sclerotic margin and usually represents a benign lesion. Type 1B is still well defined but lacks the thick, sclerotic margin, as these lesions potentially have a slightly faster growth pattern and in unusual cases may actually represent low-grade malignancies. Type 1C begins to blend with the moth-eaten pattern, representing a more aggressive pattern, including cortical destruction. Type 1C is characteristic of giant cell tumor of bone or lymphoma.⁶ Hyaline cartilage tumors are one exception to the general rule that benign lesions usually have a sclerotic rim, as most benign enchondromas lack a 1A border. Putting these radiographic features together with the clinical features will often yield a narrow differential diagnosis.

Table 2 Classic examples of bone tumors fitting specific patterns of lesional borders, bone response, and lesional matrix on plain radiographs

Radiographic category	Type	Classic examples ^a
Lesional border	Geographic (well defined)	1A Nonossifying fibroma Unicameral bone cyst
		1B Aneurysmal bone cyst Chondroblastoma
		1C Giant cell tumor Lymphoma
	Moth eaten (blurred)	Metastatic carcinoma Myeloma Lymphoma Osteomyelitis
	Permeative (poorly defined)	Osteosarcoma Ewing sarcoma Metastatic carcinoma Lymphoma
Bone response	Marginal sclerosis	Nonossifying fibroma Fibrous dysplasia
	Cortical thickening	Osteoid osteoma Osteomyelitis
	Laminar periosteal response	Stress fracture
	Endosteal expansion and scalloping	Low- to intermediate-grade chondrosarcoma
	Periosteal rimming	Aneurysmal bone cyst Giant cell tumor of bone
	Codman's triangle Cumulus cloud reaction	Osteosarcoma
	Onion-skinning periosteal response	Ewing sarcoma
Lesional matrix	Punctate rings and arcs	Hyaline cartilage tumors (enchondromas/chondrosarcomas)
	Ground-glass appearance	Fibrous dysplasia
	Osteoblastic	Osteoid osteoma Osteoblastoma Osteosarcoma Metastatic carcinoma (prostate, breast) Lymphoma

^a None of the radiographic findings here are specific, and there is considerable overlap; hence, those lesions listed may be considered classic but by no means the only ones that may present with such findings.

Bone scans help to determine whether the lesion shows uptake of the Tc⁹⁹ radionuclide, indicating an active or aggressive lesion, and whether the lesion is solitary or only one of numerous lesions. Myeloma deposits in bone serve as an exception to the rule, often being cold on bone scan. Some aggressive lesions, such as renal carcinoma metastases, may not be hot on bone scan if tumor destruction outpaces the bone's ability to form bone in response.

Positron emission tomography (PET) has come to play an increasing role in evaluation and staging of bone lesions.⁶ On average, PET avidity is greater for malignant bone tumors than for benign bone tumors. However, 18F-FDG PET avidity has been shown to be nonspecific for malignancy, and many benign tumors, ranging from nonossifying fibroma to osteoid osteomas, also show this finding, albeit with greater variability. PET scans have come to play an increasing role in staging for malignant bone tumors, but they are less sensitive than routine chest computerized tomography (CT) for pulmonary metastases.⁶

Magnetic resonance imaging (MRI) of bone tumors is indicated when the diagnosis is not evident from the plain radiographs and for determining the local extent of bone sarcomas. Specific bone tumors that may be confirmed with MRI include simple bone cysts (rim enhancement of a fluid-filled lesion) and ABCs (septations separating multiple loculated areas filled with blood, as indicated by fluid-fluid levels). Perilesional edema is common surrounding bone sarcomas but may also be seen in certain benign conditions, including osteomyelitis, osteoid osteoma, chondroblastoma, Langerhans cell histiocytosis (LCH), and chondromyxoid fibroma. CT is indicated to find the radiolucent nidus of an osteoid osteoma within the surrounding reactive bone, to assess for endosteal scalloping in a cartilage tumor to distinguish enchondroma from chondrosarcoma, to find the pattern of lesional mineralization when it is unclear, and to supplement MRI in difficult anatomic locations such as the sacrum, pelvis, and scapula.

Staging

Staging of bone sarcomas requires assessment of both the primary site and distant disease. For assessment of the primary site, radiographs and MRI of the entire involved bone should be obtained in order to check for other “skip” lesions. The two most common sites of metastases from bone sarcomas are lung followed by bone. Hence, the most crucial staging studies to obtain are chest radiograph and CT to evaluate the lungs as well as a total body bone scan or PET scan to evaluate the rest of the skeleton.

Traditionally, the staging system most commonly used for musculoskeletal sarcomas was that originally described by Doctor William Enneking and adopted by the Musculoskeletal Tumor Society (MSTS) ([Table 3](#)). Variables incorporated into the MSTS staging system include the presence or absence of metastases, grade (high or low), and local extent of the tumor (intraosseous or with extension into the soft tissues). The typical chondrosarcoma is low grade and intracompartmental (confined to the bone), so it is usually stage IA. The conventional high-grade osteosarcoma usually extends into the soft tissue, and since 80% without evidence of distant metastases, the typical stage is IIB. Evidence of metastases equates to a stage III in this system.

Table 3 Musculoskeletal Tumor Society staging system

Stage	Grade	Local extent	Metastases
I	Low	A – intracompartmental	None
		B – extracompartmental	
II	High	A – intracompartmental	
		B – extracompartmental	
III	Any	Any	Present

The current most widely accepted staging system for bone sarcomas is that of the American Joint Committee on Cancer (AJCC)⁸ (Table 4). This system has more well-documented prognostic significance (Figure 1). Variables incorporated into the AJCC system include presence or absence of metastases (with multiple/discontinuous bone tumors separated from distant metastases), grade (grade 1 or 2 vs. grade 3 or 4), and size (8 cm or smaller vs. larger than 8 cm). This system is similar to the MSTS system in separating stage I from II based on grade, but the A–B designation is based upon size here. For osteosarcoma and Ewing sarcoma, stage IIB patients have higher rates of metastases than stage IIA patients. Patients with “skip lesions” (discontinuous lesions in the same bone) are designated as stage III. Distant metastases in this system are stage IV, but since metastases to sites other than the lung (such as bone) carry a worse prognosis than lung metastases patients alone, a separate designation is reserved for those two groups (IVA and IVB). Hence, for a less than 8 cm low-grade chondrosarcoma, the typical staging would be stage IA. For a larger than 8 cm high-grade osteosarcoma without skip lesions or metastases, the typical staging is stage IIB. There were no changes in the AJCC staging between the 2002 and 2012 versions.¹⁰

Figure 1 Survival according to staging by the new American Joint Committee on Cancer staging system for bone sarcomas.

Source: ACS 2014.¹ Reproduced with permission of The American Cancer Society.

Table 4 American Joint Committee on Cancer staging system for bone sarcomas

Primary tumor [T]				
TX	Primary tumor cannot be assessed			
T0	No evidence of primary tumor			
T1	Tumor 8 cm or less in greatest dimension			
T2	Tumor more than 8 cm in greatest dimension			
T3	Discontinuous tumors in the primary bone site			
Regional lymph nodes [N]				
NX ^a	Regional lymph nodes cannot be assessed			
N0	No regional lymph node metastasis			
N1	Regional lymph node metastasis			
Distant metastasis [M]				
MX	Distant metastasis cannot be assessed			
M0	No distant metastasis			
M1	Distant metastasis			
M1a	Lung			
M1b	Other distant sites			
Histologic grade [G]				
GX	Grade cannot be assessed			
G1	Well differentiated—low grade			
G2	Moderately differentiated—low grade			
G3	Poorly differentiated—high grade			
G4	Undifferentiated—high grade			
Stage	Tumor [T]	Node [N]	Metastasis [M]	Grade [G]
Stage IA	T1	N0	M0	G1, 2 low grade
Stage IB	T2	N0	M0	G1, 2 low grade
Stage IIA	T1	N0	M0	G3, 4 high grade
Stage IIB	T2	N0	M0	G3, 4 high grade
Stage III	T3	N0	M0	Any G
Stage IVA	Any T	N0	M1a	Any G
Stage IVB	Any T	N1	Any M	Any G
	Any T	Any N	M1b	Any G

^a Because of the rarity of lymph node involvement in sarcomas, the designation NX may not be appropriate and could be considered N0 if no clinical involvement is evident. Ewing sarcoma is classified as G4.

Biopsy

Biopsy of bone tumors is indicated when a specific benign diagnosis cannot be determined based by radiographic evaluation alone. When the clinicoradiographic diagnosis of a latent lesion such as nonossifying fibroma, unicameral bone cyst, or enchondroma can be made, biopsy is generally unnecessary. Some active lesions, such as fibrous dysplasia, intraosseous lipoma, and osteochondroma do not always require biopsy if the diagnosis can be established radiographically. For most other active and all aggressive lesions, biopsy should be done to determine or confirm the diagnosis. Suspected high-grade sarcomas should be biopsied prior to initiating treatment neoadjuvant.

Careful consideration must be given when metastases are suspected, because the treatment of metastatic carcinoma to bone differs dramatically from that of a primary bone tumor. Hence, even for patients with a history of a known carcinoma with predilection to bone (breast, prostate, lung, renal, thyroid), the first bone metastases should generally be established by biopsy unless the clinical situation represents a terminal state (known wide metastases to other sites). When dealing with suspected metastatic disease requiring a biopsy,reamings are not the best way to submit a biopsy specimen, because once the intramedullary canal to and through the lesion has been breached, all associated bone and soft tissue has been potentially contaminated with tumor. If the pathology shows sarcoma, rather than metastatic disease, unnecessary contamination of previously uninvolved tissue will have already occurred.

There are four general biopsy techniques applicable to bone tumors: (1) fine needle biopsy, (2) core needle biopsy, (3) incisional open biopsy, and (4) excisional biopsy. Fine needle aspiration (FNA) biopsy provides only cells for cytology and is usually done by interventional radiologists. An FNA is useful in two general clinical situations where bone tumors are involved: (1) when the diagnosis of a bone lesion is strongly suspected (metastatic carcinoma, recurrent sarcoma) and (2) for difficult-to-access lesions (spine, pelvis, scapula). Core needle biopsies allow for interpretation of the tissue architecture in addition to the cytological detail. For bone lesions, core biopsies may be done in the same situations as FNA and for bone lesions with soft-tissue extension. Incisional open biopsy is the workhorse biopsy tool for bone lesions, as it provides adequate tissue for histological interpretation. However, there are numerous pitfalls to open biopsy which must be considered, and for most incisional biopsies, the surgeon who will be doing the definitive surgery, no matter what the final diagnosis, is the person who should do the biopsy.^{11, 12} Excisional biopsy is usually only used for bone tumors such as osteochondromas, where the radiographic features establish the diagnosis, the morbidity of excision is small, and the surface location of the lesion lends itself to excision.

Surgical margins

Surgical margins depend upon the type of excision done, and the appropriate type of excision varies according to bone tumor type. There are four types of excisions: (1) intralesional, (2) marginal, (3) wide, and (4) radical.¹³ For most benign bone lesions, an intralesional excision by way of a curettage is appropriate. When necessary, metastatic bone lesions undergoing surgery for stabilization may be treated by curettage. For aggressive benign lesions (ABC, chondroblastoma, and giant cell tumor), an extended intralesional curettage is indicated. This differs from a simple curettage in that it utilizes mechanical (high-speed burr, pulsatile lavage) and adjunctive (phenol, laser, liquid nitrogen, argon beam coagulation) techniques to extend the margin into normal bone. Recent trends suggest that most extremity low-grade chondrosarcomas may also be treated in this way. Marginal en bloc excision (through the pseudocapsule surrounding the tumor) is appropriate for osteochondromas, but wide resection (excision with a cuff of normal tissue) is indicated for most bone sarcomas.

Limb salvage versus amputation

Two issues must be considered in making the decision regarding limb salvage versus amputation: oncologic safety and function. First and foremost, in order for a patient to be a candidate for limb salvage, the oncologic procedure should not lower the expected survival beyond that which could be achieved with an amputation. This question has been addressed prospectively, and—in properly selected patients—survival is no less with limb-sparing surgery when compared to amputation.^{14, 15} However, this decision still needs to be made carefully for each patient. Oncologic safety considers two variables: response to chemotherapy (when applicable) and surgical margin. The poorer the response to chemotherapy, the greater the likelihood of local recurrence for any given margin achieved intraoperatively. Hence, for a poor response to chemotherapy (tumor progression), limb salvage surgery is a relatively strong contraindication. A wide surgical margin is the goal of bone sarcoma surgery, and it can almost always be achieved with the appropriately planned level of amputation but not always with limb-sparing surgery. If vital structures (major vessels and nerves) are encased by the soft-tissue extent of the sarcoma, necessitating their resection along with the tumor, limb salvage is contraindicated and amputation is preferable.

As with oncologic safety, if limb salvage is to be done, the expected function of the planned reconstruction should be at least equivalent to that of a comparable level amputation. In the lower extremity, function with a below-knee amputation is generally thought to be better than a distal tibial reconstruction, so a distal tibial location is a relative indication for amputation. In the upper extremity, it is preferable to be able to preserve 2 of the 3 major nerves (radial, ulnar, median) for limb salvage. Tumor encasement of more than one major upper extremity nerve and/or the axillary or brachial vessels is an indication for amputation.

Operative management of metastatic carcinoma, myeloma, and lymphoma

There are four settings that potentially require operative management for patients with bone lesions from metastatic carcinoma, myeloma, and lymphoma: (1) biopsy to establish diagnosis, (2) prophylactic stabilization of impending pathologic fracture, (3) operative fixation of pathologic fracture, and (4) en bloc resection of isolated lesions. Biopsy issues have been previously discussed but cannot be emphasized enough: the diagnosis should be established before embarking upon an operative treatment plan. Prediction of impending fracture risk is evolving. Currently, fractures are predicted based upon clinical and radiographic criteria. A rating system devised by Mirels has been devised based upon four variables¹⁶ ([Tables 5](#) and [6](#)). The Mirels system is valid across experience levels, but it still has a low specificity of approximately 33%.¹⁷ Evaluation of CT-based biomechanical analyses for this purpose are under study.¹⁸

Table 5 Mirels scoring system for predicting risk of pathologic fracture in metastatic disease

	One point	Two points	Three points
Site	Upper extremity	Lower extremity	Peritrochanteric
Size	<1/3	1/3–2/3	>2/3
Nature	Blastic	Mixed	Lytic
Pain	Mild	Moderate	Functional

Table 6 Mirels definitions, fracture risk, and treatment recommendations based upon point totals

Definition	Points	Fracture risk (%)	Recommendation
Nonimpending	≤7	<10	Observe
Borderline	8	15	Consider fixation
Impending fracture	9	33	Prophylactic fixation
Impending fracture	≥10	>50	Prophylactic fixation

Source: Mirels 1989.¹⁶ Reproduced with permission from Wiley.

When pathologic fractures occur in the setting of disseminated malignancies, they usually warrant operative fixation in order to improve function since these patients have limited life expectancy. Exceptions include moribund immediately preterminal patients, those who cannot tolerate operative intervention, and fractures that are usually managed by nonoperative means. In order for the patient to benefit from the procedure, life expectancy should be longer than the expected time required to recover from any proposed procedure.

The principles of operative fixation for fractures in this clinical situation differ from those of standard fracture fixation. Since later lesions may develop elsewhere in the bone, intramedullary nail fixation, as opposed to plate/screw fixation, is preferred in the long bones in order to protect the remainder of the bone. Immediate stability is the goal in order to avoid prolonged recovery that diminishes patient function, so bone cement is much more commonly used to supplement fixation in this situation. Fracture healing in the setting of metastatic carcinoma and myeloma is notoriously slow, so the fixation should be planned assuming there will be no fracture healing. Postoperative radiotherapy has been shown to improve function and reduce reoperation rates.¹⁹

Reconstructive alternatives

Benign bone tumors

The defects created after curettage of benign bone tumors can be filled with autologous bone graft, allograft bone, synthetic filler material, or bone cement.²⁰ Bone cement is usually reserved for defects created after extended intralesional curettage of giant cell tumors of bone. Bone cement provides immediate stability that allows full weight bearing, solidifies with an exothermic reaction that extends the margin, and provides a clear radiographic border to facilitate diagnosis of local recurrence. In cases where large lesions have been curetted, prophylactic stabilization with pins or plates/screws may be used to minimize the chance of fracture.

Primary bone sarcomas

Following resection of bone sarcomas, numerous alternatives are available to reconstruct the large bone and associated soft-tissue deficits that result. Selection of the appropriate reconstruction in each instance requires consideration of the patient age and expectations, prognosis, adjuvant treatments, type of resection, and anatomic site. In general, reconstructive techniques include endoprostheses, structural allografts, allograft–prosthetic composites, and vascularized bone grafts. Over time, the use of endoprosthetic and allograft–prosthetic composite reconstructions following resections that include a

joint has increased, while the indications for structural allografts have continued to decline. Apart from allograft–prosthetic composite reconstructions, the main role for structural allografts has been for intercalary reconstructions (when the joints above and below the diaphyseal segment can be preserved). The most frequent type of resection for sarcomas is intra-articular (removal of the bone up to and including the joint surface), requiring reconstruction of the joint surface, usually with a joint replacement. When the tumor invades the joint, an extra-articular resection (removal of both sides of the joint) is indicated, and this is often better reconstructed with a joint fusion using intervening allograft bone.

Patient age is a major consideration, since skeletally immature patients will develop limb length discrepancy unless the reconstruction accommodates the loss of growth on the operative side. For patients less than 8 years old, the potential limb length discrepancy is so profound that standard means of reconstruction is generally contraindicated. In these difficult situations, amputation, rotationplasty, and vascularized fibula grafting with open growth plates are viable alternatives.^{21–27} Rotationplasty in the lower extremity after resection of a tumor around the knee involves fixing the foot and ankle in a position rotated 180 degrees from normal so that the heel points forward and the ankle is situated at the level of and functions as the patient's knee. In this situation, the patient is able to function as a below-knee amputee rather than having to settle for a higher above-knee amputation. In patients older than 8 years old, expandable endoprosthetic reconstructions are available.^{28–32} In recent years, the availability of such growing prostheses with a noninvasive mechanism has increased their attraction.³¹ However, the complication rates have proven to be high, and their durability once the patient reaches skeletal maturity has been less than optimal.³³

Upper extremity

For reconstructions following bone sarcoma resection about the shoulder, function is most dependent on whether the deltoid muscle may be preserved during resection of the tumor.^{34, 35} If a tumor of the proximal humerus extends into the deltoid and the deltoid has to be removed to achieve a wide margin, function of the shoulder will be poor regardless of the reconstruction. When the deltoid can be preserved, consideration is often given to using an allograft–prosthetic composite reconstruction.³⁶ In this way, the patient's remaining rotator cuff tendons can be repaired to the allograft tendons, and there is potential for improved function. If an osteoarticular allograft reconstruction is chosen, there is an increased risk of nonunion of the allograft–host junction, fracture, and subchondral collapse. The scapula and all portions of the humerus may be reconstructed with an endoprosthesis. The distal upper extremity is an unusual site for bone sarcomas.

Lower extremity

Following limb-preserving bone sarcoma resection of the pelvis (internal hemipelvectomy), no reconstruction is needed when the hip joint is able to be preserved (e.g., anterior pubic/ischial rami and supra-acetabular iliac resections), and some surgeons do not reconstruct even following resection of the acetabular portion of the pelvis. The numerous reconstructive alternatives for the acetabulum and hip joint following internal hemipelvectomy are fraught with complications.^{37, 38} For the proximal femur, reconstruction is often done with either an endoprosthetic hemiarthroplasty (replacing the femoral head side but without a cup in the pelvis) or an allograft–prosthetic composite.^{39–41} The latter reconstruction allows attachment of the patient's hip abductors to the allograft tendon, which may improve stability and gait.

Most reconstructions of the distal femur utilize a distal femoral replacement endoprosthetic total knee reconstruction. Because of the attachment of the extensor mechanism through the patellar tendon to the

tibial tuberosity, resection of the proximal tibia necessitates consideration of extensor mechanism reconstruction. Here, the primary alternatives are endoprosthetic proximal tibial total knee reconstruction or allograft–prosthetic composite reconstruction. For both reconstructions, the medial head of the gastrocnemius muscle is often used both to cover the allograft and/or prosthesis and to reconstruct the extensor mechanism. With an allograft–prosthetic composite reconstruction of the proximal tibia, the patient's remaining patellar tendon may be sutured to the allograft tendon, further augmenting the extensor mechanism reconstruction.

Complications

Complications after resections and reconstructions for bone sarcomas are numerous and frequent. Infection is a concern with all reconstructions, particularly considering the large dead space created following these procedures, the prolonged wound healing while receiving adjuvant treatments, and the prevalence of chemotherapy-induced neutropenia. However, certain complications are associated with specific anatomic sites and types of reconstructions. The proximal tibia is an anatomic site particularly prone to infection and wound breakdown given the paucity of soft-tissue coverage. For endoprosthetic reconstructions of the shoulder and hip, joint instability and frank dislocation are relatively common complications. All endoprosthetic reconstructions are prone to loosening, but prosthetic survival is acceptable (proximal femur (90%), distal femur (60%), proximal tibia (50%)).⁴² Exciting new developments in alternative compliant means of fixation other than those commonly used with joint arthroplasties have been reported and warrant continued close follow-up.⁴³ Reports of their use around the knee show 80% 10-year survivorship.⁴⁴ Allografts, particularly when used alone, are prone to nonunion at the allograft–host junction and to fracture.

Radiotherapy for bone tumors

Radiotherapy plays a limited role in the treatment of primary tumors of bone, but it is a mainstay of local treatment for bone lesions resulting from metastatic carcinoma, myeloma, and lymphoma. Radiotherapy should generally be avoided in the treatment of benign bone tumors, but low-dose radiotherapy has been advocated in recalcitrant symptomatic spine cases of LCH.⁴⁵ For bone sarcomas, radiotherapy may be considered for the treatment of Ewing sarcoma, but it is not part of standard treatment for osteosarcoma or chondrosarcoma.

Potential complications of bone irradiation include postradiation sarcoma, spontaneous and fragility fracture, osteonecrosis, and—in pediatric patients—growth arrest or angular deformities. Postradiation sarcomas typically occur at a minimum of 3 years following the radiation exposure and after mean doses of 50 Gy.⁴⁶ Risk factors for postradiation fracture include periosteal stripping, neoadjuvant chemotherapy, femoral location, higher-dose irradiation, and circumferential irradiation.⁴⁷ Postradiation fractures are gaining increasing attention because of their difficulty in management, prolonged healing times and high nonunion rates (45–67%), and the frequent need for surgical treatment, multiple operations, radical bone resection/reconstruction, and/or amputation.⁴⁷

Medical management of bone tumors

The roles for medical management of bone tumors continue to expand. As a rule, high-grade bone sarcomas warrant chemotherapy to address systemic microscopic disease. Chemotherapy for bone sarcomas is usually initiated prior to (neoadjuvant chemotherapy) and completed after local surgical or

radiation treatment. Hence, the treatment of both conventional high-grade osteosarcoma and Ewing sarcoma begins with neoadjuvant chemotherapy. There is no established role for chemotherapy in the treatment of low-grade chondrosarcoma.

Use of bisphosphonates to inhibit osteoclast-mediated bone destruction has become standard of care for myeloma and many metastatic carcinomas, including breast, prostate, and lung.⁴⁸ Recently, bisphosphonate drugs have also been used off-label for specific benign bone lesions, including fibrous dysplasia and giant cell tumor, but their efficacy has not been established. Of concern, however, is the risk of bisphosphonate-related osteonecrosis of the jaw and atypical subtrochanteric proximal femur fractures.^{48, 49}

Specific benign bone tumors

Cartilage tumors

Cartilage tumors can be divided into those that derive from mature hyaline cartilage (chondromas and osteochondromas) versus those that derive from immature cartilage (chondroblastoma and chondromyxoid fibroma).

Chondromas

The WHO classification lists enchondromas and periosteal chondromas under the general heading of “Chondromas.”³ Enchondromas are the intramedullary variety of these benign hyaline cartilage tumors, and periosteal chondromas are the variety that reside on the bone surface. Enchondromatosis (multiple enchondromas/Ollier's disease and Maffucci's syndrome) is discussed under the section titled “Congenital syndromes.” The latter represents multiple enchondromas combined with hemangiomas.

Enchondromas are relatively common among primary bone tumors, representing up to 17% overall. They likely represent residual rests of hyaline growth plate cartilage left behind during skeletal immaturity. Most of these lesions are asymptomatic and incidentally noted on imaging studies done for other causes of pain.⁵⁰ Enchondromas represent the most common bone lesion seen in the small bones of the hands and feet. In the long bones, they are most commonly located in the femur (where they are frequently picked up on X-rays of patients with hip or knee pain) and the humerus (where they are picked up during radiologic evaluation of patients with common causes of shoulder pain). Solitary enchondromas of the flat bones are rare, and the possibility of chondrosarcoma needs to be considered when a cartilage lesion occurs there. Because the radiographic characteristics of hyaline cartilage are fairly typical, the primary challenge is distinguishing enchondromas from chondrosarcomas.

The natural history of enchondromas is that they become more calcified over time. Hence, mature lesions in adults almost always display a characteristic punctate pattern of calcified arcs and rings which is so distinctive as to often allow the diagnosis to be confirmed radiographically without biopsy ([Figure 2](#)). They can be associated with some endosteal scalloping. However, when they have periosteal reaction, expansion of the surrounding bone, more extensive cortical destruction, or soft-tissue extension, they have to be considered chondrosarcomas. MRI characteristics of enchondromas are a lobular pattern of organization which is dark on T1-weighted (T1W) images and bright on T2-weighted (T2W) images. Increased uptake on bone scan is typical of enchondromas and should not be considered to be a sign of malignancy; it is likely due to ongoing remodeling of the surrounding bone.

Figure 2 Enchondroma. Anteroposterior (a) and lateral (b) distal femur radiographs as well as axial (c) and coronal (d) CT scans show the characteristic punctate arcs and rings of hyaline cartilage without prominent endosteal scalloping or cortical destruction to suggest features of chondrosarcoma.

Under the microscope, enchondromas are comprised of benign, sparsely cellular hyaline cartilage, but the degree of cellularity and atypia is variable. In certain locations, such as the fingers and other small bones, the histologic features often appear more aggressive despite their benign behavior.

The vast majority of enchondromas, especially when they present as asymptomatic lesions with typical radiological findings, can simply be observed to ensure that they do not progress. However, when either the radiographic features or associated pain cast doubt on the diagnosis, the lesion may require a complete curettage and complete histological review to differentiate from chondrosarcoma. Cartilage lesions rarely recur after curettage.

Periosteal chondromas, by contrast, are distinctly unusual benign hyaline cartilage lesions. They more commonly present as a bump on a digit or as a low-grade painful lesion elsewhere. Radiographically, they usually show a typical “saucerization” of the underlying cortex of this surface lesion. They need to be distinguished from periosteal chondrosarcoma. Smaller lesions (less than 7 cm) are usually chondromas. Depending upon the location, periosteal chondromas may be removed by curettage or en bloc excision.

Chondroblastoma

This immature cartilage-derived tumor is an uncommon benign process that typically presents with joint pain, is difficult to diagnosis, and occurs in the epiphysis of the long bones.⁵¹ The vast majority of cases occur in skeletally immature patients, and their presentation with joint pain (due to their location at the end of long bones), mimicking symptoms of far more common processes, and their initially subtle radiographic findings may lead to a prolonged course prior to diagnosis. Although they may occur in numerous bones, their most common locations are the proximal humerus, distal femur, and proximal tibia.

Radiograph appearance can be subtle, since its immature cartilage usually does not cause the calcification seen so characteristically with hyaline cartilage lesions. Furthermore, the subtle epiphyseal round radiolucency of chondroblastoma is not usually surrounded by a very obvious sclerotic rim. Easier to recognize on MRI, chondroblastoma is dark on T1W and bright on T2W images and shows extensive perilesional edema. Bone scans are hot at the site of the lesion.

Chondroblastoma histology shows a preponderance of rounded cells with distinct folded “coffee-bean” nuclei arranged in a pseudolobulated “cobblestone” pattern of organization. Giant cells and chondroid

matrix may also be seen.

Treatment of chondroblastoma must take into account the fact that while it usually behaves only as an active lesion, it may also behave in an aggressive fashion. An extended intralesional curettage remains the classic treatment of choice, but more recently RFA has been employed in selected lesions with considerable success.⁵² When RFA is used for large lesions beneath weight-bearing articular surfaces, the risk of collapse must be considered.⁵² Chondroblastoma is also one of two benign bone lesions (along with giant cell tumor) that carry the potential to develop pulmonary metastases, so initial screening and subsequent surveillance of the lungs should be considered.

Chondromyxoid fibroma

Like chondroblastoma, chondromyxoid fibroma is a benign tumor of immature cartilage.⁵³ Unique from chondroblastoma, however, is the metaphyseal eccentric location in long bones, often immediately adjacent to the growth plate. It is a rare tumor, representing less than 1% of bone tumors. The most common long bone involved is the tibia. One-third of these tumors occur in flat bones. Chondromyxoid fibromas usually present with pain.

Radiographic features of chondromyxoid fibroma include its eccentric metaphyseal location, lytic lobulated, soap-bubble appearance usually without matrix mineralization, and associated cortical thinning. In some cases, the appearance may be of an aggressive tumor, with cortical breakthrough and even soft-tissue extension ([Figure 3](#)). Under the microscope, the tumor is arranged in lobules which are more cellular around the periphery than the sparsely cellular myxoid center. The characteristic cells are “stellate” in shape.

Figure 3 Chondromyxoid fibroma. Anteroposterior shoulder (a) and scapular-Y (b) radiographs, T2-weighted axial (c) and coronal (d) and proton-density axial (e) MRI images show the features of a chondromyxoid fibroma, in this case involving a flat bone, the scapula. Note the cortical thinning and focal cortical destruction that characterizes aggressive behavior and may lead to confusion with chondrosarcoma.

Treatment is typically by curettage and grafting. Local recurrence rates range from 15% to 25%. Chondromyxoid fibromas do not metastasize.

Osteochondroma

The most common tumor of bone, osteochondroma, is an exophytic growth of physal cartilage away from the growth plate and joint but paralleling the temporal course of long bone growth.⁵⁴ As the cartilage grows, it leaves behind either a sessile or pedunculated bony prominence. These tumors form and grow during the period of skeletal immaturity, cease growing at or around the time of skeletal maturity, and remain throughout a patient's life unless excised. They may present as a painless mass or with pain. Pain

is usually from irritation of the overlying soft tissues or bursitis but may also result from fracture of the stalk or malignant degeneration. Malignant degeneration is rare in solitary osteochondromas, but it occurs somewhat more commonly in patients with the hereditary form, multiple hereditary exostoses (see section titled “Congenital syndromes”).

Osteochondromas may be diagnosed radiographically with confidence. They are an exophytic metaphyseal projection characterized by continuity of the cortical and underlying medullary bone. When they have a stalk, the cap of the osteochondroma is directed away from the nearest joint. MRI is sometimes used to assess the thickness of the cartilage cap, which may be up to 3 cm in children. In adults, however, the cap should be less than 1.5 cm; thicker caps should cause suspicion for chondrosarcoma arising from the underlying osteochondroma. Under the microscope, osteochondromas have a benign hyaline cartilage cap overlying normal trabecular bone.

Treatment of osteochondromas is based on symptoms and clinical presentation. When they are asymptomatic, they may be observed. When they are painful in children, they may be excised, but the older the child and the farther away from the growth plate, the lower the risk of recurrence. In adults, any symptomatic or enlarging osteochondroma should be investigated further with an MRI to make sure that it has not developed into a chondrosarcoma.⁵⁴

Fibrous tumors

These three lesions are grouped together based on their histologic similarity in giving the light microscopic appearance of being comprised of fibrous tissue. In the latest WHO classification system for bone lesions, however, fibrous dysplasia and osteofibrous dysplasia are listed together under “tumors of undefined neoplastic nature.” “Nonossifying fibromas” are classified as “fibrohistiocytic tumors” under the current WHO outline of bone tumors.³

Fibrous dysplasia

The etiology of fibrous dysplasia has been identified to be a mutation of the GNAS gene, creating a developmental anomaly of bone formation. It is a relatively common bone process which has its onset in children but may also be diagnosed in adults. The spectrum of clinical presentation is broad and depends upon age, number of lesions, and site(s) of involvement. Patients may present with incidental lesions, painful lesions, or pathologic fracture. Monostotic (solitary) fibrous dysplasia is most commonly located in the skull, followed by the femur, tibia, and ribs. Polyostotic lesions (less common than the monostotic form) most often involve the femur, pelvis, and tibia. The polyostotic form may also present as McCune–Albright syndrome (see section titled “Congenital syndromes”) or Mazabraud's syndrome (associated intramuscular myxomas).

Radiographically, lesions of fibrous dysplasia usually present as geographic lytic lesions. In long bones, they are frequently described as “long lesions in long bones.” They affect any portion of the bone (epiphysis, metaphysis, or diaphysis) and have a characteristic “ground-glass” appearance of the matrix. In the proximal femur, extensive involvement may lead to a “shepherd's crook” deformity. Uptake on Tc99 bone scan is usually intense. Under the microscope, immature woven bone classically described as taking the form of “Chinese characters” lacks the osteoblastic rimming seen with osteofibrous dysplasia and is surrounded by bland-appearing fibroblasts.

Treatment is based upon age, location, and symptoms. When the radiographic appearance is classic, symptomatic lesions may be observed. For some symptomatic lesions, curettage and grafting may be done, but structural bone graft is usually preferred, as particulate graft materials are usually resorbed.

Prophylactic stabilization is often considered in the proximal femur, where the disorganized trabecular bone of fibrous dysplasia predisposes to stress fracture and remodeling. For symptomatic patients with polyostotic fibrous dysplasia, bisphosphonates have been used with some success.^{55, 56}

Nonossifying fibroma and fibrous cortical defect

Nonossifying fibromas and fibrous cortical defects are variants of a spectrum of developmental abnormalities of skeletally immature bone.⁵⁷ Fibrous cortical defects are smaller and generally confined to the cortex, while nonossifying fibromas are larger, extending into the medullary canal. They are so common as to almost be considered variants of normal. Fully 1/3 of children seen in the emergency room for knee injuries will show evidence of one or more of these lesions. They are almost always an incidental, asymptomatic finding. In the rare instance where they are discovered after a fracture has occurred through one, the characteristic history is the absence of pain leading to the time of fracture. This absence of pain underscores their latent nature without active features. The metaphysis of long bones is affected most frequently, particularly around the knee.

These lesions may be diagnosed with confidence on plain X-rays in nearly all cases. Their characteristic features are an at least partially intracortical, eccentric metaphyseal position, a soap-bubble lytic geographic appearance, and a thin rim of sclerotic bone around the periphery of the lesion. MRI, when necessary, shows a low signal center on both T1W and T2W sequences that is also characteristic. Perilesional edema is absent in the absence of fracture. Rarely, biopsy is needed to establish the diagnosis, and in those instances, the histopathology features a storiform, whirling background of fibroblasts with scattered giant cells.

Treatment of the vast majority of fibrous cortical defects and nonossifying fibromas should be observed alone. The unusual associated pathologic fracture should be treated according to the location and type of fracture, combining curettage and grafting of the lesion when operative management is indicated.

Osteofibrous dysplasia

In the past, osteofibrous dysplasia has been referred to as ossifying fibroma and Campanacci's disease.⁵⁷ It is unique among fibrous tumors in its location (anterior tibial shaft almost exclusively) and histology (bone islands surrounded by osteoblastic rimming and separated by a bland fibrous background). It is almost exclusively a tumor of children, and most cases occur in patients less than 8 years old. Its restricted sites of occurrence within bones that have a relatively superficial location (tibia, fibula, ulna, radius) are distinctive, as is the fact that it may be bilateral and multifocal within a single bone. It should be distinguished from adamantinoma, a bone sarcoma that also occurs most frequently in the anterior aspect of the tibia. Clinical presentation of osteofibrous dysplasia is variable, with some patients noticing a painless lump over the tibia, others presenting with episodic pain from associated stress fractures, and rare patients developing progressive tibial bowing.

Radiographically, osteofibrous dysplasia presents most commonly in the tibia within the middle or proximal third in an eccentric anterior position with a lytic, soap-bubble, or saw-toothed appearance. In older patients, there is radiographic overlap with adamantinoma, from which it must be distinguished. Unlike in adamantinoma, soft-tissue extension is not seen on MRI in osteofibrous dysplasia. As an active lesion, osteofibrous dysplasia shows increased uptake on bone scan. Under the microscope, osteofibrous dysplasia must be distinguished from both fibrous dysplasia and adamantinoma. While both osteofibrous dysplasia and fibrous dysplasia have woven bone islands within a sea of benign fibrous tissue, only osteofibrous dysplasia has osteoblastic rimming around those islands. The distinction from adamantinoma is that osteofibrous dysplasia does not show islands of epithelioid cells seen in the more aggressive

condition.

Treatment of osteofibrous dysplasia varies according to age, symptoms, and radiographic appearance. Prior to closure of the growth plate, an asymptomatic and radiographically classic lesion may be observed. If stress fractures occur, bracing should be considered. When the radiographic features are atypical, biopsy should be undertaken to establish the diagnosis. Surgical excision with or without grafting is only indicated for progressive deformity or in symptomatic patients after skeletal maturity. Some authors have suggested that due to the high incidence of recurrence after curettage and grafting, an extraperiosteal resection should be performed in all cases.⁵⁸

Giant cell tumors

Giant cell tumor of bone is a relatively common (5–10% of all bone tumors) benign tumor of bone characterized by its distinct histology and behavior.⁵⁹ In the current WHO classification system, it is classified as an “osteoclastic giant cell-rich tumors.” It is one of four benign bone tumors (along with ABC, chondroblastoma, and osteoblastoma) that have the potential to behave in an aggressive fashion. In addition, along with chondroblastoma, it is unique in its potential to create pulmonary metastases despite its benign designation. Because giant cell tumor typically behaves in an active or aggressive fashion, it presents clinically with pain, swelling, and limited range of motion at the associated joint and sometimes with pathologic fracture. It is a tumor of adulthood, peaking in young adults aged 20 to 40, and it is very unusual in skeletally immature patients. The most common locations are around the knee (distal femur and proximal tibia), wrist (distal radius), sacrum, and shoulder (proximal humerus).

Radiologically, giant cell tumor has its epicenter within the metaphysis of the long bones but almost always extends to involve the epiphysis, creating an eccentric radiolucency typically with geographic type 1C borders that abuts the subchondral bone of the adjacent joint. In skeletally immature patients, however, the lesion is usually metaphyseal. It is purely lytic without matrix mineralization, and it may show radiographic signs of aggressive behavior complete with cortical destruction and an associated soft-tissue extension. Although histologically, the predominate feature is the multinucleated giant cell, it is the background stromal cell with identical nuclear features which is the true neoplastic cell.

Local treatment of giant cell tumor depends upon location. In expendable locations, such as the proximal fibula or distal ulna, en bloc excision is appropriate. For most sites, however, the recommended treatment is extended intralesional curettage and either grafting or cementing of the defect. Extended curettage involves mechanical removal (curettes) combined with a high-speed burr and additional means of extending the margin (e.g., phenol, liquid nitrogen, or laser). The local recurrence rate for intralesional curettage of giant cell tumor varies from 30% to 47% after simple curettage but is less than 25% with extended curettage. An integral part of the care of patients with giant cell tumor is assessment for potential pulmonary metastases and extended follow-up for early diagnosis of local recurrence. Recurrences have been described up to 20 years later.⁵⁹ For “unresectable” giant cell tumors, options include radiotherapy, embolization, or denosumab. Denosumab is a Rank ligand inhibitor which inhibits the ability of the background stromal cells in giant cell tumor from coalescing to form giant cells.⁶⁰ Although early results have been promising, questions remain regarding its role in long-term use and complications that may be associated with such application.⁶¹

Hemangioma of bone

The most common benign bone tumor of the spine, hemangioma of bone is a proliferation of blood vessels that may rarely be seen in other locations. The vast majority of hemangiomas of bone, particularly in the

spine, are asymptomatic incidental findings, and the true source of any presenting symptoms should be sought apart from this tumor. Rarely, they may cause expansion of the bone or pathologic fracture. In the spine, these problems may cause neurologic compromise.

In the spine, the radiographic characteristics of hemangioma of bone are so typical that in the majority of cases, no biopsy is needed for confirmation. Radiographs show “jailbar” vertical striations. Axial CT and MRI scans show a “polka-dot” pattern. On T2W MRI images, hemangiomas show high signal; after contrast administration, these lesions enhance markedly. When radiographic features are atypical, biopsy will usually show variably sized benign blood vessels, but numerous histologic subtypes have been described. In nonspinal sites, appearances are variable, and biopsy is often needed.

Since most hemangiomas are asymptomatic, management in the majority should simply be observation. For the rare truly symptomatic, “atypical,” or “aggressive” lesion, consideration may be given to excision, radiotherapy, embolization, and sclerosing therapy.⁶²

Osteogenic tumors

Enostosis

Enostosis, or bone island, is a localized region of dense lamellar bone within cancellous bone of the medullary canal.⁶³ Enostoses are uniformly benign latent lesions that are incidental asymptomatic findings during radiographic evaluation of other problems. They are most concerning when they occur in adults as part of the autosomal dominant condition osteopoikilosis, where they present as multiple lesions and must be distinguished from osteoblastic metastatic disease.

On plain radiographs and CT scans, enostoses are densely sclerotic areas within medullary bone that are distinguished by the lack of a central nidus (as seen in osteoid osteoma), presence of radiating spicules emanating from the periphery of the lesion, and absence of uptake on bone scan (except in giant enostoses) ([Figure 4](#)). They usually do not require biopsy, but under the microscope, the histology is that of mature lamellar bone.

Figure 4 Enostosis (bone island). Anteroposterior (a) and lateral (b) radiographs of the knee show an incidental small radiodense bone lesion. Axial CT (c) shows the characteristic radiating spicules that extend from the periphery of the sclerotic bone island and interdigitate with the surrounding bone trabeculae. As in this case (d), there is usually absence of uptake on bone scan.

No treatment is necessary. Once the diagnosis is established, nothing more than observation is warranted.

Osteoid osteoma

A benign bone-forming condition that typically presents with a unique and distinctive pain pattern, osteoid osteoma is most common in adolescents and young adults.⁶⁴ The pain pattern is that of pain that is worse at night and relieved (in 70% of patients) dramatically and completely over a very short time course (20–30 min) with nonsteroidal anti-inflammatory drugs (NSAIDs). Relief with NSAIDs is theorized to be due to the beneficial effect these agents have on lowering the elevated prostaglandin levels known to be present within the nidus of osteoid osteoma. Osteoid osteomas occur with greatest frequency in the femur and tibia, but they are also one of the three most common tumors of the posterior elements of the spine (along with osteblastoma and ABC). In the spine, they may cause painful scoliosis, where they are located in the concavity of the curve. In juxta-articular locations, they may cause an arthropathy, with associated effusion and synovitis.

