Chapter 134

Gastrointestinal and hepatic complications in cancer patients

Robert S. Bresalier, MD ■ H. Franklin Herlong, MD ■ Boris Blechacz, MD, PhD

Overview

Gastrointestinal and hepatic complications represent some of the most common and potentially life-threatening disorders associated with treatment of the cancer patient. The expansion of therapeutic options for these patients has been accompanied by a growing number of direct and indirect consequences that effect the rapidly dividing cells of the GI tract. Cytotoxic, immunologic, and infectious insults often combine to increase toxicity. Recognition of these complications, together with proper evaluation and management, is key to the well being of these patients.

A growing spectrum of treatments is available to combat cancer. Chemotherapy, radiotherapy, and molecular targeted therapies including immunotherapies lead to adverse effects in several organs systems, including those of the gastrointestinal (GI) tract. GI complications are very common in patients undergoing cancer treatment. Some of these complications can be life threatening and require prompt and appropriate diagnosis and treatment. This chapter addresses common GI complications that result from cancer treatment and focuses on the evaluation and management of these problems.

Esophageal disorders

Esophagitis

Esophagitis in patients with cancer may be due to the direct cytotoxic effects of chemotherapy or radiation, or by infections due to immunosuppressive effects of cancer therapy ([Table 1](#)). Cell death leads to mucosal atrophy, ulceration, and initiation of the inflammatory response. Reactive oxygen species, proinflammatory cytokines, and metabolic byproducts of colonizing organisms may also play a role in amplifying tissue injury.^{1, 2} Synergy between chemotherapy and radiotherapy may increase the severity and extent of esophagitis observed with combined modality therapy. Esophagitis may also be due to pill-induced injury, acid reflux disease, and graft-versus-host disease (GVHD) in hematopoietic stem-cell transplant recipients. When esophagitis is suspected, particularly in an immunocompromised patient, prompt evaluation with endoscopy with biopsies and/or brushings is indicated to allow for early diagnosis and therapy.

Table 1 Common causes of esophagitis in patients receiving cancer therapy

Infectious agent/injury	Endoscopic appearance	Treatment
Candida albicans	White plaque-like lesions with surrounding erythema on the esophageal mucosa	Systemic antifungal treatment with fluconazole, itraconazole, voriconazole, or echinocandins
Herpes simplex virus	Small vesicles, coalescing to form ulcers	Acyclovir and foscarnet sodium
Cytomegalovirus	Linear or serpiginous ulcers	Ganciclovir, foscarnet sodium and valganciclovir
Varicella–Zoster virus	Small vesicles, similar to HSV ulcers	Intravenous acyclovir
Polymicrobial oral flora	Bacteria mixed with necrotic epithelial cells in biopsy samples	Broad-spectrum antibiotics
Injury due to chemotherapy and radiation	Friable mucosa with erythema and edema	Lidocaine hydrochloride, narcotic analgesics, proton pump inhibitors, and endoscopic dilation/stents (for strictures), PEG ^a

^a Percutaneous gastrostomy.

Radiation-induced esophagitis

Radiation-induced esophagitis can occur during external beam radiation treatment of lung, head and neck, and esophageal cancers. Acute radiation esophagitis is primarily due to injury to the rapidly dividing cells of basal epithelial layer, which subsequently leads to thinning and denudation of esophageal mucosa. The severity of esophagitis depends on radiation dose and is exacerbated by the concurrent use of chemotherapeutic agents such as cisplatin.^{3–5} Patients generally complain of odynophagia, dysphagia, and chest pain. Endoscopy findings include erythema, edema friable mucosa, ulcerations, or stricture formation. Treatment of acute esophagitis includes the use of local anesthetics such as oral viscous lidocaine hydrochloride, systemic narcotic analgesics, and acid suppression with proton pump inhibitors. Symptoms in some patients are so severe as to require temporary percutaneous gastrostomy (PEG) placement. Some patients undergoing extensive head and neck surgery and chemoradiation may benefit from PEG placement before treatment in anticipation of severe symptoms. A recent consensus statement of the Multinational Association of Supportive Care in Cancer (MASCC) and the International Society of Oral Oncology (ISOO) suggested the use of intravenous amifostine to prevent esophagitis induced by concomitant chemotherapy and radiation in patients with nonsmall cell lung cancer.¹ Esophageal strictures are treated by endoscopic dilation. In patients with tracheo-esophageal fistula due to esophageal cancer, covered stents (self-expanding metal or plastic stents) are the treatment of choice, and can achieve fistula closure in 70–100% of patients.⁶

Fungal infections

Esophageal candidiasis is very common in immunocompromised patients, with *C. albicans* being the most common causative organism for esophageal and oropharyngeal candidiasis (OPC). Patients complain of odynophagia and/or dysphagia. On endoscopy, esophageal candidiasis is identified by white plaque-like lesions with surrounding erythema on the esophageal wall. Esophageal biopsies or brushings may confirm the presence of invasive yeast or hyphal forms of *C. albicans*. An empiric course of antifungal therapy is

recommended in immunocompromised patient with odynophagia or dysphagia. Endoscopy should be performed if symptoms do not improve within 72 h. The general duration of antifungal treatment is 14–21 days. Candida esophagitis in immunocompromised patients requires systemic antifungal therapy; it cannot be treated with topical agents.^{7–10} Patients unable to tolerate oral agents require intravenous therapy. The treatment of esophageal candidiasis includes azoles, echinocandins, or amphotericin B.^{7–15} Azoles inhibit cell membrane formation by inhibiting the synthesis of ergosterol, a principal component of fungal cell membrane. Fluconazole, an azole, is the recommended first-line agent due to its efficacy, ease of administration, and low cost. For patients with fluconazole-refractory esophageal candidiasis who can tolerate oral therapy, newer azoles (voriconazole and posaconazole) are available. Itraconazole has been found to be as effective as fluconazole for the treatment of esophageal candidiasis, however its use is limited by significant nausea and by its potential for drug interactions owing to inhibition of the cytochrome p 450 enzymes.

Patients requiring intravenous therapy should be treated with fluconazole or one of the echinocandins (caspofungin, micafungin, or anidulafungin), rather than amphotericin B, because of their better toxicity profiles. Echinocandins inhibit synthesis of $\beta(1,3)$ -D-glucan, an essential component of the fungal cell wall. Mammalian cells do not require $\beta(1,3)$ -D-glucan, thereby limiting potential toxicity. Relapse rates are higher with echinocandins compared to azoles, and these are used as second-line therapy if treatment with azoles has failed. Amphotericin B is reserved for esophageal candidiasis during pregnancy and in individuals with drug-resistant candidiasis. OPC is a local infection. Risk factors include radiation, chemotherapy, antibiotics, and steroids. Treatment is with local agents such as nystatin or clotrimazole troches. Patients at risk of developing OPC may be given antifungal prophylaxis. Topical antifungals, such as clotrimazole or miconazole, are effective for prophylaxis.¹⁶

Viral infections

Viral infections of the esophagus are caused by herpes simplex virus (HSV), cytomegalovirus (CMV), and, rarely, varicella-zoster virus (VZV).^{8, 17} Patients usually present with odynophagia and dysphagia. Less-frequent symptoms include nausea, vomiting, heartburn, epigastric pain, and fever. In the case of HSV esophagitis, some patients may have coexistent herpes labialis or oropharyngeal ulcers. Diagnosis is made by endoscopy and biopsy ([Figure 1](#)). In the early stage, HSV lesions may appear as small vesicles, although they are rarely seen. The vesicles eventually coalesce to form large ulcers, which are usually less than 2 cm in size. The ulcers are well circumscribed with normal-appearing intervening mucosa. CMV will cause ulcers that are linear or serpiginous and deeper than HSV-related ulcers. Exudates may also be present. Biopsies taken from the edge of an HSV-related ulcer will show intranuclear inclusions and multinucleated giant cells. Inclusions can also be detected by immunohistochemistry using monoclonal antibodies to HSV. Viral cultures are helpful in identifying resistant strains in patients who do not respond to acyclovir. VZV can produce esophagitis in adults with herpes zoster, usually in the setting of disseminated infection. Endoscopically, VZV ulcers are similar to those seen with HSV. On biopsy specimens, distinction from HSV will require immunohistochemistry or culture.

Figure 1 Herpes simplex virus (HSV) esophagitis. High-power view of esophageal mucosa shows squamous cells with ground glass nuclear viral inclusions and multinucleated giant cells in a background of neutrophilic exudates.

CMV infects endothelial cells and fibroblasts, but not epithelial cells as with HSV and VZV. Routine biopsies in a CMV-infected patient show intranuclear inclusions in fibroblasts and endothelial cells. Immunohistochemistry with anti-CMV antibodies is also helpful for diagnosis.

For patients with HSV esophagitis, acyclovir (400 mg orally five times daily for 14–21 days or 5 mg/kg intravenously every 8 h for 7–14 days) is the therapy of choice.^{8, 9, 18, 19} Acyclovir-resistant HSV result from mutations in the thymidine kinase (TK) gene of HSV. Viruses with TK mutations are generally cross-resistant to valacyclovir, but remain susceptible to agents that act directly on DNA polymerase such as foscarnet (80–120 mg/kg/day IV in 2–3 divided doses until clinical response). Cases of severe persistent infection with acyclovir-resistant HSV occur almost exclusively in immunocompromised hosts. Famciclovir or valacyclovir can be considered in patients able to tolerate oral therapy, although there is limited clinical experience with these drugs for the treatment of HSV-associated esophagitis. VZV esophagitis is initially treated with intravenous acyclovir as these patients usually have disseminated infection. After clinical improvement, treatment may be changed to oral agents used for HSV esophagitis. CMV esophagitis is treated with intravenous ganciclovir (5 mg/kg twice daily) or foscarnet sodium (68 mg/kg IV every 8 h or 90 mg/kg every 12 h) for 3–6 weeks.^{8, 20–22} The patient may be switched to valganciclovir 900 mg every 12 h once the patient can absorb and tolerate oral therapy. Valganciclovir is an oral precursor of ganciclovir. Valganciclovir is an oral precursor of ganciclovir. At a dose of 900 mg daily, valganciclovir produces systemic drug exposure equivalent to 5 mg/kg of intravenous ganciclovir. The role maintenance treatment after the clearance of infection is not well defined.

Bacterial infections

Bacterial esophagitis can occur in the immunocompromised patient and is usually polymicrobial and derived from oral flora. The diagnosis is made by endoscopic biopsies and treatment is broad-spectrum antibiotics.

Pill-induced esophagitis

Pill-induced esophagitis can occur in patients taking medication at bedtime with insufficient liquid or in the recumbent position. The most common medications associated with this disorder include potassium

chloride, tetracyclines, aspirin, nonsteroidal anti-inflammatory drugs, quinidine, iron, and alendronate. Injury is caused by prolonged contact of the caustic contents of the medication with the esophageal mucosa. Patients will often present with sudden onset of odynophagia, which may be severe enough to make even the swallowing of saliva difficult and painful. Endoscopy is helpful in making a diagnosis; but more importantly, it serves to rule out other diagnoses such as infectious esophagitis and malignancy. On endoscopy, there is usually a discrete, single ulcer located in the proximal esophagus. On occasion, the injury appears as a nodular, polypoid lesion, suggestive of a neoplasm, or as a stricture ([Figure 2](#)). Esophageal biopsies are nonspecific and may show acute inflammatory changes only. There is no specific therapy for this disorder, as pill-induced ulcerations can heal spontaneously within a few days without any intervention. Strictures will require endoscopic dilation

Figure 2 Pill-induced esophageal damage. A pill is seen at endoscopy lodged above an esophageal stricture.

Malignant dysphagia

Patients with esophageal cancer often present at an advanced, incurable stage. For those who are not candidates for chemoradiation or surgery and for those who develop recurrent dysphagia after treatment, a variety of endoscopic techniques have been developed to improve esophageal luminal patency.

Esophageal dilation can be performed with through-the-scope balloons, mercury-filled rubber bougies, or wire-guided polyvinyl bougies (Savary-Gilliard dilators), but dilation, to be successful, must be repeated every few weeks and the procedure carries a risk of perforation. Self-expanding metal stents (SEMS) are used increasingly as an effective nonsurgical option for the palliation of obstructive, advanced esophageal tumors.^{23–27} SEMS are made of a variety of metal alloys in different shapes and sizes to adjust to the length and position of the malignant stricture. Furthermore, approved devices are available in the uncovered, partially covered, and fully covered design. Additionally, they vary as to construction (nitinol vs surgical steel vs plastic) and function (fully patent vs “antireflux”). SEMS are placed under endoscopic guidance with or without fluoroscopy ([Figure 3](#)). Newly designed double-layered nitinol

(Niti-S) stents are associated with longer survival time and fewer complications than previous designs. Once a metal stent is deployed, it cannot be removed. There have been several randomized trials comparing different stents in patients with malignant esophageal strictures.²⁴ Advantages of SEMS include relative ease of insertion, larger stent diameters, and low risk of perforation with elimination of the need for excessive dilation. Disadvantages include high cost, tumor ingrowth and overgrowth, stent migration, maldeployment, inadequate expansion, airway obstruction, and hemorrhage. The rate of tumor ingrowth has now been reduced with the introduction of stents covered by a polyurethane coating. Covered stents are the device of choice in the management of patients with tracheo-esophageal fistulas.⁶ A recent additional option for palliation of esophageal cancer has resulted from the development of self-expanding plastic stents (SEPS). SEPS have been reported in some cases to have a higher failure rate of stent placement and higher migration rate, and to conform less easily to strictures. Stents are also effective at providing symptom relief in patients with esophageal malignancies after chemoradiation. The risk of complications, such as esophagorespiratory fistula, increases with radiation dose. Biodegradable stents, which gradually dissolve over time, are being developed. Stents have also been proposed as a bridge to surgery in those receiving neoadjuvant therapy.

Figure 3 Self-expanding esophageal stent. (a) Endoscopic view of a self-expanding stent deployed in the esophagus for treatment of an esophageal stricture. (b) Chest radiograph showing stent deployed in the esophagus.

Ablative techniques such as lasers, photodynamic therapy (PDT), and high-dose brachytherapy have been successfully applied for palliation of malignant esophageal obstruction, but for the most part have been supplanted by SEMS. Laser energy produced by the neodymium:yttrium-aluminum garnet crystal, or Nd:YAG, delivered endoscopically through a quartz fiber has been extensively used for the palliation of esophageal cancer in the past. This approach may require prior esophageal dilation to allow passage of the endoscope. Major complications include esophageal perforation, development of tracheo-esophageal fistula, hemorrhage, and bacteremia. Disadvantages of Nd:YAG laser therapy include difficulties in treating long, tortuous lesions or lesions located in the proximal esophagus, number of treatment sessions required, and high cost. PDT uses a photosensitizing agent and low-power laser to achieve tumor necrosis and luminal patency. Porfimer sodium (Photofrin®) is the only photosensitizer approved by the Food and Drug Administration for the treatment of esophageal cancer. Photofrin® is administered as an intravenous bolus and is selectively retained at a high concentration by neoplastic tissue. Approximately 48 h after

injection, patients are exposed to monochrome laser light at 630 nm via cylindrical diffuser attached to the tip of a quartz optical fiber placed through the accessory channel of an endoscope, initiating a photochemical reaction in the tissue leading to the formation of oxygen radicals, ischemia, and tumor necrosis.

A recent Cochrane Collaboration analysis extensively reviewed 53 studies on interventions for dysphagia in esophageal cancer.²⁸ This analysis concluded that SEMS are safe, effective, and quicker in palliating dysphagia compared to other modalities, but that high-dose intraluminal brachytherapy is a suitable alternative and may provide additional survival benefit with a better quality of life. Combinations of brachytherapy and SEMS may reduce the need for reinterventions. Rigid plastic stent insertion, dilation alone or in combination with other modalities, and chemotherapy alone were not recommended for palliation of dysphagia owing to a high incidence of complications and recurrent dysphagia.

Diarrhea

Chemotherapy and radiation

Diarrhea is a common complication of cytotoxic therapy, and has been described with fluoropyrimidines (5-fluorouracil and capecitabine), irinotecan, methotrexate (MTX), and cisplatin ([Table 2](#)).^{29–31} Diarrhea also commonly occurs in patients receiving small-molecule epidermal growth factor receptor-tyrosine kinase inhibitors (erlotinib and sorafenib). Diarrhea can be very debilitating and in severe cases it can lead to treatment delays, reduced quality of life, and diminished compliance. It is the dose-limiting factor and the major toxicity of regimens containing a fluoropyrimidine and/or irinotecan. The severity of chemotherapy-induced diarrhea is often described, particularly for study purposes, using the National Cancer Institute Common Toxicity Criteria (NCI CTC). Grading is based on number of stools per day, presence of nocturnal stools, and the need for parenteral support or intensive care.

Table 2 Differential diagnosis of diarrhea in the cancer and hematopoietic cell transplant patient

Chemotherapy-related (fluoropyrimidines, irinotecan, methotrexate, cisplatin, small-molecule epidermal growth factor receptor-tyrosine kinase inhibitors: erlotinib and sorafenib), and others

Radiation therapy
Conditioning regimen
Graft-versus-host disease
Infection
Bacterial (including <i>C. difficile</i>)
Viral (including CMV)

The severity of diarrhea with 5-FU is increased by the addition of leucovorin. Moreover, diarrhea can be worse when 5-FU is administered by bolus injection as opposed to intravenous infusion. Irinotecan can cause an early-onset diarrhea accompanied by abdominal cramping, lacrimation, salivation, and other symptoms that appear cholinergic-mediated. The late diarrhea associated with irinotecan is unpredictable and can occur at all dose levels. It is seen less often when given in the every 3-week schedule compared to every week. Significant diarrhea has been reported with a combination of irinotecan, 5-FU, and leucovorin compared to 5-FU and leucovorin alone. Grade 1 to 2 diarrhea has been reported in up to 56%

of patients receiving erlotinib, and 34% of patients taking sorafenib.^{32, 33}

Radiation therapy can produce injury to the GI mucosa. Symptoms typically occur during the third week of fractionated radiotherapy. Pelvic or abdominal radiation can lead to acute enteritis, characterized by abdominal cramping and diarrhea in approximately 50% of patients. These symptoms are made worse by concomitant chemotherapy.¹

Opioid agonists are the cornerstone of therapy for chemotherapy-induced diarrhea.³⁴ Loperamide and diphenoxylate are both widely used and are approved by the US Food and Drug Administration (FDA) for this indication. Loperamide is more effective. For mild-to-moderate diarrhea, an initial dose of 4 mg loperamide hydrochloride may be given, followed by a further 2 mg every 4 h or after every stool. Severe diarrhea often requires a more aggressive regimen, with an initial dose of 4 mg loperamide hydrochloride followed by a further 2 mg every 2 h or 4 mg every 4 h until the patient is diarrhea-free for 12 h. This high-dose loperamide has been used effectively for the control of irinotecan-induced diarrhea. Octreotide, a synthetic long-acting somatostatin analog, has been used as second-line therapy in opioid-resistant patients.¹ It decreases the secretion of vasoactive intestinal peptide, prolongs intestinal transit time, and reduces secretion of intestinal fluid and electrolytes. The recommended initial dose of octreotide is 100–150 g given subcutaneously three times per day, or 25–50 g every hour if given as an intravenous infusion. Octreotide can be titrated to higher doses (500–2500 g three times daily) for the treatment of those individuals who do not respond to lower doses.

Other drugs used as adjunctive therapy in chemotherapy or radiation-induced diarrhea include absorbents such as kaolin and charcoal, deodorized tincture of opium, paregoric, and codeine phosphate.

Because of the well-recognized risk of diarrhea associated with irinotecan, several recent studies have investigated prophylactic regimens to prevent chemotherapy-induced diarrhea. Long-acting, slow-release formulation of octreotide (octreotide LAR) can be administered by intramuscular injection once a month. Once steady-state levels have been achieved, a 20-mg intramuscular dose of octreotide LAR every 4 weeks produces the same pharmacologic effects as 150 µg octreotide tid by SC injection and dramatically reduces fluctuations in peak and trough octreotide concentrations. Additionally, octreotide LAR (at a starting dose of 20 mg) effectively controls diarrhea associated with carcinoid syndrome,³¹ and monthly doses of 20–30 mg are currently being investigated for the treatment and prevention of chemotherapy-induced diarrhea.

For patients undergoing hematopoietic stem-cell transplantation (HCT), diarrhea may be due to the conditioning regimen (total body irradiation and/or high-dose chemotherapy). Pretransplant conditioning regimens can injure the GI mucosa, causing secretory diarrhea that resolves after mucosal restitution. After day 20, acute GVHD is the most common cause of diarrhea in these patients. GVHD will be discussed separately.

***Clostridium difficile*-associated diarrhea**

If diarrhea is not directly the result of chemotherapy or radiation and particularly if it occurs in a hospital setting, *Clostridium difficile* infection should be considered as this is the most common cause of infectious diarrhea in hospitalized patients. Although commonly associated with use of antibiotic therapy, risk factors for *C. difficile* diarrhea or colitis also include bowel surgery, immunocompromised state, and any process that suppresses the normal flora including antifungal and chemotherapeutic agents. Cancer patients receiving chemotherapy appear predisposed to *C. difficile*-induced diarrhea even in the absence of antibiotics. In a study of such patients, MTX, doxorubicin, and cyclophosphamide were the drugs most frequently associated with *C. difficile* infection. Clinical presentation may vary from mild diarrhea

without colitis, colitis with systemic manifestations, pseudomembranous colitis with or without protein-losing enteropathy, and fulminant colitis with development of toxic megacolon. Diagnostic testing for *C. difficile* has rapidly evolved.³⁵ Previously rapid EIA tests for toxin A or B were the most widely used diagnostic tests. These tests have a sensitivity of 75–95% and specificity of 83–98%. Two major advances in the laboratory diagnosis of *C. difficile* are the use of glutamate dehydrogenase (GDH; an enzyme produced by *C. difficile*), detection in stool (75% to >90% sensitivity with a negative predictive value of close to 100%), and nucleic acid amplification tests (PCR) for toxin genes. Endoscopically, pseudomembranes can be seen as adherent yellow plaques that vary in diameter from 2 to 10 mm ([Figure 4](#)). The rectum and sigmoid colon are typically involved, but in approximately 10% of cases, colitis is only present in the more proximal colon and can be missed during sigmoidoscopy.

Figure 4 Pseudomembranous colitis. (a) Pseudomembranes adherent to the colonic mucosa seen at colonoscopy. (b) Low-power view of colonic mucosa shows a typical volcano (mushroom)-like appearance with luminal inflammatory exudates.