The characteristic radiographic finding in an osteoid osteoma is the radiolucent nidus, which is less than 2 cm in diameter and usually surrounded by dense sclerotic reactive bone. The lesion is usually intracortical, appearing eccentrically in the bone, so the reactive bone may extend both into the medullary canal and also cause expansion of the bone externally. The reactive bone may be so dense that the nidus is only evident on CT or MRI evaluation. On MRI, the extensive perilesional edema associated with osteoid osteoma is characteristic. Osteoid osteomas are always intensely hot on bone scan. Histologically, the nidus of an osteoid osteoma is characterized by irregularly arranged seams of variably mineralized osteoid surrounded by both osteoblasts and osteoclasts within a highly vascular fibrous stroma.

Treatment of osteoid osteoma has evolved considerably over time. The mainstay of operative treatment currently is RFA.⁶⁵ Success of first-time RFA in eliminating symptoms is approximately 90%. When RFA is not feasible (spinal lesions close to nerve roots, juxta-articular or difficult to access sites), surgical excision of the nidus will eliminate the symptoms. However, the nidus is sometimes difficult to localize intraoperatively, and numerous techniques have been described. The third option is medical management with NSAIDs, but the mean duration of treatment needed before the lesion ceases to cause symptoms is 2.5 years.

Osteoblastoma

Osteoblastoma shares a great deal of similarity with osteoid osteoma, and to a large degree, the primary distinguishing feature of osteoblastoma is the larger size of its nidus.⁶⁴ Similarities include their peak occurrence in adolescent and young adult patients, predilection for the posterior elements of the spine, and their underlying histology. Differences include the absence of the typical pain pattern of osteoid osteoma, the potential for aggressive behavior, and a nidus of larger than 2 cm in osteoblastoma. In addition, a much higher proportion of osteoblastomas (up to 70%) are located in the spine, making the long bones an unusual site.

Radiological features are similar to osteoid osteoma but with a larger nidus that typically shows some faint calcifications. The microscopic appearance overlaps considerably with that of osteoid osteoma, showing irregularly arranged seams of variably mineralized osteoid surrounded by both osteoblasts and osteoclasts within a highly vascular fibrous stroma.

Because of its larger size and potential for more aggressive behavior than osteoid osteoma, treatment of osteoblastoma involves excision, usually by extended intralesional curettage. Recurrence rates range from 10% to 30%. Radiation should be reserved for recurrent lesions in difficult locations such as the spine.

Cysts and other tumors

Aneurysmal bone cyst

ABC may occur as a primary or a secondary lesion.⁶⁶ Primary ABCs are neoplastic proliferations characterized by gene rearrangements involving the oncogene USP6 and the promoter CDH11.^{67, 68} Secondary ABCs occur in association with other primary bone lesions and do not carry the same chromosomal abnormalities.⁶⁸ Along with chondroblastoma, giant cell tumor, and osteoblastoma, ABC is one of the four benign bone tumors that have the potential to behave in an aggressive manner. Peak age range is from 1 to 20 years. They typically present with pain and sometimes with swelling and/or pathologic fracture. Anatomic distribution is predominately within the long bones, with the femur and tibia being the most common, but ABC is also one of the three most common tumors of the posterior elements of the spine (along with osteoid osteoma and osteoblastoma).

Radiographically, the classic appearance of an ABC is that of an eccentric, osteolytic, aneurysmal-like “blown-out cortex” surrounded only by an “eggshell thin rim” of reactive bone. However, these features are not present in all cases, and the plain films may show an appearance that overlaps with other benign conditions such as simple bone cyst, nonossifying fibroma, and fibrous dysplasia ([Figure 5](#)). In those cases, MRI of ABC will often show septations separating loculated regions filled with blood, manifest as fluid–fluid levels. The radiographic presence of these characteristic findings, however, does not clinch the diagnosis, and underlying primary lesions should be sought. Biopsy is indicated to establish the diagnosis and to distinguish from telangiectatic osteosarcoma, which has an overlapping radiographic appearance. The microscopic appearance of ABC is that of blood-filled lakes separated by bland fibroblastic septa with evidence of hemosiderin deposition and scattered giant cells.

Figure 5 Aneurysmal bone cyst. Magnetic resonance images of this radiolucent bone lesion that presented with pain in a 4-year-old show fluid signal characteristics on T1-weighted sagittal images (a), but the septations and fluid–fluid levels characteristic of aneurysmal bone cyst are best seen in this case on the T2-weighted sagittal images (b). Intraoperative fluoroscopic images (c) show that this lesion does not show aggressive features seen with many aneurysmal bone cysts (ballooned-out cortex). This lesion was curetted completely and filled with synthetic graft material (d).

Because of its potential for aggressive local behavior and its highly vascular tissue, treatment of ABC is challenging, and the natural history is sometimes difficult to predict.⁶⁹ In most cases, an initial thorough curettage is preferred in order to allow complete histologic examination that may reveal other underlying primary lesions and to distinguish from telangiectatic osteosarcoma. Before curettage, consideration should be given to preoperative embolization, particularly for central lesions that do not lend themselves to intraoperative tourniquet control of bleeding. Intraoperative bleeding may be life threatening. Some authors have suggested embolization or aspiration/injection as definitive treatments, but these options do not allow complete histologic review.⁷⁰ Local recurrences do not always progress in an aggressive

fashion, so these may sometimes be observed closely. Low-dose irradiation should be reserved for incompletely excised, aggressive, recurrent lesions in difficult-to-access locations such as the spine.

Simple bone cyst

In contrast to ABC, simple (or unicameral) bone cyst is usually an inactive lesion and at worst an active lesion. Without a prior fracture, it is a single cavity within bone filled with serous or serosanguinous fluid. Most simple bone cysts are diagnosed during childhood and are located in the proximal humerus, proximal femur, or calcaneus. In young adults, they are more common in the calcaneus and ilium. Simple bone cysts are usually asymptomatic until fracture, and many present with pathologic fracture following minimal trauma.

Radiographically, simple bone cysts are usually centrally located within the metaphysis or metadiaphysis of a long bone, are purely radiolucent in the absence of prior fracture, lack prominent marginal sclerosis, thin and sometimes slightly expand the surrounding cortex, and may rarely demonstrate the pathognomonic “fallen fragment sign” after fracture. The fallen fragment (or leaf) sign is a thin wafer of cortical bone that is situated at the caudad aspect of the bone cyst because it passed through the fluid in the cyst to reach that position. MRI of simple bone cyst shows homogeneous fluid signal within the lesion, dark on T1W and bright on T2W sequences. Peripheral rim enhancement without any central enhancement is the norm. In some cases after fracture, blood products mixed with the serous fluid may produce a single low fluid–fluid level, but the lack of septations and numerous fluid–fluid levels should distinguish a simple bone cyst. When aspirated, clear serous fluid is obtained unless there has been a fracture, in which case, the fluid can be bloody. After curettage, histologic findings reveal only a bland fibrous membrane with scattered histiocytes.

Treatment of simple bone cysts depends upon location, age, and presentation. In the proximal humerus, pathologic fractures should be allowed to heal first. Approximately one of seven simple bone cysts will heal after fracture ([Figure 6](#)). If the cyst does not heal with fracture healing, then definitive treatment options usually employ some form of aspiration and injection. Various agents have been used in the injection, including methylprednisolone, demineralized bone matrix, bone marrow, and combinations of agents. In the only level I study comparing bone marrow with steroid injection, the steroid was superior to bone marrow alone in radiographic evidence of healing.⁷¹ In the proximal femur, the risk of fracture through unicameral bone cysts is higher, and the consequences are potentially more devastating, so consideration should be given to open curettage and grafting here in order to prevent fracture. When a proximal femoral simple bone cyst has caused a pathologic fracture, open reduction and internal fixation of the fracture should be accompanied by curettage and grafting. In some locations, such as the calcaneus and ilium, observation may be elected if the cyst is asymptomatic, since pathologic fractures in these sites are very unusual. Regardless of the means of treatment, approximately 60% respond with progressive healing of the lesion. Partial healing may occur in another 30%, but 10% persist or recur. The natural history of simple bone cyst must always be borne in mind, as those in the typical locations resolve after skeletal maturity. Hence, the closer the patient is to skeletal maturity, the less aggressive the approach should be.

(a)

(b)

Figure 6 Unicameral bone cyst (simple bone cyst). Plain radiographs of the left humerus of a 9-year-old (a) who has incurred two prior fractures with minimal trauma through this lytic geographic proximal humeral bone lesion abutting the proximal humeral growth plate. At this point, there is evidence of healing within the cyst, which occurs in approximately 1/7th of simple bone cysts after fracture. However, 2 years later (b), the cyst shows signs of recurrence, with increased radiolucency in the mid-diaphysis. Note that the proximal humeral growth plate has grown away from the bone cyst. These lesions are only active during skeletal immaturity.

Langerhans cell histiocytosis

Langerhans cell histiocytes, the cells of origin of this disease entity, are a component of the reticuloendothelial system involved in phagocytizing foreign debris and originating in the bone marrow.⁴⁵ The group of disease entities encompassed by LCH classically includes solitary eosinophilic granuloma, Hand–Christian–Schüller disease (may include classic triad of multifocal bone lesions, exophthalmos, and diabetes insipidus), and Letterer–Siwe disease (disseminated, often fatal form). The younger the patients at clinical presentation, the more likely they are to have disseminated disease, with most disseminated disease patients being less than 2 years and most patients with eosinophilic granuloma being between 5 and 20 years of age. Current classifications of LCH include involvement of “nonrisk” organs, including the bone, skin, and lymph node, “risk” organs (liver, spleen, lung, and bone marrow), and “CNS-risk” areas (orbit, mastoid, and temporal skull), the latter due to the risk for development of diabetes insipidus, other endocrine abnormalities, and brain lesions. Isolated nonrisk involvement is generally considered a benign disease.⁷² Solitary eosinophilic granuloma is more common in flat bones such as the skull, pelvis, ribs, and vertebral bodies; in the long bones, it occurs as a diaphyseal or metaphyseal lesion. In multifocal disease, the skull and jawbones as well as bones of the hands and feet are more commonly involved.

Clinical presentation varies depending upon the stage of the disease. Patients with solitary or isolated multifocal bone disease often present with pain localized to the site of involvement or a limp with involvement in the lower extremity, but the bone lesions may also be asymptomatic and discovered as incidental findings. Systemic manifestations of this disease spectrum may include diabetes insipidus,

exophthalmos, fevers, infections, hepatosplenomegaly, lymphadenopathy, and papular rash, among others. Radiological presentation is variable, and hence bone lesions in LCH are “great mimickers” (along with osteomyelitis), often simulating more aggressive processes including sarcomas ([Figure 7](#)). They typically show a lytic appearance with permeative margination and soft-tissue extension, and they are often mistaken for Ewing sarcoma. In the spine, they create a “vertebra plana” appearance, with profound flattening of the vertebral body. On MRI, these lesions will also show considerable perilesional edema. Bone scan has a 30% false-negative rate, so a skeletal survey should always be performed in patients with any form of LCH. Because of the overlap in clinical presentation with other entities, including Ewing sarcoma and lymphoma, biopsy is indicated in order to establish the diagnosis. Under the microscope, the characteristic Langerhans histiocyte (large, basophilic, coffee-bean-shaped nucleus) predominates, often accompanied by numerous eosinophils.

Figure 7 Langerhans cell histiocytosis (eosinophilic granuloma). This anteroposterior pelvis radiograph (a) of a 4-year-old boy shows a left supra-acetabular lytic bone lesion with moth-eaten borders. Cortical destruction seen on coronal (b) and axial (c) CT scans causes concern for metastatic neuroblastoma or Ewing sarcoma, but biopsy showed sheets of Langerhans cells interspersed with eosinophils. Bone scan (d) showed increased uptake in this lesion, and a skeletal survey was done to exclude other lesions that might not show up on bone scan. In this case, there were only a solitary lesion and no visceral involvement. One year after biopsy and curettage, the lesion is less apparent on radiograph (e), and the patient remains asymptomatic.

Treatment of biopsy-proven LCH depends upon the stage and the symptoms, location, size, and number of bone lesions. Systemic involvement involving “risk” organs warrants consideration of chemotherapy. Low-dose radiotherapy is sometimes employed for vertebral lesions at risk for collapse. Surgical treatment for isolated bone involvement may involve curettage alone, curettage and grafting, prophylactic stabilization, and corticosteroid aspiration/injection. Patients with solitary eosinophilic granuloma generally do well with little treatment, and in some cases, the bone lesions resolve after biopsy alone.

Patients with systemic disease have prognosis inversely proportional to age at presentation and extent of involvement.

Primary bone sarcomas

Adamantinoma

An epithelial neoplasm, adamantinoma is a rare primary bone sarcoma of low grade that is thought to be derived from ectopic rests of epithelial cells.⁷³ It represents approximately 0.4% of all bone tumors. Older children and young adults are most commonly affected, and 95% affect the tibia, particularly the anterior aspect, or both the tibia and fibula. The most common presentation is of progressive pain and swelling localized to the middle third of the lower leg.

Radiographically, adamantinoma is an eccentric destructive lytic process that usually destroys the anterior cortex of the mid-tibia and leads to an associated soft-tissue mass. The medullary border usually has a rim of sclerotic reactive bone surrounding the radiolucent areas. On MRI, the lesion is dark on T1W and bright on T2W sequences with soft-tissue extension commonly and sometimes multifocal disease. Under the microscope, it shows a biphasic arrangement with epithelial groups of cells often forming glandular structures and surrounded by a background of fibrous tissue.

Treatment of adamantinoma is surgical and involves achieving a wide surgical resection of all involved bone and soft tissue with a margin of uninvolved tissue. Although cure is achieved in 85% of cases, long-term follow-up is necessary, as these tumors may recur or metastasize years later.

Chondrosarcoma

Chondrosarcomas derive from chondrocytes, the cartilage cells that are crucial to bone growth and development.^{74–77} Among bone tumors, they are relatively common, representing the second most common bone sarcoma after osteosarcoma. The vast majority of chondrosarcomas are low-grade tumors arising in adults in a wide variety of anatomic sites. The most common locations are the pelvis, followed by the femur, ribs, humerus, scapula, and tibia. Chondrosarcomas are often painful, and this symptom often leads to their discovery. Because of the prevalence of cartilage neoplasms of bone and the overlap in clinical, radiographic, and even histologic appearance between benign and malignant, one of the most difficult challenges is the differentiation enchondromas from chondrosarcomas.

Chondrosarcomas may be classified in other ways than grade. Specific histologic subtypes (clear cell, dedifferentiated, and mesenchymal) other than conventional low-grade chondrosarcoma are discussed individually below. Conventional low-grade chondrosarcomas may arise de novo as “primary chondrosarcomas” or in association with preexisting benign cartilage lesions (enchondromas and osteochondromas) as “secondary chondrosarcomas” ([Figure 8](#)). Further, chondrosarcomas that arise within the medullary bone are “central,” whereas those arising on the surface of the bone (periosteal/juxtacortical chondrosarcoma or secondary chondrosarcoma arising within a preexisting osteochondroma) are “peripheral.”

Figure 8 Secondary peripheral chondrosarcoma. This 26-year-old woman with underlying multiple osteochondromatosis developed pain and swelling in her right shoulder. Anteroposterior (a) and axillary lateral (b) right shoulder radiographs show numerous osteochondromas arising from the proximal humeral metaphysis but also a large soft-tissue shadow associated with the bone. In addition, particularly on the lateral view, there is cortical irregularity. Magnetic resonance axial T1-weighted (c, e) and T2-weighted (d, f) images show that there is a cartilage cap measuring more than 2 cm thick, indicative of a chondrosarcoma arising from the underlying osteochondroma and extending into the underlying bone as well. (g) Uptake is noted in the right proximal humerus on bone scan. This patient underwent proximal humeral resection and prosthetic reconstruction.

On plain radiographs, conventional chondrosarcomas usually show the same sort of hyaline cartilage mineralization in the forms of arcs and rings that typify enchondromas. However, a number of features that accompany this mineralization pattern point toward a malignant diagnosis. These include cortical destruction with soft-tissue extension, progressive enlargement over time, cortical expansion and >50% endosteal scalloping, enlarging regions of radiolucency, and periosteal reaction. MRI may be more sensitive at showing soft-tissue extension and perilesional edema, but the pattern of being dark on T1W images and bright on T2W images holds true for both benign and malignant cartilage tumors. CT scan is often best at delineating the degree of scalloping and cortical destruction. Bone scans usually show increased uptake in any hyaline cartilage tumor, so they do not play a major role in distinguishing benign from malignant cartilage tumors. The classic histologic distinction between enchondromas and chondrosarcomas is the presence of “encasement” (hyaline cartilage lobules isolated and surrounded by rimming reactive bone) in enchondromas compared to “permeation” (cartilage tumor permeating around preexisting bone trabecular) in chondrosarcomas. In addition, increased cellularity, cytologic atypia, and binucleation favor chondrosarcoma. The anatomic site has to be considered as well. The histologic appearance of enchondromas arising in the hand or in the setting of Ollier's disease may have a malignant histologic appearance but nonetheless have a benign course. Overall, the histologic distinction between benign and low-grade malignant cartilage tumors is fraught with difficulty, and this process should always take into account the clinical presentation and radiographic features. In many hyaline cartilage tumors, a firm diagnosis may be established based largely on clinical and radiographic grounds.

Because of the large amount of matrix and relatively low cellularity, current treatment is usually restricted to surgical means. There is no standard role for either radiotherapy or chemotherapy in most low-grade chondrosarcomas. In recent years, there has been a shift to performing extended intralesional curettage with local adjuvants (phenol, liquid nitrogen, or laser) followed by bone grafting or cementation for grade I intramedullary chondrosarcomas rather than the classic treatment recommendation, which was to perform a wide resection of the tumor.^{78–80} However, this less aggressive approach has been limited to chondrosarcomas without soft-tissue extension and generally does not apply to grade II or grade III chondrosarcomas. Prognosis for chondrosarcoma is closely related to grade ([Table 7](#)). As with other predominately low-grade tumors, long-term follow-up is recommended.

Table 7 Chondrosarcoma survival, metastatic potential, and local recurrence rates according to grade

Type	5- Year survival (%)	Metastatic potential (%)	Recurrence rate
Grade I	90	0	Low
Grade II	81	10–15	Intermediate
Grade III	29	>50	High

Clear cell chondrosarcoma

Similar to conventional chondrosarcoma in being a low-grade sarcoma, clear cell chondrosarcoma has a distinctive location (the epiphysis of long bones) and histology (large cells with abundant clear cytoplasm in a cartilage matrix). The most common locations of this rare tumor are the proximal epiphyses of the femur, tibia, or humerus. Peak ages are 20 to 40 years. Pain is the usual presenting symptom.

Given its epiphyseal location, clear cell chondrosarcoma should be considered in the differential diagnosis of chondroblastoma but in older patients (since most chondroblastomas are in skeletally immature patients). On plain radiographs, clear cell chondrosarcoma is seen as a radiolucent lesion that extends to subchondral bone and can have an appearance very similar to that of giant cell tumor of bone. The large clear cells are distinctive under the microscope, and the permeative pattern belies its malignant behavior.

Wide en bloc resection is the standard of care for clear cell chondrosarcoma. Prognosis is very good with appropriate treatment. Overall recurrence rate is approximately 15%.

Dedifferentiated chondrosarcoma

Among chondrosarcomas, dedifferentiated chondrosarcoma is the most aggressive and carries the worst prognosis. By definition, it consists of a conventional low-grade chondrosarcoma adjacent to a region of high-grade sarcoma, often osteosarcoma. The most common locations are the femur, pelvis, humerus, ribs, and scapula. Radiographically, a lytic region developing within an otherwise typical chondrosarcoma may signify a dedifferentiated chondrosarcoma. Treatment for chondrosarcoma should be directed at the high-grade component, but the role for chemotherapy remains to be established, and prognosis is uniformly poor, with a 10–15% 5-year survival rate.^{74, 82, 83} A recent report showed a survival advantage with ifosfamide-based chemotherapy compared to standard non-ifosfamide chemotherapy when combined with surgery in one series.⁸²

Mesenchymal chondrosarcoma

The rarest of all chondrosarcomas of bone, mesenchymal chondrosarcoma is a highly aggressive chondrosarcoma which predominately affects teenagers and young adults. The most common locations are in the axial skeleton, and the tumor is usually eccentric. Under the microscope, mesenchymal chondrosarcomas show nodules of cellular chondroid tissue surrounding vascular spaces. As with most chondrosarcomas, surgery is the mainstay of treatment, although recent reports continue to explore the potential benefits of chemotherapy.⁷⁵ Prognosis has been reported as ranging from <30% to 52% 5-year survival.²

Chordoma

Chordoma is a low-grade malignancy arising from vestigial notochordal remnants that exist in the midline of the spine. Following the distribution of those remnants, chordoma is a midline tumor involving the sacrococcygeal, spheno-occipital, and other mobile spine regions. Chordoma predominately involves adults, and in the adults, the sacrum is the most common location. It is very rare in African-Americans. In younger patients, the skull is the most common location. It accounts for only 3–4% of all primary bone tumors. Clinical presentation is dependent upon location, although pain is usually a presenting symptom. In the sacrum, bowel, bladder, or sexual symptoms may be present. In the skull, cranial nerve deficits may be present. In the mobile spine, back or leg pain predominates.

Radiographs of chordoma may be difficult to interpret as the findings of lytic destruction are often subtle

in these anatomically complex sites. Only CT or MRI will show the extensive anterior soft-tissue mass that usually accompanies the bone destruction in chordoma. Under the microscope, chordoma is composed of nests or cords of physaliferous cells, distinctive large cells with bubbly vacuolated cytoplasm.

Treatment of chordoma involves wide surgical resection when possible, but irradiation improves the disease-free interval in patients with marginal or contaminated margins.⁸⁴ Chemotherapy does not play a role in this low-grade malignancy. Local recurrence is common (up to 70%), and overall survival drops from 75–85% at 5 years to 40–50% at 10 years.

Ewing sarcoma

Overall, Ewing sarcoma is the third most common bone sarcoma after osteosarcoma and chondrosarcoma.² In patients 5–30 years old (the peak ages for Ewing), Ewing is second only to osteosarcoma. Thought to be derived from primitive mesenchymal cells, Ewing sarcoma is a poorly differentiated malignant small round blue cell tumor closely related to other tumors within the Ewing family of tumors.⁸⁵ The Ewing family of tumors includes Ewing sarcoma, primitive neuroectodermal tumor (PNET), and Askin's tumor, all of which have translocations involving the EWS gene on chromosome 22. The most common locations are the femur and pelvis, but vertebral body and rib involvement is also relatively common. Presenting symptoms usually include both pain and swelling, but in approximately 20%, the symptoms may be accompanied by fever and malaise. In 10%, pathologic fractures are present at diagnosis. Increased ESR is common, and some patients may also have anemia and leukocytosis.

Radiographically, Ewing sarcoma has a varied presentation depending upon the location. Within the long bones, it has a predilection of diaphyseal involvement, and onion-skinning periosteal reaction (numerous layers of reactive new bone a few millimeters apart formed as the periosteum is lifted off by the expanding tumor and repetitively forms reactive bone) is frequent, accompanied by permeative poorly defined borders, cortical destruction, and usually an associated soft-tissue mass. The radiographic pattern is almost always lytic. Under the microscope, Ewing sarcoma is a prototypical small round blue cell tumor and is difficult to distinguish from other such entities (such as lymphoma and metastatic neuroblastoma) without special studies. Immunohistochemistry is positive for CD-99 (the MIC2 protein) in 95% of cases. The most definitive test is demonstration of the t(11;22)(q24;q12) or similar translocation (t(21;22)) by fluorescent *in situ* hybridization (FISH). Resulting fusion proteins that result from these translocations are EWS-FLI1 and EWS-ERG.

Table 8 Osteosarcoma variants according to grade

Low grade	Intermediate grade	High grade
Low-grade intramedullary	Periosteal	Conventional
Parosteal		High-grade surface
		Secondary
		Pagetoid
		Postradiation
		Small cell

Treatment of Ewing sarcoma involves neoadjuvant multiagent chemotherapy for systemic disease and

either wide surgical resection or irradiation for local disease.⁸⁵ Active chemotherapeutic agents in Ewing sarcoma include adriamycin, vincristine, cytoxan (cyclophosphamide), and actinomycin D. It has been the chemotherapy that has led to the greatest improvement in survival. The latest trend is for increased surgical resection in sites that previously would have received radiotherapy, but historically Ewing sarcoma has been considered a radiosensitive tumor. Radiotherapy is still utilized for unresectable central locations (some pelvic tumors, sacrum, spine, cranium), for metastatic disease, and as a surgical adjuvant if margins of resection are close or microscopically positive. Surgical resection has evolved from being used initially only for expendable bones (iliac wing, rib, fibula, proximal radius, distal ulna) to now being used more frequently for most reconstructable anatomic sites (femur, tibia, humerus). The pelvis remains a controversial site for local treatment of Ewing sarcoma, where surgery has been used with increasing frequency and acceptable results.⁸⁶ However, there have been no randomized studies comparing radiotherapy to surgical resection in Ewing patients, and retrospective studies suffer from selection bias, as radiotherapy has traditionally been used for the worst centrally located tumors. Currently, some trials have suggested that the prognosis is as good as 65–70% 5-year survival, but based on minimum 5-year follow-up for 3225 Ewing sarcomas collected in the National Cancer Database, 5-year survival was only 50.6% for Ewing sarcoma.²

Osteosarcoma

The most common bone sarcoma, osteosarcoma comprises a somewhat heterogeneous group of sarcomas that are predominately high grade but with three low- to intermediate-grade variants ([Table 8](#)). The common thread is that they are felt to be derived from the osteoblast cell line and are bone-forming sarcomas.^{87, 88} Ninety percent of osteosarcomas are conventional high grade. Classically, the age distribution has been described as bimodal, but the peak age is during the second and third decades of life; cases in older adults usually occur in the setting of Paget's disease (Pagetoid osteosarcoma) or following irradiation (postradiation osteosarcoma). Clinical presentation almost always involves progressively worsening pain and sometimes associated swelling. The most common locations reflect the most active areas of growth in skeletally immature patients—the distal femur followed by the proximal tibia and proximal humerus. Overall, there is a 1.5 : 1 male to female ratio.

Radiographically, osteosarcomas in general are bone-forming, relatively poorly defined metaphyseal tumors that frequently have associated soft-tissue extension accompanied by cumulus cloud-type bone formation ([Figure 9](#)). Some histologic subtypes, especially the fibroblastic and telangiectatic osteosarcomas, form radiolucent tumors without the classic bone formation. Telangiectatic osteosarcoma, due to its blood-filled lakes, can closely resemble a benign ABC on imaging studies, so this tumor should always be considered in the differential diagnosis of an apparent ABC. On MRI, the typical osteosarcoma is dark on T1W and bright but heterogeneous on T2W sequences, usually shows soft-tissue extension, and may show skip lesions within the medullary canal. They show increased uptake on bone scan. Under the microscope, there is some variation, particularly between the low- and high-grade variants, but the key element is malignant osteoid production. The most common histologic subtype is osteoblastic, followed by chondroblastic, fibroblastic, and—rarely—telangiectatic.

Figure 9 Conventional osteosarcoma. A 13-year-old girl with right shoulder pain and swelling has shoulder radiographs (a, b) showing a radiodense proximal humeral metaphyseal lesion with permeative borders and Codman triangle periosteal reaction and soft-tissue extension. Coronal T1-weighted (c) and T2-weighted (d) MRI images show the soft-tissue extension and extent of the tumor within the medullary canal. Bone scan (e) shows increased uptake in the proximal humerus. In a young patient, these features are nearly diagnostic of osteosarcoma, and a biopsy confirmed the diagnosis of high-grade osteosarcoma. After neoadjuvant chemotherapy, the patient underwent wide resection and proximal humeral allograft–prosthetic reconstruction (f).

Treatment depends upon grade and extent of the tumor. For all high-grade variants, neoadjuvant multidrug chemotherapy is key, and this involves adriamycin, ifosfamide, cisplatin, and methotrexate.⁸⁹ The advantage of neoadjuvant chemotherapy is that it allows determination of percent tumor necrosis after resection and often reduces the size of the soft-tissue extension of the tumor, facilitating surgical resection. Tumor necrosis >95% is strongly predictive of disease-free and overall survival. Drug resistance is sometimes seen due to the P-glycoprotein membrane-bound pump (coded for by the MDR-1 gene), which pumps the chemotherapeutic agents out of the cell. Local disease is addressed by wide surgical resection. There is no role for radiotherapy in standard treatment of osteosarcoma. For low-grade central and parosteal osteosarcoma (the low-grade variants), treatment only involves wide surgical resection; neither chemotherapy nor radiotherapy plays a role.

Features unique to the various clinicopathologic subtypes will be presented later.

Conventional osteosarcoma

As the classic osteosarcoma, conventional high-grade osteosarcoma has the typical radiographic appearance of a metaphyseal tumor most common in the distal femur, proximal tibia, and proximal humerus. It usually demonstrates a cloud-like bone formation with permeative borders on plain radiographs and often has cortical breakthrough with an associated soft-tissue extension bordered by Codman's triangles (reactive bone formed by the bordering periosteum as it is lifted away from the bone surface by the expanding tumor) ([Figure 9](#)).

Histologically, osteosarcoma is comprised of pleomorphic cells with frequent mitoses forming lacelike pink osteoid. Conventional osteosarcoma may show a predominance of bone formation (osteoblastic), chondroid matrix (chondroblastic), fibrous background (fibroblastic), or blood-filled pools (telangiectatic). Differentiation of chondroblastic osteosarcoma from chondrosarcoma and fibroblastic osteosarcoma from fibrosarcoma is based upon the presence of malignant osteoid.

Prognosis for osteosarcoma has improved considerably over the years due primarily to the use of multiagent chemotherapy. Clinical trials involving patients with nonmetastatic disease report actuarial 5-year survival rates of 75–80%. For all comers, including all ages and those with metastatic disease, data from the National Cancer Database of the American College of Surgeons suggests a less optimistic outlook.² Based upon 8104 osteosarcomas cases with a minimum 5-year follow-up from 1985 to 1998, the relative 5-year survival rate for high grade was 52.6%. For osteosarcoma patients younger than 30 years, the relative 5-year survival rate was 60%; for those aged 30 to 49 years, it was 50% and for those aged 50 years or older it was 30%. For the approximately 20% of patients with osteosarcoma that present with metastases, aggressive treatment leads to 5-year survival in 30–40%, but for patients who develop metastases after treatment, 5-year survival is only 15–20%.

High-grade surface

Although the other two surface osteosarcomas (parosteal and periosteal) are low or intermediate grade, this surface variant is defined by its more aggressive radiographic and histologic appearance and clinical behavior. Otherwise, the clinical presentation, demographic features, pathology, and treatment are identical to those of conventional high-grade osteosarcoma.

Low-grade intramedullary

Along with parosteal osteosarcoma, low-grade central intramedullary osteosarcoma is the only other low-grade osteosarcoma. In contrast to the two other low- to intermediate-grade osteosarcomas (parosteal and periosteal, respectively), this one is not a surface tumor; conversely, this is the only intramedullary low-grade osteosarcoma. A rare tumor, it represents only 1–2% of all osteosarcomas. Clinical presentation usually involves pain. The typical patient is slightly older than classic osteosarcoma, often being in the third decade of life.

Radiographically, the well-demarcated radiodensity that characterizes low-grade intramedullary osteosarcoma is often confused with fibrous dysplasia ([Figure 10](#)). Under the microscope, the appearance is distinctly different from high-grade conventional osteosarcoma. Like parosteal osteosarcoma, low-grade central osteosarcoma is comprised of broad bands of osteoid separated by a hypocellular fibroblastic stroma with minimal atypia and rare mitoses.

Figure 10 Low-grade central osteosarcoma. This 26-year-old woman was diagnosed with low-grade central osteosarcoma after a prolonged course with pain and swelling over several years. Plain anteroposterior (a) and lateral (b) radiographs show a sclerotic predominately intramedullary lesion of the distal femoral metaphysis. Biopsy showed streaming osteoid separated by a relatively bland fibrous background. Following wide surgical resection, the distal femur was reconstructed with a distal femoral replacement total knee arthroplasty (c).

As for both of the low-grade osteosarcomas, low-grade intramedullary osteosarcoma is treated by wide surgical resection alone without chemotherapy or radiotherapy. Overall prognosis is quite good, with local recurrences in only approximately 5% following appropriate surgery and a 90% 5-year survival rate which drops slightly to 85% at 10 years. In rare cases, dedifferentiation may occur by way of an adjacent high-grade sarcomatous component.

Parosteal

The low-grade surface osteosarcoma, parosteal osteosarcoma is a distinct clinical, radiographic, and pathologic entity that accounts for 5% of osteosarcomas. Similar to its intramedullary counterpart, the peak age is in the third decade of life. Females are affected more commonly than males (M : F 1 : 2). Parosteal osteosarcoma has a strong predilection for the posterior aspect of the distal femur (80% of cases); the proximal tibia and proximal humerus are other relatively common locations. It usually presents as a painless posterior distal thigh mass that may decrease knee range of motion.

Radiographically, parosteal osteosarcoma usually shows a lobulated, fairly densely ossified mass that has the appearance of being “stuck on” the underlying bony cortex. In unusual cases, the tumor may encircle the bone, and the underlying cortex may show reactive changes. Under the microscope, parosteal osteosarcoma looks like low-grade central osteosarcoma, with a sparsely cellular fibroblastic stroma between broad bands of osteoid.

Treatment for parosteal osteosarcoma involves wide surgical resection alone; there is no established role for chemotherapy or radiotherapy. In rare instances, dedifferentiated areas may arise. Overall prognosis is 86% 5-year survival.²

Periosteal

Another surface tumor, periosteal osteosarcoma accounts for only 1–2% of osteosarcomas. Clinical presentation and peak age are the same as for conventional osteosarcoma, but it has a predilection for the tibial diaphysis and the femoral diaphysis. Radiographically, in addition to its diaphyseal surface predilection, periosteal osteosarcoma is characterized by mineralization, which may present as a sunburst periosteal reaction or patchy calcification reflecting its often chondroblastic histology. Under the microscope, periosteal osteosarcoma is similar to conventional osteosarcoma except for being intermediate grade and usually having a chondroblastic pattern. Treatment usually employs conventional neoadjuvant chemotherapy followed by wide surgical resection. Prognosis is intermediate between parosteal and conventional osteosarcoma.

Secondary

Secondary osteosarcomas have a peak age in older patients, have the worst prognosis of all osteosarcomas, and arise within the setting of a predisposing condition, either Paget's disease of bone or previous irradiation. Osteosarcoma arising as the high-grade component of a dedifferentiated chondrosarcoma is discussed in the chondrosarcoma section.

Pagetoid

Sarcomatous degeneration within Paget's disease occurs in a small percentage (1–15%) of patients with this metabolic bone condition characterized by rapid bone turnover. Peak age is in 55–85 years old. Clinical presentation is usually heralded by a change in the patient's baseline pain and/or a new soft-tissue mass or swelling. Due to the prevalence of Paget's disease in flat bones, Paget's osteosarcoma has a predilection for the scapula, pelvis, and ribs. Radiographic presentation is usually of an aggressive osteoblastic or osteolytic area arising within Pagetoid bone. Treatment involves chemotherapy—if the patient can tolerate it—and wide surgical resection. The benefits of chemotherapy in this group remain unproven. Prognosis is poor, with 5–18% 5-year survival.²

Postradiation

The criteria for defining postradiation sarcoma are that the sarcoma arises within a previously irradiated area without a preexisting sarcoma of the same histologic type and that a latent period of at least 3–4 years has elapsed since the initial radiotherapy and the development of the sarcoma. Postradiation osteosarcoma arises within previously irradiated bone and represents 70% of postradiation bone sarcomas. Other pathologies include malignant fibrous histiocytoma and fibrosarcoma. Clinical presentation is that of swelling and pain arising within the previously irradiated region. Radiographically, postradiation sarcomas of bone appear as an aggressive lesion within the previously irradiated field. Under the microscope, they may show the histology of high-grade conventional osteosarcoma, malignant fibrous histiocytoma, or fibrosarcoma. Treatment is by surgical resection and adjuvant chemotherapy when the patient can tolerate it, although the benefits of chemotherapy in this group are unproven.⁹⁰ Prognosis is extremely poor, ranging from 5% to 30% 5-year survival.

Small cell

Other than their histologic appearance, small cell osteosarcomas resemble high-grade conventional osteosarcomas. Under the microscope, the only feature that distinguishes this tumor—comprised predominately of small round blue cells with indistinct cytoplasm—from Ewing sarcoma is the presence of osteoid, which is sometimes difficult to identify on biopsy. Treatment and prognosis are as for conventional osteosarcoma.

Vascular sarcomas

There are two major subtypes of vascular sarcomas in the current WHO classification which may involve bone: epithelioid hemangioendothelioma and angiosarcoma.^{91–93} Hemangiopericytoma, which has previously been included in this category, has been reclassified as a solid fibrous tumor in the latest WHO schema.⁹⁴ These tumors represent a spectrum of disease, with hemangioendothelioma at the less aggressive end of the spectrum and angiosarcoma at the aggressive end. These are rare tumors, as a group representing less than 1% of bone sarcomas. Clinically, they have a broad age range but are most common in middle-aged and older adults. As with most bone sarcomas, presenting symptoms include pain and swelling. Rarely, pathologic fracture may occur, more commonly with angiosarcoma. One-third of patients with vascular sarcomas will have multifocal disease, either “skipping joints” in a single limb or involving disseminated sites throughout the body. Any bone may be affected, but long bones predominate.

Radiographically, these tumors are typically lytic and destructive, but a combination of osteolysis and sclerosis may be seen. Soft-tissue extension is not usually seen in these tumors. Under the microscope, each tumor has a characteristic appearance with some evidence of rudimentary vascular channels. Treatment of vascular sarcomas may involve wide surgical resection or radiotherapy. Epithelioid hemangioendothelioma is a particularly radiosensitive tumor and may be treated primarily with radiotherapy. The role of chemotherapy for this group of tumors is not well established. For extensive or multifocal disease, radiotherapy has efficacy.

Metastatic disease to bone

The most common malignancy to affect bone is metastatic carcinoma. It is far more common than bone sarcoma or myeloma. The most common “osteophilic” primary tumors to affect bone arise from primaries of the breast, prostate, lung, kidney, and thyroid. Patients with breast and prostate cancer have usually had their primary cancer treated and then develop delayed metastatic disease to bone. Patients with metastatic lung carcinoma more commonly present with metastatic bone disease as the presenting symptom of their

lung cancer. Patients with kidney and thyroid cancer may present with either concurrent or delayed metastatic disease. For a primary carcinoma metastatic to bone in a patient with no history of cancer, the most common sources are lung and kidney primaries. Metastatic carcinoma to bone most commonly involves patients older than 40 years. In patients less than 5, metastatic neuroblastoma predominates, and in older pediatric patients, rhabdomyosarcoma is the most common primary source. Presenting symptoms may involve pain, swelling, or pathologic fracture, but in some cases, the bone lesions are asymptomatic and are discovered on routine staging studies. In the spine, neurologic symptoms and even paraplegia may be seen. The most common sites are the spine, proximal femur, pelvis, ribs, sternum, proximal humerus, and skull. Metastases distal to the elbow and knee are unusual, and when they are present, the most common source is lung carcinoma.

Evaluation of bone lesions suspected of being due to metastatic disease involves a comprehensive physical examination, laboratory parameters, and a radiographic evaluation of common sites of primary disease. Since myeloma is often in the differential diagnosis of metastatic carcinoma in adults, serum and urine protein electrophoresis is often requested. Lactate dehydrogenase may be elevated in lymphoma, although it is nonspecific. Prostate-specific antigen is usually elevated in prostate cancer. Renal cell carcinoma may cause hematuria. Standard radiographs of any involved bone, a total skeleton bone scan, and CTs of the chest, abdomen, and pelvis comprise the classic radiographic evaluation. Increasingly, PET-CTs are being utilized in this setting.

Radiographically, metastatic carcinoma may have a myriad of appearances. Some tumors, such as prostate metastases, are typically osteoblastic. Breast cancer metastases usually show a combination of osteolysis and sclerosis. Metastases from lung, kidney, and thyroid cancer are usually purely osteolytic. Bone scans usually show increased uptake at multiple sites, but solitary metastatic lesions are not uncommon, and certain very aggressive bone metastases, such as those from renal or thyroid carcinoma, may not show increased uptake. Pathology often falls into a general descriptive category, such as adenocarcinoma, squamous cell carcinoma, or poorly differentiated carcinoma. In these cases, immunohistochemistry markers are of greater importance in identifying the source ([Table 9](#)). Some tumors have specific histopathology patterns, such as clear cell carcinoma of the kidney, well-differentiated follicular carcinoma of the thyroid, and metastatic pigmented malignant melanoma of the skin.

Table 9 Examples of immunohistochemistry markers for evaluation of metastatic disease to bone

Immunohistochemistry marker	Primary tumor source
Prostate-specific antigen (PSA)	Prostate carcinoma
Thyroid transcription factor (TTF-1)	Lung carcinoma
Leukocyte common antigen (LCA)	Lymphoma

Table 10 Common primary tumors metastatic to bone: Frequency of bone involvement and survival after metastases

Primary tumor	Percentage of patients that develop metastatic disease	Fraction of patients with mets who have bone involvement clinically (%)	Median survival after diagnosis of mets (months)	Mean 5-year survival (%)
Breast carcinoma	65–75	—	24	20
Prostate carcinoma	65–75	30–40	40	25
Lung carcinoma	30–40	20–40	<6	<5
Renal carcinoma	20–25	15–25	6	10
Thyroid carcinoma	60	20–40	48	40

Treatment of metastases can be viewed as systemic and local. Systemic treatment is directed both at the primary tumor (discussed in other chapters throughout the text) and at the mediator of bone destruction, the osteoclast. Bisphosphonates have become widely accepted in the setting of metastatic bone disease to inhibit the osteoclastic bone destruction. Operative management of metastatic carcinoma, myeloma, and lymphoma has been discussed in a previous section. Once bone metastases are diagnosed, prognosis is poor, but survival varies according to the underlying primary tumor ([Table 10](#)).

Myeloma

Myeloma represents the most common primary bone malignancy. As it is covered elsewhere in this text, only the details related to bone will be presented here. Myeloma predominately affects adults aged 50 to 80 and has a propensity to affect blacks greater than Caucasians by a ratio of 2 : 1. Clinical presentation may involve pain, pathologic bone fracture, bone marrow failure (manifesting as fatigue and weakness from anemia, bruising and bleeding from thrombocytopenia, recurrent infections from neutropenia), renal failure, or hypercalcemia. A solitary plasmacytoma in the bone does not clinch the diagnosis of myeloma. Diagnostic criteria for myeloma include at least 10% plasma cells in the bone marrow, monoclonal protein in the serum (monoclonal gammopathy on serum protein electrophoresis) or urine (Bence-Jones proteins on urine protein electrophoresis), and end-organ failure (hypercalcemia, renal insufficiency, anemia, or bone lesions).