Therapy for *C. difficile* diarrhea depends on disease severity.³⁵ Standard therapy for *C. difficile*-associated diarrhea is oral metronidazole or oral vancomycin. Metronidazole at a dose of 500 mg three times daily either orally or intravenously for 10–14 days is as effective as oral vancomycin given at a dose of 125 mg four times daily. The lower dose of vancomycin 125 mg four times a day is as effective as the higher dose of 250 mg four times a day in mild-to-moderate case and is much less expensive. Metronidazole has some advantages over vancomycin including its lower cost and the observation that it can reduce selection of vancomycin-resistant enterococci (VRE). Metronidazole is therefore the initial therapy of choice in nonsevere cases of *C. difficile*-induced diarrhea. If there is no improvement in 3 days, treatment with vancomycin should be initiated. In patients with severe *C. difficile* infection and signs of systemic toxicity, the recommended treatment regimen is initial therapy with vancomycin 125 mg orally four times daily, with dose escalation at 48 h intervals up to 500 mg four times daily if patients fail to improve. If patients do not respond to oral vancomycin, the addition of intravenous metronidazole 500 mg every 8 h, or vancomycin retention enemas (0.5–1 g of vancomycin dissolved in 1–2 L of normal saline every 4–12 h), should be considered. The use of antiperistaltic agents is not recommended as they may obscure symptoms and there is evidence that decreased transit time can lead to complications and lengthen the duration of illness. Relapse of CDI is common, occurring in up to 10–25% of all patients

with CDI. Relapses usually occur within 1–3 weeks after termination of initial therapy, and are probably caused by failure to eradicate the organism rather than development of antibiotic resistance. These patients are likely to relapse repeatedly. First relapses should be treated with a second 10–14-day course of oral metronidazole or vancomycin. If a patient relapses after taking a second course of antibiotics, different approaches have been suggested, including tapered or pulsed antibiotic therapy, longer duration of treatment (several weeks), and the use of toxin-binding resins such as colestyramine or colestipol hydrochloride alone or in combination with vancomycin. Fidaxomicin is an alternative agent for treatment of an initial recurrence of CDI. For treatment of initial recurrence of CDI, the initial response to therapy with fidaxomicin and vancomycin is comparable, but the likelihood of subsequent recurrence is lower with fidaxomicin than vancomycin (20% vs 36%). If there is a third recurrence, fecal microbiota transplant should be considered. In small series, 2 weeks of vancomycin followed by 2 weeks of rifaximin has proven successful in controlling recurrent disease. A recent study used two neutralizing, human monoclonal antibodies against *C. difficile* toxins A (CDA1) and B (CDB1) in 101 symptomatic patients who were receiving either metronidazole or vancomycin, and the rate of recurrence of *C. difficile* infection was significantly lower among patients treated with the monoclonal antibodies.³⁶

Other infectious diarrhea

In the posthematopoietic cell transplant patient, infectious diarrhea is relatively uncommon. Viruses are the most common organisms found (astrovirus, adenovirus, CMV, and rotavirus), followed by nosocomially acquired bacteria (*C. difficile* and *Aeromonas*). CMV deserves a special mention as it can cause diarrhea and bleeding because of mucosal ulceration. The diagnosis of CMV is made by endoscopic biopsy ([Figure 5](#)); specimens should be sent for immunohistochemistry and viral culture. Infectious diarrhea related to *Salmonella*, *Shigella*, and *Campylobacter* species are very rare in hospitalized transplant patients. Diarrhea related to parasites (*Cryptosporidium*, *Giardia lamblia*, and *Entamoeba histolytica*) is also a rare cause of diarrhea; most of these patients are infected pretransplantation.

Figure 5 Cytomegalovirus (CMV) colitis. (a) CMV colitis as seen at endoscopy. (b) High-power view of inflamed colonic mucosa demonstrates multiple viral inclusions in stroma cells.

Colitis

Neutropenic enterocolitis

Neutropenic enterocolitis is characterized by fever and right lower quadrant pain in neutropenic patients. It is seen in children and adults with hematologic malignancies, aplastic anemia, and after myelosuppressive therapy for solid malignancies.^{37–42} Histologic examination of biopsy samples from patients with neutropenic enterocolitis is characterized by a thickened bowel wall, edema, mucosal ulcerations, focal hemorrhage, and mucosal or transmural necrosis. Numerous bacterial and/or fungal organisms have been identified in surgical specimens and peritoneal fluid from patients with neutropenic enterocolitis. A diagnosis of neutropenic enterocolitis is usually established by computerized tomography (CT). Abnormal findings on CT and ultrasound include a fluid-filled, dilated cecum, a right lower quadrant inflammatory mass and pericecal fluid, or inflammatory changes in the pericecal soft tissues. Treatment consists of bowel rest, intravenous fluids, and broad-spectrum antibiotics. Cytopenias and coagulopathy associated with oncologic treatment should be corrected as neutropenia contributes to the pathogenesis of the disease, and coagulopathy can be associated with blood loss from mucosal hemorrhage. Recombinant granulocyte colony-stimulating factor (G-CSF) may be used to hasten leukocyte recovery, which contributes to the resolution of neutropenic enterocolitis. Surgery has been recommended for patients with persistent GI bleeding despite correction of cytopenias and coagulopathy, and for patients with perforation or clinical deterioration despite pharmacologic therapy.

Colitis secondary to immune-modulatory, antineoplastic agents

Immune-modulatory agents enhance tumor-directed immune responses through modification of immune checkpoint pathways, T-cell stimulatory pathways, or with adoptive cell therapy.⁴³ However, this approach has also been associated with intestinal adverse effects, in particular with therapeutic agents targeting immune checkpoint pathways (i.e., cytotoxic T-lymphocyte antigen-4 (CTLA-4) and PD-1). CTLA-4 is a key negative regulator of T-cell activation in the adaptive immune response. Transient, antibody-mediated CTLA-4 inhibition has been shown to enhance T-cell response. Ipilimumab and tremelimumab are fully humanized, monoclonal IgG1 antibodies targeted against CTLA-4. While the GI adverse effect profile of tremelimumab was similar to ipilimumab, tremelimumab had no survival benefit over chemotherapy for melanoma in a recent randomized controlled phase III trial.⁴⁴ CTLA-4 inhibitors have predominantly been used for melanoma although they have also been evaluated in other solid malignancies such as pancreatic carcinoma, prostate carcinoma, renal cell, ovarian, and small-cell lung cancer.^{45, 46} Given the regulatory role of inhibitors such as CTLA-4 and PD-1 in adaptive immune response, they have a broad spectrum of immune-mediated Adverse Events (imAE) including enterocolitis, hepatitis, dermatitis, hypophysitis, uveitis, and nephritis; enterocolitis is the most common adverse event.⁴⁷ The majority of immune-related adverse events have been observed during the induction and reinduction periods.⁴⁶ The development of ipilimumab-associated enterocolitis is independent of the number of cycles, but appears to be dose dependent.^{47, 48} There is some evidence that the development of enterocolitis might be a positive predictor for tumor response in patients with melanoma and renal cell cancer treated with ipilimumab.⁴⁷ Enterocolitis most commonly presents with diarrhea but abdominal pain, nausea/vomiting, fever, anal pain, and constipation have been reported as well.⁵ The majority of patients who develop enterocolitis do so within 21 days following their last dose.⁴⁷ Overall, up to 33–51% of ipilimumab-treated patients experience diarrhea, including 16% with grade 3 and <1% with grade 4.^{44–46, 48} Intraluminally, the colon is particularly involved with up to 8% of patients developing colitis, including 4–5% and 0–1% with grade 3 and 4 colitis.^{45, 46} Diarrhea is usually watery with few leukocytes and only rarely positive for blood.⁴⁹ Radiologically, ipilimumab-associated colitis is characterized by mesenteric vessel engorgement, colonic wall thickening, mucosal enhancement, and fluid-filled colonic

distension. Colitis can either develop diffusely or as segmental colitis associated with diverticulosis (SCAD). While panenteritis has been described, the colon is the most commonly involved area.^{49, 50} Endoscopic presentation of ipilimumab-associated colitis is unspecific and severity dependent showing macroscopic findings such as mucosal erythema, friability, edema, and ulcerations.⁴⁷ In the majority of patients, histologic findings include neutrophilic inflammation with cryptitis and occasional crypt abscesses, or a mixed neutrophilic–lymphocytic inflammatory picture. In few patients, lymphocytic predominant inflammation is seen with increased numbers of CD8+ T-cells in crypts and CD4+ cells in the lamina propria.^{47, 49} 0.7–6.6% of ipilimumab-treated patients develop colonic perforation or require colectomy.⁵ Mortality of patients developing enterocolitis secondary to ipilimumab treatment has been reported as high as 5%.⁴⁷ Treatment of ipilimumab-associated adverse events is guided by severity ([Table 3](#)), but other etiologies need to be ruled out.⁵¹ Mild GI symptoms can be treated symptomatically without discontinuation of ipilimumab; however, frequent reassessment is imperative to identify the development of more severe symptoms or life-threatening complications. In cases of moderate enterocolitis, ipilimumab should be withheld and can be restarted 7 days after significant symptom-improvement or -resolution. If moderate symptoms persist after 7 days, initiation of treatment with systemic corticosteroids is recommended (e.g., 0.5 mg/kg/d prednisone or equivalent) until improvement to mild symptoms or symptom-resolution is observed. Once symptoms are mild and corticosteroid dose has been tapered to ≤ 7.5 mg daily, ipilimumab can be resumed. Severe enterocolitis and life-threatening complications require permanent discontinuation of ipilimumab. In these cases, systemic corticosteroids should be administered (e.g., 1–2 mg/kg/d prednisone or equivalent) once intestinal perforation is ruled out.⁵¹ In corticosteroid-refractory cases, the successful use of infliximab has been reported in a limited number of patients.^{47, 52, 53} Prophylactic initiation of budesonide concurrent with ipilimumab did not significantly decrease rates of diarrhea or colitis.^{54, 55} Programmed cell death protein-1 (PD-1) is a receptor expressed on T-cells, which attenuates T-cell activation upon binding of its ligands PD-L1 (B7-H1) and PD-L2 (B7-DC). While PD-L2 is frequently expressed by APC, PD-L1 overexpression has been observed in tumors.^{43, 56} Nivolumab and lambritzumab are PD-1-targeted, humanized monoclonal IgG4 antibodies currently evaluated in ongoing or planned randomized controlled phase II and III trials.⁴³ In a recent nonrandomized controlled trial, the most common GI adverse event in patients treated with Nivolumab was diarrhea with an incidence of 18%, with grade 3–4 diarrhea in 2%. Other GI adverse events included nausea, vomiting, abdominal pain, and dry mouth observed in 5–8% of patients.¹⁵ Rates of GI adverse events were not considerably higher with nivolumab/ipilimumab combination therapy compared to monotherapy.⁵⁷ In two clinical trials including 173 and 135 patients, lambritzumab-associated diarrhea was observed in only 1–20%.^{56, 58} Given the novelty of these agents, there is currently insufficient experience in regard to optimal management, but a severity-guided, conservative approach similar to ipilimumab-induced enterocolitis has been proposed.⁴³

Radiation-induced proctitis and colitis

Patients receiving radiation therapy to the abdomen and pelvis for the treatment of gynecologic, genitourinary, GI, and other malignancies are at risk of developing acute or chronic intestinal injury. Acute radiation injury in the rectum and distal colon usually occurs within 6 weeks of therapy and is characterized by diarrhea (see above), rectal urgency, tenesmus, and, occasionally, rectal bleeding. These symptoms usually resolve within 6 months without the need for therapy. Chronic radiation proctitis or coloproctitis has a delayed onset, occurring approximately 1 year or later after exposure to radiation. It is caused by obliterative endarteritis and chronic mucosal ischemia, resulting in epithelial atrophy and fibrosis. It may end in stricture formation and bleeding within the colon and rectum. Patients with radiation proctitis often present with diarrhea, bleeding, tenesmus, urgency, difficulties with defecation, and less commonly fecal incontinence.

The diagnosis of radiation proctitis is made by colonoscopy or sigmoidoscopy. Endoscopic findings include mucosal edema, erythema, friability, and the presence of telangiectasias. In severe cases, mucosal

ulcerations and strictures can be observed.

Treatment for radiation proctitis depends on symptoms.¹ In some studies sucralfate enemas have been used to treat chronic radiation-induced proctitis but may increase the risk of rectal bleeding, other treatments that have shown some benefit in small clinical trials include hyperbaric oxygen and short-chain fatty acid enemas. Various thermal endoscopic therapies have also been used successfully to treat bleeding associated with radiation proctitis and include argon plasma coagulation (APC). Surgery should be considered for patients with intractable symptoms such as strictures, pain, or bleeding. A detailed discussion of the endoscopic and surgical treatment of radiation proctitis is beyond the scope of this review. The selection of treatment for radiation proctitis should be based on the type and severity of symptoms as well as local expertise. Intravenous amifostine has been recommended at a dose of $>340 \text{ mg/m}^2$ to prevent radiation proctitis in patients receiving radiation therapy.¹

Intestinal manifestations of graft-versus-host disease

The use and indications of allogeneic hematopoietic cell transplantation (HCT) have significantly increased throughout the past decades with approximately 25,000 procedures per year.⁵⁹ The main complication of HCT is GVHD with GI involvement in 54% of those undergoing transplantation.^{60, 61} GVHD occurs as a response of donor T cells to genetically defined recipient cell surface proteins. Human leukocyte antigens (HLAs) are class I HLA (A, B, and C) and class II (DR, DQ, and DP) proteins. The former are expressed by all nucleated cells, while the latter are predominantly expressed by hematopoietic cells; however, HLA class II protein can also be expressed by other cell types in the setting of inflammation and injury. HLA class I and II mismatch is positively correlated with the frequency of acute GVHD.^{62, 63} However, HLA-matched patients can still develop GVHD owing to individual differences in ubiquitously expressed minor histocompatibility antigens (i.e., HY and HA-1).^{64–66} Interestingly, incidence rates of acute GVHD following mismatched umbilical cord-derived HCT are similar to rates of matched bone marrow-derived HCT, but incidence rates of chronic GVHD are higher after peripheral stem cell versus bone marrow stem-cell transplant with 53% versus 41% incident reported.^{67, 68} Autologous GVHD is a distinct entity describing an autoimmune GVHD-like syndrome that develops after autologous stem-cell transplant, and has been associated with drugs such as cyclosporine and alemtuzumab.^{69, 70}

On the basis of its chronologic correlation to the time of cell transplantation, GVHD has been classified as acute (≤ 100 days post-transplant) or chronic (>100 days post-transplant). The latter form can be an extension of acute GVHD, reoccurrence of a successfully treated acute form, or can occur *de novo*. However, this classification has been found inaccurate owing to changes in condition regimens, resulting in later onset of acute GVHD and overlap syndromes.^{59, 71} Therefore, an expert panel has suggested a new classification for GVHD ([Table 4](#)).⁷³

Table 4 Modified classification of acute and chronic graft-versus-host disease (GVHD)

Categories	Time of symptom onset post-HCT	Presence of acute GVHD features	Presence of chronic GVHD features
<i>Acute GVHD:</i>			
Classic acute GVHD	≤100 days	Yes	No
Persistent, recurrent, or late-onset acute GVHD	>100 days	Yes	No
<i>Chronic GVHD:</i>			
Classic chronic GVHD	No time limit	No	Yes
Overlap syndrome	No time limit	Yes	Yes

Acute GVHD

The most common presentation of acute GVHD is high-volume, secretory diarrhea. GI hemorrhage has been associated with a poor prognosis; it can be indicative of mucosal ulceration in the setting of GVHD but other causes have to be considered.^{74, 75} GVHD-associated diarrhea has been described as an exudative, protein-losing enteropathy; however, sensitivity and specificity of fecal α1-antitrypsin in the diagnosis of stage 2–3 GI-GVHD are only 79% and 62%, respectively.⁷⁶ Occasionally GI-GVHD can also result in pancreatic insufficiency, thereby potentially contributing to diarrhea. Other common GVHD-associated symptoms include anorexia, nausea, vomiting, abdominal pain, and ileus. The absence of such symptoms does not exclude the presence of GVHD, and the differential diagnoses for these symptoms are broad in HCT patients, given the aggressive conditioning regimens, their multidrug use, and their susceptibility to infections owing to severe neutropenia following HCT. Hence, a high level of suspicion is required. On physical examination, sequelae of GVHD manifestations and complications should be assessed such as cutaneous GVHD, dehydration and weight loss, and failure to thrive. Occasionally, patients can develop ascites. Oropharyngeal manifestations of GVHD can include gingivitis, mucositis, and erythema.⁷² Radiologic features of intestinal GVHD include bowel wall thickening, intestinal dilatation, mucosal enhancement, and gastric wall thickening. Diffuse small bowel wall thickening has been associated with worse prognosis, and any colon involvement on CT correlates with GVHD severity.^{77, 78} Radiologic findings do not significantly differ between acute and late-onset GVHD.⁷⁹ Endoscopic findings in GVHD include a spectrum from mild erythema to mucosal edema and diffuse mucosal loss. In particular, mucosal sloughing has been reported to be highly specific.⁸⁰ While endoscopy has been shown to be highly predictive for the diagnosis of GVHD, approximately one-fifth of patients with histologically confirmed GVHD have no significant macroscopic findings on endoscopic evaluation.⁸¹ Therefore, a tissue diagnosis is usually required in the diagnosis of acute GVHD. Typical histologic findings include crypt epithelial cell apoptosis, crypt destruction (“exploding crypt cells”), and variable lymphocytic infiltration of the epithelium and lamina propria ([Figure 6](#)). Importantly, similar findings can also be observed in the absence of GVHD within the immediate post-transplant period secondary to pretransplant regimens. However, non-GVHD-related histologic changes have usually resolved 20 days after transplant.²⁴ Other differential diagnoses that need to be excluded in the evaluation of GVHD-like symptoms and histologic findings include infectious etiologies (i.e., CMV and cryptosporidium) and iatrogenic adverse effects (i.e., mycophenolate mofetil and proton pump inhibitors). Histologically, GI-GVHD has historically been classified as grades 1–4 based on severity.⁷¹

Controversies around endoscopic evaluation include the extent of endoscopic evaluation. Discordance between upper intestinal biopsies and rectal biopsies has been reported in up to 45% of patients with GI-GVHD. Symptoms are not predictive of site of involvement. While some studies suggested that rectal biopsies are sufficient, other studies reported gastric biopsies as providing higher yields in diagnosing GI-GVHD. Distal colonic evaluation is frequently sufficient and associated with lower complication rates than colonoscopy.⁸² Reduced-intensity conditioning regimens were effective in reducing tissue injury and were shown to delay onset of acute GVHD to >100 days but have been associated with higher rates of relapse in some patients.^{83, 84} The mainstay of GVHD prevention is pharmacologic calcineurin inhibition (i.e., cyclosporine, tacrolimus, or sirolimus) in combination with other immunosuppressants (i.e., MTX or mycophenolate mofetil) in the early post-transplant phase^{85, 86}; however, a recent Cochrane database analysis concluded that high-quality RCTs are needed to define the optimal GVHD prevention strategy.⁸⁷ Frequently, patients who develop acute GVHD on calcineurin-inhibitor prophylaxis do so in the second month after transplant. Any form of visceral GVHD requires high-dose corticosteroid treatment, which results in resolution of acute GVHD in up to 60%.^{1, 2, 31} For cases with corticosteroid-refractory cases of GVHD, therapeutic strategies such as extracorporeal photopheresis and anti-TNF α agents (e.g., etanercept) have been evaluated, but further studies are required.⁵⁹ In addition to immunosuppressive therapy, supportive management such as infection prophylaxis, rehydration, and nutritional supplementation is required.

Figure 6 Graft-versus-host disease involving the colon. The colonic mucosa shows prominent crypt apoptosis and focal crypt dropouts in a background of granulation tissue.

Chronic GVHD

The prevalence of chronic GVHD in long-term survivors of HCT is >50%.⁷³ It is the major cause of late nonrelapse mortality in HCT patients.⁵⁹ Risk factors associated with its development include age, prior acute GVHD, time from transplantation to chronic GVHD, donor type, disease status at transplantation, GVHD prophylaxis, and gender mismatch.⁸⁸ Unfortunately, the pathomechanisms, diagnostic criteria, and optimal management are poorly understood. Recently, the National Institute of Health (NIH) developed several consensus documents on criteria for clinical trials in chronic GVHD.⁷² In this chapter, the diagnosis is based on diagnostic signs of chronic GVHD, or distinctive signs (defined as manifestations not typical for acute GVHD but not sufficient to establish the diagnosis of chronic GVHD without further testing) with confirmation by biopsy, laboratory test, or radiology. Similar to acute GVHD, chronic

GVHD can manifest as anorexia, nausea, vomiting, diarrhea, weight loss, and failure to thrive.⁷² Oropharyngeal manifestations of chronic GVHD include lichen planus-like changes, hyperkeratotic plaques, xerostomia, mucosal atrophy, mucocoeles, pseudomembranes, and ulcers. Esophageal findings can include esophageal webs, strictures, and concentric rings. Other findings include mucosal erythema, edema, and erosions. Histologic evaluation can also show epithelial apoptosis and crypt cell loss, but these changes are not specific, and, therefore, not considered diagnostic for chronic GVHD. Supportive care is one of the key elements in the management of chronic GVHD. Patients need to be monitored for infectious complications. Oropharyngeal lesions in HCT patients developing 3 years after transplant should be evaluated for squamous cell carcinoma and other secondary malignancies. Similarly, patients with dysphagia and odynophagia need to be evaluated for other etiologies such as pill or radiation esophagitis and viral esophagitis. Dysphagia due to strictures can be managed by careful endoscopic dilatation; unfortunately, studies regarding perforation rates are lacking. Patients with diarrhea need to be evaluated for infectious etiologies, malabsorption, pancreatic insufficiency, and nutritional deficiencies. Forty-three percent of patients with chronic GVHD are malnourished and 14% severely malnourished; therefore, nutritional assessment and support should be provided.^{89, 90} A key element in the treatment of chronic GVHD is immunosuppression. Topical corticosteroids can be attempted (i.e., budesonide and beclomethasone) in mild cases of chronic GVHD.^{91, 92} However, moderate or severe chronic GVHD and GVHD of nonaccessible areas require systemic corticosteroids usually at a dose of 1 mg/kg/day for 2 weeks followed by a 6–8 weeks taper; patients should be thoroughly reassessed at 3 months to decide on further tapering versus maintenance or second-line therapy.⁹³

Hepatic complications of cancer treatment

Chemotherapy-associated liver injury is an unfortunate consequence of the treatment of many cancers. Consequently it is important to assess liver function carefully before and during therapy ([Tables 5 6](#)).

Table 5 Causes of hepatic abnormalities in cancer patients

Pre-existing liver disease
Viral hepatitis
Nonalcoholic fatty liver disease
Alcoholic liver disease
Hemochromatosis
Autoimmune hepatitis
Wilson disease
Celiac disease
Alpha-1-antitrypsin deficiency
Direct effects of the tumor
Hepatic metastases
Portal vein thrombosis
Biliary obstruction
Indirect effects of the tumor
Paraneoplastic syndromes
Causes of liver disease during cancer treatment
Drug-induced liver disease
Graft-versus-host disease (acute and chronic)
Sinusoidal obstruction syndrome
Viral hepatitis
Sepsis-induced cholestasis
Ischemic liver injury
TPN
Liver disease affected by cancer treatment
Hepatitis B
Nonalcoholic fatty liver disease
Autoimmune hepatitis

Table 6 Differential diagnosis of hepatic biochemical tests abnormalities associated with cancer therapy

	AST/ALT	Alkaline phosphatase	Bilirubin
Drug-induced liver disease	2–10× ULN	2–10× ULN	2–20× ULN
Viral hepatitis	2–10× ULN	2–3× ULN	2–10× ULN
Sinusoidal obstruction syndrome	2–5× ULN	2–3× ULN	2–10× ULN
Graft-versus-host disease	2–5× ULN	2–10× ULN	2–20× ULN

Abbreviations: AST, aspartate aminotransferase; ALT, alanine aminotransferase; and ULN, upper limit of normal.