Radiographic manifestations of myeloma include single or multiple “punched-out” small lytic lesions sometimes coalescing into much larger lesions. Since 80% of myeloma bone lesions do not show increased uptake on bone scan, a skeletal survey should be considered to search for other lesions during the initial evaluation. Under the microscope, myeloma is comprised of sheets of plasma cells with large round, clockface, eccentric nuclei and perinuclear clearing.

Bone lesions from myeloma are very sensitive to radiotherapy, but for large lesions or those with pathologic fracture, surgical fixation is warranted. For surgical management of myeloma bone manifestations, please refer to the earlier section.

Bone lymphoma

Primary lymphoma of bone was first described as “reticulum cell sarcoma” and is comprised of malignant lymphoid infiltrate within bone in the absence of concurrent lymph node or visceral involvement. Just about any age may be affected, and the most common locations are the femur, ilium, and ribs. Clinical presentation may include pain, an associated soft-tissue mass, or pathologic fracture. Unlike diffuse lymphoma, these patients rarely have systemic symptoms.

Radiographically, lymphoma may be diaphyseal or metaphyseal and typically has a permeative, poorly defined border on plain films. Many cases are osteolytic, but in some cases a sclerotic appearance may simulate osteosarcoma. Under the microscope, primary lymphoma of bone is a small round blue cell tumor which requires immunohistochemistry in order to distinguish it from Ewing sarcoma. Ninety percent of primary bone lymphomas are large B-cell type. Immunohistochemical markers for B cells include CD19 and CD20.

Treatment of primary bone lymphoma requires a multidisciplinary approach. Chemotherapy is the primary treatment modality, with surgery reserved for biopsy, fracture fixation, and prophylactic fixation of impending fractures. Chemotherapy often involves cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) and rituximab (monoclonal antibody against CD20). Although local radiotherapy is often employed in addition to chemotherapy, recent reports are beginning to question its benefits to overall survival, particularly in light of its adverse effects on bone fragility and fracture healing.

Congenital syndromes

A number of congenital syndromes either involve bone lesions, predispose to development of bone malignancies, or both. Some of these syndromes are covered in this section.

Enchondromatosis

Enchondromatosis may involve simply multiple enchondromas (Ollier's disease) or the combination of multiple enchondromas with multiple soft-tissue hemangiomas (Maffucci's syndrome). Both syndromes occur sporadically. Neither has a known cause. They are uncommon and are typically diagnosed in childhood. Radiographically, the enchondromas individually are not different than those of solitary disease. The most important distinguishing feature of these two syndromes is the risk of developing malignancy.

Ollier's disease

Multiple enchondromatosis carries up to a 20–30% risk of developing one or more chondrosarcomas. Hence, these patients should be followed on an annual basis for surveillance. The most common locations for chondrosarcomas in Ollier's disease are the pelvis, proximal femur, and proximal humerus.

Maffucci's syndrome

Patients with Maffucci's syndrome are also at risk of developing chondrosarcomas, but they are at increased risk of developing numerous other types of malignancies as well. In fact, the risk of malignancy in Maffucci's patients approaches 100%. Common primaries include acute lymphocytic leukemia, astrocytoma, and gastrointestinal malignancies. Vigilant surveillance is essential for early diagnosis of these tumors.

Familial adenomatous polyposis

The early onset of multiple colorectal polyps characterizes this autosomal dominant condition caused by a mutation in the adenomatous polyposis coli (APC) gene. The only bone lesion associated with familial adenomatous polyposis (and the related Gardner syndrome) is osteoma. These lesions do not require specific treatment, nor do they predispose to bone malignancy. The only malignancy associated with this familial adenomatous polyposis is colon cancer.

Polyostotic fibrous dysplasia, McCune–Albright syndrome, and Mazabraud's syndrome

While most fibrous dysplasia lesions occur in a single location (monostotic), some involve multiple bones (polyostotic fibrous dysplasia). In addition, polyostotic fibrous dysplasia may be accompanied in 30–50% of cases by distinctive pigmented cutaneous markings with a “coast-of-Maine” irregular border, precocious puberty, or endocrinopathies, a syndrome named McCune–Albright (or Albright's syndrome). Rarely, fibrous dysplasia may occur in the setting of soft-tissue myxomas (Mazabraud's syndrome). The common etiologic thread for these conditions is the presence of activating mutations of the GNAS1 gene. Usually these patients are diagnosed in childhood or adolescence either with manifestations of their underlying bone disease (pain, limp, swelling, angular deformity, limb length discrepancy, or craniofacial abnormalities), the characteristic skin lesions, precocious puberty, or one of numerous endocrinopathies (hyperparathyroidism, hyperthyroidism, Cushing's syndrome, acromegaly, diabetes, rickets, osteomalacia, hyperprolactinemia).

Radiographically and histologically, the individual fibrous dysplasia lesions are the same as those described previously for solitary fibrous dysplasia. Treatment should address any associated condition (particularly the endocrinopathy) as well as the bone manifestations. Since polyostotic fibrous dysplasia is more often associated with progressive deformity, particularly in the proximal femur, more aggressive prophylactic treatment—including both surgical intervention and bisphosphonate therapy—should be considered. Malignancy in these conditions is rare and usually preceded by radiotherapy.

Multiple osteochondromatosis

An autosomal dominant condition attributable to mutation of either the EXT1 or EXT2 gene, multiple osteochondromatosis (multiple hereditary exostoses) is rare compared to the solitary occurrence of osteochondromas, the most common benign bone tumors. The condition is usually diagnosed in early childhood between ages 2 and 10. Typical manifestations include “knobby” protuberances near joints, short stature, shortened limbs, coxa valga, genu valgum, radial head dislocation, and pain. Radiologic features consist of multiple osteochondromas, each of which has the characteristic features of a solitary osteochondroma. As for solitary osteochondromas, excision is only recommended for symptomatic tumors. Risk of malignant degeneration has been estimated at between 3% and 10% and typically involves a low-grade chondrosarcoma ([Figure 11](#)).

Figure 11 Secondary chondrosarcoma in osteochondromatosis. A 23-year-old woman with known multiple hereditary exostoses developed pelvic pain. Radiographs were not revealing, but MRI images (a–c) revealed a mass arising from a small osteochondroma on the inner table of the pelvis beginning at the level of the sacroiliac joint and extending to the sciatic notch. Biopsy confirmed low-grade chondrosarcoma. The patient underwent internal hemipelvectomy without reconstruction (d). The pelvis is a common location for development of chondrosarcomas in osteochondromatosis, and regular screening in these patients is advisable.

Retinoblastoma syndrome

Patients with a germline mutation of the RB1 gene are predisposed to develop not only retinoblastoma but also—via a “second-hit” somatic mutation—other malignancies, the most common of which is osteosarcoma. Hence, this syndrome has also been referred to as “retinoblastoma/osteogenic sarcoma syndrome.” Patients with retinoblastoma are usually diagnosed before age 3, and the potential for osteosarcoma peaks in the adolescent age range. Radiographic presentation, histology, and treatment of the osteosarcoma are the same as for conventional high-grade osteosarcoma, discussed previously.

Rothmund–Thomson syndrome

This rare syndrome is important in the context of bone tumors because of its predisposition for development of osteosarcoma. An autosomal recessive genetically transmitted syndrome attributable to mutation in the RECQL4 helicase gene on chromosome 8, Rothmund–Thomson syndrome is usually diagnosed within the first 6 months of life based on a characteristic sun-sensitive erythematous rash that eventually leaves a hyper- and hypopigmented poikiloderma. Genetic testing confirms the disorder in a

substantial number of cases, but related conditions such as Werner syndrome and Bloom syndrome should be excluded. Other orthopedic-associated manifestations include osteoporosis, clavicular hypoplasia, syndactyly, patellar aplasia, genu valgum, and benign osseous lesions. There is no specific treatment for Rothmund–Thomson syndrome. High vigilance should be maintained to diagnosis of musculoskeletal malignancies such as osteosarcoma.

Werner syndrome

A syndrome related to Rothmund–Thomson syndrome by gene homology and clinical overlap, Werner syndrome (adult progeria) is another autosomal recessive disorder and is caused by mutation in the WRN gene on chromosome 8. The resultant RecQ helicase deficiency predisposes to development of a wide variety of malignancies, including osteosarcoma, although soft-tissue sarcomas, thyroid cancer, and melanomas are much more common. Diagnosis is not usually made until adulthood due to manifestations of premature aging (scleroderma, premature graying and alopecia, nonsenile cataracts, calcific valvular deposits, atherosclerosis, diabetes, and hypogonadism) confirmed by genetic testing and elevation of urinary hyaluronic acid level. Orthopedic-associated conditions include osteoporosis, muscle wasting, calcific deposits, and pes planus. For patients with an established diagnosis of Werner syndrome, vigilance should be maintained for the early diagnosis of malignancy.

Chapter 112

Soft tissue sarcomas

Robert G. Maki, MD, PhD, FACP ■ Chandrajit P. Raut, MD, MSc, FACS ■ Brian O'Sullivan, MD, FRCPI, FRCPC

Overview

The management of soft tissue sarcomas is driven by the anatomic site and histology of the primary and is increasingly affected by the specific genetics of the sarcoma. In this chapter, we focus on the principles of management of this group of over 50 cancer subtypes to highlight commonalities and differences from anatomical constraints of surgery to specifics of adjuvant radiation to identification of systemic therapeutics that are appropriate for each histology.

We will discuss in this chapter the etiology, presentation, diagnosis, staging, and multidisciplinary management of patients with sarcomas of soft tissue. Surgery remains paramount to achieve cure for the vast majority of sarcomas. Radiation therapy is used for larger tumors in the appropriate clinical context. The evolution of increasingly sophisticated radiation techniques is highlighted in this chapter. As pertains to systemic therapy, this chapter is written at a time in which first-line therapies for soft tissue sarcomas may change, raising anew some questions of adjuvant therapy that remain incompletely answered. Where appropriate, we attempt to link specific histologies or molecular changes to therapeutic suggestions, with the understanding and hope that novel agents will supplant the medications that are available but that have not materially affected outcomes for few diagnoses other than GIST in the past several years.

Sarcomas of nonosseous tissues, known traditionally as soft tissue sarcomas (STS), comprise a group of rare malignancies that exhibit tremendous diversity of anatomic site, specific genetic alterations, and histopathologic characteristics. These tumors share a common embryologic origin, arising primarily from mesodermal tissues. The notable exceptions are sarcomas of the neural tissues [such as malignant peripheral nerve sheath tumors (MPNST)] and possibly the Ewing sarcoma/primitive neuroectodermal tumor (PNET) family of tumors, which are believed to arise from ectoderm and angiosarcomas, which are derived from endoderm. Despite the fact that the somatic nonosseous tissues account for as much as 75% of total body weight, primary neoplasms of these connective tissues are comparatively rare, accounting for <1% of adult malignancies and 15% of pediatric malignancies. About 12,000 people receive a diagnosis of STS in the United States each year, with approximately 5000 deaths annually.¹ An understanding of these cancers is important because patients' outcomes will be compromised if initial management is not thoughtful. Furthermore, biologic insights about sarcomas are providing new strategies for the detection, treatment, and prevention of more common malignancies.

This chapter reviews current concepts in the diagnosis, staging, and multidisciplinary management of patients with sarcomas of nonosseous tissues. The evolving contributions of molecular biology and basic scientific principles underlying the varied differentiation and clinical behavior of these tumors will also be reviewed. Although histopathologic aspects of sarcomas are increasingly important in categorizing these tumors, the anatomic site of primary disease remains an important variable on which treatment and outcome may depend. Extremity sarcomas account for approximately 50% of all sarcomas and are the

primary focus of the therapy sections of this chapter. Special topics such as retroperitoneal sarcomas (RPS), gastrointestinal stromal tumors (GISTs), and dermatofibrosarcoma protuberans (DFSPs) are addressed separately later in this chapter. Sarcomas at other anatomic sites are not discussed because of their rarity. Throughout the chapter, the emphasis is on identifying what is known from definitive data and what requires additional research.

Etiology

Most sarcomas are believed to arise spontaneously, as may be increasingly understood for many cancers in general.² The conceptual frameworks that address the neoplastic transformation of mesenchymal stem cells are in rapid evolution owing to new insights from the molecular analysis of sarcomatous and normal tissues from STS patients and family members. Genetics and environmental factors appear to play a role in the neoplastic transformation of soft tissues into sarcomas.³

It has been recognized for more than 30 years that sarcomas can arise in persons with certain genetic predispositions to cancer development. One of the earliest observations of familial cancer development (i.e., genetically transmitted predisposition to malignancy) was the development of sarcoma and other tumor types (such as breast cancer) in certain families.⁴ This autosomal dominant genetic predisposition has now become known as the Li–Fraumeni syndrome, and it has been characterized at the molecular level as a germline mutation of the *TP53* gene, which presumably acts in this context as a faulty tumor suppressor.^{5, 6}

Other genetic disorders are also associated with an increased risk of developing specific sarcomas. The best-studied example of this is the predilection of patients with neurofibromatoses to develop (MPNSTs, also referred to as neurofibrosarcomas or malignant schwannomas).^{7, 8} Type 1 neurofibromatosis (von Recklinghausen disease) is an autosomal dominant disease that can disrupt the function of the *NF1* gene, located on chromosome 17q11.2. The endogenous function of the *NF1* gene product, neurofibromin, remains incompletely understood, but it appears to act as a tumor suppressor via stimulation of guanosine triphosphatase activity. Common mutations in *NF1* include truncations, with loss of function leading to uncontrolled signaling through *ras* pathways, which impact on therapeutic options.^{9, 10} *NF1* loss appears to be a fundamental process that facilitates the development of MPNSTs over time in patients with neurofibromatosis. Patients with type 1 neurofibromatosis have up to a 10% cumulative lifetime risk of developing sarcoma (usually MPNST); it is unclear why the risk is not greater, given the protean effects of *ras* activation; other factors such as inactivation of epigenetic regulators in the PRC2 complex may contribute to the neoplastic phenotype.^{11–13}

Survivors of childhood retinoblastoma have also been noted to have an increased risk of sarcoma development later in life.^{14, 15} These data provide another model of a dysfunctional or deleted tumor suppressor genetic element (in this case, the product of the *Rb* gene on chromosome 13q14). The risk of STS in retinoblastoma patients and their families is accompanied by the risk of developing several other types of neoplasms, including osteosarcomas, breast cancer, and lung cancer. No reasons have been convincingly posited for the development of one type of malignancy over another in patients with *Rb* mutations, and this remains an important question to be addressed by future research on mechanisms of neoplastic transformation.

Gardner syndrome represents an important genetic connection between dysfunctional regulation of epithelial and mesenchymal cells. Gardner syndrome represents a subset of familial adenomatous polyposis disorders of the bowel (usually the colon); patients with the syndrome also have extracolonic

abnormalities such as epidermoid cysts and osteomas. The molecular lesion has been identified as a defect within the *APC* (adenomatous polyposis coli) gene on chromosome 5q21. Patients with Gardner syndrome are at much increased risk of developing mesenteric and intraperitoneal desmoid tumors.^{16, 17} Desmoid tumors are mesenchymal cells proliferating in a pattern of aggressive fibromatosis, characterized by bland cells that—although histologically benign—act in a malignant manner with uncontrolled proliferation and infiltration of vital structures; spontaneous desmoid tumors more commonly demonstrate the β -catenin gene, *CTNNB1*, which is in the same signaling pathway as APC.^{18, 19} It remains poorly understood why some patients with Gardner syndrome develop desmoid tumors whereas others do not, and the lifetime risk of developing desmoid tumors has been estimated at approximately 10–20%, representing a nearly 1000 times greater risk than that of the general population.

Certain environmental exposures have also been associated with the development of sarcomas. One of the most important is ionizing radiation. Radiation-associated sarcoma is most often a late effect of radiotherapy (RT) given to treat another condition (often a prior malignancy). Sarcomas have been noted as a late effect of RT for breast cancer, Hodgkin lymphoma, non-Hodgkin lymphomas, and other tumor types.²⁰ The radiation dose appears to be correlated with the later development of sarcoma, with a very low risk in patients who received <10 Gy. The molecular mechanisms may be complex, as it has been noted clinically that sarcomas appear at the margins of prior RT fields. This suggests that the mutagenic effect may be maximal at the edges of prior RT where scatter radiation leads to a dose sufficient to induce mutations but insufficient to kill the mutated cells. Traditionally, radiation-associated sarcomas were thought to arise with a median of ~9 years following RT, although RT-associated sarcomas are observed earlier in some patients. MPNSTs, angiosarcomas, osteosarcomas, and undifferentiated pleomorphic sarcomas (UPS) comprise the majority of radiation-associated sarcomas. Clinical outcomes are worse in patients with radiation-associated sarcomas compared to histology-matched controls. Radiation-associated sarcomas should be approached as new primary disease and treated appropriately to optimize the patient's outcomes.

Certain chemical exposures have also been weakly linked to sarcomagenesis, although chemical-induced development of sarcomas in animal models is one of the more reliable models of studying neoplastic transformation in the laboratory. Hepatic angiosarcomas are associated with exposure to several classes of chemicals, such as polyvinyl chloride and arsenic compounds.²¹ The relationship between exposure and development of sarcoma is more tenuous for other compounds, including dioxins (such as Agent Orange and other phenoxyacetic acid-based herbicides) and chlorophenols used in wood preservatives.²²

Chronic irritation or inflammation of tissues is a controversial potential cause of sarcomas. Certainly, there is an increased sarcoma risk in the lymphedematous arms of women who have undergone radical mastectomy (the Stewart–Treves syndrome), often with the additional complicating variable of prior RT.^{23, 24} Limited data, typically case reports only, suggest that other sources of chronic tissue irritation and inflammation might be associated with sarcomagenesis.²⁵ Although a history of trauma is not infrequently elicited from patients with STSs, the impact of such trauma on sarcoma development is dubious.

Severe and chronic immunosuppression following solid organ transplantation represents yet another risk factor for the development of sarcomas. Sarcomas represent a disproportionate percentage of tumors (10%) in patients following solid organ transplantation, with Kaposi sarcoma comprising the majority of these.^{26, 27}

Screening

Given the rarity of sarcomas in the general population, no general screening is indicated beyond routine health care surveillance. However, it is important for physicians to be aware of the predisposing genetic tendencies and environmental exposures that might increase patients' risk of sarcoma development. A complete family history should reveal clues about genetic predispositions, including a family history of polyposis, neurofibromatosis, retinoblastoma, any cancer at a young age in first-degree relatives, or sarcomas. Genetic counseling is appropriate to discuss issues relating to these predispositions, in particular given the finding of Li–Fraumeni-like families that lack canonical *TP53* mutations.²⁸ In patients at increased risk of sarcoma, a more detailed clinical evaluation might be required at a lower threshold of intervention than one might use in general practice. Rapidly growing masses, especially symptomatic ones, in patients with neurofibromatosis should be considered for surgical removal to rule out the potential of sarcomatous transformation of a neurofibroma. Similarly, any superficial or deep abnormalities of skin or soft tissues in patients with a history of prior RT should be evaluated very thoroughly.

Clinical presentation, classification, and diagnosis

Sites of origin

Sarcomas of nonosseous tissues have been noted to arise at virtually all anatomic sites. The anatomic sites and site-specific histologic subtypes of more than 5113 sarcomas treated at a single referral institution are outlined in [Figure 1](#). Approximately one-third to one-half of all sarcomas of nonosseous tissues occur in the lower extremities, where the most common histopathologic subtypes have traditionally been noted to include liposarcomas and the entity “UPS”, formerly termed malignant fibrous histiocytoma (MFH). With improved pathologic tools to categorize sarcomas (e.g., immunohistochemistry, DNA, and RNA analyses), it is increasingly recognized that UPS may have some features in common with poorly differentiated liposarcomas or leiomyosarcomas, as well as other histologic subtypes.²⁹ RPSs comprise 15–20% of all STSs, with well-differentiated/dedifferentiated liposarcoma and leiomyosarcoma being the predominant histologic subtypes. Visceral sarcomas make up an additional 24%, and the head and neck sarcomas approximately 4% of sarcomas.

Source: Data from MDACC Sarcoma Database, June 1996 to June 2005.

Clinical presentation

The majority of patients with nonosseous sarcomas present with a painless mass, although pain is noted at presentation in up to one-third of cases.³⁰ Delay in diagnosis of sarcomas is common, with the most common incorrect diagnosis for extremity and trunk lesions being hematoma or “lipoma.” Late diagnosis of RPS is extremely common, as tumors in this area can grow to massive size before causing any symptoms (such as abdominal distention or psoas irritation with back or groin discomfort) or functional compromise such as hydronephrosis from ureteric obstruction.

Physical examination should include an assessment of the size and mobility of the mass. Its relationship to the fascia (superficial vs deep) and nearby neurovascular and bony structures should be noted. A site-specific neurovascular examination and assessment of regional lymph nodes should also be performed. Sarcomas rarely metastasize to lymph nodes, with those that do being limited to a few specific histopathologic subtypes. Presence of true nodal metastases should prompt the clinician to investigate whether the diagnosis of sarcoma is accurate.

Histopathologic classification

Methods of classification

In broad terms, sarcomas can be classified as neoplasms arising in bone versus those arising from the

nonosseous or periosseous soft tissues. Sarcomas of nonosseous tissues can be further grouped into those that arise from the viscera (e.g., gastrointestinal or gynecologic organs) and those that originate in nonvisceral soft tissues such as muscle, tendon, adipose tissue, pleura, synovium, and other connective tissues.

The most universally applied classification scheme for STS is based on histogenesis, as outlined in the recently updated WHO (World Health Organization) sarcoma classification system.³¹ This classification system is reproducible between pathologists for the better differentiated tumors. However, as the degree of histologic differentiation declines, the determination of cellular origin becomes increasingly difficult. For example, pathologists may vary in their criteria to consider a tumor a UPS versus a poorly differentiated leiomyosarcoma; the use of specific DNA tests and ready availability of an increasing battery of immunohistochemical markers have improved consistency in diagnosis. Nonetheless, the lack of familiarity with sarcomas in general leads to misdiagnosis in up to 20% of outside cases reviewed at reference centers.

Difficulties in establishing the specific cellular origin of STS have occasionally been viewed as having limited clinical importance because clinical investigators have not had sufficient data to tie the histologic subtype directly to biologic behavior or to specific therapeutic interventions. Important exceptions to this generalization include epithelioid sarcoma, clear cell sarcoma, angiosarcoma, and embryonal rhabdomyosarcoma, all of which have a greater risk of regional lymph node metastasis.^{32, 33} In a single-institution study, the overall rate of nodal metastasis at the time of presentation was only 2.7%; however, the rate was much higher for specific histologic subtypes: angiosarcoma (13%), embryonal rhabdomyosarcoma (14%), and epithelioid sarcoma (17%).³² Thus, treatment strategies may differ for these. For the remaining histologic subtypes, biologic behavior appears to be determined more by histologic grade than by histologic subtype. However, as the fundamental biologic and molecular understanding of the mechanisms of malignant transformation in sarcomas increases, in-depth categorization may well prove to have important clinical ramifications. The tools required to categorize or subclassify sarcomas at the molecular level are now increasingly available for many sarcoma subtypes, including GIST, synovial sarcoma, liposarcoma, Ewing sarcoma/PNET, and rhabdomyosarcomas ([Table 1](#)). Future clinical trials will need to take histologic and molecular characteristics into account in a more sophisticated manner than in the past three decades of research when markers were not so readily available.

Table 1 Selected cytogenetic aberrations in nonosseous sarcomas

Histologic subtype	Cytogenetic finding	Genes
Myxoid liposarcoma	t(12;16)	<i>FUS-DDIT3</i>
Well-differentiated liposarcoma	Rings and giant markers	Amplified 12q13–15
		<i>HMG1C</i>
		<i>CDK4</i>
		<i>HDM2</i>
Lipoma (minimal atypia)	12q abnormalities	Amplified 12q13–15
Lipoma	12q14-15 abnormalities	
	6p abnormalities	
Synovial sarcoma	t(X;18)	<i>SS18-SSX1</i> , <i>SSX2</i> or <i>SSX4</i>
Ewing's family/PNET	t(11;22) and others	<i>EWSR1-FLI1</i> and others
Rhabdomyosarcoma	t(2;13) or t(1;13)	<i>PAX3(or 7)-FOXO1</i> (alveolar)
Clear cell sarcoma	t(12;22)	<i>EWSR1-ATF1</i>
Extraskelatal myxoid chondrosarcomas	t(9;22)	<i>EWSR1-NR4A3</i>
	t(9;17)	<i>TAF15-NR4A3</i>
Dermatofibrosarcoma protuberans	t(17;22)	<i>COL1A1-PDGFB</i>
Endometrial stromal sarcoma (low grade)	t(7;17)	<i>JAZF1-SUZ12</i>
Desmoplastic small round-cell tumor	t(11;22)	<i>EWSR1-WT1</i>
Alveolar sarcoma of soft parts	t(X;17)	<i>ASPSCR1-TFE3</i>

Abbreviation: PNET, primitive neuroectodermal tumors.

Histologic grade

Biologic aggressiveness can often be predicted based on histologic grade.³⁴ The spectrum of grades varies among specific histologic subtypes ([Figure 2](#)). In careful comparative multivariate analyses, histologic grade has been the most important prognostic factor in assessing the risk of distant metastasis and tumor-related death.^{34, 36} Several grading systems have been proposed, but there is no consensus regarding the specific morphologic criteria that should be employed in the grading of STS.

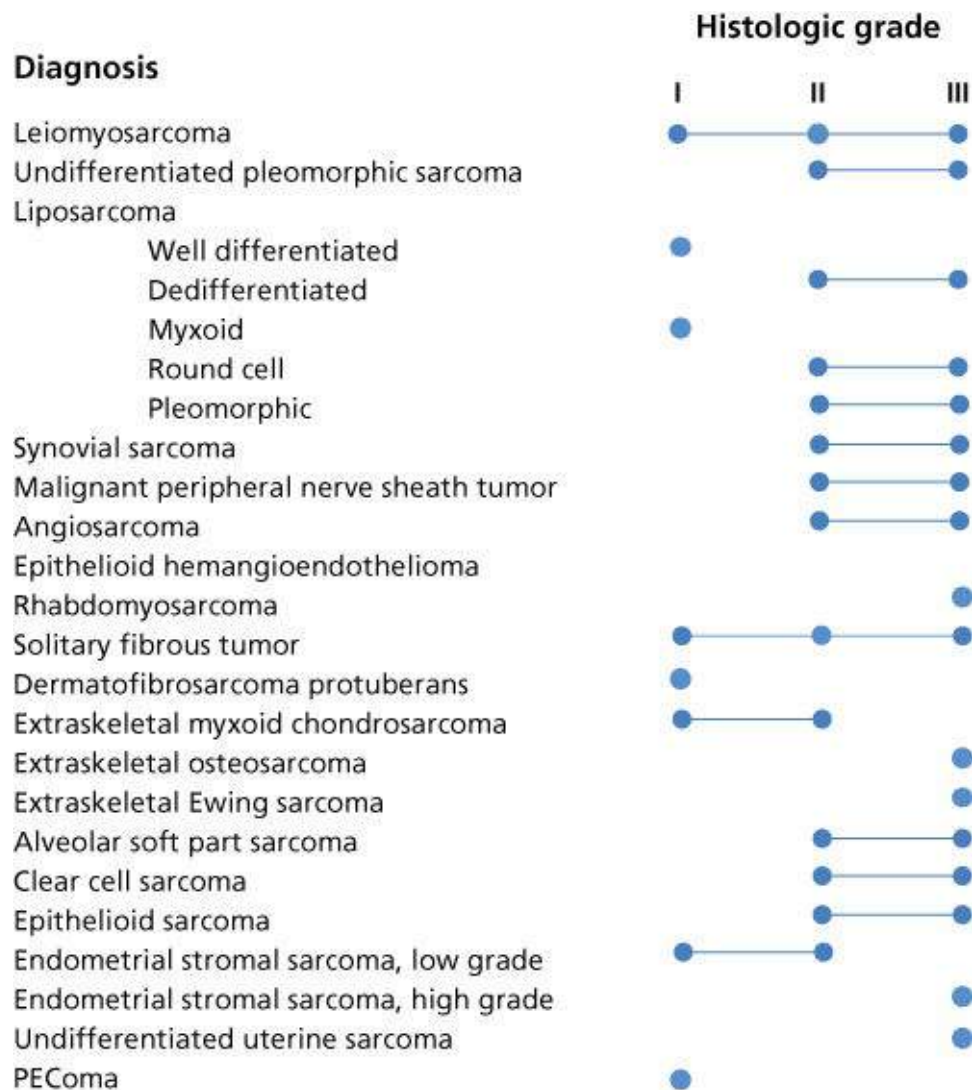

Figure 2 Spectrum of grades observed among histologic subtypes of STS.

Source: From Ref. 35. Adapted from Enzinger FN and Weiss SW, editors. Soft tissue tumors. 5th ed. Mosby-Year Book Inc; 2008.

Two of the most commonly employed grading systems, both first published in 1984, are the US National Cancer Institute (NCI) system developed by Costa and colleagues and the system developed by the Federation Nationale des Centres de Lutte Contre le Cancer (FNCLCC) Sarcoma Group.^{29, 30, 37} The NCI system is based on the tumor's histologic subtype, location, and amount of tumor necrosis, but cellularity, nuclear pleomorphism, and mitosis count are also to be considered in certain situations. The FNCLCC system employs a score generated by the evaluation of three parameters: tumor differentiation, mitotic rate, and amount of tumor necrosis. In a retrospective comparison of these two grading systems, in a population of 410 adult patients with nonmetastatic STS, univariate and multivariate analyses suggested that the FNCLCC system has a slightly better ability to predict distant metastasis and tumor-related death.³⁸ Significant discrepancies in assigned grade were observed in one-third of cases. An increased number of grade 3 tumors, reduced number of grade 2 tumors, and better correlation with overall and metastasis-free survival were observed in favor of the FNCLCC system. The FNCLCC system is the best presently available grading system and is employed as part of the AJCC/UICC STS staging system, with the caveat that several new diagnostic categories have been identified since 1984 whose histological grades are undefined by FNCLCC criteria.

In discussing grade, it is important to note well-described characteristics of sarcomas. First, there is often substantial intratumoral heterogeneity within individual sarcomas. Therefore, diagnoses based on very limited amounts of tumor may be inaccurate [e.g., diagnoses based only on fine-needle aspiration (FNA)

biopsy specimens]. This is particularly true for such histopathologic subtypes as dedifferentiated liposarcomas, where one area of the tumor might have a relatively low-to-intermediate-grade appearance and another area within the same tumor might have high-grade components more evident. Any discussion of the clinical relevance of grading must take into account this variability inherent in the diagnostic process, which will add to the clinical variability in outcomes among patients with any given grade of sarcomas.

Second, the grade of tumors may evolve over time. This process is best described in the evolution of dedifferentiated liposarcoma arising in conjunction with well-differentiated liposarcoma in the same patient. Additional examples include the round-cell liposarcoma growing from what was previously myxoid liposarcoma and fibrosarcomatous degeneration that will occasionally accompany multiply recurrent DFSPs.

Imaging

Optimal imaging of the primary tumor is dependent on the anatomic site. For soft tissue masses of the extremities, trunk, and occasionally head and neck, magnetic resonance imaging (MRI) generally has been regarded as the imaging modality of choice ([Figures 3](#) and [4](#)) because MRI enhances the contrast between tumor and muscle and between tumor and adjacent blood vessels and provides multiplanar definition of the lesion.³⁹ However, a study by the Radiation Diagnostic Oncology Group that compared MRI and computed tomography (CT) in patients with malignant bone ($n = 183$) and soft tissue ($n = 133$) tumors demonstrated no specific advantage of MRI over CT.⁴⁰ That said, although it may be true that the diagnostic evaluation is equally served by both modalities, surgery and RT planning may require additional information provided by the multiplanar capability of MRI and the ability to perform MRI/CT image fusion.^{41, 42} For pelvic lesions or evaluation of specific fixed organs, such as the rectum or the liver, the multiplanar capability of MRI may provide superior single-modality imaging ([Figure 4](#)), whereas in the retroperitoneum and abdomen, CT usually provides satisfactory anatomic definition of the lesion. Occasionally, MRI with gradient sequence imaging can better delineate the relationship of a tumor to midline vascular structures, particularly the inferior vena cava and aorta ([Figure 5](#)). More invasive studies such as angiography or cavography are rarely used in evaluation of STS.

Figure 3 (a) Weighted T2-fat-saturated magnetic resonance image of a TNM T2b high-grade sarcoma in the posterior thigh compartment of a 55-year-old woman. Note the containment by the superficial fascia overlying the posterior thigh muscles, where there is a “strip” of peritumoral edema. Anteriorly, the lesion can be seen to be separate from the femur, but the edge of the tumor is less clearly defined than its superficial component, presumably because of muscle infiltration. (b) Sagittal MRI of the same patient. The main lesion manifests a well-defined border. However, a clear zone of peritumoral edema is evident tracking proximally toward the head of the femur, seen at the top of the figure. Inferiorly, the edema seems to be even more pronounced as evidenced by the triangular signal enhancement pointing inferiorly. Whether the zone of edema harbors microscopic disease is uncertain, and this uncertainty can complicate accurate treatment planning (see text).

Figure 4 A 57-year-old man with T2 pelvic leiomyosarcoma. (a) Axial T2-weighted fast spin-echo MRI reveals a heterogeneous mass involving the rectum (arrow, air in rectal lumen). (b) Note that the mass abuts right seminal vesicle (arrow).

(a)

(b)

(c)

Figure 5 (a) Coronal fat-saturated gadolinium-enhanced MRI showing a solid liposarcoma, 8.3 cm × 6.6 cm, adjacent to and compressing the upper pole of the left kidney. The mass lies below the spleen and is separate from the kidney (line of demarcation, arrow), but is part of a larger fatty tumor. The midline vessels are well visualized. (b) CT image of the same lesion. The mass can be seen adjacent to the kidney, as before. An additional mass of fatty attenuation with gray areas of edema, inflammation, or increased cellularity can be seen bounded by a rim anteriorly (arrow). This mass has the appearance of abnormal fat, which must be considered in treatment planning. Note the displacement of the bowel containing contrast. (c) Sagittal MR image of the same case but without gadolinium. The potential advantage of MR imaging in separating the anterior edge of the retroperitoneal sarcoma (long arrow) from the normal fat anteriorly is seen. The more solid component can also be seen (arrowhead) inferior to the spleen. In addition, these images can be exported digitally to a three-dimensional RT treatment planning workstation or CT simulator workstation where the MR images can be fused to the CT planning slices. This can provide more accurate demonstration of tumor in selected cases for contouring the GTV and clinical target volume than may be possible with CT images alone. This is particularly helpful in situations where CT as well as MRI does not show tumor.

Cost-effective imaging to exclude the possibility of distant metastatic disease is dependent on the size, grade, and anatomic location of the primary tumor. In general, patients with low- and intermediate-grade tumors or high-grade tumors 5 cm or less in diameter require only a chest radiograph for satisfactory staging of the chest. This directly reflects the comparatively low risk of presentation with pulmonary metastases in these patients.^{43, 44} However, patients with high-grade tumors larger than 5 cm (T2) should undergo more thorough staging of the chest by CT owing to the increased risk of presentation with established metastatic disease in this group.^{44, 45} Patients with RPS and intra-abdominal visceral sarcomas should undergo imaging of the liver to exclude the possibility of synchronous hepatic metastases; the liver is a more common site of first metastasis from these lesions. CT is usually adequate in these patients to assess the liver, although the increased sensitivity of MRI of the liver may be valuable if any questionable findings are noted on initial CT.

Positron emission tomography (PET) scans may be used selectively to look for extent of disease, particularly when evaluating an ambiguous lesion that could represent a potential metastasis noted on other imaging. However, PET scans are not routinely utilized in staging work-up of STS.

Biopsy

Biopsy of the primary tumor is essential for most patients presenting with soft tissue masses. In general, any soft tissue mass in an adult that is enlarging (even if asymptomatic), is larger than 5 cm, or persists beyond 4–6 weeks should be biopsied. The preferred biopsy approach is generally the least invasive technique required to allow a definitive histologic diagnosis, assessment of grade. In most centers, core-needle biopsy provides sufficient tissue for diagnosis and results in substantial cost savings compared with open surgical biopsy.^{46, 47} When core-needle biopsy yields insufficient tissue for diagnosis, incisional biopsy is considered to yield optimal amounts of tissue to assess histopathology over a larger area of tumor volume, given the known heterogeneity of sarcomas, as well as to provide sufficient material for detailed molecular and cytogenetic assays. Direct palpation can be used to guide needle biopsy of most superficial lesions, but less accessible sarcomas often require imaging-guided biopsy for safe percutaneous sampling of the most radiographically suspicious area(s) of the mass. Tumor recurrences within the needle track after percutaneous biopsy are exceedingly rare but have been reported, leading some physicians to advocate tattooing the biopsy site for subsequent excision. FNA generally does not provide sufficient material for initial diagnosis, but can be used to confirm recurrence

or metastatic disease. Exceptions to this idea exist; endoscopic ultrasound-guided FNA for visceral sarcomas such as GISTs may provide enough tissue for diagnosis while minimizing risk of tumor rupture; in this scenario, it is not feasible to assess mitotic rate. The need for sufficient tissue to conduct more specific molecular testing is a final major rationale for use of core-needle biopsy over FNA. Another major limitation of FNA (compared to core-needle biopsy) is that there is no semblance of preserved tissue architecture to evaluate characteristics such as degree of tissue necrosis.

A practical approach for biopsy and staging of the patient who presents with a primary extremity soft tissue mass is outlined in [Figure 6](#). Small (<5 cm) superficial lesions on an extremity where the morbidity of excisional biopsy is minimal (i.e., remote from joints, tendons, and neurovascular structures that would compromise the surgical margin) are easily biopsied by excisional biopsy with microscopic assessment of surgical margins. For extremity lesions, incisions used for excisional biopsies should be oriented longitudinally along the length of the limb. T2 lesions, T1 lesions located beneath the investing fascia of the extremity, or superficial T1 lesions situated in proximity to joints, tendons, or neurovascular structures are best biopsied by percutaneous core-needle biopsy.

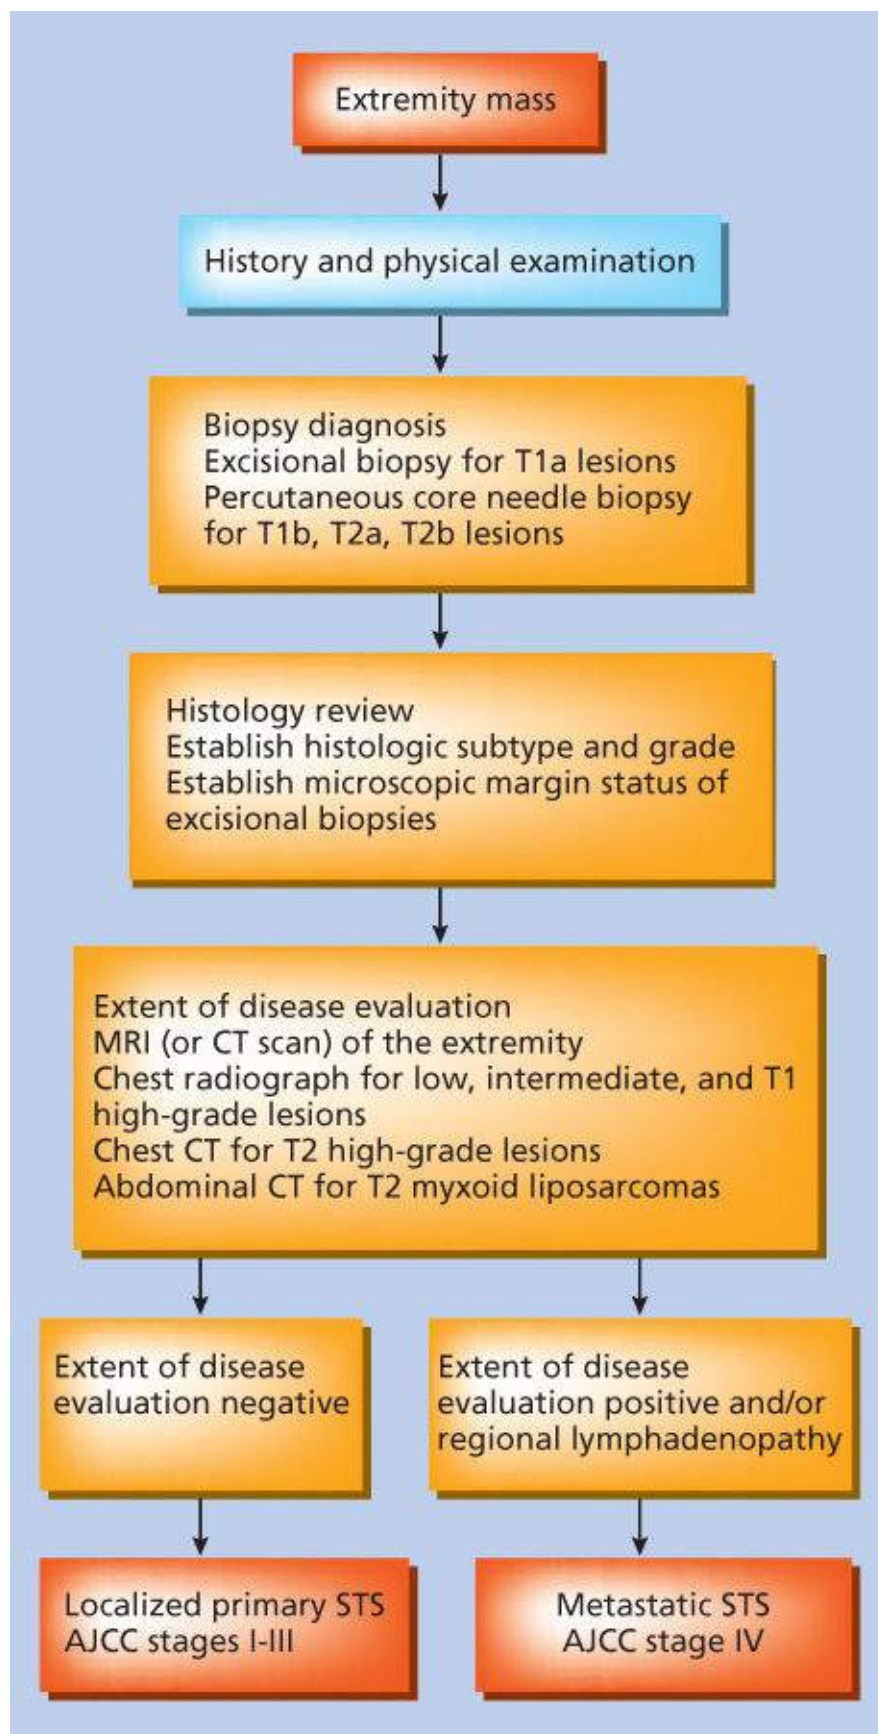

Figure 6 Approach for pretreatment evaluation and staging of the patient presenting with a primary extremity soft tissue mass. AJCC, American Joint Committee on Cancer.