Effect of pre-existing liver disease on cancer therapy

Pre-existing liver disease can not only affect the choice of therapeutic options, but for drugs that are metabolized by the liver, necessitate dosage modification. Measurement of hepatic enzymes, commonly referred to as “liver function tests,” does not assess functional capacity of the liver. They are sensitive indicators of acute liver injury but do not measure the liver's ability to metabolize drugs or synthesize important proteins. The albumin and bilirubin concentrations are surrogate markers of the liver's synthetic and biotransformation potential, but are influenced by external factors limiting their sensitivity and specificity. Consequently, a reliable assessment of liver function should not be based on a simple profile of a few laboratory tests, but a composite picture based on clinical, laboratory, and radiographic data. In addition, none of the frequently used hepatic laboratory tests can accurately assess hepatic fibrosis. Common hepatic disorders, such as nonalcoholic fatty liver disease, can progress silently to cirrhosis with normal or minimally elevated transaminases and bilirubin. The only evidence for chronic liver disease might be evidence of portal hypertension on the physical exam or nodularity of the liver on imaging studies.

For some drugs, published guidelines describe usage restrictions and dosing on the basis of readily available hepatic serologic tests. However, for many therapeutic agents, the clinician must use subjective data on which to design a treatment regimen. Many treatment protocols require dosage modification based on the bilirubin concentration, but relying on the bilirubin concentration alone can be misleading. Gilbert's syndrome, a benign disorder of bilirubin metabolism, can spuriously raise the total bilirubin concentration leading to an inappropriate modification of a treatment regimen.

Up to 30% of patients undergoing cancer therapy have evidence of pre-existing liver disease, with nonalcoholic fatty liver the most common. Many drugs can exacerbate fat deposition in the liver. The most common are hormonal therapies used to treat breast cancer and prostate cancer. Hepatic steatosis develops in up to one-third of women treated with tamoxifen but it is usually asymptomatic and not associated with progressive liver disease.⁹⁴ Antiantigen therapy for prostate cancer can exacerbate components of the metabolic syndrome, resulting in accelerated hepatic steatosis.⁹⁵

Chemotherapy or chemoradiation can lead to reactivation of underlying hepatitis B caused by intensification of the immune response to the hepatitis B virus (HBV) when immunosuppressive therapy is withdrawn. While HBV reactivation can occur with any chemotherapy regimen, the risk is highest with anti-CD20 monoclonal antibodies (rituximab and ofatumumab).⁹⁶ Reactivation can occur in patients with inapparent hepatitis B infection manifested only by a positive core antibody (anti-HBc) in the absence of detectable surface antigen (HBsAg). In one report, 5 of 21 HBsAg negative/anti-HBc positive patients receiving rituximab developed reactivation.⁹⁷ Several major societies have published guidelines for the evaluation and treatment of HBV infection in patients undergoing cancer treatment.^{98–100} Most recommend prophylactic antiviral therapy at the onset of cancer treatment and for at least 6 months after completion of therapy. Lamivudine can be used in patients with no detectable HBV DNA and with a short duration of immunosuppression (<12 months).¹⁰¹ Because of potential viral resistance, tenofovir or entecavir should be used when there is detectable HBV DNA or when anticipated therapy is greater than 1 year.¹⁰²

Patients with underlying hepatitis C appear to respond differently to chemotherapy compared to those with hepatitis B.¹⁰³ Modest increases in transaminase and HCV RNA levels develop in approximately half of HCV infected patients, but a severe hepatitis flare is rare. Consequently, dose modification is usually not indicated. Effective oral antiviral regimens for the treatment of HCV that do not require interferon suggest that many more patients with HCV infection who are undergoing cancer therapy will become candidates for antiviral treatment.

Hepatotoxicity caused by cancer therapy

Adverse drug reactions occur commonly in patients undergoing cancer treatment. Recognizing hepatotoxicity can be challenging as this population of patients is frequently on multiple medications and there can be many potential causes of abnormal liver including tumor progression, systemic infection, or parenteral nutrition.

Most hepatotoxic reactions are idiosyncratic and caused by either metabolic disruption or an immunologic reaction to the drug or one of its metabolites.¹⁰⁴ Typically these reactions occur in patients without underlying liver disease and resolve when the drug is discontinued without significant fibrosis or impaired synthetic function. With more severe drug toxicity, often manifested by elevations in the serum bilirubin, the offending agent has to be discontinued even when therapeutic alternatives may be limited.

The antimetabolites commonly used in cancer therapy include cytosine arabinoside (Ara-C), 5-FU, 6-mercaptopurine (6-MP), azathioprine, 6-thioguanine, and MTX. Hepatic metabolism plays an important role in the processing of these drugs, and dose reductions are usually necessary in patients with liver dysfunction. Ara-C, used in the treatment of acute myelogenous leukemia (AML), has on rare occasions been associated with cholestasis, which appears reversible.¹⁰⁵ Intra-arterial administration of the 5-FU metabolite floxuridine (fluorodeoxyuridine [FudR]) has been associated with two types of toxicity: one suggestive of hepatocellular injury and the second one consistent with sclerosing cholangitis, with stricturing of the intra and extrahepatic bile ducts, and elevations of alkaline phosphatase and bilirubin.^{106–108}

Combinations of 5-FU and oxaliplatin or irinotecan are used for neoadjuvant therapy in patients with colorectal cancer before the resection of liver metastases. These neoadjuvant regimens, particularly those with oxaliplatin, have been associated with steatosis and injury to the hepatic vasculature causing a disorder with features of chronic sinusoidal obstruction syndrome (SOS).^{109–112}

6-MP is often used for maintenance therapy in acute lymphoblastic leukemia (ALL). Two patterns of toxicity have been reported: hepatocellular injury and cholestasis.¹¹³ Toxicity occurs more commonly when the daily dose of 2 mg/kg is exceeded. Azathioprine is a nitroimidazole derivative of 6-MP. Its toxicity is less frequent and less dose dependent compared with 6-MP. Three different patterns of toxicity are described: a hypersensitivity reaction, a cholestatic reaction, and endothelial cell injury with development of elevated portal pressures, SOS, and peliosis hepatis.¹¹⁴

High-dose MTX therapy has been associated with reversible elevations in aminotransferases.¹¹⁵ Patients taking chronic low-dose MTX therapy for psoriasis or rheumatoid arthritis are at risk for developing hepatic fibrosis and cirrhosis. The risk is low in patients who receive less than 1.5 g of MTX as cumulative dose.¹¹⁶

Alkylating agents uncommonly cause hepatotoxicity. With the exception of cyclophosphamide and ifosfamide, patients receiving alkylating agents do not require dose reduction. Temozolomide, an alkylating agent used to treat brain tumors, has caused severe hepatotoxicity, prompting an FDA recommendation for monitoring hepatic enzymes throughout the course of therapy.¹¹⁷

Other alkylating agents (including melphalan, chlorambucil, nitrogen mustard, and busulfan) are not dependent on the liver for their metabolism and are not frequently associated with hepatotoxicity.

The antitumor antibiotics include doxorubicin and daunorubicin. Doxorubicin can cause hepatocellular injury and steatosis. Dose reduction has been recommended in patients with cholestasis to avoid greater toxicity.¹¹⁸ Similar guidelines are followed for daunorubicin.

Asparaginase, used to treat acute lymphocytic leukemia, causes a form of mitochondrial injury in the liver, particularly in those with underlying fatty liver disease. Some patients with asparaginase liver injury respond to carnitine.¹¹⁹ The breakdown of asparagine can also cause hyperammonemia.¹²⁰

Many of the molecularly targeted kinase inhibitors are metabolized in the liver and require dose adjustment in patients with underlying liver disease. Lapatinib, a dual inhibitor of both human epidermal growth factor receptor 2 and EGFR, causes hepatotoxicity in approximately half of the patients receiving the drug with several reports of potentially fatal reactions.¹²¹ The presence of certain HLA alleles is associated with an increased risk for hepatotoxicity.¹²² Pazopanib targets multiple tyrosine kinases and causes a severe hepatitis in approximately 20% of patients.¹²³ It is also associated with a more benign form of hyperbilirubinemia in individuals with underlying Gilbert's syndrome.¹²⁴

Checkpoint inhibitors are immunomodulatory antibodies that target cytotoxic T-lymphocyte-associated antigen 4 (ipilimumab and tremelimumab) and the programmed cell death-1 receptor (nivolumab and pembrolizumab). By enhancing the immune response to tumor antigens, these agents have improved survival in patients with advanced melanoma. Elevations in the transaminases, developing around 8 weeks after initiation of therapy, are seen in less than 10% of patients receiving either class of checkpoint inhibitors.^{56, 125, 126} Because the hepatotoxic reaction shares clinical and histologic features of autoimmune liver disease, immunosuppression with corticosteroids is started promptly once other potential sources of liver injury have been excluded.¹²⁶

Sinusoidal obstruction syndrome

SOS, formerly called veno-occlusive disease (VOD), occurs most commonly after HCT, but can also result from exposure to toxins (Senecio alkaloids), nontransplant chemotherapeutic agents, high-dose radiation therapy to the liver, or after liver transplantation.^{127, 128} It is characterized clinically by tender hepatomegaly, jaundice, and weight gain with ascites. The prevalence of SOS varies widely in published studies, but has been estimated at around 20%. The clinical presentation of SOS mimics the Budd Chiari syndrome where occlusion of the hepatic veins results in postsinusoidal portal hypertension. However, in SOS it is the sinusoidal and terminal hepatic venule endothelial cells, not the hepatic veins, that are targeted.^{129, 130} Following injury to the endothelial cells, there is activation of the coagulation cascade with clot formation. Fibrin plugs, intracellular fluid entrapment, and cellular debris progressively occlude the sinusoids, causing intrahepatic sinusoidal hypertension ([Figure 7](#)).

Figure 7 Sinusoidal obstruction syndrome (veno-occlusive disease) of the liver. The small hepatic vein demonstrates fibrous obliteration with fibrin deposits. The perivenular hepatocytes show prominent sinusoidal congestion.

Pretransplant risks factors for the development of SOS include older transplant recipient age, female gender, poor performance status, donor-recipient HLA disparity, advanced malignancy, prior abdominal radiation, second myeloablative transplant, reduced pulmonary diffusion capacity (DLCO), and prior liver disease.^{131–134}

The type and intensity of the transplant conditioning regimen are the greatest risk factors for developing severe SOS. Risk increases with total body irradiation dose and the use of certain drugs such as 6-mercaptopurine (6-MP), 6-thioguanine, actinomycin D, azathioprine, busulfan, cytosine arabinoside, cyclophosphamide, dacarbazine, gemtuzumab-ozogamicin, melphalan, oxaliplatin, and urethane.^{130, 131}

SOS typically presents initially with unexplained weight gain and tender hepatomegaly within the first week post-transplant. Ascites develops in about 25% of patients. Moderate elevations in the transaminases, with direct hyperbilirubinemia, follow with peak bilirubin levels less than 20 mg/dL.¹³⁵

The diagnosis can be made frequently on the basis of typical signs and symptoms after ruling out other conditions such as viral infection, GVHD, systemic infection, and tumor infiltration. Two systems for the diagnosis of SOS, the Baltimore and Seattle criteria, have been published but the accuracy of these criteria has not been established.^{135, 136} Liver biopsy, rarely required for the diagnosis of SOS, typically shows sinusoidal dilatation with zone 3 hemorrhagic necrosis. Fibrin deposition with congestion is seen in the sinusoids and centrilobular venules. With time, collagen is deposited in the sinusoidal and venular lumens with occlusion of the terminal hepatic veins. If a biopsy is necessary for diagnosis, transjugular access is the safest route and can be accompanied by measurement of the hepatic venous gradient (HVPG).¹³⁷ Assessing the HVPG can discriminate between GVHD and SOS as the HPVG is greater in the latter.

Prevention of SOS should be a goal in all HCTs. Minimizing the use of potentially hepatotoxic agents and reduced-intensity conditioning regimens can potentially limit the severity of SOS. Pharmacologic prophylaxis is used routinely in many transplant centers. With allogeneic HCT, ursodeoxycholic acid, started before the preparative regimen and continued for 3 months, resulted in a reduced incidence of SOS when compared with placebo. Some centers use continuous infusion of low-dose heparin in autologous HCT. Mild-to-moderate SOS can be treated with supportive therapy including analgesics for right upper

quadrant pain relief and diuretics to control extravascular fluid accumulation. Patients with severe SOS rarely respond to supportive therapy alone. On the basis of the histological presence of microthrombosis and fibrin deposition in the hepatic venules of patients with severe SOS, therapies that promote fibrinolysis with or without anticoagulation have been used. These treatment strategies include the use of alteplase (recombinant tissue-type plasminogen activator or tPA) alone or in combination with heparin and defibrotide. Treatment with alteplase and heparin resulted in a response rate of about 30%, but was associated with a significant risk of life-threatening hemorrhage, particularly in patients with multiorgan failure.^{138–140} Defibrotide is a polydeoxyribonucleotide with antithrombotic, anti-ischemic, and thrombolytic properties without causing significant anticoagulation. Defibrotide given intravenously in doses ranging from 5 to 60 mg/kg per day for a minimum of 14 days results in a response in 42–55% of patients, without significant treatment-related toxicity.¹⁴¹ Predictors of survival with defibrotide therapy included younger age, autologous stem-cell transplantation, and abnormal portal vein flow, while regimens based on busulfan and the presence of encephalopathy predicted worse outcomes.¹⁴² Insertion of a transjugular intrahepatic portosystemic stent-shunt (TIPS) has been reported in small number of patients with severe SOS. TIPS was effective in improving portal pressure gradient; and in some patients, it was associated with clinical improvement of hepatic and renal symptoms. Nonetheless, these effects may be transient and may not improve overall survival.^{143–145} Orthotopic liver transplantation (OLT) has been reported anecdotally as a rescue therapy in patients with SOS after stem-cell transplant, when there has been no response to medical therapy. However, the majority of patients with severe SOS are not candidates for OLT, because of the presence of malignancies and/or multiorgan failure.^{146, 147}

Graft-versus-host disease of the liver

The liver is the second most commonly involved organ in acute GVHD affecting approximately 50% of patients. Severe hepatic GVHD without other organ involvement is rare. The earliest biochemical findings are elevations in the conjugated bilirubin and alkaline phosphatase concentrations, reflecting the underlying pathologic injury.⁷² Typically, there is extensive bile duct damage with degeneration and atypia of the bile duct epithelium, cell dropout, and a mixed cellular infiltration of small bile ducts leading to cholestasis.¹⁴⁸ While clinical and laboratory data can be highly suggestive of hepatic GVHD, a liver biopsy may be required for a definitive diagnosis and to rule out confounding diagnoses such as SOS, infection, or drug toxicity. In some cases a percutaneous liver biopsy may not be feasible because of the risk of bleeding owing to thrombocytopenia soon after hematopoietic cell transplant. In these instances, if a liver biopsy is deemed to be necessary for diagnosis, a transjugular approach may be the preferred option. For acute GVHD, the first and most effective treatment option is the use of corticosteroids alone or in combination with tacrolimus. If this combination is unsuccessful in controlling hepatic GVHD, second-line treatments include antithymocyte globulin and mycophenolate mofetil.^{149, 150} Chronic hepatic GVHD can develop after previous acute GVHD or de novo without a history of previous acute GVHD. Approximately 50% of patients with chronic GVHD have hepatic involvement most often with asymptomatic elevations of the bilirubin and alkaline phosphatase concentrations.¹⁵¹ The histologic appearance of chronic hepatic GVHD mimics that of another immune-mediated liver disease, primary biliary cirrhosis, with injury to septal and interlobular bile ducts by chronic inflammatory cells.^{148, 152} The initial treatment of chronic hepatic GVHD is the same as acute GVHD with corticosteroids and tacrolimus. Patients with refractory chronic hepatic GVHD may respond to thalidomide.¹⁵³

Other GI complications of cancer therapy

Constipation

Constipation is a common problem in patients undergoing cancer treatment. In this setting, constipation is usually caused by a combination of poor oral intake, decreased physical activity, and antiemetic agents such as ondansetron and opioid analgesics. Opioid-induced constipation is one of the most frequent adverse effects of opioid therapy.¹⁵⁴ These agents slow intestinal transit time. Constipation has also been reported in patients taking vinca alkaloids, in particular vincristine and thalidomide.

Impaction, bowel obstruction, and colonic pseudo-obstruction must be ruled out before initiating pharmacologic therapy for constipation. Constipation should be anticipated in the cancer patient, and steps taken to avoid this complication. Electrolyte abnormalities and other reversible causes of constipation should be corrected. Drugs that cause constipation should be discontinued if possible. Laxatives, with or without stool softeners, can be used in the initial treatment of constipation. Stimulant laxatives such as bisacodyl and senna alter electrolyte transport by the intestinal mucosa and increase intestinal motor activity. If these agents are not effective, osmotic agents such as lactulose or sorbitol can be effective at improving stool frequency and consistency. Polyethylene glycol solutions are available in powder form and have been found to be effective at improving chronic constipation. The use of drugs to improve colonic transit has been disappointing. Metoclopramide seems to be ineffective, and tegaserod (a 5-hydroxytryptamine receptor agonist) has significant cardiovascular adverse effects, and is not available in the United States outside of an emergency investigational new drug (IND) process from the FDA. Lubiprostone, a chloride channel activator, is FDA approved for the treatment of chronic idiopathic constipation. It is a bicyclic acid that works locally on the apical part of the intestine and helps to increase intracellular fluid and intestinal motility. It may be useful in the patient with constipation whose symptoms are increased with opioid use, and with constipation induced by chemotherapy. It is FDA approved for treatment of opioid-induced constipation related to noncancer pain. Methylnaltrexone, a micro-opioid-receptor antagonist for the treatment of opioid-induced constipation in advanced-illness patients, is approved for use in the United States. The agent, a derivative of naltrexone, selectively antagonizes the peripheral microreceptors in the GI tract without effects on the CNS. In clinical trials, subcutaneous methylnaltrexone reversed opioid-induced constipation after the first dose in approximately 50–60% of the patients.¹⁵⁵ In most of the cases, effective laxation occurred within 1 h. It does not affect opioid analgesic effects or induce opioid-withdrawal symptoms. Recent advances in neurogastroenterology are leading to the development of new classes of medications, which may aid in the treatment of severe constipation.¹⁵⁶ Peripherally active μ -opioid receptor antagonists (PAMORAs) allow preservation of the central analgesic effects of these drugs, while antagonizing peripheral effects on the GI tract. Naloxegol and TD-1211 are prototypes in this class. Naloxegol is an oral PEGylated conjugate of naloxone. Naloxegol has recently been approved to treat opioid-induced diarrhea in adults with noncancer pain.¹⁵⁷

Nausea and vomiting

Nausea and vomiting frequently occur after administration of chemotherapeutic agents. The likelihood of developing nausea and vomiting following chemotherapy depends on several factors including the chemotherapy dose and the intrinsic emetogenicity of a given agent.¹⁵⁸ The emetogenic potential of intravenously administered antineoplastic agents can be assigned to five levels, ranging from minimal or less than 10% risk (e.g., bevacizumab) to a high or greater than 90% risk (e.g., cisplatin). Emesis can be acute (i.e., occurring within the first 24 h of receiving chemotherapy) or delayed.

Various antiemetic agents are now available for the prevention and treatment of chemotherapy-induced

nausea and vomiting. These include agents with a high therapeutic index such as 5-hydroxytryptamine-3 (5-HT₃) receptor antagonists (e.g., ondansetron, granisetron, dolasetron, tropisetron, and palonosetron), neurokinin-1-receptor antagonists (e.g., aprepitant), and corticosteroids (usually used in combination with other agents). Agents with a low therapeutic index are also used, such as metoclopramide hydrochloride, butyrophenones, phenothiazines, cannabinoids, and olanzapine. The preferred agent and regimen depend on the emetogenic level of a given chemotherapeutic drug. For drugs with a low emetogenic risk, antiemetics are given only before chemotherapy, while antiemetics are provided before and after chemotherapy for those chemotherapy drugs with a high emetogenic risk (levels 3 or higher).

Gastrointestinal perforation, fistula formation, arterial thrombosis, and bleeding

GI perforation, fistula formation, arterial thrombosis, and bleeding have been reported with bevacizumab, a monoclonal antibody against VEGF. Intestinal perforation has been reported in 1–2% of patients treated with bevacizumab for metastatic colorectal cancer.^{159, 160} Risk factors associated with perforation include an intact primary tumor, prior irradiation, acute diverticulitis, intra-abdominal abscess, and GI obstruction.

Acute pancreatitis

Acute pancreatitis in patients with cancer or in those who have undergone hematopoietic stem-cell transplantation can be caused by conditions present in the general population, including gallstones and alcohol. However, other etiologies should be taken into consideration when managing cancer patients who have acute pancreatitis, including medications and chemotherapeutic agents.

Drug-induced pancreatitis has no distinguishing clinical features, and therefore taking a careful drug history and excluding other etiologies are essential to make a diagnosis. Some of the most common drugs known to cause acute pancreatitis include metronidazole, sulfonamides, tetracycline, furosemide, thiazides, estrogen, and tamoxifen. During the course of chemotherapy, pancreatitis has been reported with the use of azathioprine, prednisone cytosine arabinoside, and various regimens of combination chemotherapy including vinca alkaloids, MTX, mitomycin, 5-FU, cyclophosphamide, cisplatin, and bleomycin. Associated illnesses and multidrug regimens often make it difficult to determine a cause and effect relationship.¹⁶¹

Oral mucositis or ulceration of the oropharynx

Oral mucositis or painful ulceration of the mucosal lining of the oropharynx occurs frequently in individuals undergoing radiation and chemotherapy for solid malignancies. It occurs in 20–40% of patients receiving conventional chemotherapy, 80% of patients receiving high-dose chemotherapy, and has been reported in up to 98% of individuals undergoing hematopoietic stem-cell transplantation. Evidence-based recommendations for prevention and treatment of oral mucositis have been recently published.¹ Palifermin, a recombinant human keratinocyte growth factor-1, decreases the incidence and duration of mucositis in patients with hematologic malignancies who are receiving chemotherapy and requiring stem-cell transplantation support, and has been approved by the FDA for this indication. New guidelines recommend that this agent be used to prevent oral mucositis in patients receiving high-dose chemotherapy and total body irradiation followed by autologous stem-cell transplantation for hematologic malignancies.¹ Oral cryotherapy is also recommended to be used to prevent oral mucositis in patients receiving bolus 5-fluorouracil chemotherapy. Low-level laser therapy has been recommended to prevent

oral mucositis in patients receiving human stem-cell transplantation conditioned with high-dose chemotherapy. Benzydamine mouthwash (but not other antimicrobial mouthwash or lozenges) should be used to prevent oral mucositis in patients with head and neck cancer receiving moderate dose radiotherapy without concomitant chemotherapy. Zinc supplements may be beneficial to prevent oral mucositis in oral cancer patients receiving radiation or chemotherapy. Sucralfate mouthwash is not recommended to prevent or treat mucositis in those receiving chemotherapy or radiation for head and neck cancer owing to demonstrated lack of benefit.

Chapter 135

Oral complications of cancer and their treatment

Stephen T. Sonis, DMD, DMSc ■ Anna Yuan, DMD

Overview

The mouth is a frequent site of direct and indirect adverse side effects of cancer therapy. In myelosuppressed patients, its diverse microbiota makes the oral cavity both a site of local infection and a potential source of bacteremias and sepsis. While about half of all patients being treated with chemotherapy or radiation therapy will develop some form of oral toxicity or infection, almost every patient receiving an aggressive myeloablative regimen or local radiotherapy to the head and neck manifests acute and chronic toxicities. The diversity of the tissues found in and around the mouth—keratinized and nonkeratinized mucosa, bone, salivary glands, and teeth—contributes to the range of susceptibility, acuity, and clinical implications of regimen-related oral complications. In almost all instances, precancer treatment elimination or control of existing oral diseases and aggressive management of oral health during cancer therapy favorably impacts outcomes.