Staging and prognostic factors

Staging

The relative rarity of STS, the anatomic heterogeneity of these lesions, and the presence of more than 50 recognized histologic subtypes of variable grades have made it difficult to establish a functional system that can accurately stage all forms of this disease. The staging system (7th edition) of the American Joint Committee on Cancer (AJCC) and the Union for International Cancer Control is the most widely employed staging system for STS ([Table 2](#)).⁴⁹ The system is designed to optimally stage extremity tumors but is also applicable to torso, head and neck, and retroperitoneal lesions; a separate staging system is provided for GISTs.

Table 2 American Joint Committee on cancer staging system for STSs, 7th edition

TX	Primary tumor cannot be assessed					
T0	No evidence of primary tumor					
T1	Tumor 5 cm or less in greatest dimension					
T1a	Superficial tumor					
T1b	Deep tumor					
T2	Tumor more than 5 cm in greatest dimension					
T2a	Superficial tumor					
T2b	Deep tumor					
N1	Regional lymph node metastasis					
G1	Well differentiated					
G2	Moderately differentiated

A major limitation of the present staging system is that it does not take into account the anatomic site of STS. Anatomic site, however, has been recognized as an important determinant of outcome.^{50, 51} Therefore, although site is not a specific component of any present staging system, outcome data should be reported on a site-specific basis, when feasible. Furthermore, the staging system also fails to include histology, a critical prognostic factor.

Conventional prognostic factors

A thorough understanding of the clinicopathologic factors known to impact outcome is essential in formulating a treatment plan for the patient with STS. Several multivariate analyses of prognostic factors for patients with localized sarcoma have been reported.^{52–54} However, with few exceptions, most studies

have analyzed fewer than 300 patients.

The largest studies established the clinical profile of what is now accepted as the high-risk patient with extremity STS: the patient with a large (≥ 5 cm), high-grade, deep lesion. In addition, unappreciated prognostic significance includes specific histologic subtypes, for example, MPNST, and the increased risk of adverse outcome associated with a microscopically positive surgical margin or presentation with locally recurrent disease. The type of microscopically positive surgical margins also appears important. Patients with low-grade liposarcomas have a relatively low risk of local recurrence (LR), as do those patients in whom the positive margin is planned before surgery to preserve critical structures and RT can sterilize the small amount of residual disease. However, patients with two categories of positive margin remain at relatively higher risk of LR. These include patients who underwent “unplanned” excision and still have positive margins on re-excision and those with unanticipated positive margins after primary resection.⁵⁵ An “unplanned excision” is defined as an excisional biopsy or resection carried out without adequate preoperative staging or consideration of the need to remove normal tissue around the tumor.

Unlike for other solid tumors, the adverse prognostic factors for LR of an STS are distinct from those that predict distant metastasis and tumor-related death.⁵² In other words, patients with a constellation of adverse prognostic factors for LR are not necessarily at increased risk of distant metastasis or tumor-related death. Therefore, staging systems that are designed to stratify patients for risk of distant metastasis and tumor-related death will not necessarily stratify patients for risk of LR.

Kattan and colleagues from the Memorial Sloan-Kettering Cancer Center (MSKCC) have utilized a database of over 2000 prospectively followed adult patients with STS to predict the probability of sarcoma-specific death by 12 years.⁵¹ The results have been used to construct and internally validate a nomogram to predict sarcoma-specific death ([Figure 6](#)); this and similar nomograms have been validated in a variety of clinical situations, for example, RPS, or for disease-specific contexts, for example, liposarcoma, for individual patients.^{56–59} These tools may be used for patient counseling, follow-up scheduling, and clinical trial eligibility determination.

Potential molecular prognostic factors

Specific molecular parameters evaluated for prognostic significance in STS have included *TP53* mutation, *MDM2* amplification, Ki-67 status, altered expression of the RB gene product in high-grade sarcomas, and histologic grade, but not *SS18-SSX* fusion type, which appears to be an important prognostic factor in patients with synovial sarcoma.⁶⁰ Complete discussion of the extensive literature on molecular prognostic factors in sarcoma is beyond the scope of this chapter. Readers are referred to more detailed reviews.^{61, 62}

As an example of the difficulty of using even the most commonly recognized markers as prognostic factors, one needs to look no further than Ki-67, an antigen expressed throughout the majority of the cell cycle. Ki-67 is used as a measure of the fraction of cells undergoing division. Preliminary reports of series of heterogeneous sarcomas in adults suggested that Ki-67 nuclear staining correlated with histologic grade, but was not an independent prognostic factor when histologic grade was taken into account.⁶³ Conversely, additional studies in larger numbers of patients indicated that Ki-67 status was an independent prognostic factor for clinical outcomes.⁶⁴ It is only with the development of consensus guidelines regarding the nature of Ki-67 immunohistochemistry and its interpretation that we can expect to see more careful accurate assessment of this biomarker in sarcoma outcomes.⁶⁵ It is also with the inconsistencies in the Ki-67 data that one can extrapolate the difficulty of using increasingly available genetic markers for outcome determination. Although specific protein, DNA, and RNA parameters have

been identified as having independent prognostic significance, there is presently no consensus on how these prognostic factors should be used in clinical practice.

Treatment of localized primary disease of the extremities

Surgery

General issues

Surgical resection remains the cornerstone of therapy for localized primary STS. The discussion that follows focuses on STSs in the limbs, the most common site of origin, but the principles are equally applicable to sarcomas of other primary anatomic sites.

With the development of limb-sparing techniques in the 1970s and 1980s, there was a marked decline in the rate of amputation as the primary therapy for extremity STS. Today, the widespread application of multimodality treatment strategies means that the vast majority of patients with localized STS of the extremities undergo limb-sparing, usually function-sparing treatment; fewer than 10% of patients presently undergo amputation.^{66, 67} In selected patients, limb sparing can be approached with surgery alone.

Amputation

Most surgeons consider definite major vascular, bony, or nerve involvement by STS as relative indications for amputation. Complex en bloc bone, vascular, and nerve resections with interposition grafting can be undertaken, but the associated morbidity is high. Therefore, for a few patients with critical involvement of major bony or neurovascular structures, for example, in the foot, amputation remains the only surgical option, but offers the prospect of prompt rehabilitation with excellent local control and survival rates. Other indications for amputation include tumor fungating through the skin or associated with a pathologic fracture with lack of reasonable salvage option.

Combined-modality limb-sparing treatment

Currently, at least 90% of patients with localized extremity sarcomas can undergo limb-sparing procedures. The use of limb-sparing multimodality treatment approaches for extremity sarcoma stems from phase 3 trial from the NCI published in 1982, in which patients with extremity sarcomas amenable to limb-sparing surgery were randomly assigned to receive amputation or limb-sparing surgery with postoperative RT.⁶⁸ The arms of this trial included postoperative chemotherapy with doxorubicin, cyclophosphamide, and methotrexate. With over 9 years of follow-up, this study established that for patients for whom limb-sparing surgery is an option, limb-sparing surgery combined with postoperative RT and chemotherapy yielded disease-related survival rates comparable to those for amputation while simultaneously preserving a functional extremity.

Satisfactory local resection involves resection of the primary tumor via a longitudinally oriented incision with a margin of normal tissue. Dissection along the tumor pseudocapsule (enucleation) is associated with LR rates in one-third to two-third of patients. In contrast, wide local excision with a margin of normal tissue around the lesion is associated with LR rates in the range of 10–31%, as noted in the control arms (surgery alone) of randomized trials evaluating postoperative RT and in single-institution reports.⁶⁹

In the modern era, a discussion of limb-preserving approaches must be linked to a discussion of the role of adjuvant therapies, most commonly RT. Several randomized controlled trials have addressed issues surrounding the use of adjuvant therapy and collectively have established important milestones in the

evolution of the local management of STS. With a single exception, these trials have focused on extremity lesions and the themes of surgery and adjuvant RT.

Yang et al.⁷⁰ randomized 91 patients with high-grade extremity lesions following limb-sparing surgery to receive adjuvant chemotherapy alone or concurrent chemotherapy and RT. An additional 50 patients with low-grade tumors were to receive adjuvant RT or no further treatment following limb-sparing surgery. The local control rate for those who received RT was 99% compared with 70% in the no-RT group ($p = 0.0001$). The results were similar for high- and low-grade tumors ([Table 3](#)).

Table 3 Phase 3 trials of adjuvant radiotherapy for localized extremity and trunk sarcoma stratified by grade

Histologic grade	First author/institution (references)	Treatment group	Radiation dose, Gy	Number of patients	Number of local failure (%)	LRFS (%)	OS (%)
High grade	Pisters/MSKCC ⁶⁹	Surgery + BRT	42–45	56	5 (9)	89	27
		Surgery	—	63	19 (30)	66	67
	Yang/NCI ⁷⁰	Surgery + EBRT	45 + 18 (boost)	47	0 (0)	100	75
		Surgery	—	44	9 (20)	78	74
Low grade	Pisters(/MSKCC ⁶⁹	Surgery + BRT	42–45	22	8 (36)	73	96
		Surgery	—	23	6 (26)	73	95
	Yang/NCI ⁷⁰	Surgery + EBRT	45 + 18 (boost)	26	1 (4)	96	NR
		Surgery	—	24	8 (33)	63	NR

Abbreviations: BRT, brachytherapy; LRFS, local recurrence-free survival; MSKCC, Memorial Sloan-Kettering Cancer Center; NCI, National Cancer Institute; NR, not reported; OS, overall survival; EBRT, external-beam radiotherapy.

Adjuvant RT was also evaluated in a randomized trial of 126 cases treated between 1982 and 1987 ([Table 3](#)).⁶⁹ Brachytherapy (BRT) was administered postoperatively, via an iridium-192 implant that delivered 42–45 Gy over 4–6 days. At 5 years, the local control rate for high-grade tumors was 91% with BRT compared with 70% in surgery-alone controls ($p = 0.04$). Of note, no improvement in local control with BRT was evident for the low-grade tumors (the local control rate was 74% with surgery alone and 64% with BRT). The full explanation for grade-specific differences in local control with BRT remains unresolved, although one suggestion implicates the relatively long cell cycle of low-grade tumors: low-grade tumor cells may not enter the radiosensitive phases of the cell cycle during the relatively short BRT time. Additional discussion of the pros and cons of BRT compared to external beam radiotherapy (EBRT) is included in the section on “Methods of Radiotherapy Delivery”.

Satisfactory surgical margins to omit radiotherapy

There are no randomized data to define what constitutes a satisfactory gross resection margin for a sarcoma. In general, every effort should be made to achieve a wide margin (2 cm is often an arbitrary choice) around the tumor mass, except in the immediate vicinity of functionally important neurovascular

structures, where, in the absence of frank neoplastic involvement, dissection is performed in the immediate perineural or perivascular tissue planes. Technical details of the surgical approach to extremity sarcomas are beyond the scope of this chapter, but are reviewed elsewhere.⁷¹ The principle remains that adequate clearance of potential tumor-bearing tissues can be achieved if there is sufficient distance between the surgical margin and the edge of any grossly evident tumor (e.g., at least 2 cm for the closest margin), or where an intact barrier to tumor spread is excised en bloc with the tumor. In such cases, there is little evidence that RT is required even when potential adverse prognostic factors, such as large high-grade tumors are present. The exception in cases of “unplanned” excision where significant contamination of surrounding tissues may have taken place and the precise extent of the tumor is essentially unknown. Depending on the histology, margins of <2 cm are reasonable when an appropriate biological barrier (such as muscle fascia) constitutes that margin. Histologies with infiltrative borders, such as myxofibrosarcoma, may require wider margins or resection. On the other hand, tumors with good prognoses, such as well-differentiated liposarcoma/atypical lipomatous tumor, may be managed by a more limited, marginal resection.

Management of regional lymph nodes

Given the low (2–3%) prevalence of lymph node metastasis in adults with sarcomas, there is no role for routine regional lymph node dissection in most patients.³² However, patients with angiosarcoma, embryonal/alveolar rhabdomyosarcoma, and epithelioid sarcoma have an increased incidence of lymph node metastasis and should be carefully examined for lymphadenopathy. These patients may benefit from the inclusion of lymph node regions electively in adjuvant RT fields.

For patients with STS, lymph node metastasis has been regarded as a particularly adverse finding conferring similar risk to distant metastasis in the TNM (tumor–nodes–metastasis) stage classification. Nevertheless, therapeutic lymph node dissection results in a 34% actuarial survival rate, and thus the rare patients with regional nodal involvement who have no evidence of extranodal disease should undergo therapeutic lymphadenectomy.³² Although formerly classified as being as prognostically as adverse as distant metastasis in the TNM staging classification, isolated lymph node metastasis (as opposed to synchronous distant metastasis), if treated intensively, appears to have a prognosis similar to patients with stage III tumors (i.e., those with high-grade, deep lesions, and lesions larger than 5 cm). The impact of isolated nodal disease was adjusted in the AJCC/UICC staging system by moving N1 disease alone into the stage III group.⁴⁹ The validity of including N1 disease into stage III was questioned in a follow-up manuscript, in which survival for N1 patients more closely parallels survival with stage IV than node negative AJCC stage III disease.⁷²

Radiotherapy

Rationale for combining radiotherapy with surgery

The use of RT in combination with surgery for STS is supported by two phase 3 clinical trials ([Table 3](#)) and is based on two premises: microscopic nests of tumor cells can be destroyed by RT, and less radical surgery can be performed when surgery and RT are combined.^{69, 70} Although the traditional belief was that STSs were resistant to RT, radiosensitivity assays performed on sarcoma cell lines grown *in vitro* have confirmed that the radiosensitivity of sarcomas is similar to that of other malignancies; this confirmation supports the first premise.^{73, 74} The second premise stresses the philosophy of preservation of form (including cosmesis where possible) and function as a goal for many patients with extremity, truncal, breast, and head and neck sarcomas.^{75–77} Similar principles govern the frequent use of RT for

sarcomas at problematic sites such as, for example, RPS, high-risk sarcomas of the head and neck with skull base invasion, or spinal canal invasion by paravertebral lesions. While the efficacy of RT has been confirmed through prospective randomized clinical trials for extremity sarcomas, it has not been confirmed for other sites. Currently, there is an ongoing phase III trial evaluating preoperative RT for primary RPS.

Visceral sarcomas are not ordinarily managed with RT, in part because of the mobile nature of these structures within the pelvic, abdominal, or thoracic compartments. After resection of visceral sarcomas, accurate identification of the field at risk of residual disease is particularly problematic. Contaminated loops of the bowel or mesentery may relocate remotely within the abdominal cavity after surgery, and pleural contamination and mediastinal shift may occur following intrathoracic resections. Fixed tumors in the pelvis or tumors attached to internal truncal walls may occasionally be suited to preoperative or postoperative RT. Typically, however, the vast size of the radiation fields needed to cover entire body cavities, coupled with the limited RT doses that can be safely administered to the organs within the cavities, and the overwhelming risk of distant rather than LR, confines adjuvant RT for the investigational setting.

Essential elements in treatment planning of external beam radiotherapy

Accurate tumor localization is the first essential for RT planning. It primarily uses CT for dosimetric reasons, but MRI can provide complementary information about the tumor extent and can be assimilated in the computer planning workstation through image fusion technology.^{41, 42} Further essential information is obtained from the pathology and operative reports, and metallic clips placed at the time of surgery may also help define the tumor bed.

It is usually helpful to secure the targeted area to minimize setup variations and eliminate movement during treatment. Simple maneuvers such as comfortable limb positioning or fashioning of customized thermoplastic molds for immobilization will facilitate reliable and consistent treatment setups. RT of superficial tissues, including the scar following definitive resection, with appropriate application of tissue-like bolus material should be considered, but with the recognition that fibrosis, atrophy, and telangiectasias may result. Traditionally, dose uniformity within irregular volumes was optimized using beam segmentation, compensators, or wedge filters. However, this has now largely been replaced by the use of intensity-modulated radiotherapy (IMRT), which addresses issues that include the size, shape, and location of targets and the nature of the normal tissues surrounding them including their contour and width. IMRT is particularly useful in situations where the target volume is adjacent to critical normal tissues as found at the skull base or within the abdomen. Whenever possible, the entire limb circumference, whole joints, or pressure areas (e.g., elbow or heel) should not be treated with what is considered to be a full RT dose, as this may adversely affect limb function and cause distal edema.

It is also prudent to assess baseline function before initiating RT. This is especially important with paired organs, such as eyes or kidneys, if the functional ablation of one organ by RT is expected and is a frequent problem in treating RPS. If right sided or of great size, an RPS may infiltrate the liver capsule or be “hooded” by the liver, making RT access to an appropriate tissue volume surrounding the tumor extremely difficult. This area may be particularly appropriate for IMRT approaches because of the exquisite conformality that is possible with this approach and permits the liver and the other normal tissue to be excluded from the irradiated volume.^{78, 79} Fortunately, although the tolerance of the entire liver to radiation is low, part of the liver may be safely treated to much higher doses. In these instances, if a subsequent liver resection is needed because of tumor infiltration or adherence to the capsule, detailed consultation between the surgical and radiation oncology teams is needed to ensure that an adequate

volume of nonirradiated liver remains *in situ*.

Dose fractionation issues

Total radiation doses administered postoperatively for sarcoma depend on the tumor grade and involvement of the surgical margin.^{70, 80, 81} Typical total doses are 60 Gy for low grade and 66 Gy for high-grade tumors, respectively. When RT is given preoperatively, the total dose used in most institutions is approximately 50 Gy in daily fractions administered over 5 weeks.^{81, 82} However, data regarding radiation dose response are very limited and based on underpowered retrospective studies. On the basis of the current data, higher doses of RT are probably indicated in the postoperative setting (compared with preoperative RT), but the search for an alternative lower dose postoperative schedule seems desirable. These are discussed below in relation to the volumes to be used and the consequences of using different doses in terms of potential morbidity.

The fraction size used in conventional fractionation schemes varies (usually 1.8 or 2.1 Gy).^{81, 83} Absence of late effects can be expected with smaller fraction size; this tissue is particularly important when critical structures are irradiated. Several altered fractionation schemes have been described including hyperfractionated, hypofractionated, and accelerated schedules.^{84–87} Most recently, preoperative hypofractionated RT for extremity and trunk wall STS was recently evaluated in a series of 272 patients. RT was delivered preoperatively for 5 consecutive days in 5 Gy per fraction. The LR rate was higher (19%) with the hypofractionated schedule compared to many contemporary series.⁸⁸ Longer follow-up of this novel strategy is warranted. Neither hyper- nor hypofractionation regimens are likely to replace conventional daily fractionation in the near future, for a combination of reasons that include the small nonrandomized nature of studies, resources needed for some protocols, concerns about efficacy and toxicity, and the fact that modern targeting techniques with IMRT may offset some of the potential benefits that underpin the choice of altered fractionation protocols.

Radiation dose and target volumes

Guidelines have recently been published on how to address the technical design of the radiation volumes and should be discussed for additional detail regarding this topic.⁸⁹

Many STS respect barriers to tumor spread in the axial plane of the extremity, such as bones, interosseous membranes, or major fascial planes. Consequently, extremity STS tend to spread longitudinally within the specific muscle groups of the extremity. Therefore, the margins of the RT volume must be wide in the cephalocaudal direction. In the cross-section, there may be much greater security in defining nontarget structures, especially those delimited by an intact barrier to tumor spread. Bone, interosseous membranes, and fascial planes are considered barriers to tumor spread in the axial direction, and, therefore, descriptions of radiation margins employed are principally in the cephalocaudal direction. For nonextremity lesions, the preferred direction of spread is also along the direction of the involved musculature, but care must be taken to ensure that the fascial planes are appropriately recognized and encompassed in the radiation target volume.

Earlier, this chapter summarized principles concerning anatomic planes and the preferential pathways for sarcomas to spread within tissues. This information facilitates the design of target areas for RT. The basic elements in RT planning are to first define a gross tumor volume (GTV) and then place a margin around it to encompass tissues at risk of harboring microscopic residual disease [clinical target volume (CTV)] ([Figures 7a–c](#) and [8](#)).⁹⁰ Generally, RT is phased so that an initial volume (phase 1) around the risk zone is treated to doses that are capable of sterilizing microscopic amounts of tumor cells (e.g., 45–50.4 Gy in

1.8 or 2.0 Gy fractions). When delivering RT postoperatively, it is customary to have at least one field reduction to permit an augmented dose to a smaller volume surrounding the highest risk zone (phase 2). This dose is usually 15–16 Gy but can be higher if there is gross residual disease. For the phase 1 volume, the surgical bed is expanded with a 1.5-cm radial margin and a 4-cm craniocaudal margin to encompass microscopic disease in the surrounding tissues; the boost is applied to the original sarcoma localization with a 1.5-cm radial margin and a 2-cm craniocaudal margin. In preoperative RT, historically more recent but potentially the most prevalent approach used today, the GTV is treated to a dose of 50 Gy in 25 fractions over 5 weeks with surgery following 4–6 weeks later. In general, the CTV encompasses the GTV with a 4-cm craniocaudal and a 1.5–2.0 cm radial margin for microscopic disease coverage. CTV should also include peritumoral edema as it may harbor tumor cells at some distance from the GTV.⁹¹ Following preoperative RT, a postoperative “boost” has traditionally been used but is generally restricted to patients who received preoperative RT and have margin-positive disease at surgery. This is because the local control rate for margin-negative cases is in excess of 90% even when a boost is not provided.^{81, 92, 93} A positive margin is declared when the tumor reaches the inked surface of the specimen, and clear margins can be declared if the tumor does not reach the ink irrespective of how close it is.⁸¹

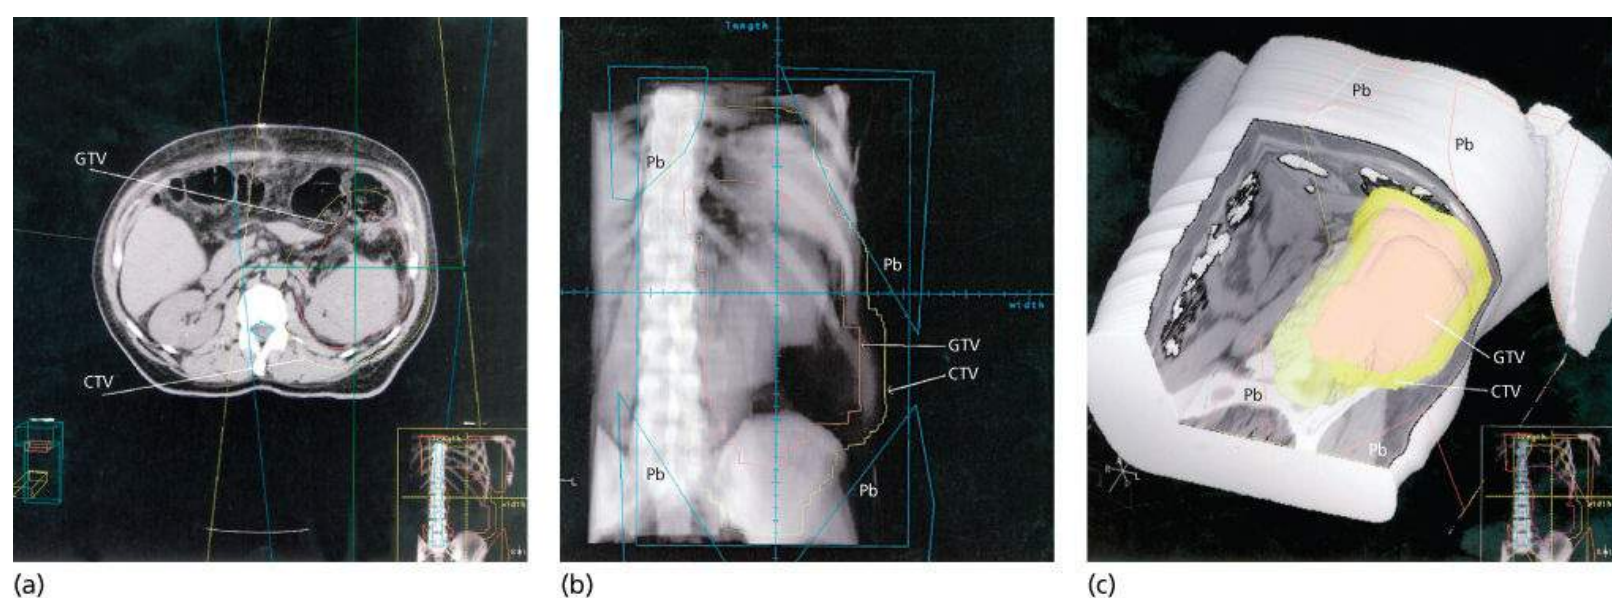

Figure 7 (a) The GTV has been contoured on a CT simulator workstation (red outline). This includes the anterior abnormal fat shown earlier (Figure 5b,c). This process is performed with many thin CT slices to permit reconstruction of the image later for three-dimensional treatment planning. The CTV is outlined in yellow to account for potential microscopic spread beyond the GTV. An additional margin will also be added to account for setup variation and organ motion. Note the displacement of the bowel loops by the tumor mass. The straight lines show the path of the beam for a conventional setup with opposed anterior and posterior fields. (b) The contoured GTV and CTV information displayed in a beam's eye view (BEV) using a digitally reconstructed radiograph created by the CT simulator. Shielding (Pb) can be placed once the path of the beam within the target areas defined is seen on the BEV. One can also discern the opaque tumor partially displacing the bowel from target area. (c) A three-dimensional reconstruction with the GTV, CTV, and areas to be shielded (Pb) shown with abdominal wall and anterior structures cut away. Generally, these “cut-away” images are most useful for visualizing the edge of the target volume adjacent to critical anatomy that must be protected and when the spatial relationship cannot be verified precisely with conventional imaging.

Figure 8 A digitally reconstructed radiograph of the head and neck of a young woman with an STS of the right cheek. Because of the proximity to the right eye, preoperative radiotherapy has been chosen because of its ability to permit maximal restriction of the CTV to the local environment of the tumor. The same process was followed using a CT simulator as described in [Figure 6](#). The GTV on the cheek can be seen with the surrounding CTV. Shielding (Pb) is also evident. A hair clip, which the patient was wearing during the CT slice acquisition, is evident in the right parietal area; one can also see her necklace. The smaller inset shows a three-dimensional image of the patient with potential beams applied.

The need for a radiation therapy boost following preoperative RT and surgery with positive resection margins has been questioned in a retrospective review of 216 ESTS (extremity soft tissue sarcomas) patients; 52 received preoperative RT (50 Gy) alone and were compared to 41 who received preoperative RT with a postoperative boost (generally 16 Gy). A portion of the population did not receive RT at all, or received postoperative RT and were excluded (123 of 216). The postoperative boost cohort had lower 5-year LR-free rates (74% vs 90% for preoperative RT only) indicating that a postoperative boost provides no obvious advantage.⁹⁴ A similar study ($n = 67$) yielded almost identical results.⁹⁵ These results suggest that a benefit from a delayed postoperative boost following preoperative RT and surgery is at best debatable, and the increased risk and challenges of managing later RT morbidity (e.g., radiation-induced fractures) resulting from the higher radiation doses involved should be considered when treating STS.

The defined external beam volumes for extremity STS reflect those of the prospective Canadian Sarcoma Group randomized clinical trial discussed later.⁹⁶ However, the recently completed UK postoperative phase III randomized “VORTEX” trial (NCT NCT00423618) compared a 5-cm longitudinal margin from GTV in the standard arm to a 2-cm margin and results are awaited.⁹⁷ A completed RTOG-0630 trial

(NCT NCT00589121) addressing the role of IMRT defined slightly smaller preoperative RT volumes (longitudinal 3 cm), although its results may be less easily interpreted owing to its nonrandomized nature.⁹⁸ In any event, the size of the RT volume margins is not appreciably smaller than the 4-cm longitudinal margin noted above and further outcome reports will be needed in the future to guide practice if target volumes are being reduced in the interest of normal tissue protection.

Despite the variations noted in target volume coverage, the local control rates reported for extremity STS using combinations of surgery and RT are approximately 90% and may suggest that the zone of microscopic involvement may be less than that was previously realized. Recent improvements in surgical technique may lessen the degree of intraoperative tumor dissemination, and irradiation of all surgically handled tissues, scars, and drain sites may be unnecessary. This seems particularly relevant for major centers where surgery is performed by teams with extensive experience in sarcoma management. One must also consider the possibility that case selection factors may explain apparent variations in practice between BRT and external beam RT approaches.

Sequencing of radiotherapy and surgery

The two most common methods of EBRT delivery are preoperative and postoperative RT. Preoperative RT is delivered to an undisturbed and potentially better oxygenated tumor site, which may be one reason why lower preoperative radiation doses do not appear to compromise local control.⁹⁹ Nielsen et al.¹⁰⁰ repeated RT planning in patients who had undergone preoperative RT and surgery and observed that the field size and number of joints irradiated in preoperative RT were significantly less than if the treatment had been administered postoperatively. Another advantage of preoperative RT is that it promotes collaboration between the surgical and radiation oncologists and facilitates the formulation of a coordinated management plan before any treatment.

The Canadian Sarcoma Group SR2 clinical trial represents the only prospective randomized comparison of preoperative versus postoperative RT.⁹⁶ As was anticipated, the trial showed that preoperative RT results in an increased rate of acute wound complications (WCs). On the other hand, as also anticipated, the trial also showed that postoperative delivery is associated with increased limb fibrosis, edema, joint stiffness, and bone fractures.

Long-term follow-up of patients treated in the Canadian Sarcoma Group NCIC trial (SR2) showed that, of 129 patients evaluable for late toxicity, 48% in the postoperative group compared to 32% in the preoperative group had grade 2 or greater fibrosis ($p = 0.07$).¹⁰¹ Edema was more frequently seen in the postoperative group (23% vs 16%), as was joint stiffness (23% vs 18%). Patients with these complications had lower function scores (all p values <0.01) on the Toronto Extremity Salvage Score and the Musculoskeletal Tumor Society Rating Scale. Field size predicted greater rates of fibrosis ($p = 0.002$) and joint stiffness ($p = 0.006$), and marginally predicted edema ($p = 0.06$). Acute wound-healing complications were twice as common with preoperative compared to postoperative RT. The increased risk was almost entirely confined to the lower extremity (43% associated with preoperative vs 21% with postoperative timing; $p = 0.01$). Of interest, additional reports, including one from the University of Texas M.D. Anderson Cancer Center, using the same criteria for classifying WCs as were used in the Canadian NCI trial, found almost identical results.⁶⁶

The influence of time interval between preoperative EBRT and surgery on the development of WC in extremity sarcoma has also been studied. While the interval had little influence, the data still suggested that the optimal interval to reduce potential WC was 4 or 5 weeks between RT and surgery.⁶⁷

In the initial report of the SR2 trial with 3.3 years median follow-up, an improvement in overall survival

(OS) ($p = 0.048$) in the preoperative RT arm was noted and partially explained by increased deaths in the postoperative RT unrelated to sarcoma.⁹⁶ The local failure rate was identical in the 2 arms (7%) ([Figure 9](#)). However, updated results were recently presented and the preliminary survival difference had dissipated.¹⁰¹ The 5-year results for preoperative versus postoperative, respectively, were local control, 93% versus 92%; metastatic relapse-free, 67% versus 69%; recurrence-free survival, 58% versus 59%; OS, 73% versus 67% ($p = 0.48$); and cause-specific survival, 78% versus 73% ($p = 0.64$). Cox modeling showed only resection margins as significant for local control. Tumor size and grade were the only significant factors for metastatic relapse-free, OS, and cause-specific survival. Grade was the only consistent predictor of recurrence-free survival.

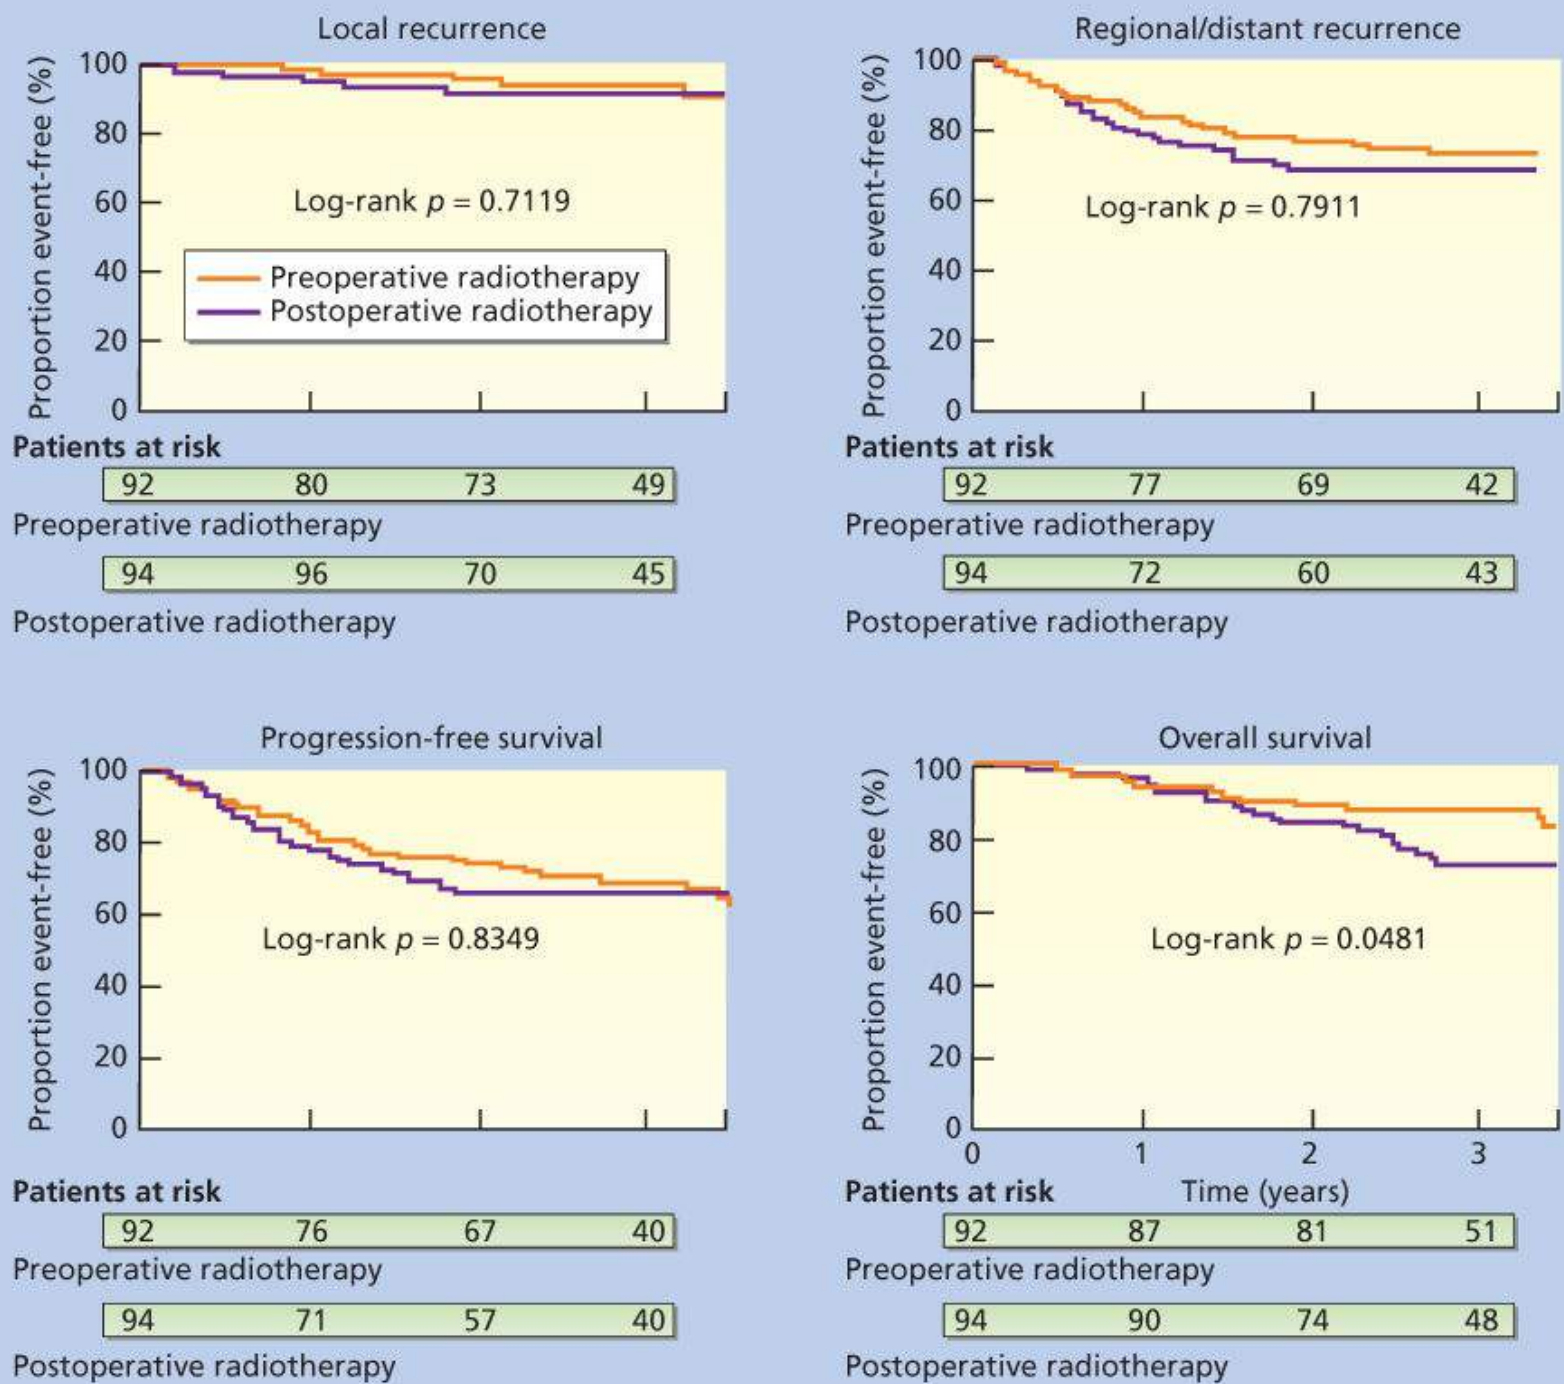

Figure 9 Kaplan–Meier plots for probability of local recurrence, metastasis (local and regional recurrence), progression-free survival, and overall survival in the Canadian Sarcoma Group randomized trial of the NCI of Canada Clinical Trials Group comparing preoperative and postoperative radiotherapy.

Source: O'Sullivan et al. 2002.⁹⁶ Reproduced with permission of Elsevier.

For the present, decisions about preoperative versus postoperative RT for extremity soft tissue sarcoma should be individualized, taking into account tumor location, tumor size, RT volumes needed, comorbidities, and risks. In general, preoperative RT provides some advantages over postoperative RT, but exposes the patient to significantly increased risks of serious postoperative WCs. A summary of the relative indications that can be used to select patients for preoperative RT is provided in [Table 4](#). In addition, although much of the discussion about preoperative RT is focused on extremity lesions, patients with RPS tolerate preoperative RT substantially better than postoperative RT. This is because the tumor acts as a tissue expander to exclude the bowel from the RT volume ([Figure 7a–c](#)). This is discussed in

detail later in the section titled “Retroperitoneal Sarcomas.”

Table 4 Relative indications for preoperative RT, despite concerns related to wound complications

Treatment context/sarcoma site	Issues of concern	Comments
<i>Head and neck</i>		
Paranasal sinus	Proximity to optic apparatus (eye, orbit, chiasma)	Major visual functional deficit can be minimized
Skull base	Proximity to spinal cord, brain stem	Other “lesser” morbidities (dental, xerostomia) may also be less due to reduced doses and volumes
Cheek and face	Xerostomia	Early caries or loss of teeth, loss of sense of taste
Split thickness skin graft reconstruction (especially lower limb)	Skin graft breakdown and consequent infection	Many months to years of recreational and/or vocational disability may occur during healing (rare)
<i>Large volume GTV or CTV occupying coelomic cavities</i>		
Retroperitoneum	Proximity to the bowel, the liver, and the kidney	Critical organs may be displaced by tumor or not fixed or adherent as is likely in postoperative setting
		Entire tumor treated before possible contamination of cavity
Some small bowel lesions	Proximity to critical anatomy, especially intestine with side wall adherence	Contamination of abdominal cavity renders postoperative RT unsuitable
Thoracic wall/pleura	Proximity to the lung or the cardiac structures	The lung may be displaced by the chest wall or pleural tumor and can be avoided with preoperative RT, or permits GTV to be treated before operative contamination
Abdominal trunk walls, pelvic side wall	Proximity to the kidney, the bowel, the liver, and the ovaries	Avoid CTV encroachment on vulnerable anatomy
<i>GTV adjacent to dose limiting critical anatomy</i>		
Thoracic inlet/upper chest	Proximity to brachial plexus	Dose limitation of critical anatomy lends itself to preoperative wall low neck RT.
<i>Additional volume considerations</i>		
Medial thigh (young male)	Proximity to testes	Permanent infertility may be avoided
Central limb tumor	Proximity to other compartments	Permits partial circumferential sparing, which would not be feasible in postoperative setting

Methods of radiotherapy delivery

In general terms, the most generally accepted methods of delivering RT include EBRT and BRT. The former also includes the controversy about its scheduling (preoperative vs postoperative) discussed earlier and in conventional terms also needs attention to the potential role of IMRT that was also mentioned earlier. No randomized trials directly comparing external beam RT and BRT have been undertaken, but both forms of RT have been compared with surgery alone. There also have been no randomized trials addressing IMRT but two prospective phase II trials exist and institutional data are emerging.