The mouth is a frequent site of acute and chronic adverse side effects of cancer therapy. These range broadly in their nature, incidence, severity, and course, but all adversely affect patients' quality of life, ability to tolerate therapy, overall cost of treatment, risk of local and systemic infection, and rehabilitation. Oral complications of cancer therapy are perceived as common in some cohorts such as patients with head and neck cancer (HNC), but relatively rare in others. This perception has been largely fueled by under-reported patients who worry that mentioning toxicity symptoms during treatment might, as a consequence of dose de-escalation, result in a compromise of their optimum anticancer therapy. While this phenomenon is not unique to oral complications, data surrounding the underestimates of oral toxicities are substantial. Additionally, oral side effects have been reported with many forms of developing therapies including cetuximab, antiresorptive medications, and mTOR inhibitors. It has also become clear that oral complications rarely occur in isolation. Rather, probably because of common biologic underpinnings, they predictably occur with other regimen-related toxicities.¹

Overall, about 40% of patients being treated for cancers, not of the head and neck, develop some form of mouth-related problems, which range from xerostomia to mucositis.² The frequency escalates to more than 75% for patients being treated for HNC, those who develop graft-versus-host disease (GVHD), and patients receiving aggressive myeloablative chemotherapy regimens. The symptomatic and functional consequences of oral complications include increases in analgesic and antibiotic use, length of hospital stays, hospitalizations for pain and fluid management, nursing resource use, diagnostic treating, and need for parenteral feeding. The impact on charges and costs is dramatic. In a study population of patients receiving treatment for HNC and nonsmall cell lung cancer, the incremental cost of oral mucositis alone was found to be \$17,244.³ In the past, oral complications were largely considered to be inevitable, often were not recognized early, and were treated retrospectively rather than in a prospective or preventive manner. Significant progress has been made in the past decade to better define the biology and epidemiology of oral complications of treatment. As a result, interventions that target mechanisms have evolved, as has a better understanding of at-risk populations.

Pretreatment assessment

The risk of many of the side effects that impact the mouth can be successfully reduced by the elimination of existing sites of dental disease before anticancer treatment is initiated.⁴⁻⁶ A pretreatment dental visit is strongly recommended as it serves a range of purposes. First, it provides an opportunity for the identification and elimination of sources of active and chronic dental or periodontal infections or chronic irritation when the patient is best able to tolerate treatment with the least risk of undesirable post-treatment sequelae, such as infection or osteonecrosis. Second, oral manifestations of the primary cancer may be detected. Third, it provides an opportunity for patient education and discussion regarding the impact of the cancer and its treatment on short- and long-term oral health. Fourth, for the patient about to undergo surgical intervention for tumors about the mouth, pretreatment evaluation is critical to optimize the fabrication of prostheses. The construction of protective appliances before the start of radiation therapy may reduce the impact of treatment on scatter-induced injury.

Not surprisingly the frequency of dental disease or faulty prostheses or restoration reported on screening of patients with cancer reflects the incidence of these conditions in the general population. While positive findings of less-than-optimal oral health were reported in two-thirds of patients evaluated before stem cell transplantation (HSCT),⁷ pathology of such severity as to require intervention is only required in about a third of screened patients.⁷ Similarly, of patients with cancers of the head and neck who were screened before radiation therapy, between half and two-thirds required dental extractions, primarily because of diagnoses associated with periodontal disease.^{8,9} Although elimination of possible oral and dental sites of infection before chemotherapy had a significant, favorable impact on morbidity relative to local infection and sepsis,⁴ definitive data demonstrating that preirradiation elimination of oral foci of infection favorably impacts outcomes is needed.¹⁰ Effective dental screening with appropriate treatment before the onset of cancer therapy results in significant cost savings, by reducing the incidence of infection during periods of granulocytopenia.¹¹

Timing of assessment and dental treatment

If oral screening is performed so close to the initiation of cancer therapy as to preclude dental intervention, the value of the process is nullified. The ideal interval between the completion of dental treatment, particularly extraction, and the initiation of radiation therapy has been the subject of much debate. Nonetheless, given the rate by which wounds of the mouth heal, particularly extraction sites, it appears that a minimum of 2 weeks is acceptable and 3 weeks desirable.¹² For patients about to undergo chemotherapy, sufficient time between the completion of dental treatment and the patient's anticipated granulocyte nadir (<500 cells/mL) is required. In general, nonemergent dental treatment should not be performed in a typical ambulatory setting if the patient is significantly thrombocytopenic ($<100,000$ platelets/mL).¹³

Because of the acute onset of some hematologic malignancies and the need for immediate chemotherapy, pretreatment dental and oral screening in this high-risk population may not be possible. In these cases, oral assessment should be performed as close to the initiation of therapy as possible for two reasons: first, such an examination provides an important baseline for oral health and second, the finding and elimination of active oral infection in this markedly myeloablated group is often critical to their overall clinical course. Eradication of identified sources of odontogenic infection should not be delayed, as there is significant data to support the conclusion that dental extractions may be performed safely in this group if they are managed well, preferably in a hospital setting.¹⁰ The complication rate for extractions in patients with hematologic malignancies is reported to be 13%, with no effect on length of hospital stay or

mortality. The most common complications include pain and bleeding. It is important to note that there is no evidence to suggest that an aggressive strategy of extraction of *asymptomatic* teeth has any benefit in the prevention of systemic infection.

Components of the pretreatment assessment include baseline data such as medical and dental histories; laboratory data—such as antibody status relative to herpes simplex type 1 virus—and a clinical assessment that should include an extraoral examination of the head and neck, intraoral soft-tissue examination, periodontal disease screening, and dental evaluation. Radiographic evaluation should include those films that are necessary to definitively diagnose periodontal disease and caries, periapical pathology, and impacted teeth. It is also important to assess the patient's knowledge of, and motivation for dental maintenance. Teeth that demonstrate evidence of untreated periapical pathology, or advanced caries, or periodontal disease should be eliminated.

Patients with removable prostheses should be encouraged to minimize their use or leave them out during their cancer therapy as even subtle mucosal trauma accelerates the risk and onset of mucositis. Similarly, the removal of orthodontic bands before the start of chemotherapy is an essential component in preventing trauma to atrophied mucosa.¹⁴

Oral complications of radiotherapy

Oral complications of radiation therapy are primarily the result of acute and chronic local tissue injury. In addition, radiation-induced xerostomia may result in secondary effects on the teeth and periodontium. The dose rate, total dose of radiation, use of concomitant chemotherapy, the size of, and structures within, the radiation field are the major determinants of oral toxicity. As a result, patients being treated for tumors of the mouth, oropharynx, tongue, nasopharynx, and salivary glands are at highest risk. Patients with hypopharyngeal or laryngeal tumors are also often affected, although at a slightly lower rate. Brachytherapy tends to be more stomatotoxic than external beam irradiation. Although intensity-modulated radiation therapy (IMRT) (*see* 84) may spare some structures, its impact on oral mucosa is significant. Oral tissues that are directly affected by radiation include mucosa (epithelium and tissues in the lamina propria), salivary glands, bone, and muscle. In children, radiation that includes the jaws negatively affects craniofacial and dental development.¹⁵

Mucositis

Both radiation and chemotherapy can produce significant damage to the oral mucosa as a side effect of treatment. The term mucositis (ICD9 code 528.1) is preferred over stomatitis when describing mucosal injury caused by antineoplastic therapy as the latter is a generic term and can be associated with a range of infectious or traumatic etiologies unrelated to chemo- or radiotherapy. The severity and kinetics of radiation-induced oral mucositis are related to dose rate and total dose that target the oral mucosa. Local mucosal irritation, secondary infection, and xerostomia are factors that amplify the damaging effects of radiation to the tissue.

Three themes have characterized the mucositis discussion in the past 5 years: first, the pathobiology has been more fully defined; second, the commonality in mechanisms by which mucosal injury occurs has been applied to all parts of the alimentary canal; and third, mucositis rarely occurs as an isolated toxicity.¹⁶ In addition, the impact of genomics on toxicity risk, including mucositis, has become clear and is being more fully defined.

Historically, mucositis was viewed as the result of direct radiation or chemotherapy-mediated injury to

stem cells in the basal layer of the oral mucosa. It was proposed that these rapidly dividing cells were indiscriminately damaged, resulting in atrophy and subsequent ulceration. Simultaneously, connective tissue injury was thought to lead to an increase in vascular permeability and tissue edema. However, studies defining the mechanisms by which mucositis occurs reveal a process that is biologically more complex. Although epithelial stem cells are the ultimate mediators of mucosal injury, it is now clear that their demise occurs by indirect, as well as direct, mechanisms.^{17, 18} In fact, direct clonogenic cell death of these cells is insufficient to produce the extent of clinical injury that is typically observed. Rather, a sequence of events¹⁸ triggered by the generation of reactive species in cells of the lamina propria produce a cascade of events in the endothelium, connective tissue, extracellular matrix, and the inflammatory infiltrate. This sequence begins almost immediately, following the initial exposure of the mucosa to radiation, and results in a range of molecular mediators and signals that permeate to the epithelium and cause injury, apoptosis, and necrosis.

Radiation-induced oral mucositis typically begins within the first 2 weeks of therapy, at cumulative doses of 10–20 Gy. Although clinical changes are observed at these doses, the cellular and tissue events producing these changes begin almost immediately following initial dosing (see below). Mucosal erythema, mild epithelial sloughing, and the formation of islands of hyperkeratosis characterize early changes of mucositis. These changes are accompanied by relatively mild symptoms characterized by a painful burning sensation that is analogous to a food burn such as that caused by hot cheese. Patients often have difficulty tolerating spicy foods. With the exception of the dorsal surface of the tongue, hard palate, and the gingiva, any mucosal surface of the mouth is susceptible. Most commonly affected areas are the buccal mucosa (cheeks), ventral and lateral surfaces of the tongue, and the floor of the mouth ([Figure 1](#)). The soft palate and oropharynx are also frequently involved and are consistent drivers of symptoms associated with pain on swallowing. Consequently, patients may complain of a sore throat early in their treatment.

Figure 1 Severe oral mucositis with ulceration and pseudomembrane formation of the lateral and ventral surfaces of the tongue and buccal mucosa induced by myeloablative chemotherapy for conditioning before HSCT.

At cumulative doses of about 30 Gy, the integrity of the mucosa breaks down and ulceration occurs.

Ulcers typically begin as isolated lesions, but then coalesce forming large, contiguous breaks in the mucosa, often covered by a collection of dead cells and bacteria in a pseudomembrane. In severe cases, the lesions may bleed ([Figure 2](#)). Ulcerative mucositis is extremely painful. Not only do ulcers cover large mucosal surface areas, but they are also deep. Patients who have undergone radiation therapy and have developed mucositis describe this complication as the most significant of their treatment.¹⁹ In many cases, mucositis results in breaks in radiation treatment, hospitalization for fluid support or pain management, and the need for parenteral feeding.²⁰ The incremental economic cost of oral mucositis in this population is significant.³ It is important that patients about to begin treatment have some concept of the severity of mucosal injury that they are likely to develop. The typical pretreatment characterization of mucositis as “mouth sores” seems to trivialize their significance to patients. It seems likely that a more realistic description and management plan would be advantageous. In most patients, ulcerative mucositis is self-limiting and resolves spontaneously 4–6 weeks following the completion of radiation.

Figure 2 Severe oral mucositis with ulceration, erythema, and pseudomembrane formation of the left buccal mucosa induced by radiation therapy for treatment of an oral carcinoma.

Evaluation of mucositis

Comparisons of the stomatotoxicity of treatment regimens and efficacy assessments of mucositis interventions have been hindered by the lack of a universally acceptable scoring system for the condition. Currently, the grading systems most commonly used to describe oral mucosal toxicity are the World Health Organization (WHO) and National Cancer Institute's common terminology criteria for adverse events (NCI-CTCAE) scales. The WHO scale combines objective findings of erythema and ulceration with the patients' ability to eat solids, liquids, or nothing by mouth ([Table 1](#)). In its latest iteration (v.4) the CTCAE scale eliminates objective assessment of mucosal health and relies completely on symptomatic and functional (oral intake) endpoints. While this approach minimizes the clinician's effort to assess mucositis, the dependence on patient-reported symptoms and function is complicated by analgesic use, individual pain perception, and nonmucositis-related function modifiers such as edentulism, nausea, and so on.

Table 1 Staging and management of medication-related osteonecrosis of the jaw

Stage	Clinical presentation	Management
At risk	No exposed bone	Patient education
0	No clinical evidence of necrotic bone, but nonspecific clinical findings, radiographic changes, and symptoms	Systemic management, including the use of pain medication and antibiotics
1	Asymptomatic exposed and necrotic bone, or fistulae that probes to bone with no evidence of infection	Patient education; antibacterial rinses; careful follow-up
2	Exposed and necrotic bone, or fistulae that probes to bone, associated with infection as evidenced by pain and erythema in the region of the exposed bone with or without purulent drainage	Patient education; antibacterial rinses; antibiotics; pain control; superficial debridement of bone to dislodge loose fragments and smooth rough contours; careful follow-up
3	Exposed bone with pain and usually with associated soft-tissue inflammation or infection; may see osteolysis extending to the inferior border of mandible or pathologic fracture; may see extraoral fistula	Patient education; antibacterial rinses; antibiotics; pain control; palliative surgery; careful follow-up

Prevention and treatment

There is currently no approved, active preventive or treatment intervention for radiation-induced mucositis in the United States. There is consensus that improved oral status may reduce the risk or severity of mucositis. Maintaining a high level of oral hygiene during treatment is thought to be beneficial.

As mucosal injury is related to the extent of mucosa exposed to radiation, the use of midline radiation blocks²² and three-dimensional radiation treatment²³ may reduce the extent of stomatotoxicity.

Benzydamine hydrochloride is a nonsteroidal rinse with anti-inflammatory, analgesic, and anesthetic properties that is approved for use in the prevention and treatment of radiation-induced mucositis in Canada, Australia, and Europe. Results of a number of studies suggest its efficacy in this application.^{24, 25} The MASCC panel recommended the use of benzydamine among patients receiving moderate dose radiotherapy.²⁶ There are no data to support its use in patients receiving concomitant chemotherapy.

A number of palliative barrier agents have been suggested to alleviate symptoms associated with oral mucositis. Gelclair, which has FDA approval as a device, purportedly forms a barrier on injured mucosa.²⁷ Sucralfate, an agent that has wide use in the treatment of gastric ulcers, forms a protein-drug complex on the site of ulcerated mucosa. Its use as a rinse in the treatment of mucositis has been reported in a number of studies, although its efficacy seems inconsistent.^{28, 29} It is specifically not recommended in the MASCC guidelines. MuGard, a hydrogel, demonstrated significant palliation in a multi-institutional, randomized, placebo-controlled trial.³⁰

A variety of topical agents exist for mucositis pain management. These include viscous lidocaine, benzocaine in Orabase, and suspensions of Benadryl in Kaopectate or milk of magnesia. Caphosol, a

rinse originally developed as a tooth-remineralizing solution for patients with xerostomia, is an electrolyte solution of sodium phosphate, calcium chloride, sodium chloride, and purified water, which purportedly lubricates the mucosa and thereby attenuates mucositis. The solution is approved as a device, but the results of clinical trials are inconsistent.^{31–33} Oral aloe vera has been available for some time as a palliative agent. However, it failed to demonstrate efficacy in a phase 2, double-blind, randomized, placebo-controlled study.³⁴ Topical palliative rinses are typically effective only for mild forms of the condition. Systemic pain management following the WHO pain ladder is often necessary. Additionally, cold foods, such as ice cream or Popsicles, may be soothing. Patients should be instructed to remove dental prostheses.

The role of microbes on the severity and course of radiation-induced mucositis is unclear.³⁵ The strategy of mucosal decontamination as a mucositis intervention has produced conflicting results. Chlorhexidine gluconate rinses do not appear to have a role in mucositis prevention or treatment in radiation mucositis and, in fact, might exacerbate the condition.³⁶ Lozenges containing polymyxin E, tobramycin, and amphotericin have been studied and seem to of marginal value and are not recommended.³⁷

Given its importance as an unmet need, the development pipeline for mucositis is rich with agents that target key elements in its pathogenesis. Clinical trials are currently in progress in which drugs targeting oxidative stress, the innate immune response, and proinflammatory elements are being studied.³⁸ Low-level laser therapy is also being investigated for its potential utility as an intervention of oral mucositis. While results of clinical trials are encouraging, the lack of substantive studies defining its biological effects as related to tumor response is troubling. More investigation is clearly needed to assure that its impact on premalignant and malignant tissue is benign.³⁹

Xerostomia

Xerostomia is one of the most consistent and bothersome side effects of radiation therapy in which the salivary glands are included in the field of treatment,⁴⁰ and may be exacerbated by concomitant chemotherapy. The effects of radiation on salivary flow are variable, and symptoms of dry mouth may not correspond to observed salivary flow. Xerostomia is caused by the effects of radiation on acinar cells, especially of the serous glands (parotid). Consequently, inflammation, degeneration, and fibrosis of the glandular parenchyma occur. The extent, duration, and degree of recovery are functions of the dose rate, total dose, and radiation port. Onset of xerostomia may be noted as early as 1 week following the start of radiation (cumulative dose of 10 Gy).⁴¹ The saliva turns thick and ropery as serous function is diminished, but mucous production remains. Patients whose radiation to the ear and neck is in cumulative doses of 60 Gy more often develop irreversible xerostomia, with an 80% loss in salivary gland function.⁴² Spontaneous recovery is unlikely for patients with xerostomia persisting for 12 months or longer.⁴³ With lesser doses of radiation, however, inflammation and edema of glandular tissue often spontaneously disappear within a year of the completion of treatment.⁴⁴

In addition to functional changes caused by xerostomia, such as dysphasia and alteration in taste, loss of saliva is also associated with a reduction in oral clearance, diminished salivary immunoglobulin A (IgA) levels, and salivary antibacterial enzymes. Consequently, patients with xerostomia are susceptible to increases in local oral infections including caries, periodontal disease, and candidiasis. Aggressive oral hygiene to reduce the tooth-borne bacterial load is critical to reducing the risk of dental disease.

Radiation-induced caries can be a common problem in patients with xerostomia.⁴² Changes in salivary composition, decreases in buffering capacity, and loss of the cleansing action of saliva result in the

accumulation of bacteria, increases in local cariogenic flora, and tooth decalcification with consequent caries development.^{45, 46} Typically, radiation caries present with lesions at the cervical margins of teeth, which then rapidly progress. Decalcification (white, chalky enamel) of the incisal edges of the teeth may also be noted. In addition to tooth loss, a major consequence of uncontrolled caries may be abscess formation in patients who are at risk for osteoradionecrosis (ORN).

Four goals should be considered for the prevention and treatment of xerostomia. Preservation of salivary function is critical. Whenever possible, tissue-sparing techniques aimed at minimizing the amount of salivary tissues exposed to direct radiation should be used. While bilateral field radiation may result in an 80% reduction of salivary flow, mantle irradiation typically causes only a 30–40% decrease. Parotid sparing using three-dimensional treatment or intensity-modulated radiotherapy techniques offers the greatest chance of glandular repair.⁴⁷ Stimulation of salivary flow should start simultaneously with radiation therapy (XRT), as should an anticaries regimen to protect the dentition. Replacement of reduced secretions may be introduced as soon as needed.

Stimulation of salivary flow may be accomplished through local or systemic means. Sucrose-free lemon drops or sugarless chewing gum may be used. Cinnamon- or mint-flavored mints or gum should be avoided as they may irritate the mucosa.

Drug therapy may also help to stimulate parotid flow.⁴⁸ Of the cholinergic agents, pilocarpine has been best studied and found to stimulate parotid function, but not submandibular or sublingual gland function in patients with Sjögren syndrome and radiation-induced xerostomia.^{49, 50} Other agents such as bromhexine, anetholtrithion, bethanechol HCl, potassium iodide, neostigmine, and reserpine have been used for salivary stimulation, but data substantiating their efficacy are scant. In contrast, substantial data exist to support the use of pilocarpine HCl tablets to stimulate salivary flow in patients with radiation-induced xerostomia.⁵¹ In cases in which pilocarpine is used after patients have completed radiation treatment and are symptomatic, at least some residual salivary function must be present, and patients should be cautioned that clinically significant improvements in salivary flow may not be realized for up to 3 months following the initiation of treatment. Alternatively, pilocarpine may be prescribed to start simultaneously with radiation therapy. In either case, the typical dose of 5 mg given three times daily may be titrated depending on the patient's response and manifestation of side effects.

Amifostine, a nonprotein, free-radical scavenger has been approved as a cytoprotective agent for salivary glands to prevent radiation-induced xerostomia.⁵² The recommended dose for amifostine is 200 mg/m², administered once daily as a 3-min infusion, starting 15–30 min before standard fraction radiation therapy. The need for intravenous infusion, frequency of dosing, cost, and potential side effects have limited amifostine's adoption. Furthermore, the results of a recent meta-analysis suggest that amifostine's efficacy is tempered among patients receiving radiation regimens in which concomitant chemotherapy is also administered.⁵³

Salivary replacement can be accomplished with the use of saliva substitutes or artificial saliva.⁵⁴ Most of these materials contain carboxymethylcellulose and may provide transient symptomatic relief of mucosal dryness. Saliva substitutes are available as over-the-counter rinses or sprays and are most effective if used before meals and at bedtime. A number of toothpastes and chewing gums have been developed specifically for use in patients with xerostomia.

Exciting new regenerative approaches to restore salivary gland function have recently been reported, but are still limited to preclinical studies.⁵⁵

The most effective protective strategy for radiation-induced caries is the aggressive use of topical

fluorides.⁵⁶ Topical fluoride supplements should be initiated at the start of radiation treatment. Continuation of fluoride following the completion of radiotherapy is critical, especially in patients who develop xerostomia. Fluorides for dental use come in three forms: rinses, gels applied by tooth brushing or in customized trays, and drops also used in trays molded to fit over patients' teeth. Patients in whom xerostomia is anticipated should have fluoride trays fabricated before the initiation of radiotherapy. Fluoride gel or drops are placed in the trays and applied by the patient each day. Use of tray-borne application can be supplemented with acidulated fluoride rinses; generally, the use of rinses in the morning and trays before sleep is most effective and easiest for patients. Acidulated fluorides tend to work best, although neutral fluoride rinses are available for patients with mucositis in whom acidulated material might be irritating, or for patients with porcelain prostheses in whom pitting of the restorations might occur. The supplemental use of a remineralizing toothpaste should also be considered.⁵⁷ Aggressive oral hygiene is to be encouraged, and patients should be seen by a dentist frequently. Regular dental visits are critical to insure early detection and intervention of caries and periodontal disease.

For patients who cannot tolerate trays because of gagging or mucositis, fluoride gels may be applied with a toothbrush, either as 1.1% sodium fluoride or as 0.4% stannous fluoride. The latter appears to be more efficacious. Patients should be instructed to avoid sucrose.

Loss of taste is a transient, but bothersome, sequelae of head and neck radiation.⁵⁸ The severity of taste loss increases rapidly up to doses of 30 Gy, but then usually plateaus. Patients who receive doses of 30 Gy or more may lose their ability to distinguish salt or sweet tastes. Fortunately, hypogeusia is typically transient and taste begins to return within 1–2 months after the completion of treatment. Total recovery may take up to a year. If there does not seem to be progression to improvement following radiotherapy, candidiasis should be ruled out.

Osteoradionecrosis

Of all of the oral complications of head and neck radiation, one of the most significant is ORN.⁵⁹ First described in 1927, ORN results in the denudation of soft tissue and exposure and necrosis of bone.^{60, 61} Although not limited to the jaws, it frequently occurs at this site. ORN causes a painful, chronic, open, and foul-smelling wound that is typically of great distress to the patient. Most cases ultimately heal with conservative treatment, but the course is usually prolonged. ORN was attributed to a triad of trauma (often tooth extractions), radiation, and infection.⁶² Subsequent studies suggest, however, that ORN represents a defect in wound healing rather than a true osteomyelitis.⁶³ The etiology appears to relate to diminished vascularization as a consequence of XRT.⁶⁴ Histologic changes of thickened arterial and arteriolar walls substantiate this hypothesis. The finding of cultivable and noncultivable bacteria may suggest an infectious component.⁶⁵

No consensus exists concerning the overall frequency of ORN, although reported ranges vary between 4% and 44%. While approximately 15% appears to be the preponderant experience,^{59, 63} a recent meta-analysis reported that only 2% of HNC patients are at risk.⁶⁶ The mandible is involved more often than the maxilla, which probably reflects the difference in blood supply and vascularity of the two bones. Time until onset of ORN following XRT is variable. Some authors have described ORN as early as 2 weeks after XRT, others report it as a late condition. Most cases occur within the first 3 years after XRT (74%). Equally controversial is the rate at which ORN risk diminishes with time after the completion of XRT, although it seems clear that the risk never reaches zero.⁶⁷

A number of risk factors for ORN have been positively identified.⁶⁸ Men have been reported to have a

risk for ORN that is threefold higher than women.⁶¹ Patients who are edentulous are twice as likely as patients with teeth to develop ORN. Furthermore, the frequency of ORN increases dramatically in individuals with active dental disease (e.g., periodontal disease, caries, periapical disease, and poorly fitting prostheses).⁵⁹ Fifty percent of cases appear to be associated with tooth extraction following radiation. These findings strongly support pre-XRT dental evaluation and aggressive repair and removal of diseased teeth. The field size, dose rate, and total dose of XRT have a marked effect on the frequency of ORN. Patients who receive cumulative doses of 65 Gy or more to the mandible or maxilla are more likely to develop ORN than are patients receiving lesser doses. Use of three-dimensional radiation techniques has resulted in a slight reduction in ORN risk.⁶⁹ Patients with tumors that are adjacent or contiguous with bone are also at higher ORN risk. It is likely that this finding is due to the inclusion of bone in the radiated field as the volume of bone exposed to XRT has a direct impact on ORN risk. Poor nutrition and immune status also appear to predispose to the condition. Diagnosis of ORN is usually based on clinical findings. In cases in which the diagnosis is questionable, magnetic resonance imaging may be of value.⁷⁰

Treatment of ORN is based on the severity and chronicity of the condition.⁷¹ Fortunately, most lesions (up to 60%) eventually heal in approximately 6 months with conservative therapy consisting of local debridement, saliva irrigation, and oral antibiotics.⁷² Results of studies in which pentoxifylline, used for its anti-TNF activity, was assessed are inconsistent.^{73, 74}

Lesions showing no improvement or demonstrate progression require more aggressive therapy. For these cases, surgical debridement and hyperbaric oxygen (HBO) may be indicated.^{75, 76} In extensive cases, radical resection of involved bone with immediate microvascular reconstruction has been used successfully in patients who have failed more conservative treatment, including HBO.⁷⁷ The use of autologous bone marrow aspirate concentrate coupled with allogeneic dental pulp stem cells with platelet rich plasma was recently reported to be successful in patient's refractory to conventional approaches.⁷⁸

Because most cases of intra-oral ORN are associated with dental disease and post-XRT extractions, eliminating potential sites of odontogenic pathology before the start of radiation is the basis for prevention. Teeth with periodontal disease, advanced caries with a risk of impingement on the dental pulp, fracture, or periapical disease should be removed before the initiation of XRT. Teeth adjacent to or involved in potential surgical sites (for tumor resection) also should be extracted. Because of the consequences of ORN, even suspiciously diseased teeth, especially in the XRT area, should be eliminated. The timing of dental extractions in patients being treated with XRT has been the subject of much analysis, discussion, and controversy; however, the consensus is that teeth should be extracted before XRT.¹³ Ideally, a minimum 21-day healing period is desirable, although a shorter time may be dictated by circumstances. In either instance, extraction before XRT is much more desirable than extraction after the start of therapy, because a number of studies suggest that post-XRT extractions carry significant risk of ORN, no matter how long after XRT they are performed. In all cases, extraction should be performed as atraumatically as possible, with special care given to the soft tissue, primary closure if possible, and good local postoperative wound management. Perioperative use of antibiotics is also recommended.

Aggressive oral hygiene, use of fluorides, and dental care are important components in preventing the development of dental disease once XRT has started. If dental disease develops after XRT and a tooth is restorable, endodontic therapy is more desirable than extraction. Inevitably, extractions are sometimes required of teeth in radiated fields.⁷⁹ The risk of ORN in these cases has been reported to be reasonable (5.6%), even without the use of HBO. The efficacy of HBO in these cases is unresolved. One study found

that, among patients having teeth removed within the first year following radiation, 98.5% of extraction sites treated pre- and postoperatively with HBO healed without complications. However, the efficacy of HBO reportedly decreased the farther out from where radiation extractions were performed.⁸⁰ The utility of HBO, with its incurred cost and multiple visits, warrants additional study.⁸¹

Oral complications of chemotherapy

Oral complications of cancer chemotherapy result from the effects of the drug acting on the oral mucosa (direct or primary stomatotoxicity), the patients' inability to contain local, minor oral disease during myelosuppression (indirect or secondary stomatotoxicity), or some combination of the two.

Risk factors

Not all patients who undergo cancer chemotherapy are at equal risk to develop oral complications. This is especially true of oral mucositis. Although a number of variables have been identified that bear on the frequency and severity of oral problems, their predictive value, in general, has yet to be definitely defined. Risk factors can be divided into those that are associated with the patient and those that are related to the treatment regimen.⁸²

Patient-related risk factors include tumor diagnosis, patient age, gender, body mass, genetics, the patient's oral condition before cancer therapy, the level of oral care during therapy, baseline xerostomia, and baseline neutrophil numbers. Patients with hematologic malignancies (i.e., leukemia and lymphoma) are at greater risk of oral complications than are patients with nonhead and neck solid tumors. For example, more than 66% of patients with leukemia and 33% of patients with non-Hodgkin lymphoma develop oral problems. It seems likely that tumor-related myelosuppression is at least partly the basis for this observation.⁸³ Almost all patients with tumors of the head and neck who receive local therapy develop problems after treatment.

The role of age as a risk factor for mucositis is unclear as there are few studies that compare the rate of mucositis among patients of varying ages with similar diagnoses. Among children, nadir of the neutrophil count, lower body weight, and higher peak creatinine levels have been observed to be associated with higher rates of mucositis.⁸⁴ Among adult patients with solid tumors being treated with 5-fluorouracil (5-FU), mucositis appears to be more severe and persistent among older persons.

Sex may affect risk. There are reports to suggest that women are more likely to have toxicities associated with 5-FU than are men.⁸⁵ This trend was also reported in patients receiving high-dose chemotherapy (BEAM) or high-dose melphalan followed by autologous HSCT.⁸⁶ A mechanism to explain this phenomenon has yet to be determined. Genetics may affect mucositis risk in at least two ways.⁸⁷ Patients with genetic defects, which affect drug metabolism, are at increased risk for mucositis.^{88, 89} For example, among a population of patients being treated with methotrexate for chronic myelogenous leukemia, increased toxicity (including mucositis) was observed in those individuals with lower methylenetetrahydrofolate reductase activity (TT genotype). Similarly, deficiencies in dihydropyrimidine dehydrogenase (DPD) predispose to toxicities mediated by 5-FU. Alternatively, genetics may affect and regulate the mechanisms, which provide the biological basis for chemotherapy-induced mucosal injury. For example, proinflammatory cytokine production varies among the population and is genetically controlled. These cytokines play a role and track closely with nonhematologic toxicities. Consequently, patients who are predisposed to be high producers of these proteins may also be at increased risk for mucositis and other toxicities. For example, among a cohort of allogeneic HSCT recipients, specific

tumor necrosis factor polymorphisms conferred a relative risk (RR) of severe toxicities in excess of 17-fold.⁹⁰ The results of a recently reported study in a pediatric cohort being treated for a variety of malignancies suggest an association among ABO blood types. The RR of oropharyngeal mucositis was 2.86 among patients with type O compared to 0.47 for type A and 0.59 for type B.⁹¹ Further study is needed to fully elucidate the impact of functional genes on mucosal injury, but it promises to be important in determining both risk and predicting responsiveness to mechanism-based interventions.⁹² It is generally agreed that patients whose pretreatment oral condition is poor are at greater risk for some, but not all, oral complications.⁹³ Chronic irritation for poorly fitting prostheses or faulty restorations predisposes patients to the development of ulcerative mucositis. Patients with advanced periodontal disease, pulpal disease, or low-grade soft-tissue infections such as those associated with partially erupted third molars (i.e., wisdom teeth) are at increased risk for developing sepsis of oral origin once they become myelosuppressed. However, elevated risks of infection are not associated with asymptomatic radiographically demonstrable periapical lesions in endodontically treated teeth.⁹⁴

The level of oral care during therapy has a marked influence on outcome relative to oral complications and infection.⁹⁵ The ability of the patients and their healthcare providers to reduce the load of oral bacterial flora favorably affects the risk of both local and systemic infection.⁹⁶ Aggressive techniques of oral hygiene, including mechanical debridement of the teeth and soft tissue, and antimicrobial rinses are effective.

Xerostomia before and during chemotherapy may be associated with an increased risk of mucositis.⁹⁷ It has been suggested that alterations in the health of desiccated oral mucosa and an overall increase in the resident oral microflora may contribute to increasing the probability of mucositis. Studies evaluating treatment strategies aimed at replenishing saliva or mouth moisture have had very mixed results. The favorable effect of pilocarpine on chemotherapy-induced mucositis reported in one study was not replicated in a similar trial⁹⁸ or among recipients of autologous HSCT.⁹⁹

The extent of mucositis correlates negatively with neutropenia. Baseline neutrophil counts of less than 4000 are associated with higher rates of mucositis.⁹⁷ This finding may explain, in part, the observation of increased rates of mucositis among patients with hematologic malignancies.

Risk of complications also relates to the form, schedule, and dose of chemotherapy used.¹⁶ Concomitant radiation, including TBI, also enhance the risk of oral problems. For example, the incidence of mucositis has been reported to be markedly lower in reduced intensity stem cell transplant recipients (30.9%) compared to patients who received conventional conditioning regimens (90.2%).⁹⁷ Significant differences exist in the degree of stomatotoxicity of drugs used for chemotherapy.¹⁶ Drugs or regimens containing anthracyclines, taxanes, platinum, and 5-FU are consistently stomatotoxic. Conditioning regimens in which TBI is used also cause mucositis at high rates. There are 17 specific drugs or combinations in which oral mucositis rates (grade 3–4) affect a significant percentage of patients (>25%):

- Docetaxel/5-FU
- Docetaxel + XRT
- Paclitaxel + XRT
- Docetaxel + 5-FU
- Paclitaxel/5-FU + XRT
- Docetaxel/platinum + XRT

- Paclitaxel/platinum + XRT
- Docetaxel/platinum/5-FU
- Paclitaxel/platinum/5-FU
- Oxaliplatin + XRT
- Platinum/taxane + XRT
- Platinum/methotrexate/leucovorin
- 5-FU/platinum
- 5-FU/leucovorin/taxane
- Irinotecan/5-FU CI + XRT
- Ara-C/idarubicin/fludarabine
- Methotrexate
- Isofamide/etoposide
- Melphalan

In viewing the above list, it is important to remember that the incidence of oral complications, particularly mucositis, tends to be vastly under-reported in terms of occurrence and severity. Virtually every chemotherapeutic agent in the current armamentarium has the potential to produce a stomatotoxic response in at least some portion of the treated population.

Repetitive, low-dose regimens tend to be less toxic than do bolus doses of the same agent. Toxicity that is secondary to radiation is dependent on cumulative dose; pulsed application of therapy does not significantly reduce stomatic changes.

Ulcerative mucositis usually occurs 5–8 days following the administration of chemotherapy and it lasts approximately 7–14 days. Lesions heal spontaneously and without scar formation. Chemotherapy-induced mucositis is confined to the movable oral mucosa: the mucosa of the cheeks, lateral and ventral tongue, inner aspects of the lips, floor of the mouth, and soft palate. Unlike radiation-induced mucositis, that produced by chemotherapy does not affect the hard palate or gingival. The dorsal surface of the tongue is also not affected. This observation is likely to be attributable to the differences in the character of the epithelium on each mucosal surface. Of the sites in the mouth, the buccal mucosa (cheeks), lateral and ventral surfaces of the tongue, and the floor of the mouth are the most commonly involved. In patients who receive multiple cycles of chemotherapy, lesions tend to reappear in the same sites. Numerous studies have confirmed that mucositis is not of infectious (particularly viral) origin.

The biologic mechanisms, which underlie chemotherapy-induced mucositis, are currently the topic of intense investigation.^{18, 100} As noted above, mucositis was viewed as the result of nonspecific toxicity of chemotherapy directed against the rapidly dividing cells of the oral basal epithelium. Although data exist to support the hypothesis, the observation that agents could alter the course of mucositis with little or no epithelial activity suggests a more broadly based pathogenesis. It appears that mucositis represents a clinical outcome due to a complex interaction of local tissue toxicity (endothelium, connective tissue, and epithelium), the level of myelosuppression, and the local environment. Disruption of connective tissue and endothelial cells initiated by free radical formation likely leads to the activation of a range of transcription factors and increased expression of a number of genes that result in stimulation of proinflammatory cytokine production and tissue damage. Simultaneous activation of other signaling

pathways and enzyme activation results in increases in ceramide, proteolytic enzymes, and other mediators of direct and indirect epithelial injury. Thus, in addition to clonogenic death of basal cells caused by direct DNA injury, secondary pathways produce a barrage of mechanisms that lead to apoptosis or necrosis. Therefore, the epithelium first becomes atrophic, as its renewal ceases, and then eventually completely breaks down to form an ulcer. It is noteworthy that in some patients, the extent of cumulative injury to the basal epithelium does not reach the threshold needed for ulceration to occur. In these patients, the thinned mucosa is mildly to moderately symptomatic (grade 1 mucositis). In cases when ulceration does occur, secondary colonization by oral bacteria (both gram positives and gram negatives) occurs. Cell wall products from these bacteria make their way into the underlying connective tissue where they effectively stimulate additional proinflammatory cytokine production by infiltrating macrophages.

The better understanding of the pathobiology of mucositis has served as the basis for the development of mechanistically based interventions.³⁸ The first of these agents to gain approval was palifermin (keratinocyte growth factor-1, Kevivance, Amgen) for the prevention and treatment of oral mucositis in patients receiving conditioning regimens in preparation for HSCT to treat hematologic malignancies. In a phase 3 trial in 212 HSCT recipients receiving a stomatotoxic conditioning regimen, palifermin, administered in multiple doses before and after transplantation was successful in significantly reducing the duration, incidence, and severity of oral mucositis, favorably affecting patient-reported quality of life outcomes, and in reducing days of opioid use and fever.¹⁰¹ It seems likely that palifermin's effect was the consequence, not only of its ability to stimulate epithelial proliferation, but also because of its cytoprotective activates mediated through increased expression of mediating transcription factors. Of the 450,000 patients who develop mucositis each year in the United States, the HSCT population comprises only 5%. Consequently, extension of these and other agents to other tumor populations is a major objective.

Low-level (helium-neon) laser therapy (LLLT) has demonstrated efficacy in reducing the severity and symptoms associated with oral mucositis.¹⁰² While additional studies are needed to confirm its value, the cost and logistics of LLLT may limit its overall utility. As more is learned about the ability of LLLT to impact a wide range of cellular and molecular pathways known to be associated with tumor progression and growth mandates studies demonstrating its lack of activity relative to impacting tumor response.

A number of cytoprotective strategies and agents have been suggested as mucositis interventions. Oral cryotherapy is inexpensive and without risk, its use for 30 min starting 5 min before the infusion of bolus 5-FU, edatrexate, or melphalan may be helpful in reducing the severity of mucositis.²⁶ Pentoxifylline has been evaluated in a number of studies with mixed results. The topical application of trefoil factor was reportedly beneficial in mitigating mucositis in patients with colorectal and HNCs.^{38, 103} The development of biologics, gene transfers, and other therapies targeting specific biological pathways is also under investigation.³⁸

Because the presence of oral micro-organisms is thought to adversely affect the course of mucositis, antimicrobial therapy has been studied extensively as an approach to intervention.³⁶ In general, the weight of data suggests that reduction of the oral bacterial load through medication does not bear significantly on the incidence or severity of mucositis. The use of topical antimicrobials such as chlorhexidine gluconate has consistently failed to improve the frequency or course of mucositis in randomized, blinded trials.^{104, 105}

Palliation has been the most widely used approach for the management of mucositis. Saline 0.9% has been used for years and is more effective than hydrogen peroxide, and at least as good as “magic mouthwashes.”¹⁰⁶ Barrier-type palliatives such as sucralfate suspension and Gelclair are available,

although their benefit has not been convincingly shown. Topical lidocaine or Benadryl in Kaopectate or milk of magnesia may offer some topical relief, but often do not eliminate the need for parenteral analgesia.

Effects of targeted therapies

Ulceration associated with mTOR-inhibitor use

Inhibitors of the mammalian target of rapamycin (mTOR) have demonstrated encouraging results in clinical trials as an intervention for advanced malignancies. Oral ulceration is among the most significant dose-limiting toxicities associated with these agents¹⁰⁷ and has been reported as mucositis. However, the clinical course, behavior, appearance, and likely pathogenesis mTOR inhibitor-induced oral ulcers strongly suggest that they are profoundly different from mucositis induced by radiation or cytotoxic agents.¹⁰⁸

Unlike typical chemotherapy-induced mucositis, aphthous lesions present as discrete, ovoid, relatively shallow ulcers, and surrounded by a characteristic erythematous margin ([Figure 3](#)). Lesions develop more quickly after drug administration and typically resolve spontaneously after an extremely painful course. Although randomized trials have not yet been performed, treatment approaches similar to those used for major aphthous stomatitis may be effective.

Figure 3 Oral mucosal ulcers associated with the administration of an mTOR inhibitor. Note that the lesions are well defined and oval with a central area of necrosis and an erythematous periphery reminiscent of aphthous stomatitis.

Dysesthesia associated with mTKIs

Multitargeted tyrosine kinase inhibitors (mTKIs) offer a specifically directed approach to cancer therapy for an increasing number of malignancies. These small molecular inhibitors have been associated with oral discomfort without evidence of physical findings. The term dysesthesia is more precise and descriptive; it is preferred to stomatitis, which is nonspecific but was used in previous studies. These dysesthesias can present as mucosal sensitivity, burning, dysgeusia or hypogeusia, xerostomia (with adequate salivary flow), and other altered sensations such as paresthesia and anesthesia. These symptoms can occur in up to 60% of patients on mTKI therapy and can be associated with other side effects of therapy including the development of palmar-plantar erythrodysesthesia.¹⁰⁹

Calcineurin-induced inflammatory fibrovascular hyperplasia

Calcineurin inhibitors used for immunosuppression can induce inflammatory fibrovascular hyperplasias in the oral cavity. While cyclosporine is associated with a more diffuse, generalized overgrowth of

densely fibrous gingival tissue, tacrolimus-induced pyogenic granulomas present as localized fibrous polyps more often seen on the tongue and buccal mucosa.¹¹⁰

Osteonecrosis

Bisphosphonates and the RANK-L inhibitor denosumab have been administered concomitant with chemotherapy as a strategy to reduce metastases to bone. Among patients being treated in this way, osteonecrosis of the jaws, particularly of the mandible (twice as common compared to maxilla), has been reported with increasing frequency.¹¹¹ The frequency of the condition has been reported to be between 3% and 8.5%.¹¹² Newer cases have been reported with angiogenesis inhibitors such as sunitinib and bevacizumab, prompting the nomenclature designation as medication-related osteonecrosis of the jaw (MRONJ).²¹ The presentation of osteonecrosis in this population varies in symptomatology. Although some patients experience pain, others do not. The majority of cases appear to be associated with dental manipulation, such as extraction, or soft-tissue trauma. The mechanism underlying this pathology is yet to be defined, as is a full appreciation of the natural history of the condition. Conservative treatment seems to be most appropriate ([Table 1](#)). Presently, the most judicious strategy is to assure aggressive dental screening and treatment before the initiation of treatment so that the possible need for dental intervention is minimized.

Infections

Simultaneous with the breakdown of the oral epithelium, the patients' ability to deal with the abundant oral microbial flora is compromised by their myelosuppression. Thus, the mouth becomes an important source of bacteremia and sepsis in the granulocytopenic cancer patient, as well as locoregional secondary infection. These manifestations of indirect stomatotoxicity parallel the bone marrow status; hence, they are maximal at, or just proceeding toward the patient's granulocyte nadir. Systemic invasion of oral viridans streptococci is particularly common. Of these, *Streptococcus mitis* is associated with the most serious sequelae.

Fungal infections

Local oral infections in myelosuppressed patients are attributable to fungal, viral, and bacterial organisms, in order of descending frequency. Candidiasis is the most frequent oral infection and may appear in its characteristic white, curdy form or as erythematous, macular lesions.¹¹³ It most frequently occurs on the palate, tongue, and corners of the mouth. Poorly controlled oral candidiasis increases the risk of aspiration and the development of candidal esophagitis or fungemia. In addition, aspergillosis and mucormycosis are not uncommon in myelosuppressed patients; these lesions can appear as invasive oral ulcerations that are painful and may involve bone.

As systemic candidiasis is associated with high rates of morbidity and mortality,¹¹⁴ antifungal prophylaxis may be a reasonable consideration among patients in whom prolonged neutropenia is anticipated, that is, HSCT or stomatotoxic, myeloablative chemotherapy recipients. In general, topical agents are ineffective in this group. Treatment options include fluconazole, caspofungin, and micafungin.¹¹⁵

Topical antifungal prophylaxis directed against *Candida* may be beneficial for patients receiving head and neck radiation and promotes xerostomia, and in patients who are immunosuppressed with steroids. The polyene antifungal agents (e.g., nystatin) or the imidazole agents, clotrimazole (Mycelex) are equally efficacious. Nystatin is formulated as a thick, cherry-flavored suspension that is not a favorite of chemotherapy-nauseated individuals. Mycelex is dispensed as a troche. For pediatric patients, nystatin

popsicles made by putting the drug plus water into an ice cube tray seem to work well. Two other imidazoles also are available: ketoconazole (Nizoral) and fluconazole (Diflucan); both have demonstrated efficacy for the prophylaxis and treatment of existing disease. The requirement of an acidic environment for ketoconazole, however, may limit its usefulness in patients who have difficulty eating. Azole resistance may be of relevance in the treatment of fungal infections. Some of the candida species such as *Candida glabrata* and *Candida krusei* are inherently less sensitive to azole antifungal medications.¹¹⁶

The efficacy of chlorhexidine gluconate rinses as a topical antifungal agent is unclear.¹¹⁷ In vivo data suggest that chlorhexidine reduces the activity of nystatin.¹¹⁸ Hence, its simultaneous use with nystatin is not recommended.