Intensity-modulated radiotherapy

Target coverage and protection of normal tissues from high-dose areas appear to be superior for IMRT compared to traditional techniques in ESTS.¹⁰² A recent retrospective review spanning noncoincident treatment time periods compared surgery combined with either IMRT ($n = 165$) or conventional EBRT ($n = 154$). Allowing for known limitations associated with studies involving treatments deployed over different eras, IMRT showed significantly reduced LR for primary ESTS (7.6% LR for IMRT vs 15.1% LR for conventional RT; $p = 0.02$).¹⁰³

Two prospective phase II trials [from Princess Margaret (NCT00188175) and the Radiation Therapy Oncology Group (RTOG 0630: NCT00589121)] investigated if preoperative image-guided radiotherapy (IGRT) using conformal RT/IMRT could reduce RT-related morbidities.^{98, 104} The characteristics of the Princess Margaret (PMH) and RTOG 0630 trials differed in several ways, particular relating to the exclusion of upper extremity lesions in the PMH trial, the use of a boost following preoperative RT in RTOG 0630 as well as the potential to use chemotherapy in the RTOG trial, and some aspects of the choice of target coverage mentioned below. The two trials also differed regarding their primary endpoints.

The PMH trial showed reduced wound-healing complication (WC) rates (31%) in lower extremity compared to the 43% risk in the previous Canadian Sarcoma Group NCIC SR2 trial that only used 2D and 3D RT.⁹⁶ The need for tissue transfer, RT chronic morbidities, and subsequent secondary operations for WCs were reduced while maintaining good limb function and local control (93%). The RTOG-0630 trial reported a significant reduction of late toxicities in comparison to the NCIC-SR2 trial (11% vs 37% in SR2), which is very similar to the IGRT PMH trial. Importantly, both the PMH and RTOG-0630 trials defined the CTV differently (longitudinal margin of 3 cm from the gross tumor for high-grade lesions and 2 cm for low-grade lesions versus 4 cm longitudinal margins in the PMH trial). Potentially, the reduction in CTV margins of this degree could explain the improvement in limb function with comparable local control, although an alternative possibility is the reduction in normal tissues receiving the target dose in all dimensions, which is shared by both studies. In the end, it also seems that IMRT is capable of conforming the dose more suitably to the desirable target volume compared to traditional conformal techniques.

Perhaps the greatest advantage to this approach is not only the possibility of improving local control but also the ability to spare bone toxicity and late fractures by achieving bone avoidance, which are often overlooked in the discussion of combined-modality treatments of extremity sarcoma. A recent study addressed evidence-based dose volume bone avoidance objectives for IMRT planning in 230 patients

(176 lower and 54 upper extremity) with a median follow-up of 41.2 months.¹⁰⁵ The overall risk of fracture was 2% (4/230 patients), which compares favorably to a previous reported incidence of 6%, and suggests that efforts to achieve bone avoidance are appropriate.

Brachytherapy

BRT has some putative advantages over external beam, including a shorter overall treatment time (4–6 days vs 5–6.5 weeks) and quicker initiation of RT after surgery while clonogenic numbers are at a minimum. Because of its brevity, BRT is also more easily integrated into protocols that include systemic chemotherapy than is external beam RT, with its protracted courses. The irradiated volume is also smaller with BRT, which may confer functional advantages. BRT may also have an advantage in situations in which normal tissue tolerance to RT is compromised. One such scenario would be when a postoperative RT boost to the operative bed is desired in patients who received preoperative RT. The use of BRT with surgery in previously irradiated tissues is another situation to achieve limb salvage.^{106, 107} As noted earlier, no apparent benefit for BRT over surgical excision alone is evident with low-grade lesions, and external beam appears more effective for these tumors ([Table 3](#)).^{69, 70, 108} BRT also permits radiation volumes to be mapped according to intraoperative findings. The American Brachytherapy Society Guidelines differ from those for EBRT and also advise that BRT as a sole treatment modality is contraindicated in the following situations: (1) the CTV cannot be adequately encompassed by the implant geometry, (2) the proximity of critical anatomy, such as neurovascular structures, is anticipated to interfere with meaningful dose administration, (3) the surgical resection margins are positive, and (4) there is skin involved by tumor.^{109, 110}

BRT seems less useful where implant geometry is not optimal, such as in the upper extremity or more proximal limb regions.¹¹¹ The results of the BRT randomized trial were discussed earlier. In addition, BRT was compared retrospectively to IMRT in 134 high-grade ESTS with similar adverse features.¹¹² The 5-year local control rate was 92% for IMRT compared to 81% for BRT ($p = 0.04$). Unfortunately, while the results of BRT, including its more restrictive criteria for use, suggest lower efficacy compared to EBRT, there is no randomized controlled trial comparing these seemingly effective local adjuvants.

Traditionally BRT studies, including those mentioned above, used low-dose rate techniques. High-dose rate (HDR) BRT has potential logistic advantages including lower radiation staff exposure, outpatient delivery, and optimized dose distributions by varying dwell times. However, wound-healing complications may occur in sarcoma management and caution is also recommended when placing catheters adjacent to neurovascular structures. As yet, no large series evaluating HDR BRT for STS is available nor has it been directly compared to LDR, partly because of technical differences.

Additional approaches to RT delivery

In addition to external beam RT, BRT, and IMRT, several other approaches for RT delivery exist. These include particle beam RT (electrons, protons, pions, or neutrons), intraoperative radiotherapy (IORT) using external beam or BRT approaches, and combinations of other techniques (e.g., hyperthermia) with RT. IORT has been used most often in the management of RPS and will be discussed later. Some reports also describe IORT for extremity sarcomas.^{113, 114} Formal clinical trials have not compared the relative merits of these approaches, and their use may be governed as much by the availability of an approach at a given center as by any special advantage that it may confer. In the case of proton beam RT, its ability to achieve accurate targeting provides an advantage when tumors lie in proximity to critical structures.^{115, 116} In general, however, although reports on the use of many of these approaches exist, the problems of

selection bias need to be considered in interpreting these small series in which treatments were not randomly assigned.^{117, 118}

Systemic therapy

Systemic agents, including both traditional cytotoxic chemotherapy drugs and newer small molecule oral kinase inhibitors (SMOKIs), are used widely in the metastatic setting for patients with STSs. The use of chemotherapy in the adjuvant setting remains somewhat controversial. However, if chemotherapy is going to have the same impact as radiation and surgery in the management of sarcomas, more effective drugs must be identified to help improve the cure rate for patients with primary tumors and unseen microscopic metastatic disease. This section will review the use of chemotherapy in the adjuvant and metastatic settings. A brief discussion of chemotherapy combined with radiation therapy is also included in this section.

Adjuvant systemic therapy following primary surgical resection

Although local or local–regional recurrence is a problem for a small subset of patients following primary therapy, the major risk to life in sarcoma patients is uncontrolled systemic disease. The availability of systemic therapy with proven, albeit often limited, ability to induce shrinkage of advanced sarcomas has raised the question of whether the early use of systemic treatment might affect microscopic metastatic disease and yield improvements in OS and disease-free survival (DFS).

Certainly for Ewing sarcoma/PNET, rhabdomyosarcoma, and osteogenic sarcoma, adjuvant or neoadjuvant chemotherapy is an appropriate standard of care.^{119–122} However, for more common STSs such as leiomyosarcoma, liposarcoma, and high-grade UPS (formerly known as MFH), the benefit of chemotherapy, if there is one, is small.¹²³ As adjuvant therapy is utilized by many practitioners for more common diseases where the benefit is a relatively small one, such as stage I breast cancer and stage II colon cancer, this small potential benefit is an issue that needs to be discussed on an individualized basis. Certainly, the lack of available effective agents for metastatic sarcoma has impeded progress in this area, but the utility of imatinib in both the metastatic and adjuvant setting in GIST gives hope that new agents will contribute to the ultimate goal of any type of systemic therapy specifically increasing the cure rate for people with new diagnoses.

There have been over a dozen studies of anthracycline-based adjuvant chemotherapy for STSs that date back nearly as long as the initial development of doxorubicin.^{124, 125} These will not be reviewed here, as anthracycline/ifosfamide-based therapy constitutes a better standard of care in patients offered adjuvant chemotherapy, and only one of the studies completed by 1992 had used ifosfamide.

In one of the largest combination chemotherapy studies, the Italian Sarcoma Study Group (ISSG) examined patients with primary or recurrent resected STS of the extremity or limb girdle treated or not treated with radiation.^{126, 127} A total of 104 patients were randomized to receive no chemotherapy or to receive ifosfamide (1800 mg/m²/day for 5 consecutive days with mesna) and epirubicin (60 mg/m² on 2 consecutive days), with filgrastim support. Interim analysis in 1996 led to early conclusion of the trial because the study had reached its primary endpoint, specifically improved DFS. At a median follow-up of 36 months, OS in the chemotherapy arm was 72%, compared with 55% for the control arm ($p = 0.002$). However, with long-term follow-up, the OS difference showed only a trend to statistical significance on an intention-to-treat analysis.¹²⁶ This study is the strongest single study in the literature supporting the use of adjuvant chemotherapy for STS. Interpretation of the study is made more difficult with the observation of equivalent distant \pm LR rates at 4 years.

Conversely, no survival benefit was observed in an EORTC phase III study of adjuvant chemotherapy versus observation (doxorubicin 75 mg/m², ifosfamide 5 g/m² per cycle for 5 cycles, with filgrastim support).¹²⁸ A total of 351 patients were accrued between 1995 and 2003, and 130 (80%) of the 163 patients receiving chemotherapy completed all 5 cycles. OS was not statistically different between arms (HR 0.94, 95% confidence interval 0.68–1.31 for the treatment arm, $p = 0.72$) and relapse-free survival was also not statistically different (HR 0.91, CI 0.67–1.22, $p = 0.51$). The 5-year OS rate was 67% for the treatment arm and 68% for the control group. The major differences between this study and the ISG study were a lower dose of ifosfamide and use of epirubicin in the ISSG trial, but it is unclear based on data from metastatic disease of the relevance of these differences.

The most recent and comprehensive overview of adjuvant chemotherapy for extremity sarcomas to date was the 2008 meta-analysis of 18 studies encompassing sarcomas of all anatomic sites.¹²⁹ In this analysis, 93 potential studies were considered and 18 ultimately selected, constituting 1953 patients with STSs of extremity and nonextremity. Pathology review was not centralized. The results of the meta-analysis, including the actuarial outcome probabilities and the hazard ratios, are summarized in [Figure 10](#) and [Table 5](#).

Overall survival	0.84 (0.68–1.03)	0.56 (0.36–0.85)	0.77 (0.64–0.93)

Source: Pervaiz et al. 2008.¹²⁹ Reproduced with permission of Wiley.

Study data from the 18 trials were combined without examining individual patient data. Combining all data, LR risk, distant recurrence risk, overall recurrence risk, and OS were superior with chemotherapy. For OS, the relative risk of death was 0.77 with chemotherapy (95% CI, 0.64–0.93), $p = 0.01$, and relative recurrence risk was 0.67 (95% CI, 0.56–0.82), $p = 0.0001$. The absolute risk reduction of any recurrence was 10% and absolute risk reduction for OS was 6%. However, as pointed out in a commentary on a prior meta-analyses,¹³¹ these data have to be interpreted with caution. For example, (1) individual patient data were not reviewed and interrogated, (2) in an older analysis, 18% of patients did not have histology available for review, recognizing the error rate in pathology review at expert centers, (3) ineligibility rates were high, and (4) the largest individual trial was not included (published after the meta-analysis publication). Although the meta-analysis cannot replace a well-designed randomized study, it reinforces many of the findings from smaller studies that local and distant recurrence-free survival is definitely improved, and OS modestly so, at least in unselected patients.

Preoperative (neoadjuvant) chemotherapy

Preoperative chemotherapy has theoretical advantages over postoperative treatment. First, preoperative chemotherapy provides an *in vivo* test of chemotherapy sensitivity. Patients whose tumors show objective evidence of response are presumed to be the subset that will benefit most from further postoperative systemic treatment. In contrast, it is assumed that the population of nonresponding patients will derive minimal or no benefit from further chemotherapy and can therefore be spared its toxicity. On the other hand, it is conceivable that the patients whose tumors respond to chemotherapy may not be those who would derive the most from chemotherapy, because these lesions with favorable biology might be those destined to do well irrespective of any systemic treatment. In contrast, those who do not respond may be those with unfavorable disease who could derive the greatest benefit from the discovery of highly effective systemic treatments.

A second potential advantage of preoperative chemotherapy is that it treats occult microscopic metastatic disease as soon as possible after the cancer diagnosis. This may theoretically prevent the development of chemotherapy resistance by isolated clones of metastatic cells or prevent the postoperative growth of microscopic metastases, but given the nature of growth of sarcomas, at most one or two doublings of the tumor would be affected, far fewer than the >35 typically required in the development of a >1-cm tumor. Chemotherapy-induced cytoreduction may permit a less radical and consequently less morbid surgical resection than would have been required initially. In patients with large STS of the extremities, cytoreduction may reduce the morbidity of limb-sparing surgical procedures and possibly even allow patients who might otherwise have required an amputation to undergo limb-sparing surgery.

Investigators from the MD Anderson Cancer Center reported long-term results with doxorubicin-based

preoperative chemotherapy for AJCC stages IIC and III (formerly AJCC stage IIIB) extremity STS.¹³² In a series of 76 patients treated with doxorubicin-based preoperative chemotherapy, radiologic response rates included complete response, 9%; partial response, 19%; minor response, 13%; stable disease, 30%; and disease progression, 30%. The overall objective major response rate (complete plus partial responses) was 27%. At a median follow-up of 85 months, 5-year actuarial rates of LR-free survival, distant metastasis-free survival, DFS, and OS were 83%, 52%, 46%, and 59%, respectively. The event-free outcomes reported from MD Anderson are similar to those observed with chemotherapy in the phase 3 postoperative chemotherapy trials. Furthermore, comparison of responding patients (complete and partial responses) and nonresponding patients did not reveal any significant differences in event-free outcome. Conversely, only 1/29 patients in a smaller study from Memorial Sloan-Kettering demonstrated WHO defined tumor shrinking after two cycles of doxorubicin-based therapy.¹³³

Ifosfamide-containing combinations also have been used in the preoperative setting. Selected patients treated with aggressive ifosfamide-based regimens have had major responses, and preliminary results suggest that response rates may be higher than in historic controls treated with non-ifosfamide-containing regimens.¹³⁴ However, as noted above, the randomized phase 2 neoadjuvant study of doxorubicin and ifosfamide chemotherapy showed no benefit for the treatment arm, although the study was not specifically designed to determine a survival advantage.¹³⁵

Regional administration of chemotherapy

It is hypothesized that the antineoplastic action of adjuvant chemotherapy will be improved by modifying factors related to drug delivery. One such modification is administering chemotherapy regionally rather than systemically. Intraperitoneal chemotherapy is used in primary therapy of ovarian cancer or appendiceal carcinoma, where it remains more superficial and accessible to peritoneal chemotherapy compared to other cancers that more commonly form more distinct masses that intraperitoneal chemotherapy cannot penetrate. For a period of time, intraperitoneal chemotherapy was used for GIST and gastrointestinal leiomyosarcomas that spread to the peritoneum, but this approach was abandoned given the access to tyrosine kinase inhibitors for GIST. Perhaps the situation in which regional therapy is most commonly used for sarcoma is intra-arterial chemotherapy used in some centers for osteogenic sarcoma, which provides both a higher concentration of drug locally as well as systemic effects after infusion. In some situations, chemotherapy is administered with radiation (see below).

Other investigators evaluated whole-body or regional hyperthermia to enhance the efficacy of combination chemotherapy, using methods to increase the temperature of the entire body or a specific region alone to 41°C.^{136–138} In the 341 patient randomized study of primary and locally recurrent high-risk sarcomas, combination of preoperative hyperthermia and EIA chemotherapy (etoposide, ifosfamide, and doxorubicin) was superior to EIA alone in terms of local control and disease-free survival, although OS was not impacted. The study was criticized for not being able to sort out the contribution of radiation and hyperthermia, and what appeared to be a high frequency of R1 and R2 resections for patients going on study. Concurrent hyperthermia and chemotherapy is an approved treatment in some European countries, but remains investigational in the United States.

Combined preoperative chemotherapy and RT

Data regarding combination chemotherapy and radiation are more developed than hyperthermia and chemotherapy, largely from the commonality of the former being available at various institutions. As with combinations with hyperthermia, the primary putative advantage of preoperative chemotherapy with radiation is the potential to shrink selected lesions resectable only by amputation sufficiently that they

become amenable to a limb-sparing approach.

Concurrent chemotherapy and radiation has been employed extensively by Eilber and colleagues at UCLA and has been modified and examined by other groups.^{139, 140} The first chemotherapy–radiation treatment protocol typically involved intra-arterial doxorubicin with high dose per fraction RT (35 Gy of external beam radiation delivered in 10 daily fractions, which was reduced to 17.5 Gy in 5 daily fractions to minimize local toxicity). Although the intra-arterial route delivers chemotherapy more directly to the tumor, it is more complex, expensive, and prone to complications than intravenous chemotherapy.¹⁴¹ Indeed, a prospective randomized trial comparing preoperative intra-arterial doxorubicin with intravenous doxorubicin, both followed by 28 Gy of radiation delivered over 8 days and then surgical resection, showed no differences in LR or survival.¹⁴⁰

The largest study to date directly studying systemic chemotherapy combined with RT examined razoxane as the radiation-sensitizing agent in a randomized study of drug versus no drug in combination with radiation therapy for resectable or unresectable STSs.¹⁴² Acute skin reactions were enhanced in the razoxane arm, but late toxicity was not greater than in the control arm. Although there are imbalances in the arms of the study, for the 82 of 130 evaluable cases examined with gross disease RT (median dose 56–58 Gy) with razoxane (daily oral doses of 150 mg/m² throughout RT) showed an increased response rate (74% vs 49%) and improved local control rate (64% vs 30%; $p < 0.05$) compared with external beam radiation alone.

Either ifosfamide or cyclophosphamide has been routinely combined with radiation therapy as part of the definitive therapy for Ewing sarcoma and rhabdomyosarcoma in an attempt to continue systemic therapy at the same time as maximizing local control.¹¹⁹ In general, toxicity does not appear to be greater than that seen for radiation alone. However, skin toxicity from the combination was greater in one study than that seen with radiation alone.¹⁴³

An alternative sequential chemotherapy and radiation strategy in patients with localized, high-grade, large (>8 cm) extremity STSs has been examined.^{144–146} This treatment protocol involved 3 courses of doxorubicin, ifosfamide, mesna, and dacarbazine (MAID) with two 22-Gy courses of radiation (11 fractions each) for a total preoperative radiation dose of 44 Gy. This was followed by surgical resection with careful microscopic assessment of surgical margins. An additional 16-Gy (8 fraction) boost was delivered for microscopically positive surgical margins. The outcomes of 48 patients treated with this regimen were compared with those of matched historic controls and was superior to that of the historical control patients.¹⁴⁴ The 5-year actuarial local control, freedom from distant metastasis, DFS, and OS rate were 92% versus 86% ($p = 0.1155$), 75% versus 44% ($p = 0.0016$), 70% versus 42% ($p = 0.0002$), and 87% versus 58% ($p = 0.0003$) for the MAID and control patient groups, respectively. Febrile neutropenia was a complication in 25% of patients. Wound-healing complications were substantial and occurred in 14 (29%) patients receiving the chemotherapy/radiation sequential therapy. One patient who received chemotherapy developed late fatal myelodysplasia. Given the favorable results of this study in comparison to historical controls for high-risk extremity STS, the Radiation Therapy Oncology Group conducted a multi-institutional trial, modifying the chemotherapy in an attempt to address the local toxicity issue. The report of the trial suggested combined-modality treatment can be delivered successfully in a multi-institutional setting albeit with some toxicity. Efficacy results are consistent with previous single-institution results.^{145, 146} The question remains whether this approach in high-risk, extremity STS confers significant survival benefits following and intense regimen of neoadjuvant chemoradiotherapy and surgery, which seems sustained even with long-term follow-up.

Although significant toxicity was observed, local control was improved in the prior studies compared to

historical controls, raising the possibility that combined chemotherapy and radiation could be combined safely to decrease local control risk. Pisters et al.¹³² examined concurrent doxorubicin and irradiation in the neoadjuvant setting in 27 patients with extremity STS. Preoperative external beam radiation was administered in 25 fractions of 2 Gy each. Doxorubicin was administered in escalating doses with a bolus followed by 4-day continuous infusion weekly. Radiographic restaging was performed 4–7 weeks after chemoradiation. Patients with localized disease underwent surgical resection. The maximum tolerated dose of continuous infusion doxorubicin combined with standard preoperative radiation was 17.5 mg/m²/week; 7 of 23 (30%) patients had grade 3 dermatologic toxicity at this dose level. Macroscopically complete resection (R0 or R1) was performed in all 26 patients who underwent surgery. In 22 patients who were treated with doxorubicin at the maximum tolerated dose and subsequent surgery, an encouraging 11 patients (50%) had 90% or greater tumor necrosis, including 2 patients who had complete pathologic responses. This approach appears valid with other radiation-sensitizing agents as well, such as gemcitabine.¹⁴⁷ Further studies of combination therapy are also discussed later in the section titled “Retroperitoneal Sarcomas.”

Other multicenter trials of adjuvant therapy for STS

It is well recognized that different sarcoma subtypes have different chemotherapy resistance/sensitivity patterns, details of which are discussed in greater detail elsewhere.⁶¹ For example, synovial sarcoma is typically resistant to gemcitabine–docetaxel, and leiomyosarcomas are typically less sensitive to ifosfamide than other forms of sarcoma. Synovial sarcoma and myxoid/round-cell liposarcoma appear to be more sensitive to chemotherapy in the metastatic setting than other subtypes of sarcoma and may well be two subtypes that respond to both anthracyclines and ifosfamide. These data argue that adjuvant chemotherapy should be examined on a subtype-specific basis. Combined nonrandomized data from UCLA and MSKCC showed that adjuvant chemotherapy may indeed be useful in the setting of synovial sarcomas and myxoid/round-cell liposarcoma and argued for the use of chemotherapy in the neoadjuvant setting for all types of STS, based on institutional databases.^{148–150} Notably, data of all patients treated or not treated with chemotherapy from MD Anderson and MSKCC indicated in the adjuvant or neoadjuvant setting that there was no statistical difference in OS in the group of patients who received chemotherapy versus those who did not.¹⁵¹ However, these data are inherently biased in that it is likely that younger, healthier patients with higher risk tumors were those selected to receive chemotherapy. Even though there was no statistically significant difference between the group of patients who received chemotherapy and those who did not, there were still shifts in the frequency of patients with larger sarcomas with a predominance of liposarcoma toward receiving chemotherapy, perhaps representing the selection bias that allowed a group of patients with an inherently poorer outcome to do as well as those with a better outcome.

In summary, for AJCC stage III STS, if there is a benefit to chemotherapy in the adjuvant setting, it appears to be a modest one. There is variation in practice between centers and between practitioners as to who is an appropriate candidate for chemotherapy. Given this situation, it is the authors' practice to attempt to compare benefits and risks of systemic therapy and individualize the plan of treatment for a given clinical setting. Patients below age 50 may be those who benefit most among this very heterogeneous patient population. Certainly, the finding of 35% or more of STS with specific genetic translocations or mutations brings hope that the benefit seen with GIST and adjuvant imatinib therapy will carry over to the adjuvant setting for a subset of patients with STS of the extremities and trunk when traditional adjuvant cytotoxic chemotherapy is combined with novel therapeutics.

“Pediatric” sarcomas and adjuvant therapy

The standard of care for nearly all sarcomas specific to the pediatric population involves chemotherapy. It is of proved benefit in patients with osteogenic sarcoma, Ewing sarcoma, and rhabdomyosarcoma. A few brief comments on these chemotherapy-responsive tumors follow.

Neoadjuvant chemotherapy is the standard of care for the initial treatment of osteogenic sarcoma.¹²¹ In the era before systemic therapy, cure rates for osteogenic sarcoma, even in the setting of amputation for primary disease, was only on the order of 15%. With chemotherapy, the survival rate is 65–70%. Yet the 30–35% of patients who relapse remain a frustrating problem because the addition of new agents has changed the chance for cure comparatively modestly, and the one agent demonstrating benefit in a randomized trial was not approved in the United States.¹²⁰ The outcome of adjuvant chemotherapy (degree of tumor necrosis after chemotherapy) is directly associated with improved clinical outcome and provides the opportunity for changing chemotherapy for a poor initial response. The standard of care for adjuvant chemotherapy is a backbone of cisplatin and doxorubicin, with methotrexate employed in most pediatric and some adult patients. The benefit for methotrexate as part of adjuvant treatment was called into question in a 1997 paper in which the combination of doxorubicin and cisplatin alone was shown equivalent to a more complicated and toxic regimen containing high-dose methotrexate.¹⁵² However, the methotrexate component of neoadjuvant therapy has been observed to be important in a variety of studies and remains an integral part of combination therapy for osteosarcoma.¹⁵³ Less questionable is the benefit from nonspecific immune system stimulator muramyl tripeptide (MTP), which was shown in a large pediatric clinical trial to improve OS when used in the adjuvant setting, while there was no benefit in survival seen with the addition of ifosfamide to the standard methotrexate–doxorubicin–cisplatin (MAP) backbone.¹²⁰

Through a series of international clinical studies, the adjuvant program for rhabdomyosarcoma typically involves an induction course of chemotherapy, followed by combination chemotherapy and radiation, followed by the completion of chemotherapy, which will last approximately 48 weeks in pediatric population. The standard of care is the combination of vincristine, dactinomycin, and cyclophosphamide, as this combination was shown as effective as VAI and VIE and less toxic.¹¹⁹ The addition of doxorubicin to the vincristine, dactinomycin, and cyclophosphamide regimen did not appear to improve OS and is omitted in the treatment of pediatric rhabdomyosarcoma.¹⁵⁴ The frequent dosing of vincristine is extremely difficult to complete for adults and requires dose adjustment or shorter courses of therapy for adults than for children with this diagnosis. Children with this diagnosis appear to fare better than adults with the same diagnosis stage in most studies, as well as in everyday practice.^{155, 156}

For patients with Ewing sarcoma, in distinction from rhabdomyosarcoma, the addition of additional agents (ifosfamide and etoposide) to an existing backbone of vincristine, doxorubicin, and cyclophosphamide chemotherapy improved outcome for localized disease, with a 2-week schedule superior to a 3-week schedule of treatment;¹²² however, not published were data that the 2-week schedule was not beneficial for patients over age 18. This 5-drug regimen is a good standard of care for patients with a new diagnosis of Ewing sarcoma. It is often difficult to administer the 14 cycles of chemotherapy to adults, and abbreviation to the adjuvant therapy program is often necessary. It is also not clear if all 14 cycles are necessary for best outcomes. As with rhabdomyosarcoma, children with Ewing sarcoma fare better than adults with the same diagnosis, all else being equal.^{157–159}

Treatment of locally advanced disease

Hyperthermic isolated limb perfusion, isolated limb infusion, and regional hyperthermia

Hyperthermic isolated limb perfusion (ILP), an investigational technique in the United States (although recently approved by regulatory agencies in other parts of the world), has received considerable attention in the treatment of locally advanced, unresectable sarcomas of nonosseous tissues. ILP involves local perfusion of high-dose chemotherapy (most commonly melphalan) and, when available, tumor necrosis factor alpha (TNF α) under hyperthermic conditions. An oxygenated circuit is established by local arterial and venous cannulation on a bypass pump. Systemic circulation is minimized by placement of a tourniquet proximally.

ILP has been evaluated in two settings: (1) attempted limb preservation in cases of locally advanced extremity lesions surgically amenable only to amputation and (2) function extremity preservation for the short survival duration anticipated in cases of locally advanced extremity lesions with synchronous pulmonary metastases (stage IV disease).

A multicenter phase 2 trial evaluated a series of 55 patients with radiologically unresectable extremity STS using HILP with high-dose TNF α and melphalan, and interferon- α in some patients.¹⁶⁰ A major tumor response was seen and limb salvaged in over 80% of patients. Regional toxicity was limited, and systemic toxicity was minimal to moderate. There were no treatment-related deaths. Despite the high rate of complete responses (15–30%) and limb sparing (>80%) achieved by ILP, no randomized trials have compared ILP to aggressive limb-sparing resection with RT for STS. Therefore, ILP should be considered as a potential treatment, when other options are limited or not available, in appropriately selected patients. Eligible patients should be referred to centers where this therapy is available.

Isolated limb infusion (ILI) has been evaluated in extremity STS in a more limited manner, and parallels work done with intra-arterial chemotherapy. Like IPL, ILI relies on circulating high-dose chemotherapy in an isolated extremity. Unlike ILP, ILI is conducted through percutaneously placed catheters and is performed under hypoxic conditions. However, there is limited experience with ILI in extremity STS. Similar to ILP, ILI has not been directly compared to aggressive limb-sparing resection with EBRT in a randomized trial. However, patients under consideration for ILP and ILI are often not candidates for surgery with EBRT at first evaluation, and therefore ILP and ILI may be considered as potential therapies in appropriately selected patients.

Definitive radiation for local control

Apart from patients with some very radiosensitive subtypes of sarcomas, most patients who undergo RT as the sole treatment modality for sarcoma have been deemed to have locally advanced unresectable disease. RT alone is a rare treatment choice that should be done only at centers skilled in the management of sarcomas; medically fit patients with grossly “unresectable” but nonmetastatic disease should always be referred to a specialty center for multidisciplinary management, which may combine surgery, RT, and possibly chemotherapy. For example, proximal inguinal or axillary tumors that encircle major vascular structures in the proximal leg or arm may be resected along with the involved vasculature and the vessels reconstructed. Adjuvant RT is also generally used. Rarely, a patient with truly inoperable locally advanced disease may require RT alone, with either photon or particle (proton, neutron, or pion) beams.^{161–163} No formal clinical trials have been performed to compare these strategies with each other, and they are generally administered in an adverse clinical setting. Local control has been reported in 40–70% range.

Treatment of metastatic disease

Clinical problem of metastases

The diagnosis of recurrent or metastatic disease in patients with STSs is often heartbreaking. Patients and physicians are aware that, in general, such a diagnosis is typically fatal. The role of the multidisciplinary sarcoma team in the management of patients with metastatic sarcoma is to recognize opportunities in which multimodality care might still improve important outcomes such as survival or quality of life. Both surgery and systemic chemotherapy can play an important role in improving these outcomes in selected patients. Overall, it is important to recognize that chemotherapy is usually given with the palliative aim of prolonging life and improving quality of life.

The most common site of metastasis from STS of the extremities is the lungs. Indeed, the lungs are the only site of metastasis in approximately 80% of patients with metastases from primary extremity and trunk STS.⁶¹ Primary visceral and gastrointestinal sarcomas such as GIST commonly metastasize to the liver, while other visceral sarcomas may metastasize to lungs as well. Extrapulmonary metastases are uncommon forms of first metastasis from extremity sarcomas and usually occur as a late manifestation of widely disseminated disease. The median survival after development of distant metastases is approximately 12 months ([Figure 11](#)),¹⁶⁵ although more contemporary data suggest that median survival may presently be 15–18 months for unselected patients who receive cytotoxic chemotherapy; the optimal treatment of patients with metastatic STS requires an understanding of the natural history of the disease and individualized selection of treatment options based on patient factors, disease factors, and limitations imposed by prior treatment.

Figure 11 Postmetastasis survival (from time of diagnosis of M1 disease) in a cohort of 230 patients with primary STS of the extremities. The median postmetastasis survival was 11.6 months.

Source: Slater et al. 1986.¹⁶⁴ Reproduced with permission of Elsevier.

The approach to patients with advanced or metastatic sarcomas is changing over time. We increasingly realize clinical trials must be stratified rationally for data of value to be derived. Studies of “sarcomas” without stratification by histology or molecular features will soon seem as naïve as studies of “cancer” without further qualification. These mesenchymally derived diseases lumped under the heading of “sarcomas” can be quite different, and studies need to take that into account. In a similar manner, the consideration of a specific sarcoma histology may be supplemented or even superseded by the genetic profile of the tumor. To generate studies of sufficient size and power, large-scale collaborations on a national and international level will be required. Such collaborations are already in place among the nations of Europe individually and collectively (e.g., the Soft Tissue and Bone Sarcoma Group of the EORTC), Canadian centers, and cooperative trials groups and other clinical trials collaborations such as SARC (Sarcoma Alliance for Research through Collaboration) in the United States. With these collaborations, it is hoped that further research will rapidly translate research findings into the novel therapeutics that are so desperately required by patients with sarcomas.

Resection of metastatic disease

Many investigators have reported their experience with pulmonary metastasectomy for metastatic STS in adults.^{166, 167} Three-year survival rates following thoracotomy for pulmonary metastasectomy range from 23% to 54%. As a result, some patients can be resected with curative intent, similar to the situation for osteogenic sarcoma. As the ability to completely resect all metastatic disease is an important determinant of outcome, the reported interinstitutional variability in postmetastasectomy survival rates is partially a

function of whether survival was reported for all patients who underwent thoracotomy or only for the subset who underwent complete resection.

It remains difficult to predict which patients with pulmonary metastases will benefit from pulmonary resection. A number of clinical criteria have been evaluated by univariate analysis in this regard, including the disease-free interval, number of metastatic nodules, and tumor doubling time. Multivariate analyses from both the NCI and Roswell Park Cancer Institute confirm that a short disease-free interval and incomplete pulmonary resection are adverse prognostic factors for survival for patients with pulmonary metastases.^{166–169} A multivariate analysis from MD Anderson suggested that, in addition, the presence of more than three metastatic pulmonary nodules on preoperative chest CT is an adverse prognostic sign. The most important prognostic factor impacting survival appears to be the ability to completely resect all disease. In the review of postmetastasectomy outcomes in one series, the median survival among patients who were able to undergo complete resection of metastases was 20 months as compared with 10 months among patients who did not have complete resection ([Figure 12](#)).¹⁶⁵ In summary, the ability to achieve complete resection and the number of pulmonary nodules present appear to best define the postoperative prognosis for these patients.

Figure 12 Postmetastasis survival stratified by resection of pulmonary metastatic disease. The median survival among patients undergoing complete resection of pulmonary metastatic disease was 20 months.

Source: Billingsley et al. 1999.¹⁶⁵ Reproduced with permission of Wiley.

Unfortunately, metastasectomy benefits only a fraction of patients who develop pulmonary metastases. This is best illustrated by data from MSKCC, where a population of 716 patients who presented with primary extremity sarcoma were followed for the subsequent development and treatment of pulmonary metastases ([Figure 13](#)).¹⁷⁰ Of an initial group of 716 patients, 148 patients (21%) developed pulmonary metastases. Isolated pulmonary metastases occurred in 135 (91%) of these 148 patients. Of the 135

patients with pulmonary-only metastases, 78 (58%) were considered to have operable disease, and 65 (83%) of those taken to thoracotomy were able to undergo complete resection of all of their pulmonary metastatic disease. Thus, 44% of all patients with pulmonary metastases were able to undergo complete metastasectomy. The median survival from the time of complete resection was 19 months, and the 3-year survival rate was 23%. All patients who did not undergo thoracotomy died within 3 years. For the entire cohort of 135 patients developing pulmonary-only metastases, the 3-year survival rate was only 11%.

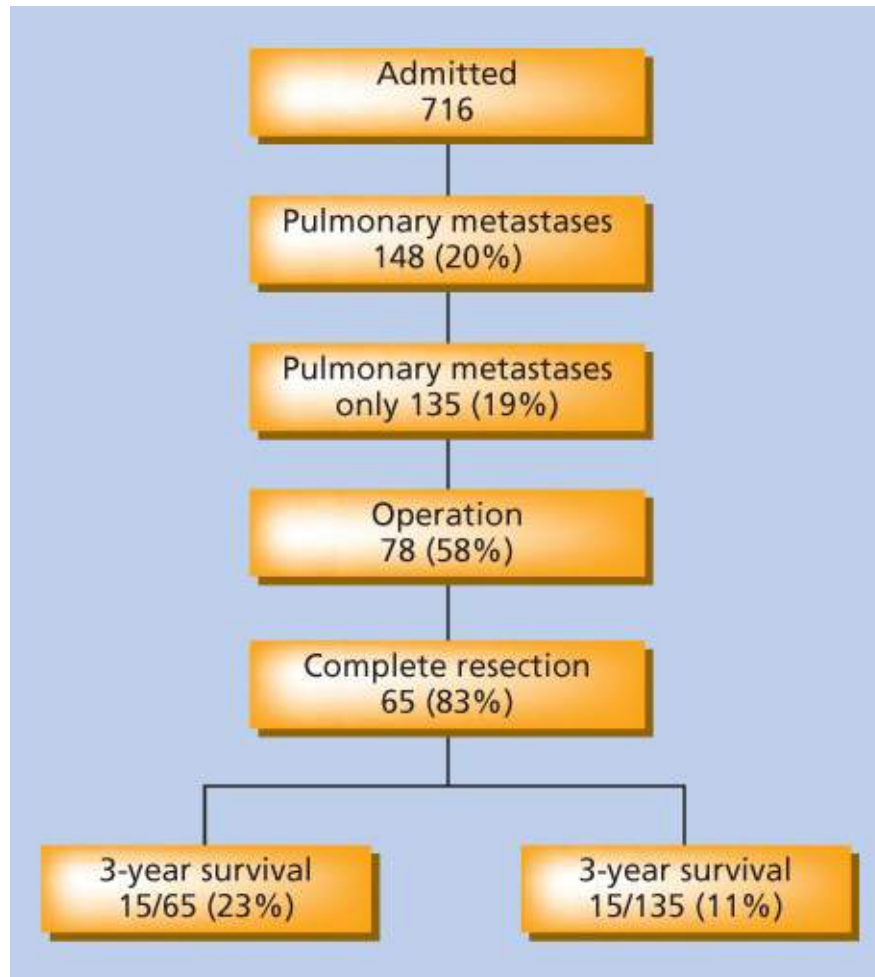

Figure 13 Risk and subsequent management of pulmonary metastases in 716 patients with primary or locally recurrent extremity STS.

Source: Brennan 1996.¹⁷⁰ Reproduced with permission of Elsevier.

Several series of repeat pulmonary metastasectomy also have been published. In a series of 43 patients thus treated at the NCI, 72% of patients could be rendered free of disease at the second thoracotomy, with a median survival duration from the time of second thoracotomy of 25 months.¹⁷¹ In a report from MD Anderson of a series of 39 patients undergoing reoperation for a second pulmonary metastasis after successful initial metastasectomy, factors predicting long-term survival included the presence of a solitary metastasis and the ability to perform a complete resection.¹⁷² Patients with isolated second metastatic sites fared better than those with multiple resected lesions.

The disappointing overall results of treatment of metastatic disease underscore the importance of careful patient selection for resection of pulmonary metastases. The following criteria are generally agreed upon: (1) the primary tumor is controlled or is controllable, (2) there is no extrathoracic disease, (3) the patient is a medical candidate for thoracotomy and pulmonary resection, and (4) complete resection of all disease appears possible. With careful patient selection, the morbidity of thoracotomy (or repeated thoracotomies) can be limited to the subset of patients who are most likely to benefit from this aggressive

treatment approach. The potential role of systemic adjuvant chemotherapy following complete metastasectomy is discussed below in the section “Individualized Therapy” on individualizing chemotherapy for metastases.

Chemotherapy for metastatic disease

Natural history of metastases

A good place to begin a discussion of chemotherapy for unresectable metastatic sarcoma is the expected course of the disease. The EORTC contributed greatly to define the expected course of unresectable metastatic sarcoma by publishing its large series of more than 2000 patients with advanced sarcomas of soft tissues to describe prognostic features and the response to anthracycline-based chemotherapy in an era before GIST was recognized as a unique entity.¹⁷³ In this study reviewing more than 20 years of experience, the median OS was approximately 1 year. Subsets of patients had longer median survival; such patients were typically those who were younger, had a better performance status, had low-grade sarcoma, had no liver metastases, and had developed metastatic disease following a longer interval from initial diagnosis. Importantly, this study concluded that the variables predicting improved survival were actually different from variables predicting objective response to chemotherapy (the latter variables include such items as high-grade tumor and liposarcoma subtype). Thus, one interpretation that is reasonable is that the most important predictors of survival with metastatic sarcoma are variables dependent on the tumor biology itself, as well as certain patient factors such as age and comorbid disease. These data are critical to understand so that information regarding the impact of new drugs and treatments can be interpreted appropriately, based on a comparison with the correct expectations for the natural or treated history of the disease in past clinical trials.

Individualized therapy

The approach to patients with advanced or metastatic sarcomas is evolving as are new therapeutics, and in this context, the use of therapies directed at specific histologies or DNA alterations is evolving, as are the entirely orthogonal approaches involving immunotherapy. We increasingly recognize that clinical trials must be stratified rationally for data of value to be derived. Studies of “sarcomas” without stratification will soon seem as naïve as studies of “cancer” without further qualification; each of the >50 mesenchymal cancers lumped under the heading “STSs” has a distinct biological behavior, and studies need to take that into account. To generate studies of sufficient size and power, large-scale collaborations on a national and international level will be required.

Tremendous effort has gone into testing multiple, commercially available and experimental agents in STS. Of all of these tested since the common use of ifosfamide, only trabectedin has been approved in Europe and pazopanib in many countries for use in metastatic soft tissue sarcoma; eribulin was also recently approved in the U.S. for liposarcoma; behind this are other novel variations on standard agents being studied, such as aldoxorubicin. For specific diagnoses, imatinib and other SMOKIs have activity, but are not specifically approved for use in sarcomas, save for imatinib in DFSPs. That said, gemcitabine with either docetaxel or DTIC in combination has been shown superior in progression-free and overall survival versus gemcitabine only in randomized studies. Some highlights of these data are noted in the following section.

Anthracyclines and ifosfamide

With the caveat that specific sarcomas demonstrate differential sensitivity to different chemotherapy

agents, doxorubicin and ifosfamide remain the most active agents for metastatic sarcoma, with RECIST response rates in the 10–20% range for each drug.¹⁷⁴ Depending on the ratio of sensitive versus less sensitive subtypes of STSs in past studies, the response rate can be significantly higher. For example, synovial sarcoma and myxoid/round-cell liposarcomas are relatively sensitive to ifosfamide (as well as doxorubicin), while GIST, alveolar soft part sarcoma, and extraskeletal myxoid chondrosarcoma appear to be largely resistant to both agents.

It is important to recognize that response rates *per se* increasingly are being criticized as poor surrogates of clinical benefit. Many sarcomas contain acellular desmoplastic stromal tissues. Even when chemotherapy successfully induces significant tumor cell kill *in vivo*, the matrix left behind appears largely unaffected, leading to falsely negative imaging findings of tumor response to chemotherapy. Thus, objective response rates based on imaging may underestimate the antitumor efficacy of chemotherapy. Conversely, simply shrinking a tumor and achieving a nondurable response may not be worth the toxicities of aggressive multiagent chemotherapy. Thus, from both standpoints, RECIST-defined responses may not be an ideal indicator of antitumor efficacy in sarcoma management in general, with GIST a case in point.^{175, 176} Increasing attention in the field of sarcoma drug development is thus being paid to other important indicators of clinical outcomes, such as progression-free survival duration, percentage survival at a given time point, and OS rate.

Some drugs may slow disease progression and prolong survival even if objective response rates are low, although the clinical data to support those claims must be generated with rigor and careful attention to consistency of follow-up. Nonetheless, despite observations that clinical benefit might be underestimated by RECIST, it remains the yardstick by which radiological responses are measured.

Dose–response relationships

The sensitivity of sarcomas to chemotherapy was first convincingly demonstrated with doxorubicin in the early to mid 1970s.¹²⁴ Subsequent studies of doxorubicin in sarcomas have widely been viewed as supporting a dose–response relationship, with doses of 50 mg/m²/cycle or less associated with less antitumor activity than doses of 60 mg/m²/cycle or higher. Although a dose–response relationship is evident, it is important to recognize that other variables may affect antitumor efficacy, such as histopathologic subtype of sarcoma, as noted above. Nonetheless, as a dose threshold for optimal activity has been documented with doxorubicin in another chemotherapy-sensitive solid tumor, specifically breast cancer, it seems reasonable to conclude that doxorubicin is best used at doses above 60 mg/m²/cycle. In addition, analogous to breast cancer, improved response rates above 75 mg/m²/cycle dose range are difficult to demonstrate.

A wide variety of dose- and schedule-ranging studies have been performed with ifosfamide. It is clear that antitumor response is improved by higher doses of ifosfamide.^{134, 177} This point has been made most convincingly by the responses to high-dose ifosfamide (≥10,000 mg/m²/cycle) in patients who had previously failed to respond to the same drug at lower doses (i.e., ≤6000 mg/m²/cycle). However, given the toxicities of this drug at higher doses, high-dose ifosfamide is best reserved for a subset of patients with disease that is expected to be chemotherapy sensitive to achieve meaningful responses (e.g., before planned surgical extirpation of metastases).

Single-agent versus combination chemotherapy

A continuing controversy is whether the optimal approach to patients with advanced sarcomas is combination chemotherapy regimens or sequential single agents. One of the best prospective randomized

trials of combination chemotherapy for advanced disease came from a US intergroup study in which ifosfamide was or was not given to previously untreated patients with metastatic or advanced STS receiving doxorubicin plus dacarbazine. This study demonstrated no survival advantage for the group receiving ifosfamide in combination with doxorubicin plus dacarbazine, although this group had a statistically significant increase in objective response rate.^{178, 179} The role of combination chemotherapy is further called into question for broad use given the statistically significant increase in toxicities when ifosfamide was added. Thus, despite the increased anticancer activity as evidenced by the small but significant improvement in response rates, no survival benefit was obtained by adding a third drug.

In a similar manner, the addition of higher dose ifosfamide (10 g/m² per cycle) to doxorubicin (75 mg/m² per cycle) was associated with a statistically significantly higher RECIST response rate (26% vs 14%), median progression-free survival rate (7.4 months vs 4.6 months), greater toxicity burden, and a trend to a survival advantage (14.3 months vs 12.8 months, $p = 0.076$).¹⁸⁰ It was not clear from these data if sequential use of the two agents would yield similar outcomes to combination treatment. The survival data in particular serve as a touchstone by which we determine success for therapy in metastatic sarcomas. The data from these two randomized trials support the use of combination chemotherapy for patients with symptomatic disease who are in need of a response; by the same token, it is not unreasonable to use single agents sequentially to minimize patient toxicity for less symptomatic or asymptomatic patients who remain in need of therapy.

Strategies to improve the therapeutic index of chemotherapy

Dose intensification using stem cells

An obvious strategy to increase response rates has been to increase dose intensity, adding stem cell support, as examined in hematological malignancies, breast adenocarcinoma, and other malignancies. This was initially attempted solely with provision of autologous bone marrow support and in the past decade has been significantly facilitated by the availability of hematopoietic cytokines to improve hematologic tolerance to myelosuppressive chemotherapy. It is clear that peripheral blood progenitor cells can be mobilized and harvested following standard chemotherapy for sarcoma supported by granulocyte colony-stimulating factor.¹⁸¹ Testing the limits of high-dose therapy, full-dose doxorubicin, ifosfamide, and cisplatin are possible with stem cell support not clearly better than standard dosing in osteogenic sarcoma.¹⁸² Even in chemotherapy-sensitive diseases such as Ewing sarcoma, dose intensification with autologous stem cell support does not appear to be beneficial for improving survival, although contamination of stem cells with tumor cells may be a contributing factor to its lack of efficacy. The use of high-dose chemotherapy with stem cell and cytokine support remains investigational for sarcomas.

Encapsulated anthracyclines

Another strategy to increase the therapeutic index of anthracyclines is to encapsulate the drug within a liposomal vehicle. At least three liposomal preparations of anthracyclines have been tested, and all have shown some efficacy against sarcomas. Notably, the most widely used agent has decreased cardiac risk in comparison to older preparations of larger liposomes containing doxorubicin. Pegylated liposomal doxorubicin (Doxil/Caelyx) is a small liposome with polyethylene glycol anchored within the lipid bilayer, acting as a hydrophilic coating to preserve the circulating half-life of the liposome and prevent degradation within the reticuloendothelial system. This preparation, given at a dose less than that of unencapsulated doxorubicin, is better tolerated than doxorubicin, with substantially less myelotoxicity,

cardiac toxicity, and alopecia at the cost of hand–foot syndrome and idiosyncratic reactions to the first dose of therapy; while its dose is lower, it has long half-life in the circulation (30–70 h), leading to an area under the curve for 50 mg/m² that is 300 times that of doxorubicin itself. In a randomized phase 2 study, pegylated liposomal doxorubicin demonstrated similar activity to normal doxorubicin (9% vs 10% response rate in the era before GIST was recognized as a separate type of sarcoma); formal noninferiority or equivalence was not determined, but pegylated liposomal doxorubicin was significantly less toxic than doxorubicin.¹⁸³ Less toxic anthracycline preparation has yielded a way to extend systemic therapy to patients with poorer performance status and in principle is a novel way of treating very slowly growing connective tissue lesions such as myxoid liposarcomas or desmoid tumors.

Beyond anthracyclines and ifosfamide

Few other agents beyond doxorubicin and ifosfamide demonstrate activity in soft tissue sarcoma, but this is a generalization in an era in which more histology specific data are needed for treatment decision making. It is recognized that dacarbazine (DTIC) has minor activity in STS, and studies have demonstrated that leiomyosarcoma and to a lesser degree solitary fibrous tumor are two diagnoses in which dacarbazine and its orally absorbed relative temozolomide have greatest activity.^{184–186} Gemcitabine and docetaxel as a combination was first demonstrated to have activity in uterine leiomyosarcoma, after relatively disappointing phase 2 trials of gemcitabine as a single agent, suggesting true synergy between the two agents.^{187, 188} Randomized study of gemcitabine and docetaxel showed the combination was superior to gemcitabine alone with respect to both PFS and OS in a group of unselected sarcomas.¹⁸⁹ Notably, responses were most common in UPS and pleomorphic liposarcoma, more than leiomyosarcoma. A randomized study demonstrated the superiority in PFS and OS of gemcitabine and dacarbazine over dacarbazine alone, the second in which gemcitabine combinations were superior to single agents in important radiological and clinical outcomes.¹⁹⁰ The addition of bevacizumab to the gemcitabine–docetaxel combination did not add to the chemotherapy backbone, and progression-free survival was numerically, although not statistically, inferior to treatment with the two chemotherapy drugs alone.¹⁹¹ Thus, either the gemcitabine–docetaxel or gemcitabine–dacarbazine combinations are good options after failure of doxorubicin and/or ifosfamide. Indeed, the perception of toxicity of gemcitabine-based therapy versus doxorubicin-based therapy has led to its acceptance in first line in metastatic sarcoma patients in the United States.¹⁹² The author generally employs gemcitabine–dacarbazine for leiomyosarcomas and gemcitabine–docetaxel in UPS, pleomorphic liposarcoma, and pleomorphic liposarcoma, given the responses seen to date on and off trial.

Newer agents

Sarcomas represent a fertile ground for the field of drug development. Doxorubicin was first recognized as an effective agent against sarcomas and subsequently was developed into one of the most widely used anticancer agents ever discovered. Imatinib and its spectacular results in a chemotherapy-resistant diagnosis provided a proof of principle that has since been borne out in other solid tumors with EGFR inhibitors, BRAF inhibitors, and the like. A few of newer agents and their utility in sarcoma are noted below. The next edition of this chapter will no doubt contain much more information on new drug and new targets in a specific histology or molecularly characterized subset of sarcomas, much as is happening across medical oncology.

Trabectedin (ET-743, ecteinascidin)

Trabectedin is a marine-derived drug from the marine tunicate *Ecteinascidia turbinata*. It covalently

binds to the minor groove of the DNA and blocks the cell cycle in late S and G2 and affects the transcription in part by prevention of binding of transcription factor NF-Y, thus decreasing expression of a variety of genes, including multidrug resistance genes. After initial promising results in phase 1 studies, multiple phase 2 trials were performed, the most successful of which (a randomized phase II study of two schedules of drug) led to the drug's approval in Europe for refractory STS.^{193, 194} A follow-up randomized study showed greater activity of trabectedin than dacarbazine.¹⁹⁵

The randomized phase 2 study of trabectedin in patients with metastatic leiomyosarcoma and liposarcoma compared a weekly schedule of drug with a 24-h infusion schedule.¹⁹³ In this 270 patient study, the longer 3-weekly infusion was associated with median time to progression of 3.7 months versus 2.3 months, $p = 0.03$; OS showed a numerically longer median OS for the 3-weekly infusion, 13.9 months versus 11.8 months, $p = 0.19$. Particular activity is noted in myxoid-round-cell liposarcoma, although activity in other histologies has been observed.

In a similar manner, the microtubule-targeted agent eribulin demonstrated activity in a phase 2 study,¹⁹⁶ which led to the conduct of a study similar to that of the trabectedin trial above, in which eribulin was tested against dacarbazine in a phase 3 trial in leiomyosarcoma and liposarcoma. The phase 3 data confirmed the activity seen in phase 2. The OS was not significantly different between trabectedin and dacarbazine in this study (12.4 months vs 12.9 months), there was a significant improvement in PFS with trabectedin over dacarbazine (median 4.2 months vs 1.5 months) in this randomized phase III trial.

Beyond cytotoxics, the most important result to date involves the SMOKI pazopanib. After the demonstration of activity in a phase 2 trial,¹⁹⁷ a phase 3 study termed PALETTE was conducted, involving 369 patients with STS progressing after standard therapy. With a 2 : 1 randomization for pazopanib 800 mg versus placebo, the pazopanib arm demonstrated statistically superior PFS. Median PFS in the placebo arm was 4.6 months in the placebo arm and 4.6 months in the pazopanib arm, with a corresponding HR of 0.35 ($p < 0.001$) as assessed by independent radiology review. Median OS at final analysis was 10.7 months in the placebo arm versus 12.6 months in the pazopanib arm, HR = 0.87, $p = 0.26$.¹⁹⁸ These data were sufficient to obtain broad international approval for pazopanib for metastatic STS worse after standard therapy.

Increasingly, the molecular characteristics of specific sarcomas will dictate therapeutic options. On the basis of the tumor DNA alterations (gene loss, translocation, or mutation), mTOR inhibitors such as sirolimus have activity in perivascular epithelial cell tumors (PEComas),¹⁹⁹ and imatinib and other inhibitors of PDGF receptor and CSF1 receptor have activity in DFSPs²⁰⁰ and tenosynovial giant cell tumor (TGCT).^{201, 202} Crizotinib, the ALK inhibitor, is active in ALK translocation positive inflammatory myofibroblastic tumor (IMT). There will be increasing numbers of such agents demonstrating activity as targets other than kinases come into focus therapeutically, perhaps including chondrosarcomas with their frequent *IDH1* and *IDH2* mutations, and synovial sarcoma, Ewing sarcoma, and MPNSTs, which appear to have alterations in epigenetic regulators PRC1, LSDs, and BRD4, respectively, each becoming targetable imminently as are other epigenetic regulators such as EZH2.

Management of local recurrence

If an isolated LR is identified, the treatment goals are the same as for patients with primary tumors, namely, optimal local control while maintaining as much function and cosmesis as possible.¹⁰⁷ Early identification of local relapse may improve the chance of successful salvage therapy, and, like newly diagnosed patients, these patients are probably best managed in specialized multidisciplinary sarcoma

centers. An approach to the evaluation and management of locally recurrent STS is summarized in [Figure 14](#). The initial evaluation must include a full review of previous therapy because this will have a bearing on the therapeutic options available. Therefore, all prior surgery and pathology reports should be examined, as should reports on previous chemotherapy and previous RT, especially volume treated, dose, and energy of radiation.

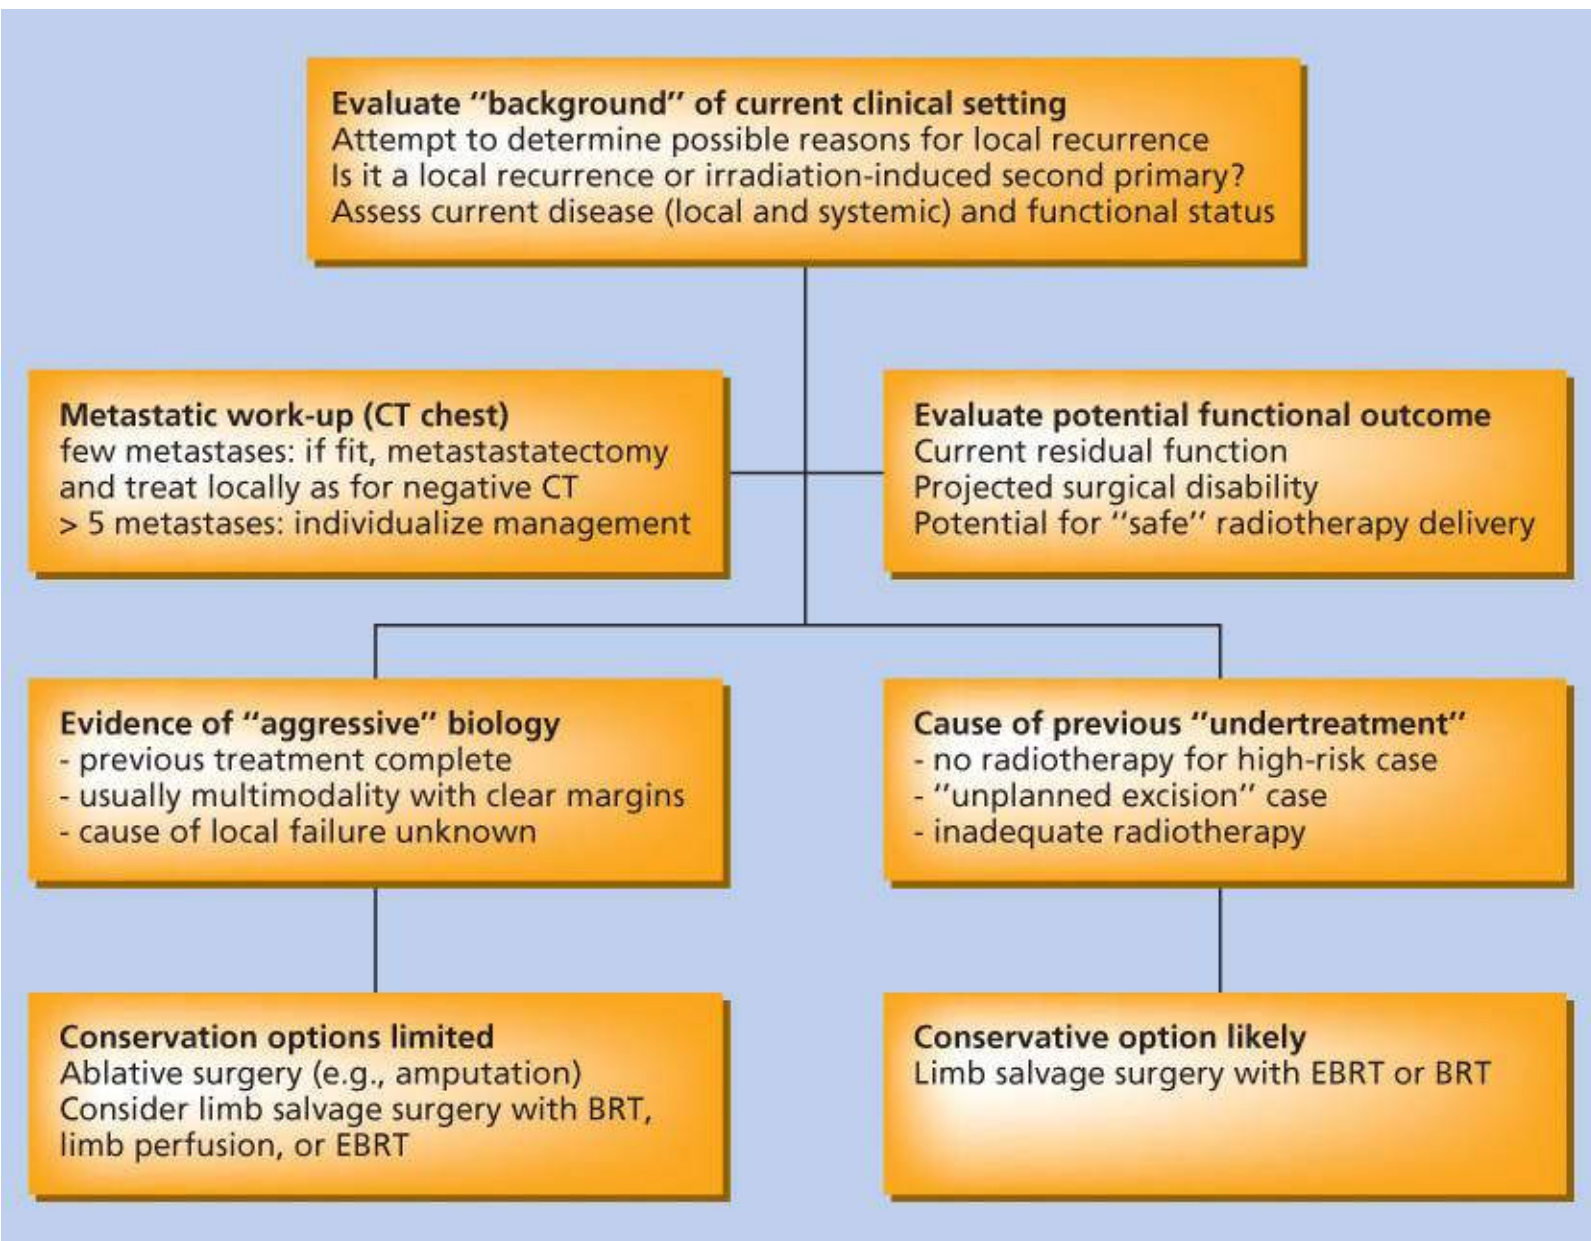

Figure 14 Schema for approaching the patient with local recurrence of STS. The schema is oriented toward extremity lesions but is equally applicable to other anatomic sites (e.g., head and neck and retroperitoneum). *Abbreviations:* BRT, brachytherapy; EBRT, external beam radiotherapy.

Source: Catton et al. 1999.¹⁰⁷ Reproduced with permission of Elsevier.

Staging should be performed in the same way as for newly presenting patients. The areas adjacent to the original lesion and potentially contaminated by previous surgical interventions should be scrutinized carefully. Both these areas and tissues adjacent to the recurrent tumor, containing potential tumor extensions, should be considered at risk and candidates for resection and/or inclusion in radiation fields.

Several distinct groupings are evident under the rubric of “locally recurrent” disease: (1) cases in which prior treatment did not include RT, (2) cases treated with RT in the past, (3) cases in which distant metastases are also present, and (4) cases in which it is difficult to distinguish between recurrence and

secondary tumors induced by RT. Although the therapeutic options available are more limited in recurrent disease and the challenge posed by these cases are much more formidable, a proportion of these patients can be cured. Clinical experience is needed to determine which therapeutic options are appropriate in a given case of recurrent disease.

Gastrointestinal stromal tumors

No discussion of sarcomas would be complete without noting the remarkable advances made with one particular sarcoma subtype, GIST, which has changed the way people think about solid tumors. With the recognition of KIT as a good marker for GIST to distinguish it from other sarcomas and the recognition of *KIT* or *PDGFRA* activating mutations that are likely responsible for the constitutive activation of *KIT*,²⁰³ clinical studies followed rapidly and have been done in parallel to studies investigating the biology of GIST. Of note, presence of an immunohistochemical marker cannot be equated with tumor response, as is suggested by companies that purport this to be the case. Ewing sarcomas can mark positive for KIT by immunohistochemistry, but *KIT* is not mutated in these tumors and Ewing sarcomas do not respond to imatinib.

Surgical principles for management of primary GIST differ from those for other sarcomas and visceral adenocarcinomas. In general, resection requires a minimal margin of normal tissue, not the wide margins of other sarcomas or visceral adenocarcinomas. Unlike gastric cancer, GIST do not generally metastasize to local–regional lymph nodes (except in some GIST arising in the pediatric population), rendering lymph node dissection unnecessary in the vast majority of patient. Thus, gastric GISTs can often be removed by simple wedge resections, and large gastric resections are only rarely required, generally due to anatomic constraints. Similarly, GISTs arising in the small intestine, the colon, or the rectum may be resected with minimal margins. Furthermore, patients with GIST undergoing a macroscopically complete resection and with positive microscopic margins are not at increased risk for LR compared to those resected with negative margins.²⁰⁴

After the recognition of *in vivo* efficacy of imatinib in a GIST cell line,²⁰³ treatment of metastatic disease has rapidly advanced from treating a single patient to phase 1, 2, and 3 studies for patients with metastatic disease.^{205–209} The results have been remarkably consistent. Imatinib is at least 10-fold more active than any agent ever examined for treatment of GIST (formerly called GI leiomyosarcoma). The response rate to imatinib is approximately 50%, 30–35% with stable disease, and ~15% with overt progression on therapy. The US phase 3 data indicate that 400 and 800 mg yield equivalent time-to-progression curves, but the European/Australian phase 3 study indicates that time to progression is improved with the higher dose (800 mg daily) arm.²⁰⁶ Remarkably, patient kinase genotype determined relative sensitivity to therapy ([Figure 15](#)).²¹⁰ Patients with *KIT* exon 11 mutation had an 80–90% response rate, while patients with *KIT* exon 9 mutation had a high response rate only one-third to one-half. Patients with no mutation in *KIT* or *PDGFRA* had a much lower response rate, but still higher than that observed for any other chemotherapy drugs. For the time being, regardless of mutation status, imatinib remains the first-line standard of care for metastatic GIST. A dosage of 400 mg daily is a reasonable starting point for most patients, with increase toward 800 mg if there is evidence of progression of disease or the presence of exon 9 mutation.²¹¹ Therapy should not be interrupted if new hypodense lesions appear in the liver; these likely represent occult metastatic disease, as has been borne out with radiological and clinical experience.¹⁷⁶

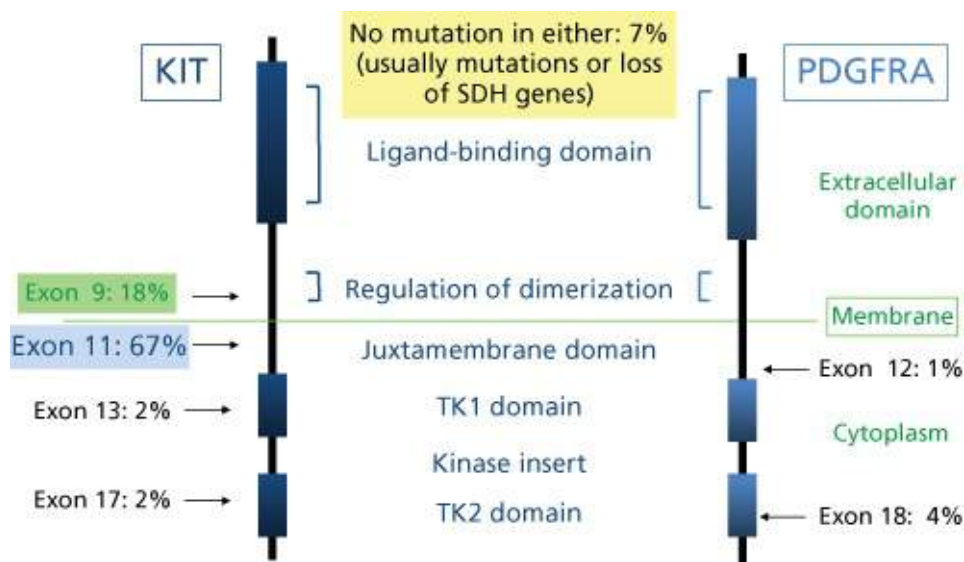

Figure 15 Mutation status of gastrointestinal stromal tumors and location on the KIT or PDGFRA protein.

The median time to progression for patients with metastatic GIST on imatinib is approximately 2 years. Patients with progression on a lower dose of imatinib can respond further with dose increases. The phase 1 study of imatinib indicated that the maximum tolerated dosage is 800 mg daily (400 mg by mouth bid). Patients with progression of disease have had unusual patterns of progression, the so-called tumor within a tumor, which represents clone(s) with second resistant *KIT* mutations.¹⁶⁰ In some cases, tumor regrowth in an apparently necrotic tumor is observed, and in others only one metastatic deposit is seen to progress instead of the multiplicity of lesions seen in many patients with advanced GIST. As a result some patients have been treated with carefully planned operations to remove problematic individual sites of metastatic disease.

The rationale for consideration of metastasis surgery for patients with responding or stable metastatic disease on imatinib is based on the observations that (1) pathologic complete response to imatinib is very rare (<5%) and many (perhaps most) patients will eventually develop secondary resistance to imatinib owing chiefly to the development of secondary resistance mutations. Reports from high-volume centers demonstrate that carefully selected patients treated by imatinib and subsequent metastasectomy appear to have very favorable progression-free survival rates. Whether this is due to case selection or bona fide clinical benefit related to surgery is unclear.^{212, 213} Randomized controlled trials of the impact of metastasectomy in patients with stable or responding disease were planned in the United States, Europe, and China. Poor accrual led to the closure of the European and Chinese trials, and the American trial was never started.

The utility of imatinib in metastatic GIST spawned new SMOKIs, some of which have been through phase 3 trials with subsequent regulatory approval. In the setting of imatinib resistance for metastatic disease, the addition of mTOR inhibitor everolimus to imatinib demonstrated minor activity.²¹⁴ However, greater activity has been observed with other KIT-targeted SMOKIs. Sunitinib is active in imatinib-resistant GIST and is associated with both significantly improved progression-free survival and OS in comparison to placebo.²¹⁵ With the demonstration of activity of sorafenib in GIST,^{216, 217} regorafenib (a fluorinated form of sorafenib) was found active in phase 3 trial of drug against placebo, in which better attention was paid to the placebo group; in this so-called GRID study, the patients on placebo were crossed over more rapidly to drug than the study involving sunitinib, perhaps accounting for the lack of OS benefit seen in the GRID study.²¹⁸ After failure of other agents, some form of SMOKI appears to be indicated for further therapy; use of imatinib was superior to placebo in late stage patients in a randomized trial.²¹⁹

Given the remarkable activity of imatinib in the metastatic setting, it is not surprising that imatinib has been tested in the adjuvant setting as well. Data for studies of 0 versus 1 year of imatinib, 0 versus 2 years of imatinib, and 1 year versus 3 years of imatinib have all consistently demonstrated the benefit of the longer course of therapy. Adjuvant imatinib was initially approved in the United States by virtue of the ACOSOG Z9001 study, in which 1 year of imatinib (400 mg/daily) was compared to placebo following complete resection of GISTs >3 cm in size. This study was halted to further accrual after accruing 762 patients when a planned interim analysis for the primary endpoint demonstrated superior progression-free survival in the imatinib arm (97% vs 83% in the placebo arm).²²⁰ A randomized trial comparing 1 year versus 3 years of adjuvant imatinib subsequently demonstrated improvement not only in the recurrence-free survival but also in the OS, favoring longer duration of adjuvant therapy.²²¹ Whether longer adjuvant treatment with imatinib for longer periods adds further benefit is uncertain and is the subject of a single-arm 5-year trial of imatinib. At this juncture, the best recommendation that can be made is that 3 years of adjuvant treatment be considered for patients with intermediate- and high-risk resected primary GISTs. Risk is well stratified by clinical, pathological, and molecular features of the primary tumor.^{222–224}

Locally aggressive lesions: DFSPs, tenosynovial giant cell tumor (TGCT), perivascular epithelial cell tumor (PEComa) as targets for small molecule oral kinase inhibitors

DFSP is a nodular “protuberant” lesion arising from the dermis with characteristically slow but persistent growth over many years. Although histologically of low grade or borderline malignant potential, DFSP has a propensity for LR after simple excision. A chromosomal translocation t(17;22) and gene fusion product ([Table 1](#)) result in the expression of a COL1A1-PDGFB fusion protein that is processed to mature PDGF-B, resulting in apparent autocrine or paracrine interaction with the PDGF-B receptor on the cell surface of DFSP. Notably, imatinib inhibits the PDGF tyrosine kinase receptor in a similar manner that it inhibits the BCR-ABL tyrosine kinase receptor of chronic myeloid leukemia and KIT kinase of GIST. In recurrent DFSP, imatinib has activity, confirming that kinases can be very good targets in solid tumors, even rare ones, if the genetics of the tumor are suggestive.^{200, 225–227}

For a similar reason, the t(1;2) *COL6A3-CSF1* generates a fusion protein that is responsible for the aggressive inflammatory infiltrate of TGCT (formerly termed pigmented villonodular synovitis). Imatinib has activity against CSF1R (FMS, CD115) and can cause recurrent lesions to shrink.²⁰¹ More specific SMOKIs or monoclonal antibodies against CD115 can also shrink recurrent TGCT lesions. Finally, PEComa, found in the genetic syndrome tuberous sclerosis, and the related lesion lymphangiomyomatosis lack either TSC1 or TSC2, tumor suppressor genes. TOR (target of rapamycin) is activated downstream after TSC1 and TSC2 inactivation, and thus it is not surprising that SMOKI sirolimus and structurally related compounds are active in these conditions, as further proof of principle of blockade of a “driver” kinase in a solid tumor can yield radiological and clinical benefit for patients.¹⁹⁹

Retroperitoneal sarcomas

RPS comprise about 15% of STS. RPS present late and are located in regions where the administration of both surgery and RT is often compromised (e.g., adjacent to the small bowel and the liver). Consequently, the local control rates achieved with combined-modality treatment of extremity STSs are not seen in RPS.^{54, 228–232} For example, in a series of 102 RPS patients treated at Princess Margaret Hospital,

complete excision was achieved in only 45, gross disease remained in 29, and only a biopsy was possible in 28.²³² The overall local–regional relapse-free rates were 28% and 9% at 5 and 10 years, respectively. RT did not improve survival but appeared to significantly lengthen the time to local–regional relapse, especially with higher doses. Complete tumor resection was the only significant prognostic variable for survival and local–regional and distant failure, similar to other series referenced above. RPS patients should be evaluated in a multidisciplinary clinic before treatment so that patients can benefit from the expertise and investigational approaches available in such centers.

Controversial reports from Europe explored extended surgery termed compartmental resection as a strategy to improve local control for patients with RPS.^{233, 234} These retrospective reports from France and Italy have suggested that local control may be enhanced by resecting adjacent involved viscera—primarily the kidney and the colon. Interpretation of these reports is complicated by significant selection bias and, as outlined in an editorial that accompanied these papers,²³⁵ no specific therapeutic recommendation could be made based on these data. At this time, there are no clinical trials demonstrating improved local control with more radical surgery that involves resection of adjacent uninvolved viscera.

Pre- and postoperative radiotherapy approaches

A variety of adjuvant RT approaches have been used for RPS. One approach, evaluated in a prospective randomized trial, used an IORT boost (20 Gy) to the tumor bed followed by postoperative external beam (35–40 Gy); this approach was compared with conventional postoperative RT (50–55 Gy). In this study of 35 patients, the incidence of local–regional recurrence was lower in the experimental treatment arm, but no improvement in survival was demonstrated.²³⁶ IORT was associated with a high rate of peripheral neuropathy when large, sometimes overlapping, RT portals were used to cover the sacral plexus region. However, gastrointestinal complications were more common in the control group, in whom higher doses were delivered to the bowel.

Other researchers have investigated strategies employing preoperative RT. Gieschen et al.²³⁷ from the Massachusetts General Hospital reported on 37 patients who underwent preoperative RT, resection, and then, when feasible, electron beam IORT. The grossly complete resection rate was 83%, and the 5-year actuarial OS, DFS, local control, and freedom from distant disease rates were 50%, 38%, 59%, and 54%, respectively. Earlier reports from the same group described a 70% complete resection rate and 81% 4-year local control rate. The more recent report also indicates that complete resection and IORT improved OS and local control rates (74% and 83%, respectively) compared with no IORT (30% and 61%, respectively). However, the study was not randomized, and potentially more favorable and accessible lesions may have been chosen for IORT. Petersen and colleagues at the Mayo Clinic found improved local control, at least of primary tumors, using a similar treatment approach.²³⁸

The University of Toronto Sarcoma Group described an unusually favorable outcome, especially for primary lesions, in a single-arm prospective trial of preoperative RT (median dose of 45 Gy in 25 fractions) plus postoperative BRT in selected cases.²³⁹ Of interest, acute toxicity resulting from preoperative RT was differentiated prospectively from the effects of other treatments. Although the median radiation volume exceeded 7 L, preoperative external beam RT was associated with extremely low gastrointestinal toxicity scores. Furthermore, no patient was hospitalized for acute toxicity, and there were no treatment interruptions or cessations of treatment because of acute toxicity. The remarkably low toxicity of the preoperative RT with enormous volumes has been attributed to the displacement of the bowel outside the target volume. In contrast, the selective use of postoperative BRT was associated with

toxicity, and there was little evidence that BRT contributed to the enhanced tumor outcome reported.

The University of Texas MD Anderson Cancer Center and Princess Margaret Hospital groups combined the data from their phase 2 and pilot studies. This pooled analysis demonstrated very favorable OS rates for patients treated with preoperative radiation combined with surgical resection.²⁴⁰ However, we again caution against overinterpretation of results that could be explained by surgical technique at major referral centers or by case selection. Similarly, it remains unclear what contribution was provided by the BRT or IORT, which should probably remain protocol based or be reserved for nonstandard use in selected cases. Notably, however, the preoperative RT approach seems to continue to demonstrate favorable local control and OS in very long-term follow-up of the PMH study.

The results of these three reports add credence to the advantages posited for preoperative RT in RPS: (1) the tumor bulk often displaces the small bowel from the high-dose RT region, resulting in a safer and less toxic treatment; (2) the bowel is unlikely to be fixed by surgical adhesions as when RT is given postoperatively, enabling safe delivery of a higher dose to the true area at risk; (3) optimum knowledge of the gross tumor location is possible, permitting better radiation targeting; (4) the tumor is contained by an intact peritoneal covering, providing a physical barrier to immediate tumor dissemination; (5) the risk of intraperitoneal tumor dissemination at the time of surgery may be reduced by the biologic impact of preoperative RT; and (6) using traditional principles of sarcoma RT, the radiation dose believed to be biologically effective is lower in the preoperative setting. Although RT planning for RPS can be complex, the use of conformal techniques or intensity modulation usually permits the RT dosage to be administered safely to the critical organ preoperatively. It is imperative that members of both the surgical and radiation oncology teams be present in the operating room when a significant amount of the liver has been irradiated preoperatively to evaluate the planned residual liver volume. We cannot overemphasize the detailed evaluation of dosimetry and treatment planning films are needed to be certain that a sufficient volume of unirradiated liver is left unresected at the time of surgery.²⁴¹

The only standard that exists at present for RPS treatment is that complete surgery should be performed wherever possible. The adjuvant RT approaches described above should be considered experimental and be the subject of further assessment. Recently, it was also suggested that a more scientifically sound approach to study design should be undertaken in RPS, particularly exploring the role of external beam RT through a randomized controlled trial.¹⁷⁴ The European Organisation for Research and Treatment of Cancer (EORTC) is currently conducting a phase 3 randomized study of preoperative RT plus surgery versus surgery alone (NCT01344018) that is readily on target for completion.²⁴²

Chemoradiation approaches

Although chemotherapy alone has not been associated with obvious improvements in outcome of RPS, chemoradiation, as in other solid tumors, is a subject of interest as a treatment strategy for RPS. This is especially relevant in high-grade RPS, which have a more adverse prognosis than the more common low-grade lesions.

Pilot studies using concurrent preoperative chemotherapy and external beam radiation have been reported, often in patients with extremely large tumors, with acceptable toxicity and with achievement of local control in patients in whom a negative-margin resection was possible.^{141, 243} These reports demonstrate that chemoradiation approaches are feasible. Additional phase 2 studies will be necessary to clarify response rates and toxicity profiles and determine whether chemoradiation should be tested in phase 3 trials. As discussed earlier, the Radiation Therapy Oncology Group completed a phase 2 study of preoperative doxorubicin and ifosfamide followed by preoperative RT and then by surgical resection

with an intra- or postoperative radiation boost in patients with intermediate- and high-grade RPS. This study demonstrated significant toxicities and event-free outcomes that were considered modest.^{144, 146}

Additional issues in STS management

Functional outcome and morbidity of treatment

The functional result of extremity sarcoma management has become an important component of outcome assessment. Assessing the functional result is difficult, as it requires methods that are valid and reproducible. Many centers have yet to become experienced in the development and use of these methods, and much of the literature contains significant heterogeneity in patient samples.

Thus far, the variables associated with poorer functional outcome include large tumor size, higher doses and larger volumes of radiation, nerve sacrifice, postoperative fracture, and wound-healing complications.^{244, 245} To evaluate and compare functional outcome, it is imperative that functional data be reported consistently. Three disease-specific scoring scales have been reported as useful in assessing functional outcome.²⁴⁶ This area has been discussed in detail by Davis, who observed that “function” has many meanings in the literature.²⁴⁶ The concepts of impairment, disability, and handicap following extremity STS are likely misunderstood and certainly not used consistently. Davis noted that impairment is a disorder of structure or function whereas disability is a restriction or lack of ability to perform an activity. Handicap results from impairment and disability and prevents or restricts an individual from performing in a role that is normal for the individual. For sarcoma patients, impairments can be manifested as soft tissue fibrosis, loss of motion at a joint, and decreased muscle strength; disability can be manifested as limited mobility and difficulty performing routine self-care and activities of daily living; and handicap can be evident in limitation in family roles, social functioning, and the capacity for employment.

Impairments are the most frequently reported deficits following limb-preserving therapy for extremity STS, and up to 50% of patients appear to experience significant impairments.²⁴⁶ Disability occurs less frequently, although reports are contradictory. It seems likely that many sarcoma patients learn to accommodate their impairments. Handicap has received little attention in the literature. However, the limited data suggest that up to 50% of patients may experience changes in their employment and vocation status after treatment of extremity STS. The continuing challenge in treating sarcomas is to define the therapeutic ratio for the patient with sarcoma of the extremity. Specifically, the aim of the multidisciplinary team will be to minimize the amount of treatment while maintaining or improving current standards of disease control to reduce treatment morbidity and enhance patient outcome.

Wound complications

Considerable variability in reporting wound-healing complications exists in the literature. WCs have been reported in up to 40% of patients undergoing extremity sarcoma surgery.^{85, 247–249} Differences in the definition of WCs probably account for some of the variability in reporting. The retrospective data suggest that factors associated with compromised wound healing include advanced patient age, poor nutritional status, lower extremity tumor location, large tumor size, and preoperative adjuvant treatment, especially RT.^{247, 248, 250} Particularly high complication rates were noted with combination preoperative RT and hyperthermia.¹¹⁷ Although many authors have reported an association of WCs with preoperative RT, reports of high rates of surgical complications without RT or chemotherapy also exist.²⁵¹ Most likely, these relate to the risk of major WCs associated with extensive tumor resection, particularly in the lower

extremities. The use of vascularized tissue transfers to replace resected tissues and optimize wound closure may decrease the risks of major WCs and allow for more extensive limb-sparing surgical approaches.^{250, 252, 253} As noted earlier, the SR2 trial results have confirmed the adverse effect of preoperative RT on wound healing in a prospective manner, but did not resolve the contribution of tissue transfer for wound reconstruction as its use was determined on an individual basis at the surgeon's discretion.⁹⁶

Molecularly and pathobiologically based sarcoma management

Management of sarcomas is increasingly being driven by the specific nature of the disease entity, most importantly the pathophysiologic subtype. The work of Pasteur and Koch was fundamental for the recognition and definition of pathogenic microbes; similarly, many laboratories today are identifying molecular lesions that will redefine the field of sarcoma research. An example of this work is in the recognition of soft tissue Ewing sarcoma/PNET family of tumors as relatives of their bony primary counterparts by virtue of the same spectrum of translocations in each clinical setting. These tumors should be treated with curative intent using an aggressive multimodality approach that begins with multiagent chemotherapy. If primary surgery has removed measurable disease, adjuvant chemotherapy is definitely indicated, with consideration of adjuvant RT. By adopting similar strategies for PNETs and Askin tumors as for conventional Ewing sarcomas, outcomes improved. The molecular similarities between tumors of this family have led to the current convention of considering them morphologic and clinicopathologic variants of the same underlying molecular disease process.^{254, 255}

Greater understanding of the biology of translocation gene products points to epigenetic events being important in sarcomagenesis and should impact on the efficacy of chemotherapy. Ewing sarcoma and synovial sarcoma are chemotherapy-responsive STS subtypes. While *TP53* could be posited as a reason that certain sarcomas are chemotherapy sensitive, *TP53* status is not the only factor dictating chemotherapy sensitivity as there are other *TP53* wild-type sarcomas that are far less sensitive to chemotherapy, for example, extraskeletal myxoid chondrosarcoma and alveolar soft part sarcoma. Striking research on the epigenetic mSWI/SNF (BAF) complexes and their role in synovial sarcoma hopefully will shed light on some of the basic mechanistic aspects permitting synovial sarcoma survival, in order to better engender tumor cell death.^{256, 257}

As a final example, the multiple histopathologic subtypes of liposarcomas are becoming increasingly well researched and well understood, and mechanisms by which some forms acquire their characteristic DNA signature are beginning to become understood.²⁵⁸ Myxoid and round-cell liposarcomas usually exhibit a characteristic chromosomal rearrangement t(12;16) (q13;p11) *FUS-DDIT3*. These liposarcomas tend to be relatively sensitive to chemotherapy, with trabectedin standing out as most active in this specific diagnosis. Trabectedin appears to inhibit the binding of the FUS-DDIT3 fusion protein to DNA, which then causes liposarcoma cell death or differentiation.^{259, 260} The rarer pleomorphic liposarcoma subtype has more in common with undifferentiated pleomorphic sarcoma than other liposarcomas. Finally, well-differentiated liposarcomas exhibit ring and giant marker chromosomes on cytogenetic analysis and these karyotypic abnormalities, often involving massive amplification of chromosome 12q, carry through in dedifferentiated liposarcomas. Unraveling the ability of the *CDK4* and *HDM2* loci on 12q to amplify hundreds of times in well-differentiated–dedifferentiated liposarcoma may provide insight on how better to attack these relatively chemotherapy-insensitive sarcomas.^{261–263}

Immunotherapy for STS

As of the time of this publication, the examination of the immune system as treatment for sarcoma cannot even be considered in its infancy, but rather in a prenatal state. Immunotherapy is already approved in some countries for osteogenic sarcoma, with the nonspecific immune adjuvant mifamurtide (MTP-PE) improving the cure rate when used as part of adjuvant treatment.¹²⁰ While the proof of principle of engineered T-cell therapy in NY-ESO-1-positive sarcomas such as synovial sarcoma already has been demonstrated by Robbins et al.,^{264, 265} the potential benefit of immune checkpoint blockade is still very much unclear, as no studies were able to be started in sarcomas until 2015. If the hypothesis holds that the cancers with the most DNA mutations and alterations will be most responsive to immunotherapy, then we expect to see undifferentiated pleomorphic sarcoma, leiomyosarcoma, and osteosarcoma among the best responders and much less activity in translocation-associated sarcomas. Conversely, CAR T-cell therapy may be more easily targeted to translocation-associated sarcomas if an appropriate target antigen can be identified.