While the use of surveillance cultures for predicting the presence or course of fungal infection has long been shown to be of little value, PCR may have a role in the rapid diagnosis and speciation of oral candidal infections.¹¹⁹

Viral infections

Herpes simplex virus type (HSV-1) is the most common oral viral infection in patients receiving chemotherapy or head and neck radiation, and determination of antibody status is an important part of risk assessment. Oral HSV-1 infection can result from a primary infection with the virus or the reactivation of latent virus in a previously exposed host.¹²⁰ It is the latter that is most frequent in patients receiving cancer therapy. Individuals with prior HSV-1 exposure who are seropositive for the virus are at much greater risk than are patients who are negative. The most common manifestation of infection with HSV-1 is oral ulceration. While this may appear to be clinically similar to other forms of mucositis, it usually differs in its course and distribution.

The timing of HSV-1 infection in patients receiving chemotherapy or HSCT is typically quite consistent.¹²¹ Lesions generally are seen approximately 18 days following the start of therapy. This temporal relationship is important in differentiating lesions that likely result from HSV-1 from those that result from direct stomatotoxicity, which are noted 5–7 days after the start of treatment, and from secondary surface infection (usually bacterial) that are seen at the patient's maximum myelosuppression (i.e., granulocyte nadir), which occurs around 12–14 days. Lesions can appear on any mucosal surface including the most heavily keratinized tissues of the hard palate and gingiva. Viral culture is the most definitive way to diagnose HSV-1 infection, and aggressive culturing is recommended, especially in patients who are seropositive. Systemic acyclovir remains the treatment of choice for prophylaxis and treatment of HSV infection.¹²¹

Herpes zoster also may present with oral lesions in patients who receive therapy for cancer.¹¹⁵ These lesions tend to be crop-like. Although they begin as vesicular lesions, they quickly rupture and form painful, small, ulcerative lesions. Unlike those from HSV-1, these lesions usually are unilateral and linear, often following one of the branches of the fifth cranial nerve.

Bacterial infections

The oral cavity may be a frequent source of local and systemic bacterial infection in the myelosuppressed patient with cancer, as evidenced by the increasing frequency of streptococcal infections among patients with granulocytopenic cancer.¹¹⁵ Bacterial infections may be of soft tissue or gingival or odontogenic origin. Patients receiving cancer therapy often have increased numbers of oral organisms as a consequence of reduced hygiene and xerostomia. Additionally, the composition of the oral flora shifts

from one in which gram-positive organisms predominate to one with an abundance of gram-negative pathogens.

Most often, odontogenic infections result from degeneration and infection of the dental pulp subsequent to bacterial invasion secondary to caries. Because of a patient's inability to mount an inflammatory response, conventional signs of dental infection (e.g., abscess formation, swelling) are absent, and patients complain of localized tooth pain. Percussion or thermal sensitivity with clinical and/or radiographic evidence of caries progressing into the pulp is diagnostic. Neurotoxicity may cause dental pain that mimics odontogenic infection in patients receiving plant alkaloids. Odontogenic infections predominantly result from anaerobic species that are similar to those found in dental plaque. Treatment should consist of eliminating the source of infection, and in most cases, this involves tooth extraction. The safety of tooth extraction in the face of myelosuppression has been reported by a number of investigators.¹²² These studies indicate that extraction may be performed with antibiotic coverage, platelet transfusion if needed, attention to tissue management, and good closure. Use of hemostatic agents such as Gelfoam in extraction sockets is discouraged, because they may act as foci of infection. Generally, platelet transfusion is not necessary for counts greater than 50,000 cells/mL. Systemic antibiotic coverage is indicated until the wound is epithelialized.

Gingival infections are relatively common in patients receiving myelosuppressive therapy. Some are localized, such as those that are associated with partially erupted third molars (i.e., wisdom teeth), whereas others tend to be more diffuse. Acute gingival and periodontal infections are worse in patients with pre-existing chronic gingival inflammation or periodontal disease.

The clinical appearance of acute gingival infections, which occur during periods of granulocytopenia, resembles that seen in acute necrotizing ulcerative gingivitis. Pain and loss of the gingival architecture, particularly necrosis of the interdental papillae, are characteristic. These lesions tend to be of a mixed bacterial nature, and include a variety of pathogens, such as *Staphylococcus epidermidis*, *Pseudomonas aeruginosa*, and bacteria typically associated with periodontal disease such as bacteroides and veillonella.

Treatment should include local debridement in addition to systemic antibiotics. Local culture of lesions may be more useful than blood culture, because invasion of intact organisms may not occur. Empirical treatment is recommended regardless of culture results.

Mucosal infections in the myelosuppressed patient often are superimposed on ulcerated areas that have broken down as the result of direct stomatotoxicity. Ulcers may appear to be penetrating, with rounded borders and yellowish-white necrotic centers. Because of the lack of an inflammatory response, erythematous borders are usually absent. If the ulcerations are precipitated by trauma, secondary hematoma formation may occur in the patient with thrombocytopenia. Soft-tissue infections tend to be of gram-negative etiology, although HSV-1 must be ruled out. Treatment should include debridement, palliation, and antimicrobial therapy. Bacterial and viral cultures should be performed as well.

Strategies for the prevention of oral infection include eliminating sources of mucosal irritation and reducing the quantity of the local oral flora.⁶ In addition, treatment of low-grade, asymptomatic infection before the start of therapy minimizes the risk of acute episodes once myelosuppression occurs. Reduction in the oral flora may be accomplished by mechanical and/or chemical means. Local debridement of the teeth can be accomplished with conventional tooth brushing; soft brushes should be used. Thrombocytopenia is not a contraindication to mechanical debridement if common sense is used. Brushing should be discontinued in the face of significant bleeding. Alternatively, cotton swabs or a towel-wrapped finger may be used to clean the teeth. Dental floss is an excellent adjuvant for cleaning but may

be difficult for patients to use if they are unfamiliar with it. It also may be used until patients become profoundly thrombocytopenic. Essentially, anything that the patient or provider can use to physically wipe debris and micro-organisms from the teeth will be beneficial. Cotton swabs, sponges, and rubber tips all may be of use.

Rinses are of varying degrees of help in maintaining oral hygiene. Any fluid that flushes the mouth, including water, will be of some help. Saline and diluted peroxide are frequently used. Generally, mouth rinses containing alcohol as their active agent cause burning of the atrophic mucosa and are not recommended. Mixed results have been reported with chlorhexidine gluconate rinses. If chlorhexidine is used, its administration should be timed to avoid contact with nystatin, because the effects of the latter may be inactivated by chlorhexidine. Similarly, povidone iodine rinses have demonstrated efficacy in reducing the resident oral flora. Other drugs have been tried as preventatives, and fluoride rinses reduce the ability of oral bacteria to adhere to teeth. Consequently, they also may be helpful.

Patients with removable prostheses should be instructed to remove them during periods of myelosuppression. Oral bleeding during such periods most often is of gingival origin. Spontaneous gingival bleeding is a rare occurrence when platelet counts exceed 20,000 cells/mL. Slow oozing may be noted at lower platelet levels, especially in areas with preexisting periodontal disease. Local treatment of gingival bleeding includes initial debridement, nondisturbance of formed clots, and topical application of thrombin under pressure. Gingival bleeding usually is interpreted as evidence that the platelet count is low enough to allow other, more threatening hemorrhage.

Hematoma formation often occurs in areas of trauma, especially the buccal mucosa, alveolar mucosa, or edentulous areas. Areas of submucosal hemorrhage form bluish, blister-like areas, which then form a yellowish-white, tumor-like mass of fibrin. Epithelialization occurs beneath the mass. If bleeding occurs before healing is complete, topical therapy may include thrombin, microfibrillar collagen, or other hemostatic gel. Before healing is complete, the clot may serve as a focus for microbial growth. It should be checked daily and removed as soon as epithelialization is complete. Unchecked sublingual bleeding may cause respiratory embarrassment by elevating the tongue.

Oral complications associated with HSCT

Mucositis

The risk of mucositis in the HSCT population is largely dependent on the intensity of HSCT conditioning regimen and varies widely to a high incidence of 76%.¹²³ The inclusion of total-body irradiation also impacts the risk of developing mucositis.¹⁶ As with other forms of chemotherapy-induced mucositis, lesions are localized to the movable oral mucosa and are most frequent in the floor of the mouth, lingual frenum, and labial and buccal mucosae ([Figure 1](#)). There appears to be no significant difference in either the onset of mucositis following transplantation or the duration of mucositis among recipients of autologous or allogeneic HSCT. Woo and colleagues¹²⁴ reported a mean time of mucositis onset as 5 days following HSCT for autologous recipients, as compared to 6 days for allogeneic recipients. The mean duration of mucositis for both groups was approximately 6 days, with resolution in 10–12 days. In another study in which autologous HSCTs were performed in patients who received cyclophosphamide and TBI, the duration of WHO grade 3/4 mucositis was longer. Mucositis almost always resolves by 3 weeks after transplant, an important diagnostic observation when patients go on to develop GVHD. There is an association between absolute neutrophil count (ANC) and mucositis resolution. Unless patients have extremely severe lesions, mucositis usually spontaneously resolves with an ANC of greater than 500

cells/mL. However, it does not appear that the administration of either GCSF or GM-CSF prevents or minimizes the mucositis development.

The mechanism of mucositis induction is discussed elsewhere in this chapter. It is important to note that the condition occurs independently of oral mucosal infections with either viral or fungal etiology. As noted above, palifermin has recently been approved for the prevention and treatment of oral mucositis in autologous HSCT recipients (see above).

Infection

Oral infection is a major cause of morbidity among HSCT recipients. Of special importance in this patient population is the oral cavity as a source of systemic or distant infection.¹²⁵ The incidence of streptococcal infections in HSCT recipients has increased dramatically. Consequently, pretreatment screening to identify and eliminate asymptomatic, dormant, or potential sources of dental infection or irritation should be mandated for HSCT recipients.

In addition to bacterial infections, HSCT recipients are at risk for oral viral and fungal infections during the period of their granulocytopenia. As with other myelosuppressed patients, the clinical presentation of these infections in the BMT population often varies from the classic descriptions typically associated with these lesions. Consequently, early and aggressive culturing is mandated. Members of the herpes group account for most viral infections; herpes simplex, varicella, and herpes zoster are associated with oral infections in HSCT patients. The routine practice of acyclovir prophylaxis, however, generally has been discontinued. In addition, acyclovir resistant mucocutaneous herpes simplex infections have been reported in HSCT populations. Candidiasis is the most common fungal infection, although both mucormycosis and aspergillosis have been reported. Lesions of the deep fungal infections generally present as nonhealing gingival ulcerations. Biopsy is the diagnostic method of choice.

Graft-versus-host disease

The mouth is a common site for manifestations of both acute and chronic GVHD.^{126, 127} Although there are relatively few reports on the oral manifestations of acute GVHD, three clinical patterns of oral lesions have been described and are noted as early as 3 weeks following transplantation and almost 1 week after the onset of skin lesions ([Figure 4](#)). Initially, multiple, small, white, and papillated lesions are present on the movable mucosa. These progress to the development of keratotic, white, and lacey lesions that clinically resemble lichen planus and, in fact, have been described as lichenoid in appearance. Desquamative lesions may then develop. These also are similar to the lesions of erosive or bullous lichen planus, and unlike the other two forms, these tend to be symptomatic and require intervention.

Figure 4 Oral manifestations of graft-versus-host disease characterized by mucosal blistering and lichenoid changes.

Source: Courtesy of Dr. Nathaniel Treister.

The mouth is only second to the skin as a site for manifestations of chronic GVHD. The oral lesions of chronic GVHD appear approximately 3 months or later following transplantation. Approximately 70% of patients with GVHD develop oral lesions, which most typically are lichenoid in appearance. Symptomatic lesions usually present as erosive, vesiculobullous lesions of the oral mucosa, with peripheral areas of keratotic striations. Additionally, xerostomia is a frequent finding among patients with chronic GVHD. Both mucosal and salivary gland changes result from lymphocytic infiltration; the resulting tissue changes are analogous to those seen in other autoimmune changes in the mouth.

Biopsy of the minor salivary glands of the lip appears to be an accurate and sensitive way to confirm the diagnosis of chronic GVHD, and it is more predictive than either biopsy of the buccal mucosa or the parotid gland. Technically, minor salivary gland biopsy is easily performed in an office setting with local anesthesia and a minimum of tissue manipulation. Histologically, one notes acinar atrophy and/or destruction accompanied by a lymphocytic infiltrate that is rich in CD3⁺ T cells.

Lichenoid lesions generally respond to topical or systemic steroid therapy. Ultraviolet A light therapy reportedly has benefit in the treatment of severe, nonresponsive lesions. Therapy for xerostomia was discussed earlier in this chapter. As with other patients having xerostomia, patients with GVHD are at increased risk for caries and should be managed accordingly.

Additional late effects of HSCT and GVHD also affect the mouth. Of sites for secondary malignancies in this population, the mouth is among the most common. Consequently, patients should receive routine and thorough oral examinations to screen for the development of squamous cell carcinoma. Pediatric HSCT has also been reported to be associated with significant long-term oral and craniofacial complications. Early referral and aggressive follow-up care by pediatric dental specialists are recommended.

Chapter 136

Gonadal complications

Vignesh Narayanan, MD ■ Catherine E. Klein, MD

Overview

Improvements in cancer therapy over the past 50 years have allowed survivors of pediatric sarcomas and leukemias, and young adults with high-grade lymphomas, Hodgkin disease, and testicular tumors to reach adulthood but suffer the long-term consequences of those therapies. Alterations in gonadal function are frequent and distressing side effects of modern cancer therapy. Women face symptoms of premature ovarian failure, including menopause, sterility, and presumably accelerated osteoporosis and possible early heart disease. Men experience oligo-azoospermia and subclinical Leydig cell dysfunction, leading to infertility and long-term effects of “andropause” including decreased bone density, lean muscle mass, decreased libido, and increased risk of coronary artery disease.

With recognition has come better documentation of the frequency and severity of these complications, more effective patient counseling, and innovative approaches to attenuate gonadal toxicity. Options include hormonal manipulation, selection of alternative treatments, and pretreatment cryopreservation of embryos or germ cells, but these choices must be offered pretherapy, and patients remain uninformed of potential loss of fertility or options to preserve it. As cancer therapies improve and the number of cancer survivors increases, the practicing oncologist must address these issues in a timely and sensitive manner.

Improvements in cancer therapy over the past 50 years have allowed survivors of pediatric sarcomas and leukemias, and young adults with high-grade lymphomas, Hodgkin disease (HD), and testicular tumors to reach adulthood but some suffer the long-term consequences of those therapies. Alterations in gonadal function are frequent and distressing side effects of modern cancer therapy. Women face symptoms of premature ovarian failure (POF), including menopause, sterility, and presumably accelerated osteoporosis and possible early heart disease. Men experience oligo-azoospermia and subclinical Leydig cell dysfunction, leading to infertility and long-term effects of “andropause” including decreased bone density, lean muscle mass, decreased libido, and increased risk of coronary artery disease.

With recognition has come better documentation of the frequency and severity of these complications, more effective patient counseling, and innovative approaches to attenuate gonadal toxicity. Options include hormonal manipulation, selection of alternative treatments, and pretreatment cryopreservation of embryos or germ cells, but these choices must be offered pretherapy, and patients remain uninformed of potential loss of fertility or options to preserve it. As cancer therapies improve and the number of cancer survivors increases, the practicing oncologist must address these issues in a timely and sensitive manner.

Historical background

Radiation impact on gonadal function was recognized a century ago. Atomic Energy Commission studies of normal men in the 1960s confirmed exquisite sensitivity of spermatogonia to as little as 10 cGy of

irradiation.¹ Oocytes were more resistant but also displayed a dose-dependent sensitivity, which resulted in sterility and POF with an age-related frequency. Research published in 1939 demonstrated that 500 cGy to human ovaries was associated with amenorrhea that persisted up to 18 months. All women over the age of 40 became permanently infertile.²

Initial reports suggesting detrimental effects of chemotherapy on reproductive function were confirmed by a pathologic study of testicular tissue of 30 men who received nitrogen mustard in the 1940s. Twenty-seven of these men had testicular atrophy and absent spermatogenesis.³

The first convincing report of menstrual irregularities in women undergoing chemotherapy appeared in 1956.⁴ Four women starting busulfan for chronic leukemia developed menopausal symptoms within 3 months. Ovarian and endometrial tissue showed findings consistent with POF. Gonadal toxicity from other drugs was soon recognized, and the list continues to grow ([Table 1](#)).

Table 1 Probability of decreased gonadal function associated with commonly used antineoplastic agents

Frequency	Men	Women
Common	Cyclophosphamide	Cyclophosphamide
	Nitrogen mustard	Nitrogen mustard
	Procarbazine	Procarbazine
	Nitrosoureas	Nitrosoureas
		Busulfan
		Melphalan
		Thalidomide
Possible	Vinblastine	Vinblastine
	Etoposide	Etoposide
	Cisplatin	Cisplatin

Assessment of gonadal function after gonadotoxic therapy

Assessment in males

Semen analysis has been the cornerstone of assessment of gonadal function in men, and measurement of gonadotropins (FSH, LH), anti-Müllerian hormone (AMH), and inhibin-B levels are used in children and prepubertal boys.

AMH is produced by Sertoli cells and impacts male sexual differentiation by causing regression of Müllerian ducts.⁵ After age 9, AMH levels decline indicating androgen effect on Sertoli cells and early spermatogenesis.⁶ In prepubertal boys older than 9 years, Inhibin-B and basal testosterone levels assume more relevance. Leydig cells are more resistant to the effects of chemotherapy than germ cells, thus childhood survivors of cancer may have normal testosterone despite being azoospermic.⁶

Semen volume, sperm concentration, mobility, and morphology are markers of testicular function in adult men. Markers of spermatogenesis such as FSH and inhibin-B levels fluctuate widely and are not predictive of reproductive outcomes. Low or normal testosterone levels along with elevated LH levels are seen commonly in adult survivors of cancer,⁷ but are also subject to interindividual variability and lack sensitivity to detect small but meaningful changes in testicular function. Novel biomarkers including sperm messenger RNA, micro-RNAs, histone modifications, and DNA methylation patterns are under development.⁷ Genetic testing of sperm using fluorescent *in situ* hybridization (FISH) and DNA fragmentation identify chromosomal aneuploidy in the sex chromosomes and assess the extent of DNA damage after gonadotoxic therapy. A higher incidence of sperm aneuploidy was noted in men treated with BEP chemotherapy for testicular cancer as well as the ABVD regimen for HD.^{8,9} Aneuploidy returned to baseline values within a few months, but some patients had persistent abnormalities for up to 2 years after therapy. Future impact of these measurements is potentially intriguing.

Assessment in females

Oocyte numbers are fixed at birth and are not replenished.¹⁰ Advancing age and anti-neoplastic therapy quantitatively and qualitatively decrease this pool and adversely affect fertility. Assessing ovarian reserve before fertility preservation is important, especially in women aged over 35.

Measurement of FSH, inhibin B, clomiphene citrate challenge test, antral follicular count (AFC), and AMH assess ovarian reserve and predict the oocyte yield with assisted reproduction. Elevated FSH (>20 mIU/mL) in the early follicular phase of the menstrual cycle indicates impaired ovarian reserve and predicts failure of assisted conception.¹¹ However, FSH level varies during the menstrual cycle, and neither FSH nor inhibin-B levels are reliable in prepubertal girls. The AFC can be quantified by transvaginal ultrasound to assess ovarian reserve but is not useful in determining oocyte quality or predicting pregnancy outcomes with IVF.¹²

The granulosa cells of ovarian antral follicles produce AMH, and serum levels are a surrogate for the number of developing ovarian follicles. AMH levels decline toward menopause. Unlike FSH and inhibin-B, serum AMH levels do not fluctuate through the menstrual cycle and are valid in children.¹⁰

Low serum AMH levels were first described in women with prior childhood cancer who still had regular menses indicating low ovarian reserve.¹³ Well-conducted studies have found low AMH levels in breast cancer and childhood HD survivors with a clear dose–response relationship between the number of chemotherapy cycles and serum AMH levels.^{14,15} Therapy with alkylating agents and pelvic/total-body

irradiation often results in low or undetectable AMH levels.¹⁶ Women with low pretreatment AMH levels are more likely to develop amenorrhea after chemotherapy for breast cancer.¹⁷ Nomograms incorporating age and AMH levels have been developed to predict postchemotherapy ovarian recovery in newly diagnosed breast cancer patients and accurately gauge the need for fertility preservation techniques. AMH levels do not predict spontaneous conception of pregnancy or pregnancy outcomes.

Effects of cytotoxic chemotherapy on gonadal function

Effects in boys

Early reports of therapy in prepubertal and pubertal boys suggested relative resistance of the less mature testicle to chemotherapy-induced effects. The frequency of testicular dysfunction, however, varies widely among studies. Three major factors determine the extent of testicular damage among prepubertal boys receiving cytotoxic chemotherapy: the specific drug, the cumulative dose of the drug, and the pubertal stage. The majority of boys progress normally through puberty without supplemental androgen.^{18, 19} Testicular volume may be reduced, however, and elevated LH levels indicate some degree of Leydig cell dysfunction.⁶

Years after treatment with single-agent cyclophosphamide, the prevalence of normal adult sperm counts has been reported in small, heterogeneous case series to range between 0% and 100%.^{20, 21} Oral cyclophosphamide cumulative doses of 0.7–52 g caused gonadal damage in 16% of prepubertal boys, but 67% of pubertal boys had evidence of gonadal dysfunction.²² Chlorambucil and azathioprine for renal disease in patients aged 6–15 years produced azoospermia in 17 of 21 patients for up to 11 years after cessation of treatment.²³

Most available data relate to multiagent chemotherapy. MOPP chemotherapy in boys with HD impairs subsequent spermatogenesis, a defect reported to last for years.^{19, 24}

A meta-analysis of 30 studies comprising 456 patients who received cyclophosphamide for renal disease, HD, or leukemia found that fewer than 10% of prepubertal boys receiving less than 400 mg/kg (total dose) of cyclophosphamide had gonadal dysfunction, whereas 30% of those over 400 mg/kg did.²⁵ Gonadal dysfunction ranged from 0% to 24% in prepubertal boys, but was 68–95% in sexually mature men. A recent analysis of 214 adult male survivors of childhood cancer treated with alkylating agents found the incidence of oligospermia and azoospermia to be 28% and 25% respectively.²⁶ Impaired spermatogenesis was unlikely when the cumulative cyclophosphamide equivalent dose (CED) was less than 4000 mg/SqM. CED was associated with a statistically significant increase in the risk per 1000 mg/SqM for azoospermia and oligospermia.²⁶ Unfortunately, poorly understood exceptions to these general trends and lack of reliable predictions for any given patient are problematic. Even small doses of alkylating drugs in prepubertal children can cause permanent sterility.

Whether Leydig cell function is affected in pubertal males is less clear. Gynecomastia with elevated FSH and LH has been reported in pubertal boys receiving MOPP treatment.¹⁹ Other studies find normal basal and stimulated gonadotropin tests,¹⁸ and abnormal testosterone responses to human chorionic gonadotropin (hCG) challenge are uncommon. Gonadotropin secretion was normal in 29 of the 32 patients studied in a cohort of 40 men treated in childhood for HD; 26 of 28 had elevated gonadotropin levels but normal serum testosterone and secondary sexual characteristics. Eleven of thirteen were azoospermic and remained so for up to 17 years.²⁷ Seventeen adult survivors of childhood sarcoma demonstrated azoospermia in 58%, oligospermia in another 30%, but normal testosterone in 94%. LH was elevated in

92% (40% of those with normal testosterone levels), suggesting Leydig cell insufficiency.⁶ Although levels of LH, FSH, and serum testosterone following chemotherapy in prepubertal boys may be normal, testicular biopsies after combination chemotherapy for acute lymphoblastic leukemia or HD commonly show seminiferous tubular damage and interstitial fibrosis.

Effects in men

Single-agent alkylating drugs induce permanent damage to adult seminiferous epithelium. Cyclophosphamide cumulative doses over 9 g result in universal azoospermia; with doses over 18 g that change is irreversible.²⁸ Multiple studies of HD patients receiving combination chemotherapy with or without procarbazine indicate that this drug is uniquely gonadotoxic. In one study of 19 patients treated with cyclophosphamide, vincristine, procarbazine, and prednisone (COPP) regimen, all remained oligospermic 11 years after therapy; 7 of 10 treated with COPP without procarbazine had return of spermatogenesis within 3 years.^{29, 30}

Methotrexate causes minimal long-term reproductive toxicity. That vincristine may be less toxic than vinblastine is inferred from the slightly lower incidence of infertility following MOPP therapy than MVPP (mechlorethamine, vinblastine, procarbazine, and prednisone). Although studies of single-agent daunorubicin are not available, it appears to have minimal long-term effect when used in combination therapy not containing cyclophosphamide. When used with cyclophosphamide, however, daunorubicin appears to potentiate gonadal toxicity. Long-term administration of azathioprine does not seem to affect semen quality.

Most data has been derived from studies of combination chemotherapy and indicate permanent infertility among HD and some nonseminomatous testicular cancer survivors. Complicating the interpretation of these studies is the observation that before therapy as many as 30% of men with HD and 50% with germ cell tumors are oligospermic; disorders of sperm motility and morphology are more common.^{31–33} Multivariate analysis found that elevated erythrocyte sedimentation rate and advanced stage are predictors of pretherapy infertility among HD.³⁴ Pretreatment FSH levels may provide a prognostic marker for subsequent spermatogenesis in young men with germ cell cancer.³⁵ MOPP or MOPP-like regimens to treat HD render all men infertile during therapy, and recovery is unlikely ([Table 2](#)). In a prospective study of 37 men receiving MVPP, 12 had low sperm counts before treatment, but all were azoospermic after two cycles and remained so for the first 12 posttreatment months.³⁸ Longer term follow-up finds only 5–15% ever regain spermatogenesis. Studies comparing MOPP chemotherapy to ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) conclude that the latter combination produces less gonadal toxicity.^{22, 36} For patients with advanced HD, BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) is increasingly employed. The German Hodgkin study group (GHSG) found that the incidence of azoospermia was significantly higher among those treated with eight cycles of BEACOPP or four cycles of COPP/ABVD compared to two cycles of COPP/ABVD (93%, 91%, and 56%, respectively).⁴⁵ An update of the Stanford V regimen (vinblastine, doxorubicin, vincristine, bleomycin, mustard, etoposide, and prednisone) reported 19 conceptions in 13 male survivors.⁴³

Abbreviations: ABVD, Adriamycin (doxorubicin), bleomycin, vinblastine, dacarbazine; ChIVPP, chlorambucil, vinblastine, prednisone, procarbazine; CMF, cyclophosphamide, methotrexate, 5-fluorouracil; COPP, cyclophosphamide, vincristine, prednisone, procarbazine; 5-FU, 5-fluorouracil; MACOP-B, methotrexate, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), prednisone, bleomycin; MOPP, mechlorethamine, Oncovin (vincristine), prednisone, procarbazine; MVPP, mechlorethamine, vinblastine, prednisone, procarbazine; NOVP, mitoxantrone, vinblastine, vincristine, prednisone; PACE BOM, doxorubicin, cyclophosphamide, etoposide, bleomycin, vincristine, methotrexate, prednisolone; PEB, cisplatin (Platinol), etoposide, bleomycin; L-PAM, L-phenylalanine mustard; PVB, Platinol (cisplatin), vinblastine, bleomycin; PVB + dox, cisplatin, vinblastine, bleomycin, doxorubicin; VAPEC-B, vincristine, doxorubicin, prednisone, etoposide, cyclophosphamide, bleomycin.

Data on outcomes after treatment for non-Hodgkin lymphoma (NHL) are less robust, but evidence suggests that the cyclophosphamide, vinblastine, and prednisone regimen is less toxic than MOPP.³⁰ A report of 14 men treated with vincristine, doxorubicin, prednisone, etoposide, cyclophosphamide, and bleomycin suggests that this may be an effective, relatively nontoxic regimen for NHL.⁴⁷ Leukemia therapy appears less toxic,⁷¹ although both allogeneic and autologous stem cell transplant (SCT) increase the likelihood of long-term infertility. Kreuser found 100% recovery during maintenance therapy among 10 patients aged 14–38 years treated with combination chemotherapy.^{39, 52}

The majority of men presenting with testicular tumors are oligospermic. In 41 patients studied prospectively, Drasga reported that 77% were oligo-azoospermic and 17% were azoospermic; only 6% had adequate sperm counts for cryopreservation.⁴⁸ Abnormalities of sperm motility are at least as prevalent. Following 2 months of therapy with cisplatin, vinblastine, and bleomycin, with or without doxorubicin, 94% of men in Drasga's study were azoospermic.

Recovery of spermatogenesis following chemotherapy for testis cancer is common. Most studies show a time-dependent recovery of spermatogenesis, with nearly 50% of patients recovering some sperm production after 2 years ([Table 2](#)).^{50, 51} Longer follow-up has shown no adverse effects on fertility or sexual function.⁵¹ Recovery seems to be partly related to the cumulative dose of cisplatin. In those who receive over 400 mg/m², permanent infertility should be anticipated. Limited data suggest that ifosfamide may cause less irreversible infertility than its similarity to cyclophosphamide might predict.^{70, 72}

As in boys, Leydig cell function is more resistant and is usually well compensated; despite frequently elevated gonadotropin levels, few men require androgen replacement.^{24, 30} Subclinical Leydig dysfunction may have underrecognized sequelae, including excess cardiovascular morbidity increased hypercholesterolemia and obesity, in conjunction with lower testosterone and elevated LH/FSH.⁷³

Effect in prepubertal girls

The ovarian effects of chemotherapy in prepubertal girls are variable and depend on the drug, dose, and duration of therapy. Single-agent cyclophosphamide for nonmalignant disorders rarely causes either a delay in puberty or permanent sterility.⁷⁴ Most girls treated with procarbazine or nitrosoureas for brain tumors show biochemical evidence of primary ovarian dysfunction, but progress normally through puberty. Ovarian function returns to normal over a period of years, and elevated gonadotropin levels decrease to baseline in most women. Eighty percent of girls treated for ALL also proceed normally through puberty.⁷⁵ In a large study of survivors of childhood cancer, the likelihood of premature menopause was 13-fold higher when compared with siblings: 8% by age 40.⁷⁶ This increase was associated with higher doses of alkylating agents, ovarian radiation, and a diagnosis of HD. In Ewing sarcoma survivors, 67% developed POF at a median follow-up of 5.7 years. All who underwent pelvic irradiation had POF.⁷⁷

Histologically, however, prepubertal ovaries are significantly damaged by cancer chemotherapy. Follicular maturation arrest, stromal fibrosis, and a partially depleted ova population have all been

reported following single-agent cyclophosphamide as well as cytosine arabinoside (ara-C)-based antileukemic therapy.

Effects in women

The effects of antineoplastic agents on the female gonadal function have been inferred from the incidence of amenorrhea, gonadotropin levels, and long-term fertility rates and outcomes. One autopsy series of acute leukemia patients showed no difference in the number of primary follicles, but secondary follicles were markedly depleted.⁵¹ Clinically, women receiving these agents develop POF: vaginal dryness with dyspareunia, endometrial hypoplasia, decreased libido, hot flashes, oligomenorrhea evolving into amenorrhea, and low serum estrogen levels with compensatory elevations of serum FSH and LH levels.^{33, 78}

The frequency of amenorrhea and infertility depends on the drug, its total dose, concomitant radiation, and the patient age when treated. Single-agent alkylating drugs are those most consistently associated with POF. Small series report that 50–75% of women treated with cyclophosphamide develop amenorrhea within a month of starting therapy, although there is a strong age-related susceptibility. In one study, the total dose of cyclophosphamide received before the onset of amenorrhea was 5.2 g for patients over 40, 9.3 g for those 30–39, and 20.4 g for those 20–29. Menses returned in 50% of women under 40.⁶³ Return of menstrual function was correlated with the dose administered after the cessation of menses.

Old studies of adjuvant chemotherapy with L-phenylalanine mustard for breast cancer showed significant, age-related POF: 73% of the women aged 40–49, but only 22% of the women under 39, developed amenorrhea during therapy.⁵⁹ Single-agent treatment with busulfan or chlorambucil is associated with well-documented age and dose-related ovarian toxicity.^{79, 80}

Sarcoma patients treated with high-dose methotrexate rarely report amenorrhea and serum gonadotropin levels remain normal during and after therapy.⁵⁴ Lower dose methotrexate for gestational trophoblastic tumors appears to exert no significant toxicity, although one survey from England found that menopause occurred on average 3 years earlier in chemotherapy-treated women.⁸¹ Fluorouracil, daunorubicin, and bleomycin as single agents are also well tolerated.

Few data are available for etoposide, but ovarian dysfunction has been reported among women receiving the drug for gestational tumors.⁸²

Tamoxifen appears to exert a mild estrogenic effect associated with decreased gonadotropin levels in both premenopausal and postmenopausal women treated for breast cancer. Menstrual irregularities are common, but the incidence of persistent amenorrhea is unclear. Successful pregnancies have been reported among women on chronic interferon therapy for a variety of malignant and nonmalignant diseases.⁶⁵

Most reported outcomes come from studies of multiagent therapy. The incidence of amenorrhea in women treated with MOPP, MVPP, or COPP ranges from 15% to 80% ([Table 2](#)).^{29, 35, 44, 83–85} Two-thirds develop amenorrhea during therapy. A dose–response relationship is unclear. In one study, there appeared to be no difference between three and six cycles of MOPP.⁸⁶ Age at the time of treatment, however, is an important variable affecting the incidence and onset of permanent amenorrhea. Sixty to hundred percent of patients over age 25 develop permanent amenorrhea during therapy. POF occurs with initiation of therapy in 5–30% of women under 25 and in an additional percentage over the next months. Younger women experience at least a 50% likelihood of POF 5–10 years of therapy.⁸⁷ Preliminary reports suggest that HD regimens such as ABVD or doxorubicin, cyclophosphamide, etoposide, bleomycin, vincristine,

methotrexate, and prednisolone may have lower rates of prolonged amenorrhea.^{38, 56} Horning has reported 24 conceptions among 19 women treated with the Stanford V regimen V.⁴³ Women receiving methotrexate, doxorubicin cyclophosphamide, vincristine, prednisone, and bleomycin for aggressive lymphomas appear, in small series, to maintain fertility.⁴¹ Women treated with four cycles of Mega-CHOP for NHL had recovery of ovarian function.⁸⁸ Eight of these patients conceived spontaneously. In a second study of women younger than age 40 receiving CHOP therapy for NHL, only 2 of 36 women developed POF.⁸⁹ Fifty percent of these women conceived in first remission of their disease.

Women receiving cisplatin-containing therapy for germ cell tumors typically become amenorrheic during treatment, but over 90% resume menstruation within a few months of completing treatment.^{57, 90–92} Among women with breast cancer, who may already have age-related decreased reproductive potential, 80% receiving adjuvant therapy with cyclophosphamide, methotrexate, and 5-fluorouracil (CMF) become menopausal within 10 months of beginning therapy.^{61, 62} The reported ranges, however, vary between 20% and 100%.⁹³ Those given doxorubicin and cyclophosphamide usually become anovulatory within 3 months; sooner if they are perimenopausal. Few women under age 30 treated with doxorubicin-containing regimens experienced amenorrhea; about one-third of women aged 30–40 years, and nearly all those over 40 years of age do so. Epirubicin-containing regimens are similar. Adjuvant docetaxel with doxorubicin and cyclophosphamide resulted in a 61% rate of amenorrhea in a patient population whose average age was 49.⁹⁴

Fertility following high-dose chemotherapy

Case reports and small series have documented the recovery of fertility in very few patients treated with high-dose regimens. A retrospective survey of over 37,000 SCT patients found that only 0.6% subsequently conceived.⁹⁵ Follow-up of 187 young women previously treated with SCT for either aplastic anemia or leukemia found the anticipated age-dependent effect of cyclophosphamide on ovarian function.⁵³ Fifty-seven percent of female patients had fertility impairment at 2.3 years following SCT. Only 7% of 144 patients recovered fertility, and recovery took longer in women than in men. A longitudinal study of 217 childhood allogeneic SCT patients found that 56% of men had fertility impairment with elevated FSH/LH and low testosterone after a median of 2.6 years. Azoospermia was documented in 14 of 15. Only 3% recovered fertility 3.4 years after SCT.⁹⁶ Patients transplanted for aplastic anemia overall do somewhat better, particularly those under age 25.

Effects of radiation therapy on gonadal function

Effects in men

Therapeutic irradiation in boys with acute leukemia was a standard practice to prevent testicular relapse. Doses below 1200 cGy were insufficient to control disease, and early protocols were replaced by those delivering 2400 cGy to both testes. This dose induced permanent Leydig cell damage, puberty was delayed, testosterone levels were diminished, and gonadotropin levels were increased in most patients.⁹⁷

In adults, single 400–600 cGy doses of testicular radiation may produce azoospermia for 5 years or longer.¹ Berthelsen evaluated men undergoing prophylactic radiotherapy for seminoma and found that two-thirds became azoospermic from scatter dose of 201–130 cGy.⁹⁸ Shapiro has documented oligospermia/azoospermia lasting up to 24 months after as little as 27 cGy.⁹⁹ Adult Leydig cell

dysfunction, with elevated LH values, occurs at radiation doses greater than 2000–3000 cGy, and can require hormone replacement. Fractionated radiation appears to produce tubular damage equivalent to that seen with single doses. Recovery occurs in the majority of those who are treated for germ cell tumors; series report 37–66% success rates in men wishing to conceive a pregnancy.¹⁰⁰

TBI for SCT conditioning is routinely associated with permanent azoospermia. Secondary infertility has been reported in association with radiation administered to the hypothalamus or pituitary in conjunction with chemotherapy for intracranial neoplasms.¹⁰¹

Whether there are permanent effects on the surviving germ cells of men receiving radiation remains uncertain. Most studies have been unable to document an increase in malignancies in offspring.¹⁰²

Effects in women

The radiation sensitivity of the human ovary has not been well defined. Small primordial oocytes are considerably more sensitive than large follicles, and ovarian sensitivity to radiation is dose and age dependent. In adult women, single doses of 500 cGy produce menstrual irregularities in women of all ages. For women over 40, 600 cGy reliably induces menopause. Women aged 20–30 can tolerate up to 3000 cGy if fractionated over 6 weeks.¹⁰³ Uterine radiation in childhood increases risk for nulliparity, spontaneous abortions, and intrauterine growth retardation, so fertility is not assured even if ovarian function is preserved. In a retrospective study of 162 patients with stage II/III colorectal cancer, the incidence of amenorrhea in patients was higher among women with rectal cancer compared to colon cancer (94% vs 4.2% respectively), possibly related to pelvic irradiation in rectal cancer patients.¹⁰⁴

Effects of targeted therapies on gonadal function

In the era of molecularly targeted therapy, several new drug classes have entered clinical use, but there is a paucity of data regarding their effects on fertility. Furthermore, cytotoxic agents are often used concurrently, and the effect of combination therapy on gonadal function has not been studied.

Effect of TKIs

Imatinib inhibits c-KIT, crucial for Leydig cell function, and platelet-derived growth factor receptor (PDGFR) essential for gonocyte migration. c-KIT and PDGFR are also expressed in oocytes and have important roles in folliculogenesis and female fertility. Oligozoospermia, gynecomastia, and testicular failure have been described in prepubertal boys.¹⁰⁵ Case reports document oligospermia in men, but most men father normal offspring.¹⁰⁶ Women treated with imatinib appear to conceive normally but may have an increased risk of congenital malformations, hence discontinuation of therapy before pregnancy is recommended.¹⁰⁷

Rapid onset of hypogonadism and low testosterone has been described in men treated with crizotinib.¹⁰⁸ A follow-up study documented low testosterone levels with reductions in sex-hormone binding globulin, LH, FSH, and free testosterone, suggesting central hypogonadism.¹⁰⁹ Dasatinib and sunitinib have been associated with gynecomastia, but their effects on fertility are unknown.

Effects of m-TOR inhibitors

Sirolimus and everolimus also inhibit c-KIT. The reproductive side effects of m-TOR inhibitors are inferred from organ-transplant patients. Men treated with sirolimus and everolimus have low testosterone

and oligospermia, with elevated FSH and LH; effects are reversible after discontinuation of therapy.¹¹⁰ In human ovarian cortical strips treated *in vitro* with rapamycin, oocyte destruction by granulosa cells was discovered, although previous reports had implicated m-TOR inhibitor-mediated apoptosis as the mechanism for oocyte loss.¹¹¹

Effects of monoclonal antibodies and immunotherapy

Alemtuzumab, a monoclonal antibody against CD52, causes immobilization and agglutination of sperm because CD52 is also expressed on the surface of the sperm.¹¹² Cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) blockade with ipilimumab and programmed cell death-1 (PD-1) receptor agents for the treatment of melanoma can cause hypophysitis and hypopituitarism. In the sentinel trial of ipilimumab in melanoma, the incidence of serious hypopituitarism was low at 1.8%.¹¹³ The incidence of reproductive side effects with CTLA-4 and PD-1 blockade is not known.

Protective measures

Protection for men

It has long been speculated that halting spermatogenesis through hormonal manipulation might ameliorate testicular damage, as most chemotherapy agents are selectively toxic to dividing cells. In clinical trials of men receiving chemotherapy for HD, two attempts using GnRH analogs have been unsuccessful.^{114, 115} For men who desire fertility following combination chemotherapy for advanced HD, ABVD is clearly preferable to MOPP.³⁸ Use of GnRH analogs does not shorten the recovery time to spermatogenesis. Masala et al. documented some protection with the use of testosterone in patients treated with cyclophosphamide. ASCO Guidelines indicate this procedure to be experimental.

Men anticipating cancer therapy should consider semen cryopreservation. The process of sperm cryopreservation is no more detrimental to sperm quality in cancer patients than in noncancer controls.¹¹⁶ Because of the high prevalence of abnormal pretherapy semen analyses, many patients have been considered poor candidates, but successful impregnation has been achieved following artificial insemination using semen with quite low sperm counts and poor sperm motility.¹¹⁷ With meticulous reproductive assistance, fertilization may be effective in up to 45% of cases. In addition, *in vitro* fertilization and subsequent implantation has been successful in cases of even lower sperm counts and motility.¹¹⁸ With the advent of intracytoplasmic sperm injection (ICSI), where only a single live spermatozoon is selected and injected into an oocyte, the chance of conception can be greatly enhanced despite exceedingly low sperm counts. Garcia compared ICSI in patients with malignancies with noncancer patients who underwent the same assisted reproductive procedure. The cumulative pregnancy and cumulative live birth rates in cancer patients were 69% and 62%, respectively, comparable to noncancer patients.¹¹⁹ Fertilization has been reported using spermatozoa retrieved by testicular biopsy and with sperm extracted from the vas deferens at the time of orchiectomy in several azoospermic testis cancer survivors.¹²⁰ Many centers nonetheless report that the overall success rate among men who elect to preserve semen may be somewhat limited, and perhaps is influenced by factors other than semen quality. One series from Memorial Sloan-Kettering Cancer Center reported locating 48 of 69 men who had banked sperm, but at a median of 27 months posttreatment only 11 had attempted to use their sperm for artificial insemination. Of these, only three achieved successful pregnancies.^{117, 121}

Penile vibratory stimulation and electro-ejaculation may provide an option for pubertal boys.¹²² Very

preliminary studies of testicular circulatory isolation suggest that this mechanical procedure is protective in a rat model and might be feasible in human clinical trials.¹²³

Testis sperm extraction is reported to recover spermatozoa in 55–85% of men with nonobstructive azoospermia of various etiologies. Damani reported a series of men azoospermic after chemotherapy. Spermatozoa were found in 65%. A total of 26 ICSI cycles were performed in 12 couples. Fertilization rate was 65%. All babies born to date have had normal neonatal examinations.¹²⁴

Testicular tissue biopsy and cryopreservation is experimental, as is isolation of germ cells from testicular tissue for storage. Gonadal shielding remains the mainstay of protection from therapeutic radiation. No convincing studies to suggest benefit from scrotal cooling are currently available.

Protection for women

Reversible suppression of ovarian function by oral contraceptives or GnRH analog might offer gonadal protection to cycling women about to undergo potentially sterilizing radiation or chemotherapy. Some animal models have validated the hypothesis, both in protection from radiation and in chemotherapy-induced ovarian damage.¹²⁵ Results of such trials in humans have been conflicting, however, and the number of patients studied remains small. Most promising of these reports is that of Chapman and Sutcliffe, who administered oral contraceptives to women anticipating receiving MVPP therapy for HD. Five of six women had resumption of normal menses at a mean follow-up of 26 months.¹²⁶

Pacheco administered leuprolide acetate to 12 patients aged 15–20 anticipating treatment for lymphoma.¹²⁷ Suppression was continued monthly with depot administration until 1 month after cessation of chemotherapy. All 12 treated patients resumed normal menstrual cycling within 6 months, compared to none of the four women in this study who did not receive leuprolide suppression. Three pregnancies were reported. In a meta-analysis of six randomized controlled trials (RCTs) that examined reproductive outcomes among women with HD and ovarian and breast cancer, administration of GnRH analogs with chemotherapy was associated with a statistically significant increase in resumption of spontaneous menstruation and ovulation (OR 3.46 and 5.70, respectively).¹²⁸ Subsequent meta-analyses of RCTs exclusively among patients with breast cancer have yielded conflicting results regarding prevention of POF and spontaneous resumption of menses with GnRH agonists.^{129–131} In a large trial evaluating the effect of adjuvant chemotherapy in premenopausal women with node positive breast cancer (NSABP-B-30 trial), those with prolonged amenorrhea had better disease-free survival and overall survival.¹³² Thus, ovarian suppression in breast cancer patients for fertility preservation is controversial.