Summary

It is clear that STS management has improved in the past 10 years. In fewer than three decades, the standard of care has shifted toward coordinated multimodality care in specialty centers, with increased rates of function-sparing surgery and better outcomes for patients. Judicious use of aggressive multimodality approaches shows promise to decrease relapse rates and improve survival rates. The genomic and immunological revolutions in cancer are furthering the fundamental understanding of these unusual diseases and providing novel approaches for diagnostic techniques, which will banish the vagaries and lack of consistency that have plagued this field of clinical investigation and also will provide resources for selecting new targets for therapy. New therapeutic initiatives are attacking the basic mechanisms of sarcomatous transformation of cells in some subtypes of STS, and it is hoped that these initiatives will improve outcomes for patients with less morbidity than current treatments entail. Large collaborative studies should further this work.

Chapter 113

The myelodysplastic syndrome

Lewis R. Silverman, MD

Overview

The existence of a hematopoietic disorder characterized by anemia and dyspoiesis preceding the onset of acute myelocytic leukemia (AML) has been recognized since the early part of the twentieth century. Initially designated as preleukemia, the syndrome was ill defined and could only be established with certainty retrospectively. Moreover, the terminology itself conveyed an unwarranted confidence in predicting the outcome that often belied the facts. The more accurately descriptive and appropriate designation as a myelodysplastic syndrome (MDS) was adopted in 1976 by the French–American–British (FAB) study group. The FAB classification permitted the prospective identification of patients within this heterogeneous clonal disorder.

MDS, derived from a multipotent hematopoietic stem cell, is characterized clinically by a hyperproliferative bone marrow, reflective of ineffective hematopoiesis, and is accompanied by one or more peripheral blood cytopenias. Bone marrow failure results, leading to death from bleeding and infection in the majority, while transformation to acute leukemia occurs in up to 40% of patients. The evolution of the disease proceeds in accordance with the multistep pathogenesis theory of carcinogenesis and can thus serve as an important model in furthering our understanding of the processes involved in neoplastic transformation.

This constellation of findings raises the question of whether MDS represents a frank neoplastic state or is merely a preneoplastic condition in transition. The syndrome appears to represent a spectrum where the initial lesion in the genome, though clinically undetectable, subsequently evolves, with the acquisition of additional genetic and epigenetic lesions, to a state of frank neoplasia.

The designation of this disorder as an MDS, rather than preleukemia, permits its distinction from other abnormalities that are known to be associated with the development of acute leukemia. These latter include the classic myeloproliferative syndromes (polycythemia vera, chronic myelocytic leukemia, agnogenic myeloid metaplasia, essential thrombocythemia), aplastic anemia, paroxysmal nocturnal hemoglobinuria (PNH), as well as Fanconi, Bloom, and Down syndromes. These particular “preleukemic states” are beyond the scope of this chapter.

MDS can be further divided into primary and secondary syndromes. The former arise *de novo* and are of indeterminate etiology, while the latter are induced by identifiable environmental, occupational, or iatrogenic causes.

Estimates of the incidence of MDS range from a frequency equal to that of AML or approximately 14,000 new cases per year in the United States to almost twice that of AML. The SEER database now tracks the disease; thus more accurate data will be available in the future. An estimate based on medical insurance claims indicated a total of 107,000 cases in the observation period from 2009 through 2011. The consensus is that the incidence is increasing owing to a number of factors, including greater awareness, greater diagnostic precision, and the aging of the population.

History

Luzzatto first described a case of chronic anemia associated with bone marrow erythroid hyperplasia, which he designated as “pseudoaplastic anemia.”¹ It was not until Rhoads' and Bomford's description of this entity, however, that the designation of the disease as refractory anemia (RA) became generally accepted.^{2, 3}

In the early 1950s, it became apparent that some patients with RA could develop leukemia, which led to the term preleukemia.^{4, 5} The designation as “preleukemia” often seemed erroneous, since many patients succumbed as a result of bone marrow failure without developing leukemia. In 1976, the FAB established diagnostic criteria for MDS that would permit prospective diagnosis.⁶

Estimates of the incidence of MDS range from a frequency equal to that of AML or approximately 14,000 new cases per year in the United States to almost twice that of AML.^{7, 8} The SEER database now tracks the disease; thus more accurate data will be available in the future. An estimate based on medical insurance claims indicated a total of 107,000 cases in the observation period from 2009 through 2011.⁸

Classification

Based⁹ on bone marrow cellularity, the syndrome was divided into three groups: acquired sideroblastic anemia, refractory anemia with excess blasts (RAEB), and chronic myelomonocytic leukemia (CMML). In 1982, the FAB group updated and expanded their classification to include five categories of MDS based on morphologic characteristics and the percentage of blasts in the bone marrow and peripheral blood.⁶ These included (1) RA, (2) refractory anemia with ringed sideroblasts (RARS), (3) RAEB (>5% to <20% blasts), (4) CMML, and (5) refractory anemia with excess blasts “in transformation” (RAEB-T) (20% to <30% blasts). Concerns that the classification might result in an underdiagnosis of M6 myeloid leukemia (erythroleukemia) led to further revision and refinement in 1985.¹⁰

Some debate focuses on the category of CMML and whether this truly represents a subgroup of MDS or should more appropriately be considered a subgroup of the myeloproliferative disorders (MPD). Some patients with CMML have features of both MDS and MPD and thus an overlap syndrome with characteristics of both.⁹ The biologic behavior appears related most closely to the percentage of blasts in the bone marrow.^{11–13}

The International Prognostic Scoring System (IPSS) has been advanced based on the percentage of bone marrow blasts, cytogenetics, and degree of cytopenias.¹⁴ The IPSS has predictive value for both survival and risk of transformation to acute leukemia ([Table 1](#)). The IPSS was revised (IPSS-R) and now separates patients into five subcategories with greater predictive value and utilizes peripheral blood count values in a more discriminatory manner.¹⁶ The cytogenetic subgroups have also been revised based on further risk assessment. These revisions were based on analyses of 7012 patients compared to 816 for the original IPSS. The IPSS-R is better able to segregate patients into risk groups and is dynamic able to predict prognosis not just for patients newly diagnosed but also patients at anytime during their course of disease. These classifications have been validated and have become, along with the World Health Organization (WHO) classification,¹⁷ the standard classifications ([Tables 2](#) and [3](#)). If cytogenetic data are not available, however, the predictive power of the IPSS models diminish significantly.

Table 1 IPSS score

	Score value				
Prognostic variable	0	0.5	1.0	1.5	2.0
Bone marrow blasts (%)	<5	5–10	—	11–20	21–29
Karyotype	Good	Intermediate	Poor	—	—
Cytopenias	0/1	2/3	—	—	—
Scores	Cytogenetics				
Low: 0	Good: normal				
Intermediate: 1: 0.5–1.0	-y				
Intermediate: 2: 1.5–2.0	del (5q)				
High: >2.5	del (20q)				
	Poor: chromosome 7 abnormalities				
	Complex ≥ 3 abnormalities				
	Intermediate: other

In 1999, another classification system was published by a working group of the WHO, not only relying more closely on the FAB system's conventional morphologic criteria but also considering cytogenetic markers ([Table 3](#)). Data from 1600 patients with primary MDS were evaluated, expanding the FAB system by two categories for a total of seven, all having a high degree of correlation with prognosis. CMML with WBC > 13 × 10⁹/L was eliminated from the WHO categories and included with MPNs, while those with WBC < 13 × 10⁹/L are still classified as MDS/MPN. RA was split into pure refractory anemia (PRA) and refractory cytopenia with multilineage dysplasia (RCMD). Some conditions previously classified as RARS were placed in the pure sideroblastic anemia¹⁹ group, while those with additional dysplastic features were put into the RCMD category, along with RAs without ringed sideroblasts. RAEB was divided into RAEB-I and RAEB-II, based on medullary and peripheral blast counts. RAEB-T was included under AML.

Additionally, MDS associated with karyotypic abnormality 5q was separated as a distinct entity, although its relatively benign nature prevails only if the proportion of medullary blasts is less than 5%. The WHO classification has been updated with some modification as noted in [Table 3](#).

Etiology

Although the etiologic agent cannot be identified in the majority of patients with MDS, in some, exposure to ionizing radiation, chemicals, drugs, or other environmental agents can be implicated.

Radiation exposure has been clearly linked to the development of stem cell abnormalities.²⁰ In addition, the leukemias that developed in survivors of atomic bomb explosions were often preceded by a preleukemic state.²¹ Atomic bomb survivors continue to exhibit an increased incidence of genetic instability seen as structural and numerical chromosomal abnormalities long after the initial exposure, which may contribute to the development of MDS and AML.²²

Chemical injury to the marrow is a well-established phenomenon, and an increased risk of leukemogenesis has been noted among workers exposed to petrochemicals, particularly benzene, and the rubber industry.²³ Many of the initial cases of benzene-induced leukemia were associated with a preleukemic syndrome. Exposure of human cell lines to hydroquinone, a benzene metabolite, is associated with the development of abnormalities of chromosomes 5, 7, and 8 and may be responsible, in part, for the DNA damage associated with the chemical exposure.²⁴ In patients with or without ringed sideroblasts, exposure to diesel oil fumes ($p < 0.01$), diesel oil liquids ($p < 0.01$), or ammonia ($p < 0.05$) was associated with the development of MDS.²⁵ A careful history of exposure to environmental and occupational hazards should be an integral part of the work-up of all patients with MDS. Additional environmental factors may include use of hair dye and cigarette smoking.²⁶

Therapy-related myelodysplasia and leukemia following treatment with radiation and/or chemotherapy have been recognized, since these were initially observed in patients treated for Hodgkin's disease.²⁷ Since the initial reports following treatment of Hodgkin's disease, therapy-induced MDS has been reported following treatment of cancers of the breast, lung, ovary, and gastrointestinal tract, non-Hodgkin's lymphomas, seminoma, multiple myeloma, polycythemia vera, chronic lymphocytic leukemia (CLL), as well as nonmalignant conditions.²⁸⁻³⁰ The leukemogenic potential is greatest for alkylating agents, nitrosoureas, and procarbazine. The risk associated with exposure to these particular agents is further substantiated by the increased frequency of abnormalities involving chromosomes 5 and 7 in comparison with the much lower frequency of abnormalities involving these chromosomes in patients treated with anthracyclines, which nonetheless carry risk, or antimetabolites.³⁰ Leukemogenicity appears to be a function of both dose and time of exposure, as observed in patients with ovarian cancer treated with melphalan or chlorambucil. The use of etoposide in combination with cisplatin or other alkylating agents in patients treated for germ cell tumors is associated with an increased risk of MDS or AML.³¹ The relationship of the cumulative dose of etoposide or teniposide to development of MDS or therapy-related AML remains to be determined.³² Abnormalities involving deletions of a portion of the short arm of chromosome 17 (17p) associated with either mutations or overexpression of the TP53 oncogene have also been described related to prior chemotherapy.¹⁹ This has been identified in both patients with lymphoid neoplasms treated with alkylating agents as well as in those with MPNs treated with either hydroxyurea or p. 32. Recently, treatment-related MDS has been reported in association with both fludarabine and cladribine.²⁰

It has long been debated whether the increase in leukemogenic potential derives as a direct result of exposure to radiation and/or chemotherapy or more simply reflects a natural predisposition related to the underlying disease. The risk of developing MDS and/or metachronous leukemia has been reported to be increased in association with certain cancers, such as multiple myeloma, lymphoma, carcinoma of the lung, and CLL.^{33, 34} However, the difference in the rates of developing leukemia after various treatments for polycythemia vera or Hodgkin's disease point to treatment as the most critical etiologic factor. In patients with polycythemia vera, the risk of developing leukemia is significantly elevated in those treated with chlorambucil compared with those treated with phlebotomy alone.³⁵ Similarly, patients with Hodgkin's disease treated with doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) have a much lower incidence of therapy-related leukemia than those treated with the nitrogen mustard, vincristine, procarbazine, and prednisone (MOPP) regimen.³⁶ The recognition of this potential risk has led to efforts to develop equally potent but less leukemogenic therapies, particularly in diseases with the potential for long-term survival. In a registry review of patients with chronic neutropenia treated with filgrastim, 9% of patients with congenital neutropenia developed MDS and/or leukemia compared with none of the patients with cyclical or idiopathic neutropenia.³⁷ The relationship of the use of filgrastim and

the development of MDS in these patients is uncertain.

High-dose chemotherapy with stem cell support is being applied as a curative approach in a number of malignancies, non-Hodgkin's lymphoma among them. As noted previously, an increased risk of developing MDS or metachronous leukemia in association with lymphoma has been suggested. Although therapy-induced MDS in patients with non-Hodgkin's lymphoma treated with standard doses of chemotherapy has been identified, MDS has now been recognized as a late complication of treatment with high-dose chemotherapy regimens.³⁸ The reported actuarial risk ranges from 6.4% up to 18% at 6 years.³⁹ Strategies currently under study that use high-dose myeloablative treatments earlier in the course of this disease in patients with poor prognosis make the identification of the magnitude of this problem an increasingly important issue. Studies demonstrate that there are multiple abnormal hematopoietic clones in patients with MDS which coexist and can give rise to subclones.⁴⁰ These clones can give rise to the leukemic clone in patients who transform to AML.⁴¹

Pathobiology

Clonal origin

A substantial body of evidence has accumulated that points to a clonal origin for MDSs. The identification of nonrandom chromosomal abnormalities detectable in 30–70% of patients with MDS confirmed the likelihood that these were clonal disorders.^{42–47} Evidence that these disorders originate from pluripotent stem cells was suggested by reports of patients developing biphenotypic and lymphoid leukemias following MDS.^{42, 48}

Analysis of the patterns of inactivation of an X-linked polymorphic enzyme such as glucose-6-phosphate dehydrogenase (G6PD) has proven to be a useful tool in the analysis of the clonal origin of tumors. Raskind et al.⁴⁹ have demonstrated that 21 of 24 B lymphoblastoid lines transformed by Epstein–Barr virus expressed a single light chain immunoglobulin and contained only one of the G6PD isoenzymes. In contrast, the T cells expressed both the A and B G6PD isoenzymes. The frequency with which the lymphoid lineage is involved as part of the abnormal clone in MDS is variable. B lymphocytes being involved more regularly than T cells.^{50–53} Other studies have found evidence that only cells committed to the myeloid lineage are involved in the clone but that lymphocytes are of polyclonal origin.^{50–53} Fluorescent *in situ* hybridization (FISH) or polymerase chain reaction analysis of loss of heterozygosity has confirmed the involvement of an early stem cell that can give rise to CD34+ cells as well as those of erythroid, megakaryocytic, and myelomonocytic lineage, but not lymphocytes.⁵⁴ Subsequently, in a study using combined techniques of immunophenotyping and FISH, B lymphocytes were found to be involved in patients with the 5q-syndrome.⁵⁵ Molecular and flow cytometric analysis of T-cell clonality has also suggested involvement of T cells in the MDS clone of some patients. The reason for the discrepant findings is unclear but may reflect the heterogeneity of the disease and interpatient variability. Molecular studies have demonstrated a variety of clones present in MDS patients, a founding clone, and a number of subclones bearing recurrent gene mutations and mutations of novel gene pathways.⁴¹

In vitro progenitor growth characteristics

A variety of abnormalities in the growth of hematopoietic progenitors has been detected in colony assays *in vitro* of both bone marrow and peripheral blood from patients with all categories of MDS.⁵⁶ None has proved instructive of clinical response.

Bone marrow microenvironment

Histologic examination of bone marrow trephine biopsies has pointed to abnormalities of the microenvironment.⁵⁷ They noted the presence of clusters of immature precursor cells in the central intertrabecular region of the marrow, rather than along the endosteal surfaces. They cited this as evidence of abnormal localization of immature precursors (ALIP). In a series of 40 patients, the presence of ALIP correlated significantly with shortened survival and was associated with an increased risk of transformation to AML. These findings were independent of the FAB subtype and were detected even in patients with RA. However, care must be applied to differentiate true ALIP from pseudo-ALIP. In the latter case, the clusters of cells are either of erythroid or megakaryocytic origin and do not convey the same prognostic information compared with the former, where the immature cells are of myeloid origin. The determination of the immature precursor phenotype by immunohistochemical methods may be helpful in distinguishing pseudo- and true ALIP. ALIP is not, however, specific to patients with MDS and, therefore, not helpful as a diagnostic tool.⁵⁸

Recent data in a mouse model suggest that osteoblasts have a modulating influence on leukemic blasts in the bone marrow microenvironmental niche.⁵⁸ Reduction in osteoblasts is associated with leukemic progression and shortened survival.⁵⁹ This opens a possibility that osteoblast number could be a drug target in modulating progression of MDS/AML.

Signal transduction

Whether the primary pathophysiologic defects resulting in disordered maturation and function are intrinsic to hematopoietic progenitor cells or derive from their interaction with accessory cells and other microenvironmental factors or a combination thereof is uncertain. Hematopoietic cell defects may relate not only to quantitative abnormalities of progenitors but also reflect abnormalities in signal transduction in response to cytokines or other regulatory molecules that trigger proliferation and differentiation pathways. Hematopoietic cells from MDS patients display impaired responses to a number of cytokines and are unable to respond to external signals owing either to abnormalities in number or function of cytokine receptors or to dysfunctional postbinding signal transduction.

Hematopoietic progenitors have impaired responses to cytokine stimulation with decreased CFU-GM, CFU-GEMM, and BFU-E colony number.⁶⁰ Purified blast cells from MDS patients proliferate but do not mature in response to granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF). Purified populations of CD34+ cells from MDS patients also demonstrate impaired responses to G-CSF.⁶¹ Receptor abnormalities in MDS are not commonly observed^{62–64} although in some patients their number is either diminished or their structure aberrant. In patients with a truncated erythropoietin receptor progenitor, differentiation to erythropoietin is blocked and cells undergo apoptosis.⁶⁵ On the other hand, defects in signal transduction appear to play a larger role in the aberrant response of hematopoietic progenitors to regulatory molecules.^{63, 64, 66} This pertains both to the cytokine signal transduction pathways and factors which regulate apoptosis.^{63, 64, 66} Patients with MDS have defective activation of STAT5 in response to erythropoietin but not IL-3, suggesting a defect in the erythropoietin signaling pathway. Despite the relative impairment, increasing concentrations of cytokines can partially correct the defects.^{67, 68} Epigenetic changes resulting in transcriptional silencing are another potential mechanism affecting cytokine signaling. Evidence demonstrates aberrant hypermethylation of the SOCS-1 gene in 31% of MDS patients associated with increased activity of the JAK/STAT pathway.⁶⁹ Hypermethylation which occurs in other genes such as p15 may be explained in part by the overexpression of DNA methyltransferases 1 and 3A that have been identified in bone marrow

of MDS patients.⁷⁰

The majority of patients with MDS have hypercellular bone marrows with evident proliferation of various cellular lineage components. One interpretation of this finding is a compensatory response in the marrow to feedback signals secondary to the peripheral blood cytopenias. Yet, the response does not translate into effective hematopoiesis; a role for increased apoptosis has been suggested.^{71–73} A deficiency in cytokines or relative resistance to their effects could explain this phenomenon of ineffective hematopoiesis. In several studies, bone marrow cells from MDS patients have demonstrated increased expression of Fas and Fas ligand. In marrow cultures, strategies that block tumor necrosis factor-mediated (TNF) signals, such as the use of anti-TNF- α antibody, significantly increased the numbers of hematopoietic colonies compared with untreated cells. Additional studies have implicated a dysregulated Fas pathway and TNF- α as contributing to ineffective hematopoiesis.^{71–73} Inhibition of the TGF-B signaling pathway, which is overexpressed in some patients, can restore hematopoiesis, suggesting a negative regulatory role for TGF-B.

Increased apoptosis was identified in both mature cells and immature CD34+ cells by assays for annexin V, measurements of mitochondrial membrane potential, and caspase 3 activity from cell lysates in patients with MDS compared with patients with de novo AML. These results demonstrated that the patients with MDS had increased apoptosis in all FAB subcategories, which was distinctive compared with patients with AML and was equally applicable to the RAEB-T alone group.⁷⁴

Cytogenetics

Chromosomal abnormalities, found in 30–70% of MDS patients, are similar to those seen in patients with AML and involve complete or partial deletions, most frequently involving chromosomes 5(-5,5q-), 7(-7,7q-), and 8(8+).^{75, 76} Certain karyotypic abnormalities that are associated with core binding factor rearrangements, such as t(15;17) in acute promyelocytic leukemia (M3), t(8;21) in AML (M2), and inv 16 in AML (M4), have only rarely been identified in MDS. Moreover, patients with these AML subtypes have good prognoses with potential for cure. Thus, they should be viewed as having AML and should be managed accordingly. Furthermore, abnormalities involving partial deletions of the long arm of chromosome 20 (20q-), seen frequently in MDS, particularly RARS, polycythemia vera, and myeloproliferative syndromes, are usually not seen in patients with de novo AML. Abnormalities are identified most frequently in patients with higher risk. Although specific chromosomal abnormalities have been identified, unlike AML, no specific abnormality has been associated with any specific subcategory. Techniques using FISH have identified additional chromosomal abnormalities in patients beyond those with banding alone and are complementary to standard techniques.⁷⁷

Many studies have demonstrated that the presence of karyotypic abnormalities is an independent prognostic variable. Furthermore, more complex abnormalities are associated with shortened survival compared with either single clonal abnormality or a normal karyotype. Certain specific clonal subtypes have varying prognostic significance for both survival and the risk of leukemic transformation. Monosomy 7 or 5 and 7q are associated with shortened survival, while deletions of the long arms of chromosome 20 (20q-) and 5(5q-syndrome) and deletion of y⁷⁸ as the sole abnormality are associated with longer survival. In the IPSS, cytogenetic findings are an independent prognostic variable classifying patients according to three subgroups: good, intermediate, and poor risk. Further studies have improved our understanding of the cytogenetic risk groups in MDS. Analysis of cases in the German–Austrian and MD Anderson databases demonstrated that cytogenetics was underweighted as a risk factor in the IPSS and suggested that poor-risk cytogenetics was just as poor a risk factor in patients as those with > 20%

blasts.⁷⁵ This led to a revision of the IPSS cytogenetics group. Nineteen different cytogenetic subgroups were identified among more than 2900 patients. These groups were categorized into five prognostic subgroups including: very good, good, intermediate, poor, and very poor and were incorporated into the revised IPSS ([Table 4](#)).¹⁶

Table 4 Cytogenetics: revised cytogenetic IPSS-R groupings

Risk group	Cytogenetic groupings	Doublet	Complex	Median overall survival (months)
Very low	Del 11q -Y	—	—	60.8
Low	Normal del (5q) del (12p) del (20q)	Including del(5q)	—	48.6
Intermediate	del 7q +8 i(17p) +19 any other independent clones	Any other	—	26
High	Inv(3)/t(3q)/del(3q) -7	Including -7/del(7q)	3	15.8
Very high	—	—	>3	5.9

Source: Adapted from Schanz 2012.⁷⁶

Genetic instability as demonstrated by clonal evolution occurs in a substantial percentage of patients. Around 20–35% have been found to undergo clonal evolution during the course of the disease, independent of karyotypic status at the outset. The significance of clonal evolution with respect to leukemic transformation and survival is contradictory at the outset. In some studies, clonal evolution was associated with a poor prognosis without an increased risk of leukemic transformation. In contrast, Glenn and colleagues have demonstrated karyotypic changes in clinically stable patients.⁷⁹ One study of 31 patients evolving to AML from MDS suggests that additional abnormalities involving chromosomes 1, 7, 8, 11, and 17 may contribute to the transformation process.⁸⁰ Subclonal evolution suggests genomic instability. Microsatellite instability involving defects in the DNA mismatch repair system has been identified in some MDS patients, particularly those with therapy-related disease.⁸¹ Assessment of the clonal architecture in the marrow of MDS patients demonstrates that there is a founding clone and multiple secondary clones with acquisition of additional mutations leading to clonal evolution.⁴¹

One particular abnormality involving a deletion of part of the long arm of chromosome 5 (5q-) deserves special note. As originally described, the del 5q-syndrome is associated with a refractory macrocytic anemia, a normal or increased platelet count, giant thrombocytes, dyserythropoiesis, hypolobulated megakaryocytes, female predominance, prolonged survival, and a low rate of leukemic transformation. It is important to differentiate the del 5q-syndrome from instances where this deletion is found in combination with other chromosomal abnormalities or in association with FAB subtypes other than RA that have a more aggressive clinical course associated with shorter survival. Patients with del 5q have

been identified to have a deficiency in RPS14 ribosomal RNA as the genetic defect responsible for the bone marrow failure in these patients (see section “Gene mutations and dysregulation”).⁸²

Patients with MDS secondary to exposure to mutagenic or carcinogenic agents have similar findings in terms of the types and significance of the chromosomal abnormalities. Patients treated with epipodophyllotoxins (etoposide and teniposide) can develop specific translocations involving the breakpoint at 11q23. This leads to transcription of a fusion protein involving the mixed-lineage leukemia (MLL) gene.

Additional techniques have been explored that can detect abnormalities in the genome not identifiable by normal metaphase cytogenetics (MC).⁸³ Single nucleotide polymorphism arrays (SNP-A) reveal a higher percentage of genetic abnormalities than indicated by MC.

Gene mutations and dysregulation

Alterations in the control and expression of proto-oncogenes in the cellular genome, leading to abnormalities of cellular proliferation and differentiation, are thought to contribute to the molecular basis of neoplastic transformation.⁸⁴ Point mutations of the ras family of oncogenes have been identified in association with a number of human tumors, including lung, pancreatic, colorectal, and hematopoietic neoplasms.⁸⁵ Activated ras genes with specific point mutations involving codons 12, 13, and 61 have been identified in 20–30% of patients with AML and 9–48% of patients with MDS. These findings have suggested that activation of ras genes either may contribute to the development of MDS or, once established, to the process of transformation of the commonly affected stem cell. Ki-ras with H-ras is involved in only a few cases. CMML was the FAB subtype most frequently associated with a ras mutation. The abnormality was found in 40% of cases.^{86–88}

Recently a number of genes have been identified with recurrent somatic mutations in patients with MDS involving a number of different pathways including those involved in epigenetic regulation, RNA splicing, signal activation, and transcription factors ([Table 5](#)). Many of these mutations are oncogenic, and there are patterns of association or mutual exclusions in some of these abnormalities. These mutations are not exclusive to MDS but are seen in the myeloid spectrum of disease including AML and the MPNs.^{89, 90} The data in some of these studies indicate that there are mutations that appear early in the process of MDS, whereas others are later appearing mutations. The presence of some mutations has prognostic significance particularly EZH2, TP53, Runx1, DNAMT3A, and ASLX1.⁹¹ Some of these mutations may lead to an increased propensity to subclonal evolution, and an increased number of mutations appear to be associated with poorer outcome and higher rate of transformation to AML. The functional dysregulation of some such as TET2 or IDH1 and IDH2 mutations results in abnormalities of the hydroxymethylation, but the major impact on pathways of these abnormalities is unknown. These recurring mutations will provide insight into disease mechanism and prognostic information and offer potential for therapeutic targets ([Figure 1](#)).

Table 5 Gene mutations in MDS

Candidate gene	Chromosome	Frequency in MDS (%)	Putative functional significance
<i>Epigenetic pathway</i>			
ASXL1 *612990	20q	11–15	Unknown

ZRSR2	—	3	Alternate protein splicing

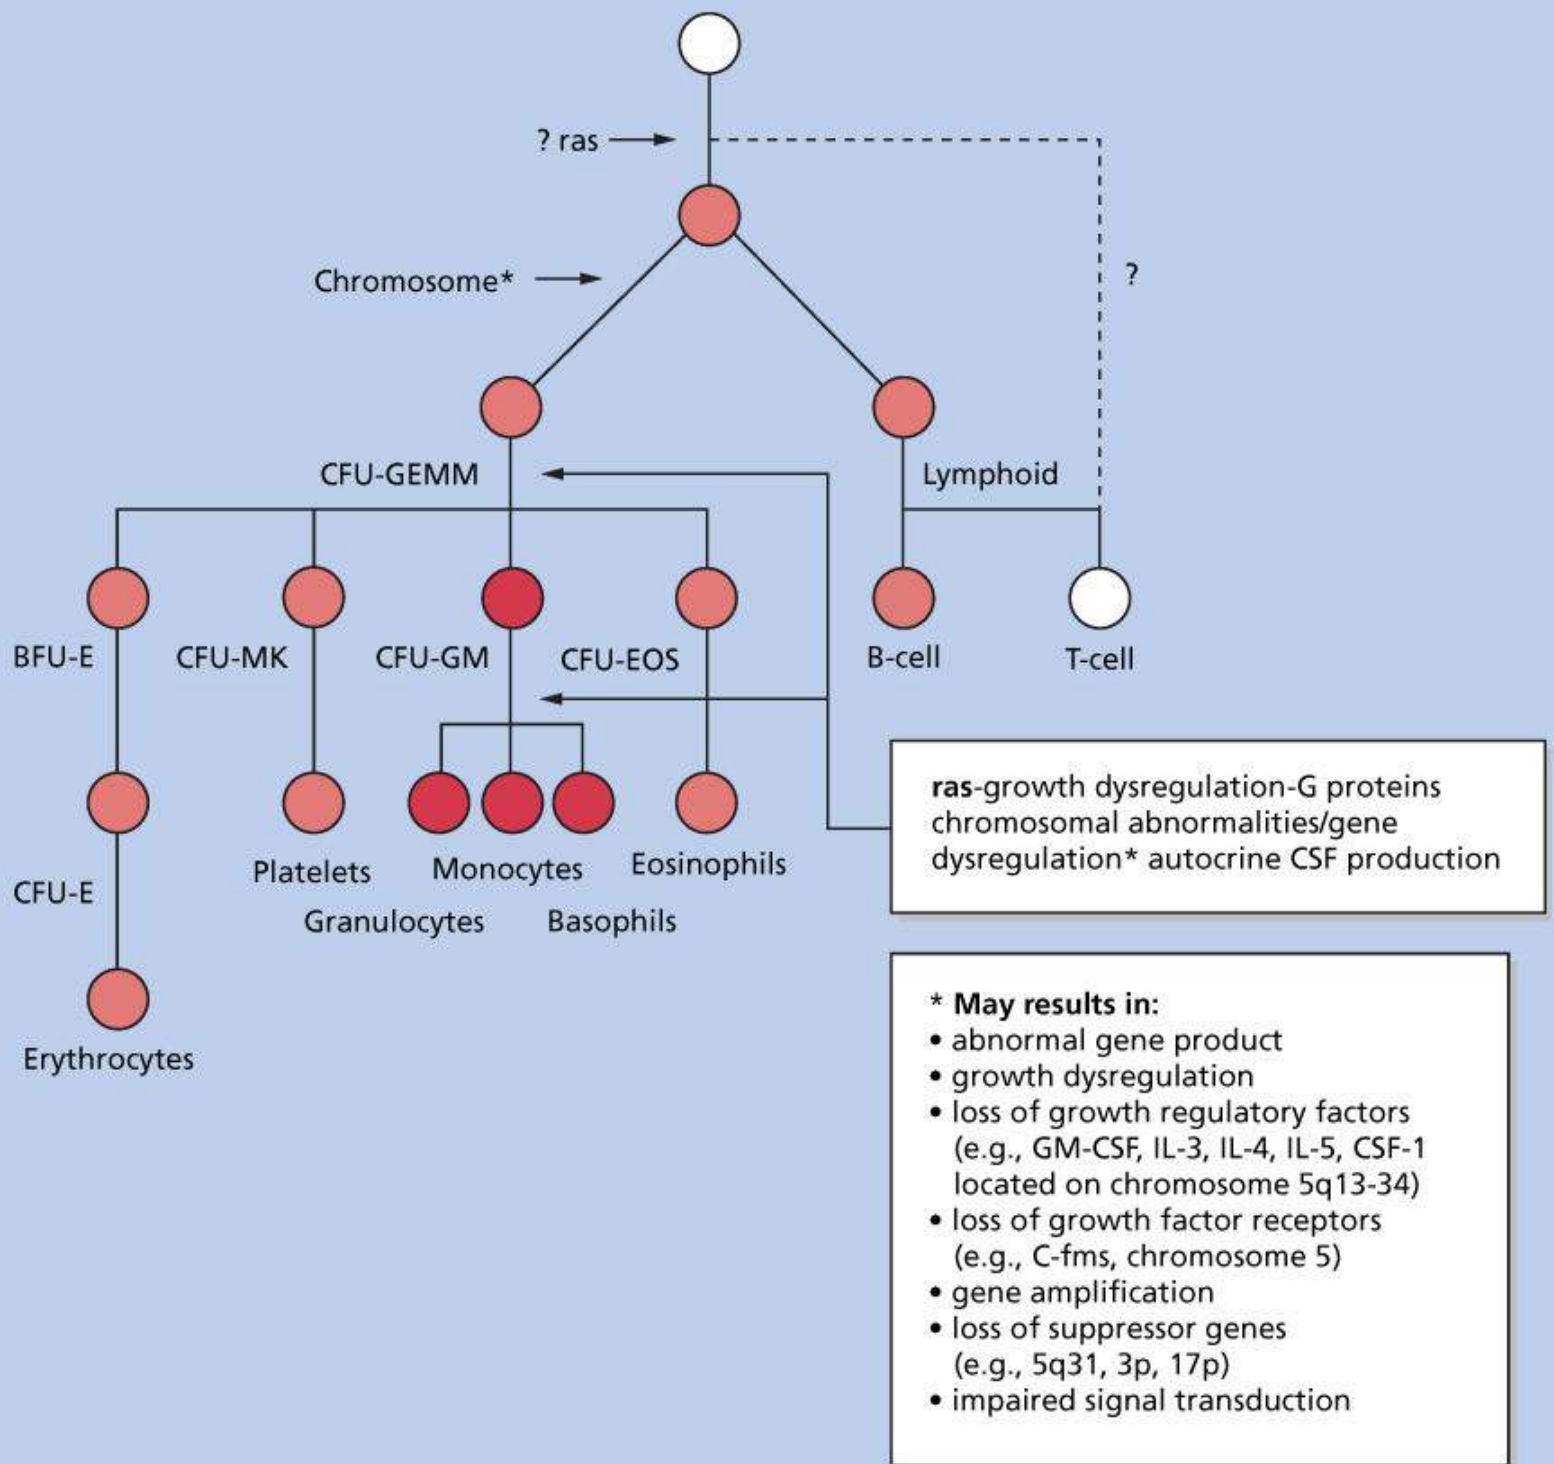

Figure 1 Multiple steps involved in the pathogenesis of MDS affecting a pluripotent hematopoietic stem cell (white circle). Chromosomal abnormalities and ras mutations may occur as early or late events in the pathogenesis of the disease. In younger patients, disease appears to originate in a stem cell committed along a more restricted lineage pathway (●) and is similar to the stem cell origin in some patients with de novo AML. In most patients with MDS, the disease originates from a multipotent stem cell affecting progeny involving multiple hematopoietic lineages (●●). *May result in abnormal gene product; growth dysregulation; loss of growth regulatory factors (e.g., GM-CSF, IL-3, IL-4, IL-5, CSF-1 located on chromosome 5q13–34); loss of growth factor receptors (e.g., cfms, chromosome 5); gene amplification; loss of suppressor genes (e.g., 5q31, 3p, 17p); impaired signal transduction. *Abbreviations:* IL, interleukin; CSF, colony-stimulating factor.

CD34⁺ progenitors modified to express a mutated N-ras were found to have defective differentiation in

response to erythropoietin. This was manifest as reduced proliferation, increased doubling time, and decreased number of cells in S/G2M, leading to a failure to express the differentiation program in the late erythroblast stage. These cells also tended to undergo accelerated apoptosis, suggesting that expression of a mutated N-ras could be partially responsible for the pathophysiology underlying MDS.⁹²

Deletion of all or part of chromosome 5 in a substantial number of patients with either de novo or secondary MDS has led to the hypothesis of a tumor suppressor gene located within a short segment of the long arm in the so-called critical region at 5q21–5q34. This region has been the focus of intensive study, and candidate genes either deleted or dysregulated have been identified, narrowing the region of interest. The interferon regulatory factor-1 (IRF-1) is a DNA binding regulatory factor that regulates, in part, expression of interferon and interferon-inducible genes by binding to promoter regions. It functions as an activator, has antiproliferative and antioncogene activity, and can reverse a transformed phenotype. The *IRF-1* gene has been mapped to the 5q31 region. A loss of one or both IRF-1 alleles in patients with MDS or AML with a del 5q has been described. *In vitro* studies have suggested that loss of the *IRF-1* gene is associated either with a transformed phenotype and/or with chemo- and radiation-induced apoptosis. Although these data suggest a potential role for the *IRF-1* gene, studies have not confirmed these observations.^{93, 94} A recent study suggests a role for overexpression of IRF-1 leading to an upregulation of Toll-like receptors, resulting in an activated apoptotic pathway. The lack of identification of a definitive tumor suppressor gene responsible for the disease has led to other approaches investigating the underlying mechanism. Ebert and colleagues used RNA-mediated interference (RNAi) to identify genes that might be involved. They identified a partial loss of function of the ribosomal subunit protein, *RSP14* gene, that was associated with a block in erythroid differentiation in progenitor cells from patients with the del 5q-. Using the RNAi *in vitro*, they were able to recapitulate the phenotype of cells from patients with del 5q-. Overexpression of the *RSP14* gene in cells from patients with del 5q was able to rescue the phenotype and restore normal erythropoiesis, suggesting that this gene is causal for the del 5q- hematopoietic picture. The loss of function of the *RSP14* results in reduction in processing of the 18s pre-rRNA levels. This is similar to the mechanism involved in the Diamond–Blackfan anemia, the congenital bone marrow failure state.⁸²

Point mutations in the TP53 tumor suppressor gene have been reported in 8% of MDS cases.⁹⁵ In one series, patients with secondary myelodysplastic syndrome (sMDS) or therapy-related acute myelocytic leukemia (tAML) were found to have a higher than expected prevalence of TP53 mutations in leukemic, but not germline tissues. Accumulation of TP53 abnormalities with sequential follow-up was identified in patients as they transform to AML.⁹⁶ Microsatellite instability was identified and was consistent with a mutator phenotype, suggesting that these patients were at higher risk of developing therapy-related MDS/AML. Patients have been described with a 17p-syndrome characterized by dysgranulopoiesis with pseudo-Pelger–Huët hypolobulation and small vacuoles in neutrophils. In one series, 15 of 16 patients with this deletion had an associated deletion of TP53, suggesting a potential role for loss of a tumor suppressor gene as a contributing factor to the morphologic, cytogenetic, and molecular phenotype of this syndrome. The expression of several other genes, including EVI-1, c-mpl, PDGF, MLL, and the CSF-1 receptor, has recently been described to be dysregulated in some patients with MDS.⁹⁷ The EVI-1 gene, located on chromosome 3, has been shown to play a role in both myeloid and erythroid differentiation. Dysregulation of gene expression is associated with blocks in myeloid and erythroid maturation.⁹⁷

The V617F JAK 2 mutation has been described in patients with the MPDs, polycythemia vera, myelofibrosis, and essential thrombocythemia. There is also a small subset of patients with MDS with the mutation. These patients usually have high platelet counts and may have sideroblastic anemia. Some have designated this small subset RARS-T (T = thrombocytosis).

Clinical and laboratory features

The clinical and laboratory picture in patients with MDS is dominated by and derives from the defect involving a multipotent hematopoietic stem cell. Although the disease has occasionally been described in children and adolescents, it is primarily encountered in adults in their sixth decade or older. In most reports, the median age is over 65, and there appears to be a male predominance. The clinical presentation is nonspecific. The symptoms relate primarily to the cytopenias, with those attributable to anemia being most common. These include fatigue, weakness, pallor, dyspnea, angina pectoris, and cardiac failure. Other signs and symptoms encountered less frequently include easy bruising, ecchymosis, epistaxis, gingival bleeding, petechiae, and bacterial infections, particularly respiratory and dermal. Physical findings are nonspecific. Hepatic and/or splenic enlargement is reported in 10–40% of patients and is most commonly found in CMML. Lymphadenopathy and skin infiltration are uncommon. Nontherapy-related MDS has been reported in association with other neoplasms, including lymphoproliferative and plasma cell disorders as well as carcinomas.

The characteristic hematologic findings include peripheral blood cytopenias associated with dysmyelopoietic morphology and functional abnormalities involving one or more of the cell lines and are detailed in [Table 6](#). The bone marrow is hypercellular in the majority and features the dysmyelopoietic morphology of part or all of the progenitors. Abnormalities involving erythrocyte enzymes, surface antigens, hemoglobin production, and iron metabolism have been described. Some of the changes in enzyme activity, such as pyruvate kinase, may affect red cell survival. Impaired activity of A and H transferase and galactosyltransferase has resulted in changes in blood types. Hemoglobin production is affected with increased fetal hemoglobin, aberrant globin chain synthesis, and disordered ferrokinetics.

[Table 6](#) Morphologic and functional cellular abnormalities in myelodysplastic syndromes

<i>Erythrocytes</i>
Morphology
Anisocytosis
Poikilocytosis
Oval macrocytes
Microcytes
Basophilic stippling
Howell–Jolly bodies
Circulating nucleated red cells
Megaloblastoid maturation
Multinucleated precursors
Nuclear budding
Karyorrhexis
Defective hemoglobinization
Ringed sideroblasts
Increased stainable iron
Enzymes

Increased hexokinase
Decreased pyruvate kinase
Decreased 2,3-diphosphoglycerate mutase
Decreased phosphofructokinase
Increased adenosine deaminase
Increased pyruvate kinase
Decreases or loss of blood group antigens
Increased fetal hemoglobin
Aberrant globin chain synthesis
Disordered ferrokinetics
<i>Leukocytes</i>
Morphology
Pseudo-Pelger–Huët cells
Abnormal chromatin clumping
Abnormal nuclear bridging
Monocytosis
Defective granule formation (hypogranulation)
Megaloblastoid maturation
Auer rods
Increased LAP
Decreased myeloperoxidase
Increased muramidase (CMML)
Loss of granule membrane glycoproteins
Inappropriate surface antigens
Lineage infidelity
Decreased adhesion
Defective chemotaxis
Deficient phagocytosis
Impaired bactericidal activity
<i>Megakaryocytes</i>
Morphology
Micromegakaryocytes
Hypolobulated nuclei
Large mononuclear forms
Circulating megakaryocyte fragments
Giant thrombocytes

Defective platelet aggregation
Deficiency in thromboxane A2
Bernard–Soulier-like defect
<i>Immune deficiencies</i>
Decreased T-cell IL-2 receptors
Decreased IL-2 production
Decreased NK activity
Decreased NK response to gamma interferon
Decreased response to mitogens
Decreased T4 cells
Immunoglobulin abnormalities
Autoantibodies
Autoimmune phenomenon
Impaired self-recognition

The myeloid series often reveals leukopenia with immature forms and increased numbers of large unstained cells (LUC). Neutropenia is more commonly found in patients with RAEB and RAEB-T than RA and RARS.²⁷ Leukocytosis most often accompanies CMML and, by definition, requires an absolute monocytosis ($>1 \times 10^9/\text{L}$) for diagnosis. Monocytosis may, however, also be present in the other MDS subtypes. Cytoplasmic abnormalities result in cells with hypo- or defective granule formation, Auer rods, or abnormal azurophilic granules. Histochemical studies reveal cells with increased or decreased levels of leukocyte alkaline phosphatase, decreased myeloperoxidase staining, and loss of granule membrane glycoproteins. Surface antigen analysis has shown loss of lineage-specific antigens, with persistent or increased expression of inappropriate antigens and lineage infidelity. In some instances, the abnormal persistence of antigens or an increased proportion of cells expressing those antigens was associated with an increased risk of leukemic transformation and shortened survival. Abnormal expression of an activated surface phenotype on monocytes has been demonstrated in patients within all FAB subtypes, while expression of activated surface antigens on granulocytes was almost exclusively seen in patients with excess blasts. Impaired granulocyte function includes impaired respiratory burst, deficit in chemotaxis and superoxide release, as well as a defect in neutrophil stimulation signaling.^{98, 99} Nuclear and functional abnormalities are outlined in [Table 6](#).

Megakaryocytes can be decreased and their morphology is often bizarre ([Table 6](#)). Patients with RAEB and RAEB-T more commonly have thrombocytopenia, decreased megakaryocytes, and greater degrees of dysmegakaryopoiesis. Megakaryocyte fragments and giant thrombocytes may circulate in the peripheral blood. Hemorrhagic symptoms in these patients may be due not only to thrombocytopenia but also to functionally defective platelets as well. Dysfunction can result from defective platelet aggregation, deficiencies in thromboxane A2 activity, or the development of a Bernard–Soulier-type platelet defect. This latter defect has developed from a deficiency in the membrane glycoprotein GP Ib-IX complex.

A small percentage of patients present with hypoplastic bone marrows and cytopenias that morphologically may be difficult to distinguish from aplastic anemia.¹⁰⁰ Cytogenetic analysis with or without interphase FISH may be helpful in establishing a diagnosis.

The relationship of MDS to abnormalities of the immune system is of particular interest given the broad range of abnormalities described. There is a decrease in the number of T-cell interleukin-2 (IL-2) receptors, as well as IL-2 production. The latter is due, in part, to a failure of immunoregulatory B cells. NK cell activity and responsiveness to α -interferon are decreased, as is α -interferon production, while total numbers of NK cells are variable. There are decreases in the number of T cells, responsiveness to mitogenic stimulation, the total number of cells, and the T4/T8 ratio. The latter is due predominantly to a decrease in T4 cells.

Immunoglobulin abnormalities manifest as autoantibodies or a positive direct Coombs' test is often present. The relationship of the disease to the immune abnormalities is poorly understood. A general dysregulation of the immune system appears prevalent in many patients. Consistent with this is the finding of altered antibody repertoires of self-reactive IgM and IgG in MDS patients, indicating a disturbance in self-recognition mechanisms. Whether some abnormalities relate, in part, to the number of red cell transfusions or whether they are reversible with effective treatment is unknown. Given the nature of the defect in a multipotent stem cell with potential to differentiate along multiple pathways, the dysregulation of T and B cells should not be surprising.

Establishing a diagnosis

The diagnosis in most patients is readily established with standardized testing, which should include history and physical examination, complete blood count, and review of the peripheral blood smear. The findings of cytopenias in the absence of explanation from biochemical, vitamin deficiency, hemorrhage, toxin/drug, or infectious etiology should lead to a bone marrow aspirate and biopsy. Routine cytogenetic evaluation should be included as well. The diagnosis of MDS is based primarily on morphologic criteria demonstrating dysmorphic features in the peripheral blood and bone marrow precursors ([Table 6](#)). Although some of the classification systems include cytogenetic information (IPSS, IPSS-R, and WHO), they are based primarily on bone marrow and peripheral blood morphology. Analysis of the marrow population using flow cytometric analysis has become standard for the diagnosis and subtyping in patients with acute leukemia. It is more routinely being applied to establish a diagnosis of MDS as well. Abnormal populations and skewed antigen expression can be identified. However, comparative studies of bone marrow morphology and flow cytometry results have not been conducted, and thus one cannot be certain if used alone whether flow cytometry results can reliably establish a diagnosis and classification of MDS. Accurate classification according to FAB, IPSS, IPSS-R, or WHO criteria must be based, at least in part, on bone marrow morphology. Thus, flow cytometry should be viewed as a complementary examination but not sufficient to establish the diagnosis and classification. Cytogenetics are abnormal in up to 70% of patients, with abnormalities that are not diagnostic but maybe suggestive of the diagnosis. Gene mutation analyses of genes commonly mutated in myeloid diseases are becoming commercially available and can be used to support a diagnosis of MDS. However, gene mutations have been described in normal patients with no manifestation of a hematologic malignancy and whose significance is uncertain.¹⁰¹ So gene mutations alone are insufficient to establish a diagnosis.

Diagnostic dilemmas

Some patients with MDS present with features also suggestive of an MPN, representing an “overlap syndrome.”¹⁰² In these patients, cytopenias may present simultaneously with elevated white or platelet counts. In some patients, an increased leukocyte count may be accompanied by monocytosis. Under current classification systems, some of these patients will be clearly defined as MPN, while others are

still categorized as MDS, depending on the upper limit of WBC permitted in the classification system. Others may have myelofibrosis with or without marked splenomegaly and peripheral blood cytopenias yet also have dysplastic features suggesting MDS. These patients are more difficult to classify. Those with myelofibrosis with markedly enlarged spleens and a leukoerythroblastic peripheral smear are more likely classic myelofibrosis with myeloid metaplasia, while patients without significant splenomegaly and/or the peripheral leukoerythroblastic picture may be considered to have primary MDS with fibrosis. The presence of V617F Jak2 mutation would favor a diagnosis of an MPN over MDS except in patients with RARS-T.

The hypoplastic MDS variant is often indistinguishable from aplastic anemia and may have many features in common.^{103, 104} Those patients with increased expression of HLA-DR 15 and the PNH phenotype (decreased expression of CD59), whether MDS or aplastic anemia, may respond to immunomodulatory treatments. Cytogenetic abnormalities, if present, involving chromosomes frequently abnormal in MDS, may suggest the diagnosis of MDS, but do not completely exclude aplastic anemia. In these patients, therapeutic options may be the determinants in the orientation of the diagnosis in the absence of other criteria.

Finally, there are patients who present with severe pancytopenia and bone marrow findings that are nondiagnostic (i.e., minimal, if any, dysmorphic changes; no increase in myeloblasts) and without any cytogenetic abnormalities. Some of these patients may have MDS, and only with continued observation and testing will a diagnosis be unequivocally established. Gene mutations may also suggest MDS. Others may have been exposed to a bone marrow insult (toxin, infectious agent, etc.), which may never be identified, but which may permit eventual complete or partial marrow recovery, which takes months or years. In these latter individuals, in the absence of clear diagnostic evidence, patience, continued observation, and supportive care (SC) are usually the best approaches pending a declarative diagnosis. One other consideration for these patients would be an immune-mediated injury to hematopoietic stem cells. The differential in these patients would include large granular lymphocytic (LGL) leukemia, where T-cell receptor and immunoglobulin gene rearrangement studies and T-cell subsets may be informative.¹⁰⁵

Pathogenesis and relation to leukemic transformation

Initiation and promotion of an abnormality affecting a multipotent stem cell may be related to a variety of factors, including chemical insult, radiation, or infection, leading to modification of gene expression. Since most patients with MDS are in the sixth, seventh, or eighth decades, cell senescence may also play a role. Once established, the clonal lesion follows the multistep process of oncogenesis and results in the transformation to acute leukemia in up to 40% of patients. It is likely that multiple events occur and lead to evolution of the disease and ultimate emergence of a dominant clone of cells.^{106, 107} Based on the knowledge of a number of abnormalities that do occur, one may speculate on the possible interrelationship of these events that contribute to the pathogenesis. Mutations of the *ras* oncogene, either as an early or late event in the development of the disease, may be one of the steps in this process. One model of *ras* mutation results in impaired growth and differentiation along with impaired response to erythropoietin and increased apoptosis, similar to the response of the *in vivo* phenotype. Such mutations may serve to confer a growth advantage to the mutated cells, resulting in their progressive expansion. As a late event, the selective growth advantage may be sufficient to trigger a leukemic transformation. However, when alteration of the *ras* gene occurs as an early event, it may be insufficient to trigger further progression and may require the concerted action of other factors such as those accompanying chromosomal abnormalities and the attendant gene dysregulation that occurs. The identification of many more somatic mutations involving differing pathways including those involved in epigenetic regulation,

signaling, transcription factors, and RNA splicing suggests that the pathogenesis is more complex. Models that will allow the study of the role of these mutations will be critical.¹⁰⁸

The impaired response of hematopoietic progenitors suggests an underlying abnormality of signal transduction. Mutations of cytokine receptors can result in a signal that is muted or overexpressed. Mutations have been identified of the FLT3 and G-CSF receptor in association with transformation to AML in patients with MDS. Most studies, however, have not identified abnormalities of cytokine receptors, suggesting a defect further downstream from the ligand–receptor interaction.^{109, 110} The increase in apoptosis in the bone marrow with apparent dysregulation of TNF- α and TGF- β further suggests cytokine dysregulation. Hematopoietic progenitors with impaired cellular response to cytokine signals could behave as though deprived of obligate survival factors and thus undergo accelerated apoptosis. This would be the predominant phenotype until further genetic or growth regulatory changes occurred that would trigger a proliferative advantage and transformation to AML. In patients with severe congenital neutropenia, evolution to an MDS or acute leukemia is usually accompanied by acquired mutations in the G-CSF receptor.¹¹¹ Point mutations of the G-CSF receptor gene cause truncation of the C-terminal cytoplasmic region of the receptor. Cells with this defect fail to undergo terminal maturation to granulocytes in response to the G-CSF. In a mouse model, the equivalent G-CSF receptor mutation leads to expansion of the G-CSF receptor-responsive progenitor population. Treatment with G-CSF leads to neutrophilia, accompanied by increased activation of transcription factors and prolonged external cell surface expression owing to defective internalization. Further genetic mutations in the face of clonal expansion can contribute to leukemogenesis.

Karyotypic abnormalities have been described in up to 79% of patients with MDS and appear to be a later phenomenon. This is suggested by the identification of karyotypic abnormalities in cells belonging to already established clones derived from a multipotent stem cell and by their greater frequency in patients with increased bone marrow blasts. The association in some studies of complex karyotypic abnormalities with an increased risk of leukemic transformation further suggests that these anomalies confer a growth advantage to a clone, as well as reflecting underlying genetic instability. This instability, manifest by clonal evolution with the subsequent acquisition of additional chromosomal abnormalities, has also been associated with disease progression, either to a more malignant subtype or to frank AML. Finally, most of the karyotypic abnormalities involve complete or partial deletions of chromosomes and suggest that gene loss may play a role in the pathogenesis. The critical region on the long arm of chromosome 5, in the interstitial region q13–q34, contains genes encoding a number of important proteins, including GM-CSF, IL-3, IL-4, IL-5, CSF-1, and the oncogene *cfms*, which codes for the CSF-1 receptor. Changes in this critical region may result in the production of an abnormal gene product or a point mutation. Deletion or loss of chromosomal material may result in a cell hemizygous for a mutant allele, which can be expressed, or loss of a tumor suppressor gene. Several chromosomal regions that are commonly deleted in patients with MDS have been identified, including del 1q, del 5q, del 17p, and del 3p, and may contain tumor suppressor genes whose loss may contribute to the transformation process.

Dysregulation of the cell cycle may occur and contribute to the leukemic transformation. The cyclin-dependent kinase inhibitor (CDKI) gene p15INK4B undergoes aberrant methylation of the CpG islands in up to 50% of patients with MDS studied in one series. Patients with high-risk MDS had the highest frequency of hypermethylation compared to those with low-risk MDS. In addition, hypermethylation became more prominent as disease progressed.

Treatment

For many years, the management of patients with MDS was a frustrating and daunting task, compounded

by the age of the patients, their debility secondary to bone marrow failure, comorbidities, and a lack of effective treatments. The mainstay of therapy was primarily SC, consisting of transfusions and antibiotics in an effort to alleviate symptoms, but without impact on the disease outcome. Therapeutic efforts are complicated by the heterogeneity of the disease, which determines individual prognosis. Additional complicating features, including the general lack of randomized trials and the lack of uniform response criteria, made the interpretation of therapeutic results more difficult. The last decade has witnessed an expanded interest in the treatment of MDS, with the identification of new effective therapeutic strategies.

Differentiation-inducing and novel-acting agents

There has been great interest in the potential of differentiation therapy as an antitumor modality since Charlotte Friend and her colleagues first demonstrated that dimethyl sulfoxide (DMSO) could induce differentiation of murine erythroleukemic cells *in vitro*, thus altering their malignant phenotype.¹¹² The phenomenon although readily achieved *in vitro* is more difficult to demonstrate in the clinical setting. A number of agents that have effectively induced differentiation *in vitro* were tested in MDS without significant success (e.g., cis- and trans-retinoic acid, vitamin D3, butyrate, and hexamethylene bisacetamide [HMBA]).

The hypomethylating agent (HMA) azacitidine (AzaC) has produced significant benefit ([Table 7](#)).^{113–116} The promoter region of genes that are not expressed is often associated with hypermethylated CpG islands. Aberrant acquired changes in methylation, or epigenetic events, affecting intergenic and intron regions as well result in gene silencing and can have important effects on genes regulating the cell cycle and differentiation programs. A series of experiments by Christman, Acs, Taylor, and Jones and colleagues led to the development of a biochemical model that provided an explanation for the action of AzaC as an inducer of differentiation through its effects on DNA methylation.^{117–119} AzaC, once incorporated into DNA, covalently binds to DNA methyltransferase, the enzyme in mammalian cells responsible for methylation of newly synthesized DNA. This binding results in hypomethylated DNA distal to the binding point and leads to transcription of previously quiescent methylated genes. In patients with β -thalassemia,¹²⁰ treatment with AzaC resulted in an increase in fetal hemoglobin production, which was associated with hypomethylation in the region of the gamma globin chain gene. Based on this model, two trials testing the efficacy of AzaC in MDS were undertaken by the Cancer and Leukemia Group B (CALGB) which demonstrated a 50% response rate in patients with higher-risk MDS.^{115, 121} This led to the conduct in the CALGB of a phase III trial of AzaC compared with SC. In the trial design, patients with progression could cross over to treatment after a minimum of 4 months in the SC group. Responses occurred in 60% on the AzaC arm (7% CR, 16% PR, 37% improved) compared with 5% (improved) for SC ($p < 0.0001$). The median time to leukemic transformation or death was significantly delayed for those on AzaC (21 mos. vs. 13 mos. for SC [$p = 0.007$]). Probability of transformation to AML as the first event was lower on AzaC (15%) than SC¹¹⁶ ($p = 0.001$). The quality of life (QOL) of patients on the AzaC arm was significantly superior to that experienced by individuals in the control group as measured by several test methods. Striking improvement in their QOL ensued. Patients on the AzaC arm experienced significantly greater improvement over time than patients in the SC group in fatigue, physical functioning, dyspnea, psychosocial distress, and positive affect. After crossover to AzaC, significant improvements occurred in fatigue, physical functioning, dyspnea, and general well-being.¹²² Median survival for AzaC and SC (analyzed by intent to treat regardless of crossover) was 20 and 14 months, respectively ($p = 0.1$). The probability of survival at 24 months was 41% for AzaC compared with 25% for SC ($p = 0.03$). In order to eliminate the confounding effect caused by including the 49 crossover patients in the survival analysis, a landmark analysis was done in which the survival of three subgroups of patients was

compared from a 6-month landmark date. These subgroups were SC patients who never crossed over or who crossed over only after 6 months, SC patients who crossed over before 6 months, and patients who were initially randomized to AzaC. The 36 patients who died before the landmark date were excluded. The additional median survival (after the 6-month landmark date) for these three groups was 11, 14, and 18 months, respectively. The AzaC group was significantly different from the SC subgroup who crossed over late or never ($p = 0.03$). SC patients who crossed over early (subgroup 2) had a longer median survival than the patients who crossed over late or never (subgroup 1), though this did not reach statistical significance ($p = 0.11$). Results demonstrate that patients treated with AzaC had significantly higher response rates, improved QOL, delayed time to progression, improved survival at 24 months, delayed time to leukemic transformation or death, and significantly reduced risk of transformation to AML compared with SC. On crossover to AzaC treatment, the same individuals were evaluated for QOL according to the same serial interviews. Striking improvement in their QOL ensued. Patients on the AzaC arm experienced significantly greater improvement over time in fatigue (EORTC, $p = 0.001$), physical functioning (EORTC, $p = 0.002$), dyspnea (EORTC, $p = 0.0014$), psychosocial distress (MHI, $p = 0.015$), and positive affect (MHI, $p = 0.0077$) than patients in the SC group. Significant differences persisted after controlling for RBC transfusions. Prior to crossover, the QOL of patients on SC was stable or worsening. After crossover to AzaC, significant improvements occurred in fatigue (EORTC, $p = 0.0001$), physical functioning (EORTC, $p = 0.004$), dyspnea (EORTC, $p = 0.0002$), and general well-being (MHI, $p = 0.016$). Detailed analyses make unlikely placebo or Hawthorne effects as explanations for improvements in QOL by AzaC. Additional analyses demonstrated that AzaC results in transfusion independence in 45% of patients and is effective in producing responses in patients according to the WHO AML classification (blasts $> 20\%$) with a median survival of 19.3 months, suggesting a potential benefit in this patient population.¹²³ Thus, AzaC is the only agent other than allogeneic bone marrow transplantation to alter the natural history of MDS. Furthermore, AzaC is not age restricted, as is marrow transplantation. A second randomized controlled trial has confirmed and extended these observations demonstrating a significant survival advantage for patients treated with AzaC compared to a conventional care regimen (a physician-directed choice of either best SC, low-dose cytarabine, or induction chemotherapy with an anthracycline and cytarabine) with median overall survival (OS) for AzaC of 24.4 months compared to 15 months for the conventional care regimen.¹⁸ Time to AML or death was significantly delayed for patients in the AzaC-treated group. Transfusion independence occurred in 45% of patients, and there was a reduction by 33% in the infections requiring intravenous antibiotics in the AzaC-treated patients. Time to initial response is slow, requiring repetitive monthly cycles to see a response, with the median time to response of three cycles—an observation seen consistently across all AzaC studies. Additional analyses suggest that maintenance therapy with AzaC is also beneficial.¹²⁴

Table 7 Randomized controlled trials in patients with MDS drug versus supportive care ± placebo

Agent	Response to treatment	Quality of life	Frequency of transformation to AML	Time to progression	Time to AML or death	Survival at 24 months
<i>Cis-retinoic acid</i>	NSSD	—	—	—	—	NSSD
Low-dose cytarabine	Cytarabine	—	NSSD	NSSD	NSSD	NSSD
G-CSF	G-CSF	—	NSSD	NSSD	SC ^a	SC ^a
GM-CSF	GM-CSF	—	NSSD	—	—	NSSD
Azacitidine	Azacitidine ^b	Azacitidine ^c	Azacitidine ^b	Azacitidine ^d	Azacitidine ^e	Azacitidine ^f
Decitabine	Decitabine	Decitabine	NSSD	NSSD	NSSD	NR

^a Differences are for patients with RAEB. For those with RAEB-T, there was NSSD between G-CSF and SC.

^b $p < 0.001$.

^c Fatigue ($p = 0.001$), physical functioning ($p = 0.002$), dyspnea ($p = 0.0014$), and mental health index ($p = 0.0077$).

^d $p < 0.0001$.

^e $p = 0.004$.

^f $p = 0.03$.

Abbreviations: NSSD, no statistically significant difference between agent tested and placebo or supportive care (SC); —, endpoint not assessed in trial; NR, not reported.

AzaC acts via a number of mechanisms. It can be a cytotoxic agent, but *in vitro* data indicate that it also functions as a biologic response modifier, affecting cytokine signal transduction pathways.¹²⁵ Another hypomethylating agent, decitabine (2-deoxy-5-AzaC), has also been evaluated.^{126–129} Although response criteria are different, decitabine, like AzaC, produces responses. In a North American randomized trial of decitabine compared to SC, decitabine was superior with a response rate of 17% CR + PR compared to 0% for SC. However, there was no difference in the second coprimary endpoint of time to AML or death between the two groups.¹²⁹ In a second randomized trial conducted in Europe by the EORTC of decitabine compared to SC in patients with intermediate-2 or high-risk disease, there was no difference in time to AML or death or survival between the two groups.¹²⁶ An alternative dosing regimen of 20 mg/m²/day × 5 days every 4 weeks has yielded response rates that are comparable but maybe less myelosuppressive.^{130, 131} However, this was not a controlled trial, and the effects on modifying disease outcome are uncertain.¹³²

Epigenetic combinations

Single-agent HMAs produce responses in half the patients treated but are not curative. Combination epigenetic therapy with HMAs and a variety of histone deacetylase inhibitors (HDACs) has been explored.¹³² *In vitro* combinations of HMAs and HDACs are synergistic in reexpressing epigenetically silenced genes. The effect is sequence dependent with the HMA required to be administered before the HDAC to see the effect, and this observation has led to a series of combination translational trials. AzaC has been combined with entinostat in a randomized trial comparing the single agent to the combination. There was no difference between the combination and AzaC monotherapy in response or OS. Analysis of

the methylation differences between the two arms suggests that there was a negative interaction between the combination and monotherapy with reduced hypomethylation in the patients treated with the combination.¹³³ AzaC combined with vorinostat in phase I–II study demonstrates a response rate up to 75% with an increase in time to AML or death and overall survival in the cohort of AzaC 75 mg/m²/day 1–7 and vorinostat 200 mg BID days 3–9.¹³⁴ The combination studies are associated with GI toxicity, nausea, vomiting, and fatigue being described in many patients. This toxicity can be tolerated by some but may hinder longer-term tolerance among patients and may contribute to an inability to maintain patients on treatment to obtain the full effect. AzaC in combination with mocetinostat has also shown positive clinical response; however, pericardial inflammation was observed and studies were halted.

Signal inhibitors: Multikinase inhibitors

Rigosertib is a Ras mimetic molecule with multikinase inhibitory activity. It is a broad inhibitor of the PI3 kinase/AKT pathway and has been tested alone and in combination in MDS.¹³⁵ As a single agent, rigosertib administered IV has shown improvement in peripheral blood counts and a reduction in marrow blast percentage in patients that were predominantly HMA failures.¹³⁵ In a randomized phase III study, patients were randomized to either rigosertib or BSC (which could include low-dose cytarabine) with OS as the primary endpoint in patients who were HMA failures. The trend was in favor of rigosertib, 8.2 months versus 5.9 ($p = 0.33$, HR 0.87 [95% CI 0.67–1.14]). Although the trial did not meet the primary endpoint, there were several subgroups that demonstrated a survival benefit.¹³⁶ Rigosertib is being tested in a new phase III study. Rigosertib is also being studied in combination with AzaC based on *in vitro* studies which demonstrated synergistic interaction enhancing apoptosis between the two agents. Data from the phase I study of the combination demonstrates the regimen to be well tolerated and yields responses in patients with MDS and AML including those that have failed prior treatment with an HMA.¹³⁷

Retinoic acid and related compounds, highly effective inducers of differentiation *in vitro*, have been disappointing in their lack of efficacy in several clinical trials.¹³⁸

Anti-TNF and the IMiDs. The observations regarding the potential role of TNF in the pathophysiology of MDS (described in the section titled “Signal transduction”) have led to therapeutic strategies targeting TNF in small pilot studies. Etanercept, an anti-TNF fusion protein, caused erythroid response of 30% in one trial and a lower response in the other.¹³⁹ Thalidomide has not only been tested based on potential anti-TNF activity but also because of effects on vascular endothelial growth factor (VEGF). Responses predominantly in the erythroid lineage ranged from 10% to 19%.¹⁴⁰ Somnolence and neuropathy forced withdrawal of patients from treatment. Lenalidomide, an analog without sedative or neuropathic side effects and with more potent *in vitro* anti-TNF and anti-VEGF effects, was tested in a phase II trial. Of the 148 patients with low and intermediate-1 disease with del 5q either isolated or combined with other cytogenetic abnormalities, 67% patients became red cell transfusion independent.¹⁴¹ The median duration of transfusion independence was 115 weeks.¹⁴¹ These data were confirmed in a second study wherein 10 mg/day should be the initial dose. In a second study of low and intermediate-1 disease in patients without a deletion 5q, 26% patients achieved transfusion independence for a median of 41 weeks. Lenalidomide has been combined with AzaC and produced an overall response rate of 67%.¹⁴² The combination was well tolerated but will require more testing to determine if it is better than either agent alone.

Novel fusion proteins for TGFβ superligand family with ligand trap activity toward the activin type 2 receptors are in clinical development in patients with lower risk, red cell transfusion-dependent MDS. In early phase trials, these agents, sotatercept and luspatercept, have reduced transfusion need in some

patients and eliminated RBC transfusion requirement in patients with low transfusion burden lower-risk disease.¹⁴³ These agents are undergoing further clinical testing.

Hormones

Although used as a nonspecific stimulant of erythropoiesis in aplastic anemia with some benefit, androgens have not proven to be useful in MDS. Initial observations suggesting that treatment with androgens accelerated the disease and was associated with an increased rate of leukemic transformation were not confirmed in subsequent studies, nor was any efficacy identified.^{144, 145}

Glucocorticoid therapy yielded an overall response rate of only 9%, and furthermore, 24% of nonresponding patients experienced significant deleterious side effects.

Danazol has been reported to produce improvements in the thrombocytopenia and anemia in patients with MDS. Danazol may be helpful in those patients where immune-mediated cell destruction contributes to the deficit.

Chemotherapy

Chemotherapeutic agents, alone and in combination, have been used to treat patients with MDS. These agents have been employed in a variety of regimens ranging from attenuated low-dose schedules⁹⁹ to the more conventional antileukemic myelotoxic-type strategies. These have been employed to treat patients at all stages of disease. Antileukemic-type treatments have not substantially altered the outcome of the disease for most patients and have been associated with significant toxicity in many. In a retrospective analysis of chemotherapy induction compared to an HMA, the trend suggested a benefit for the HMA.¹⁵

The pharmacologic interaction between fludarabine and cytosine arabinoside increases intracellular ara-CTP and has been exploited in a regimen with activity in patients with relapsed AML. Subsequently, the combination with (FLAG) or without (FA) G-CSF has been tested in patients with MDS and de novo AML.¹⁴⁶ The two regimens yielded comparable complete response (CR) rates of 60% and 55%, respectively, with the response rate generally higher in the subgroups of MDS with excess blasts. Overall, 27% of patients (MDS and AML) died during induction. The median projected survival was 29 weeks for FA and 39 weeks for FLAG. These differences were not statistically significant. In patients with deletion of chromosome 5 or 7, FLAG produced a response rate of 64% versus 36% for FA. However, the differences were attributed by the authors to factors other than an effect of treatment. Use of G-CSF was associated with a more rapid recovery of neutrophil count, but this did not translate into decreased rates of infection or infection-related mortality. Overall, there were no differences in treatment outcome for patients with MDS compared with AML.

Cytosine arabinoside has been extensively tested. In a review of the literature, low-dose cytosine arabinoside was reported to produce 16% CR in 170 patients.^{147, 148} Median duration of CR was 10.5 months, but achievement of a response appeared to have little effect on overall survival. In a randomized trial conducted by Eastern Cooperative Oncology Group (ECOG) and Southwest Oncology Group (SWOG), patients with MDS were treated with either low-dose cytarabine or SC. Patients in SC who progressed could cross over and receive treatment with cytarabine. There was no significant difference between the cytarabine and SC groups with respect to overall survival, time to progression, or frequency of transformation to AML ([Table 7](#)). In a subset analysis in the most recent randomized trial, AzaC compared to a conventional care regimen was superior to low-dose cytarabine improving survival significantly in patients with intermediate-2 and high-risk MDS.¹⁸

Clofarabine use in varying doses ranging from 15 to 40 mg/m² IV daily × 5 days has yielded responses between 25% and 50% of patients with variable duration of response in both untreated and those that have failed HMA therapy. The role and utility of clofarabine in MDS treatment remain to be determined.¹⁴⁹

In general, results from earlier studies indicated that responses to treatment of patients with either MDS or AML following MDS are less favorable than treatment of de novo AML. Age appears to influence the rate and duration of response, with younger patients achieving CR more frequently and remaining in remission longer compared with older patients. Achievement of a CR in MDS is associated with improved survival in comparison to nonresponding patients, but the duration of the response is substantially shorter in comparison with patients with de novo AML who achieve response. Treatment prior to the transformation to AML and patients with shorter intervals between the diagnosis of MDS and leukemic transformation are associated with higher response rates. However, aggressive antileukemic-type treatment is associated with high rates of morbidity and mortality, with up to 30% of the patients dying from drug-related complications.

Iron chelation. For patients with lower-risk disease who are red cell transfusion dependent, accumulation of iron leading to iron overload and ultimate tissue damage from hemochromatosis is a long-term problem. Use of chelation is recommended for patients who have received ≥ 20–25 units of lifetime transfused RBC or a serum ferritin > 1000–2000 ng/mL (NCCN Guidelines Version 2.2014). Use of deferasirox has been shown to reduce serum ferritin and labile plasma iron.¹⁵⁰ Some studies have suggested an impact on survival, but there have been no randomized trials and other factors could be at play as well including patient selection bias. However, chelation should be part of the management strategy for lower-risk RBC transfusion-dependent patients. In patients with higher risk, the role of chelation is undetermined. In the absence of effective primary therapy for the MDS, chelation in this patient population is probably not warranted until or unless the patients achieve a hematological response to primary therapy.

Bone marrow transplantation

Results of allogeneic and syngeneic bone marrow transplantation from a series of reports containing small numbers of MDS patients have suggested that 35–40% can achieve durable long-term disease-free remissions when treated with this modality.¹⁵¹ This has been substantiated with the results from two larger single-institution series. In one large series, 251 patients treated between 1981 and 1996 were evaluated. Appelbaum and colleagues reported an estimated (Kaplan–Meier) 5-year disease-free survival (DFS) of 40%. Younger age, shorter duration of disease, female gender, and de novo MDS were predictors of better DFS. Patients under the age of 20 years had a 60% DFS rate compared with 40% and 20% for those 20–50 years old or over the age of 50, respectively. Patients with low-risk MDS had a 55% DFS at 6 years compared with only 30% for those with high-risk MDS.^{152, 153} This difference correlated with a higher rate of relapse among those with more advanced disease. Among patients with low and intermediate-1 risk according to the IPSS score, there were almost no relapses. The 5-year DFS for those in the low and intermediate-1 groups was 60%, 36% for those in intermediate-2, and 28% for those in the high-risk group. Patients undergoing matched unrelated donor (MUD) marrow transplants fare less well. In an analysis of results from the National Marrow Donor Program, patients receiving MUD transplants during the first 4 years of registry data (1986–1990) had a disappointing DFS of only 18% at 2 years and 24% OS at 2 years. In one study, patients with primary MDS demonstrated a survival advantage over those with secondary MDS (56% vs. 27%).

The exact role and timing of bone marrow transplantation remain to be determined, as does the optimal

conditioning regimen. A recent analysis of patients with low-risk disease suggests that watchful waiting until evidence of disease progression increases life expectancy compared with immediate transplantation. For patients with high-risk disease, transplantation shortly after diagnosis was associated with better life expectancy.¹⁵⁴ These data were recently updated for patients 60–70 years old and favor transplant for higher-risk patients with some gain in life expectancy, whereas nontransplant approaches are favored for lower-risk patients.¹⁵⁵ For patients 40 years or younger with a compatible related donor, however, transplantation should be favored, since no other therapy thus far is curative. However, selection of transplant candidates for patients under the age of 50 remains problematic. There are some younger patients with low-risk MDS with a median survival greater than 15 years treated with SC alone.¹⁵⁶ Fewer patients over the age of 40 have been transplanted, but limited data for those with related donors suggest that up to 30% may survive disease-free. Transplantation for those without a related donor is a more difficult choice in view of the data noted previously. Given the age of most patients with MDS and the availability of donors, transplantation in the foreseeable future is likely to be of limited value, benefiting only about 5–10% of all patients with MDS.¹⁵¹

Because of the age of most MDS patients and the potential toxicity of fully ablative transplantation regimens, interest has developed in reduced-intensity conditioning hematopoietic stem cell transplantation as an alternative. These treatment strategies use conditioning regimens, often fludarabine based, which are better tolerated and not intended to be fully ablative. They permit chimerism to be established with either sibling or volunteer unrelated matched donors. Recent reports demonstrate that this strategy can be used in patients over the age of 60 years with mortality rates ranging from 0% to 21%. Chimerism was established in 83% of patients. Duration of remission and relapse is dependent on the IPSS classification, similar to fully ablative transplantation. Thus, this is a feasible approach that can be extended to older patients, but further studies will be necessary to determine its potential role in therapy.^{151, 155}

AzaC has been explored as both a bridge to transplant with administration prior to allogeneic transplant and a maintenance strategy postallogeneic transplant.^{157, 158} Treatment is well tolerated in both the pre- and posttransplant setting, but randomized trials will be required to assess whether AzaC in either the pre- or posttransplant setting positively impacts disease outcome.

The use of high-dose chemotherapy with either autologous bone marrow or peripheral blood stem cell (PBSC) infusion has been used in a limited fashion. The European group reported on 79 patients treated with intensive chemotherapy and autologous bone marrow transplantation in first CR. Fifty-five of the 79 in whom the duration of first CR was known were matched with 110 patients with de novo AML. The 2-year survival for all 79 patients was 39%, and the DFS at 2 years was 28% for the 55 patients with MDS/sAML versus 51% for patients with de novo AML. Relapse rates were 69% for MDS/sAML and 40% for de novo AML ($p = 0.007$).^{159, 160} Use of PBSC infusion is more problematic given that adequate collection from patients with MDS is obtained in only half the patients.

Growth factors. The hematopoietic growth factors are regulatory glycoproteins that control the proliferation and differentiation of bone marrow stem cells.¹⁶¹ Several studies have defined the effects of GM-CSF in MDS.¹⁶² In a controlled study, patients were randomized to observation or treatment with rhGM-CSF. Those treated had significant increases in neutrophils, eosinophils, monocytes, and lymphocytes, while the frequency of infections was decreased in comparison with those observed in the absence of this cytokine. There were no differences in platelet count, hemoglobin, or transfusion requirements between the two groups. The risk of leukemic transformation appeared greatest for those patients with greater than 15% blasts in the bone marrow and may be a critical level with respect to leukemic transformation.

Filgrastim (G-CSF) has also been evaluated. In a randomized controlled trial, 102 patients with RAEB or RAEB-T were treated with either G-CSF or SC.¹⁶¹ No differences in frequency or time to progression to AML were seen between the two groups. There was no difference in survival for those with RAEB-T. However, among patients with RAEB, those in the treatment group had a significantly shortened survival compared with patients in the control group, resulting in early termination of the study.

Erythropoietin has also been studied in patients with MDS, with red cell responses being demonstrated in 20–25% of the patients tested.^{77, 163, 164} Responses were confined to the erythroid lineage. A meta-analysis suggests that efficacy declines as bone marrow failure progresses. Those who have lower serum erythropoietin levels and less transfusion need are more likely to respond. The observation that *in vitro* erythropoiesis improved in patients treated *in vivo* with G-CSF led to two clinical trials of erythropoietin and G-CSF in combination. The response rate ranged from 35% to 40% and appeared to enhance the activity of erythropoietin. Serum erythropoietin levels in these trials, as in others, are of predictive value with few responses in patients with levels above 500 U/L. In another report, the response-enhancing effect of G-CSF was not substantiated. In a series of 191 patients treated with the combination, the overall response was 39%. Low-risk disease was associated with a higher response, and patients achieving a CR had a longer duration of response. An algorithm based on transfusion need and serum erythropoietin levels may be a useful guide for patient selection. Effects of erythropoietin therapy on survival suggest that elimination of a transfusion requirement may be beneficial.⁷⁸

For patients with a variant of MDS characterized by severe hypoplasia and pancytopenia, which may resemble severe aplastic anemia (hypoplastic MDS), administration of antithymocyte globulin produced responses in 11 of 25 patients treated (9 of 14 RA; 2 of 6 RAEB).^{79, 80} Responses were characterized predominantly by loss of transfusion requirement, and 3 of 25 had normalization of their counts. There were no changes in the dysplastic features or in bone marrow cellularity. In the completed study, 61 patients were treated, with 21(34%) responding. Transfusion requirement was eliminated in 76% of responding patients or 25% overall. The effect may be mediated, in part, through an immunosuppressive effect alleviating a T-cell suppression of hematopoietic progenitors. Patients who are younger and have more cytopenias, shorter duration of red cell transfusion dependence, and the presence of HLA-DRB1-15 appear more likely to respond.

Clinical management

The management of patients with MDS presents a series of difficult choices ([Figure 2](#)). For patients with RA or RARS, low- or intermediate-1-risk groups, who have better prognoses and in whom the disease is manifest predominantly as asymptomatic anemia, observation and SC should be the mainstay. For those who require red cell transfusions, which in and of itself is a negative prognostic variable, a trial of erythropoietin with or without G-CSF appears reasonable.⁸¹ Treatment with lenalidomide or AzaC in patients who fail an ESA or have severe leukopenia or thrombocytopenia is a consideration. Those patients with a karyotypic abnormality (other than the 5q-syndrome, very good risk cytogenetics) have a less favorable prognosis. Such patients warrant closer follow-up and are candidates for investigational studies, particularly if they manifest an increasing number of blasts in the bone marrow or develop significant neutropenia or thrombocytopenia. Patients with low-risk disease who fail therapy with erythropoietin with or without G-CSF for anemia or who have severe cytopenias in other lineages can be considered for treatment with AzaC, which has demonstrated efficacy in low-risk disease with amelioration of symptoms. Single-agent lenalidomide or an HMA can lead to transfusion independence in between 25% (lenalidomide) and 50% (AzaC) of patients. For patients with lower-risk disease that is progressing, who fail lenalidomide and/or HMA and who have a compatible donor, allogeneic bone

marrow transplantation should be considered, since it is the only therapy that has so far achieved cures.^{154, 155}

Figure 2 Treatment algorithm for patients with the myelodysplastic syndrome.

Patients with higher-risk disease (intermediate-2 or high risk; high risk and very high risk—IPSS-R) have a poorer prognosis and are candidates for treatment with an HMA. Those with RAEB-I (5–10% blasts) without other poor prognostic features (i.e., abnormal karyotype, severe thrombocytopenia or severe neutropenia) could be closely observed to determine the relative stability of the disease. Those with evidence of progression are candidates for immediate intervention.

Patients with higher-risk disease can benefit from treatment with AzaC which should be considered the standard first-line therapy for these patients. It has demonstrated significant benefit compared with SC, induces remission, decreases transfusion requirements, extends survival, and improves the QOL.^{116, 122} This therapy may now represent the standard of care. Alternatively, they can be treated as part of an investigational program. Stem cell transplantation is a consideration for those patients as a potential curative strategy and should be considered early in the evaluation process after the diagnosis is established, if a donor is available, and if the patient's age and risk classification warrants it. However, the rate of relapse is high, and many centers will not consider these patients as candidates. Strategies aimed at inducing a remission prior to transplantation may be useful.^{154, 155, 165}

For patients who have transformed to leukemia, aggressive antileukemic chemotherapy can be undertaken or an HMA is a consideration for older patients. The CR rate for antileukemic chemotherapy ranges between 30% and 60% but is associated with a high rate of treatment-related morbidity and mortality. Most patients relapse. The HMAs have been used in these patients and may improve survival.¹⁶⁶ Patients with hypoplastic MDS, particularly if younger, may benefit from antithymocyte globulin with or without cyclosporine or other immunomodulatory effects. Patients who have either primary or secondary HMA failure have a poor prognosis, and an investigational agent should be considered.¹⁶⁷

Future directions

Progress in the prevention and therapy of MDS depends on a better understanding of the basic biochemical and molecular defects that contribute to the development of this syndrome. Identification of gene mutations and in the epigenome will be informative and will help to individualize therapeutic decisions. Well-designed clinical trials using clearly defined biologic endpoints are critical. Survival is the ultimate goal, but too global a composite to serve as the sole working criterion. QOL assessments have gained favor as useful tools in the measure of the effects of treatment. These assessments should be included routinely in phase II and III studies and help as a critical measure of a palliative treatment. Finally, cost analysis is another useful gauge of treatment efficacy. Pharmacoeconomic studies should also be included in future phase III studies.

In a disease characterized by the development of a progressive uncoupling of cellular maturation and proliferation, induction differentiation is an attractive approach. This has proven to be a highly provocative strategy in the treatment of acute promyelocytic leukemia with trans-retinoic acid. AzaC, which may act in part as a biologic response modifier with effects on the epigenome and gene signaling, may be advantageously combined with other agents such as HDACs.¹³² Drugs that interfere with or block abnormal signal transduction (e.g., tyrosine and multikinase inhibitors) may prove beneficial.¹³⁵ Tumor vaccines and the use of immunomodulatory strategies that can stimulate auto- or allogeneic T cells will be explored in the coming years with PD-1/PDL-1 checkpoint inhibitors.