The highest live birth rates are reported following ovarian stimulation and embryo cryopreservation, and are therefore the best current option for women in stable relationships. Superovulation is required before fertilization, and neither the time required nor the hormone manipulation necessary may be acceptable. The implantation rates range from 8% to 30%. The cumulative pregnancy rate can be more than 60%.¹³³

Cryopreservation of ovarian tissue remains experimental but could be considered in women who require urgent cancer treatment. Ovarian cortical tissue also has the advantage of containing large numbers of follicles and thereby increasing the potential for successful future pregnancies. The ovarian tissue can ultimately be transplanted back in to the patient, thus restoring ongoing fertility. Transplanted tissue has been reported to restore normal menstrual cycling¹³⁴ and live births have been reported following orthotopic transplantation of cortical strips to the remaining ovary. In 114 Belgian women treated for various malignancies who underwent cryopreservation, a total of 49 spontaneous pregnancies in 33 patients and two induced pregnancies were reported after a mean follow-up of 50 months.¹³⁵ This

technique may ultimately offer an option for young girls as well as sexually mature young women. Recently, the Edinburgh selection criteria for identifying patients at risk for POF after gonadotoxic therapy was validated and may be useful in selecting patents for intervention.¹³⁶ Unresolved medical and ethical issues have fueled debate regarding these techniques.¹³⁷

For patients undergoing pelvic radiotherapy, oophoropexy can be considered. At the time of exploratory or staging laparotomy, the ovaries are moved either medially behind the uterine fundus or laterally out of the radiation port. Radiation exposure is decreased 90%, and hormonal function is preserved in 55–95% of patients; however, fertility is still compromised, possibly owing to the abnormal tubo-ovarian anatomy or radiation scatter. A small trial of laparoscopic propriosacral ovariopexy offers the possibility of a less invasive approach to fertility preservation.¹³⁸ One option in this setting is the transposition of only one ovary and removal of the second for cryopreservation.¹³⁹ Specific ovarian shielding may be useful in some cases.

Protection for children

No proven methods for protection of future fertility in children are available at this time. Some centers offer ovarian tissue or testicular tissue cryopreservation as an experimental approach, but research in this area is fraught with ethical problems. Many excellent reviews of the technical and ethical issues of fertility preservation are available ([Table 3](#)).^{127, 135}

Table 3 Options for preservation of fertility in patients with cancer

	Males	Status	Females	Status
Children	Testicular tissue cryopreservation	Unproven	Ovarian tissue cryopreservation	Unproven
Adults	GnRH analog	Unproven	GnRH analog suppression	? Effective
			OCP suppression	Unproven
	Sperm cryopreservation	Accepted	Oocyte cryopreservation	Experimental
	Testicular sperm extraction	Experimental	Ovarian tissue cryopreservation	Available
			Embryo cryopreservation	Available
			Ovarian tissue transposition	Experimental

Abbreviations: GnRH analog, gonadotropin-releasing hormone analog; OCP, oral contraceptives.

Outcomes of pregnancy

Chemotherapy

Case reports document successful conception and delivery of normal infants to patients who have received even the most aggressive of chemotherapy regimens; neither male nor female permanent infertility can be presumed following chemotherapy for cancer. Several retrospective series have evaluated the outcome of pregnancy in women treated with chemotherapeutic agents as children or young adults who completed therapy and then became pregnant.

One large study evaluating offspring of children treated for a variety of cancers found that in a total of 286 subsequent pregnancies there was no increase in congenital anomalies, and chromosomal analysis was normal in 23 of 24 children tested.¹⁴⁰ Pregnancies in women previously treated for trophoblastic tumors

also appear to have no associated increased risk of congenital anomalies, spontaneous abortions, or neonatal mortality.¹⁴¹

Holmes evaluated women treated for HD and compared the 93 pregnancies in their chemotherapy-treated patients to 288 sibling-control pregnancies. Overall, there was no difference between the groups, although when the subgroup that received both radiation therapy and chemotherapy was analyzed separately, it appeared that combined treatment produced more spontaneous abortions in wives of male patients, and those female patients were slightly more likely to produce abnormal offspring than control women.¹⁴²

Offspring of fathers treated with prior chemotherapy likewise appear to be normal. When large series are combined, nearly 1400 live-born children have been reported to have a congenital defect incidence of about 4%, not significantly different from the general population. Most of these anomalies represent common, nongenetic abnormalities.¹⁴²

Further follow-up suggests that offspring growth, development, and school performance are probably normal. A National Cancer Institute study to address the question of cancer in offspring of treated patients found a slight and statistically insignificant excess of cancers in these children when compared to offspring of sibling-matched controls (0.3% vs 0.23%), numbers not different from those expected in the general population. When analyzed by age and sex, however, it appeared that there was an excess of cancers diagnosed in male offspring under age 5.¹⁴³

Risk to the fetus exposed *in utero* to chemotherapy agents depends on gestational age and the drug and dose administered. Folate antagonists should not be administered during the first trimester. Other antimetabolites have rarely been associated with congenital abnormalities. First trimester exposure to 5-fluorouracil, cyclophosphamide, busulfan, and chlorambucil has been associated with low birth weight in infants and other abnormalities on rare occasion.¹⁴⁴ Fetal myocardial necrosis has been reported following maternal administration of anthracyclines.¹⁴⁵ Imatinib has demonstrated teratogenicity in animal models, but case reports have documented successful pregnancies in women who conceive during treatment.¹⁴⁶ Rituximab given unintentionally to a pregnant woman resulted in an uncomplicated pregnancy delivering an apparently healthy infant. Interferon- α has been given safely during pregnancy in a small number of women.¹⁴⁷

Whether the risk to the fetus is further increased with drug combinations is uncertain. Case reports and small series indicate that exposure in the second and third trimesters is associated with minimal risk to the fetus and that long-term development of these offspring is normal.^{148, 149} Nonteratogenic effects including low birth weight, intrauterine growth retardation, and more subtle developmental abnormalities remain to be defined. *In utero* exposure to diethylstilbestrol has been linked to the development of genital clear cell carcinomas in the female offspring of these women, but other clear documentation of carcinogenesis from *in utero* exposure to chemotherapy is lacking. No information is available on the reproductive potential of these children.

Radiation therapy

Most of what is known about the genetic effects of radiation therapy is inferred from data on survivors of atomic bomb exposure. The increase in untoward outcomes of pregnancies (major congenital defects, stillbirth, and death during the first week of life) is small, estimated at 0.00182/gonadal rem (roentgen-equivalent-man)—the quantity of any ionizing radiation equivalent to the biologic effect of 1 rad (cGy).

Among women treated with radiation therapy below the diaphragm, preterm delivery in up to 20% of pregnancies and an excess of low birth-weight infants have been reported. That these adverse outcomes

are often clustered in the first posttreatment year suggests they may result from local uterine or hormonal factors and may not be because of genetic defects.^{46, 150}

In utero exposure to irradiation produces the greatest risk of teratogenesis during the period of organogenesis from the second to the eighth week, with growth retardation, eye problems, and microcephaly appearing as the predominant abnormalities. A safe dose has not yet been defined, but generally, a therapeutic abortion is recommended for any uterine dose of 10 cGy during the first trimester. Supradiaphragmatic irradiation is associated with considerable scatter to the fetus, much of which can probably be prevented with abdominal shielding. Local irradiation of the neck and axilla may be safe during the first trimester.¹⁴⁴

Psychosocial issues

The psychosocial issues of disfigurement, loss of fertility, anxiety about birth defects, sexual performance, and recurrence of tumor all have important impacts on the unmarried patient facing dating and mate-selection issues, as well as on married patients in a stable relationship, for whom the separation rate may be fourfold of that of the general population.^{46, 149, 150} Detailed discussion of these important issues is beyond the scope of this publication, but excellent reviews are available for the interested reader seeking further information.^{42, 149, 151–155}

For physician assessment of sexual functioning, Andersen has proposed a model that helps the provider address many issues before they arise.⁴²

Summary

- Gonadal dysfunction is related to drug-dose and is age-related
- Younger patients are more likely to preserve fertility
- Alkylating drug therapy causes damage in all age groups
- Children of both genders enter puberty normally after chemotherapy
- Traditional endocrine measures of gonadal toxicity are insensitive
- Alkylating drugs appear to be the most toxic; procarbazine particularly
- Many cytotoxic drugs are not well-studied
- ABVD for HD should replace MOPP if possible for young patients with HD
- Perimenopausal women with breast cancer are likely to become menopausal with chemotherapy
- New agents have theoretical risks but are not well-studied
- Risks to fertility should be part of chemotherapy consent discussion
- Proven options to preserve fertility in men are limited to semen cryopreservation
- Many men with HD or testicular tumors are oligospermic at presentation
- Oligospermia should not prevent cryopreservation
- New and effective options to preserve fertility in women are under development

- Fetal exposure to most chemotherapy agents is safe after the first trimester
- Outcomes of pregnancy during chemotherapy are good
- Outcomes of pregnancy after childhood chemotherapy are normal
- Early fetal exposure to folate antagonists must be avoided

Chapter 137

Sexual dysfunction

Leslie R. Schover, PhD

Overview

Sexual problems related to cancer are usually caused by physiological damage from treatment, but are exacerbated by psychosocial issues such as poor communication, relationship conflict, or preexisting sexual dysfunction. Sexual dysfunction affects almost two-thirds of the estimated 14 million cancer survivors in the United States, including over 50% of those treated for pelvic or breast cancers and at least 25% for other sites. Optimal treatment is multidisciplinary, addressing both physical damage and coping skills. If a committed relationship exists, it is best to include the partner in education and intervention.

Historical perspective

Sexual dysfunction has been recognized as a morbidity of cancer treatment since the 1950s. Early publications focused on mutilating surgery for breast cancer, impaired body image, and loss of feminine identity.¹ Research later revealed that systemic therapy plays a much greater role in sexual morbidity than local treatment of the breast.²

By the 1980s, radical pelvic surgery was redesigned to spare autonomic nerves responsible for penile blood flow.³ However, nerve-sparing radical prostatectomy resulted in a return to baseline erectile function in less than 25% of men.⁴ More recently, robotic-assisted laparoscopic prostatectomy (RALP) has claimed to increase the accuracy of nerve-sparing and enhance recovery of normal erections. Although RALP shortens hospital stays and decreases acute complications, two large studies using Medicare and Surveillance, Epidemiology, and End-Results (SEER) databases found no advantage over open surgery in preserving sexual function and a disadvantage in urinary incontinence.^{5,6}

Attempts to minimize sexual consequences of pelvic radiotherapy began with the introducing brachytherapy⁷ or computerized three-dimensional conformal fields for external beam treatment.⁸ Long-term preservation of sexual function again proved disappointing, as did later efforts using intensity-modulated radiation therapy or proton beams.^{8,9}

In the 1980s, sexual function began to be considered in women with gynecological malignancies.¹⁰ As in men, attempts were made to spare nerves and tissues contributing to sexual pleasure and function during surgery or adjuvant radiation therapy.⁹ However, premature ovarian failure and exacerbation of vulvovaginal atrophy by pelvic radiotherapy were increasingly recognized as risk factors for sexual dysfunction.¹¹ Techniques from cognitive behavioral sex therapy, a short-term, action-oriented type of psychological treatment¹² were used with male and female cancer patients, including efforts to enhance relationship satisfaction and sexual communication.¹³

Nevertheless, fewer than 20% of cancer patients/survivors currently seek help when they have a sexual

problem.^{14, 15} Few cancer centers offer treatment for sexual problems and sexual dysfunction remains a long-term unmet need for cancer survivors.^{16, 17}

Although recognition of cancer-related sexual problems began in the 1950s, most men and women still do not seek professional help for their dysfunctions and attempts to modify cancer treatment to spare sexual function have been disappointing.

Incidence and epidemiology—local and worldwide

About 59% of an estimated 14 million male cancer survivors in the United States, and 66% of women were treated for pelvic or breast tumors¹⁸ with at least a 50% prevalence of long-term, severe sexual dysfunction.¹⁹ Sexual problems affect at least 25% of survivors of treatment for nonreproductive cancers, including hematologic malignancies²⁰ and cancers of childhood.^{21, 22}

Given comparable prevalence and types of cancer in Europe and other industrialized nations, the risk for sexual dysfunction is similar.²³ Little information is available on sexual consequences of cancer in countries with low medical resources, but cancers potentiated by the human immunodeficiency virus (HIV) and the human papillomavirus (HPV) such as cervical, vulvar, anal, and penile cancer are more common, with a high likelihood of sexual morbidities.²⁴ The diagnosis can lead to divorce and ostracism in rural areas where cancer is stigmatized.²⁵

Sexual problems related to cancer are severe and generalized, including loss of desire for sex or ability to get aroused and reach orgasm, and interference from fatigue, pain, or incontinence.¹⁹ Without professional treatment, most problems do not resolve with time. Most dysfunctions are caused by cancer treatment,¹⁹ including damage to autonomic nerves in the pelvis, reducing genital blood flow during sexual arousal,^{3, 4} especially for men,²⁶ and direct damage to genital blood vessels and tissue from pelvic radiation therapy.⁹ Male erectile dysfunction also results from decreased genital blood flow after surgical interruption of blood vessels²⁷ or radiation damage.⁹ Without regular inflow of oxygenated blood, erectile tissue in the penis atrophies. As a result, too much blood drains into the venous system, limiting erectile rigidity.²⁷

Although the vagina expands and the clitoris swells with sexual arousal in women,²⁸ damage to hemodynamics is poorly understood. It is clear that estrogen deprivation plays a major role in female sexual problems,^{19, 29, 30} decreasing the lubrication produced during sexual arousal by the vaginal mucosa. With vulvovaginal atrophy, sexual caressing and penetration become painful, often leading to loss of desire to engage in sex and difficulty reaching orgasm.³¹

In both men and women, loss of desire frequently ends with avoiding sexual encounters.¹⁹ Low androgen levels are sometimes a factor in loss of desire for men, for example, during anti-androgen therapy for prostate cancer,³² after intensive chemotherapy,³³ or after radiation that damages the testes.³⁴

Toxicity from cancer treatment leads to severe and long-term sexual dysfunction affecting desire, arousal, orgasm, and pain.

Risk factors—premorbid sexual function, cancer treatments, and behavioral characteristics

Many people have sexual problems before their cancer diagnosis, especially men. Erectile dysfunction is

strongly associated with age-related cardiovascular disease, hypertension, diabetes, smoking, sedentary lifestyle, and obesity.^{35, 36} Erectile dysfunction is the most common reason that aging couples stop having sex.³⁷ At least half of women over age 50 are no longer sexually active because of lack of a functional sexual partner.³⁸ Being sexually active and functional at cancer diagnosis increases distress about new sexual problems in men and women.^{39, 40}

Cancer treatments with a high risk of sexual dysfunction include intensive chemotherapy, total body irradiation, graft versus host disease after allogeneic transplant,⁴¹ treatments leading to abrupt ovarian failure in premenopausal women,³⁰ pelvic radiation therapy,⁹ radical pelvic cancer surgery in men,^{4-6, 42} chemoradiation for pelvic tumors,⁴³ anti-androgenic therapy for prostate cancer,³² and aromatase inhibitors for breast cancer.⁴⁰ Although penile and vulvar cancers are rare in Western nations, radical surgery removing major areas of genital tissue obviously also causes problems.^{44, 45} Vaginal reconstruction for advanced cervical or rectal cancer often fails to restore women's sexual pleasure.⁴⁶

Psychosocial or behavioral factors also contribute to cancer-related sexual problems. Patients with a history of sexual abuse or trauma may have difficulty coping with cancer treatment, especially if the malignancy is in the reproductive system.⁴⁷ Relationship conflict and poor communication is also associated with poor sexual outcomes.⁴ Traditional beliefs on masculinity and suppression of emotion may contribute to deterioration of sexual function after treatment for prostate cancer.⁴⁸ Both men and women scoring high on neuroticism, a personality trait involving depression and anxiety, have higher rates of sexual problems after cancer.^{49, 50}

Prevention—surgical, medical, behavioral

Modifications of cancer surgery to prevent sexual dysfunction have included sparing autonomic nerves near the prostate,³⁻⁶ not only during radical prostatectomy but also in radical cystectomy or surgery for colorectal cancer.^{42, 51} Enhancement has had limited results, as has avoiding damage to accessory arteries to the penis during pelvic surgery.⁵² Animal research and theoretical models support penile rehabilitation after surgery, using treatments for erectile dysfunction to promote penile blood flow, but benefits on recovery of erections in humans are unclear.²⁷ Nerve-sparing in radical hysterectomy has little impact on female sexual function.²⁶ Tissue-sparing surgery has been used instead of partial penectomy to treat localized penile cancer⁴⁴ or substituted for radical surgery in women for vulvar cancer,^{45, 53} but a majority of patients still have major sexual problems. Breast conservation or reconstruction also has few advantages over mastectomy in preserving women's sexual pleasure and desire.²

Cancer treatments that preserve ovarian function in younger women, such as conservative surgery for low-grade ovarian cancer⁵⁴ or local therapy alone for ductal carcinoma *in situ*,⁵⁵ leave most women with normal sex lives. Intensive chemotherapy increases sexual dysfunction in both men³³ and women,⁵⁶ but less toxic regimens rarely achieve equivalent survival benefits. One exception is treating early-stage Hodgkin lymphoma with nonalkylating chemotherapy.⁵⁷ The trend toward personalized medicine and use of biological response modifiers may eventually lessen sexual morbidity, but little information is yet available on their sexual side effects.

Behavioral strategies may help prevent cancer-related sexual problems. Staying sexually active or stretching genital tissues with vacuum erection devices or vaginal dilators may prevent atrophy.^{27, 58, 59} Counseling that promotes more open sexual communication, and continued, noncoital sexual intimacy, certainly may prevent a loss of satisfaction within a couple's relationship or a reduction in sexual self-

Risk factors for sexual dysfunction after cancer include:

- Intensive chemotherapy
- Radiation damage to the gonads or genitals
- Hypogonadism due to cancer treatment
- Removal of areas of genital tissue
- History of sexual trauma
- Relationship conflict
- Personality factors such as neuroticism or traditional gender beliefs

Prevention may include:

- More conservative cancer surgery
- Less toxic chemotherapy
- Using behavioral strategies to preserve genital tissue or promote intimacy

Screening

Patients should be screened for sexual concerns and problems across the continuum of cancer care. During treatment planning, potential damage to sexual function from cancer treatment should be explained, including a mention of any conservative treatments. Although most patients rank survival over sexuality, a few would risk poorer cancer control for a treatment that would preserve sexual function. During treatment and at follow-up visits, sexual function should be monitored, at least with a periodic question, for example: “Sexuality is one important part of quality of life. Do you have any questions or concerns today about changes in your sex life since your cancer treatment?” In a study of patients in palliative care, about half wanted to continue sexual activity, despite a very high prevalence of sexual problems.⁶² In 2013, a new National Comprehensive Cancer Network survivorship guideline recommended systematic screening for sexual dysfunction by interview or questionnaire, followed by further evaluation and referrals for treatment. Although the guideline was categorized under survivorship, it includes patients at any point of care.⁶³

A brief questionnaire can be used to screen for sexual dysfunction. The National Cancer Institute sponsored creation of the Patient-Reported Outcomes Measurement Information System (PROMIS) Brief Sexual Function profiles for men and women. These multiple choice questionnaires with 8 and 10 items, respectively, can be administered as an entire scale or using computer adaptive software, only by asking relevant items.⁶⁴

Diagnosis

Because sexual dysfunction is most typically measured by self-report, diagnostic nomenclature has been varied and controversial.⁶⁵ Many labels do not help clinicians in choosing evidence-based treatments for problems. It is helpful to categorize sexual problems as affecting the following:

- ability to desire sex and experience subjective arousal

- ability for the genitals to engorge with blood during sexual arousal (i.e., erection in men and vaginal lubrication and expansion in women)
- ability to experience a satisfying orgasm
- problems with pain interfering with sexual pleasure
- urinary or fecal incontinence during sex

Most people treated for cancer have more than one specific sexual problem. For example, a woman who had chemoradiation for localized cervical cancer may have vulvovaginal atrophy and vaginal stenosis, causing dryness and acute pain with sexual caressing or penetration. As a result, her desire for sex and ability to reach orgasm are also impaired. A man may be unable to get or keep firm erections after radical prostatectomy. Urine may also drip from his penis with arousal and at orgasm. If he uses a medical treatment for erections, he may realize that his penis has shrunk in size or developed a curvature.⁶⁶ These problems lead him to avoid sex.

Taking the time to elicit a full description of the patient's sexual problems remains the most important aspect of diagnosis. For women, a pelvic examination with attention to pain and atrophy on the vulva and inside the vagina is crucial.⁶⁷ For men with erectile dysfunction, urologists may conduct a color duplex ultrasound imaging studies of the penis, before and after injecting drugs to create an erection.⁶⁸ Such testing may identify venous insufficiency due to atrophy of the erectile tissue, which can limit the efficacy of oral medication or penile injection therapy. However, many urologists prescribe treatments empirically for erectile dysfunction, starting with oral medication and proceeding if necessary to penile injection therapy, a vacuum device, or a urethral suppository, with a penile prosthesis as the final step.⁶⁹ In many aging men, cardiovascular disease complicates the treatment of cancer-related sexual problems.⁷⁰

Screening and diagnosis should be multidisciplinary, using brief questionnaires, a careful interview, and relevant focused examinations to get a full picture of the type of problem and its medical and psychosocial causes.

Prognostic factors

Only a few prognostic factors for sexual rehabilitation have been identified. Men or women who were not sexually active before cancer diagnosis are unlikely to seek help after cancer, unless they had previously sought treatment for their problems.^{37, 40} Younger men who start out with normal erections are more distressed and likely to seek help after surgery for prostate cancer.⁷¹ Having a partner who still enjoys sex is also crucial.⁷² For women, being in a sexual relationship is key to help-seeking.⁴⁰

Poor general and sexual communication are barriers to success with cognitive-behavioral treatment of sexual problems.¹³ In fact, couples with troubled relationships are less likely to enter clinical trials of sexual counseling.^{73, 74} Research on treatment outcomes is not available for people who are single or in a same-sex relationship.^{75, 76}

Since research focuses on medical or counseling treatments that are short term, it is not surprising that barriers to success include a history of sexual problems, lack of a motivated partner, and poor sexual communication.

Multidisciplinary care

Research suggests that a multidisciplinary approach, combining medical and psychosocial care, is the most effective for cancer-related sexual problems.^{72, 74} [Table 1](#) lists common sexual problems and suggested treatment components. Resuming a satisfying sex life requires good communication,^{104, 105} acceptance that intimacy may include noncoital sexual stimulation,^{72, 74, 104} and ability to cope with some “performance” limitations. On the other hand, intervention programs using brief counseling without any medical treatments may reduce distress about sexual problems or improve sexual satisfaction somewhat, but do not resolve sexual dysfunction.^{72, 105, 106}

Table 1 Components of multidisciplinary care for common, cancer-related sexual problems in men and women

Sexual problem	Patient education	Brief sexual counseling	Physiological treatments
Male low desire	Problem often multifactorial, not simply hormonal (shame about erections, fatigue, medications, poor body image)	Help with loss of masculine self-esteem, poor body image, relationship conflict	Androgen replacement only if hypogonadal, ^{33, 34} controversial after prostate cancer; ⁷⁷ change medications that may contribute
Erectile dysfunction	Aging, premorbid risk factors, and cancer treatment all can damage erections	Help with decision-making on medical treatments; inclusion of partner; help with sexual communication to increase adherence ^{14, 78}	PDE5 inhibitors, vacuum erection devices, penile injection therapy, urethral suppositories; ⁷⁸ penile prosthesis surgery ⁷⁹
Changes in orgasmic pleasure	Cancer treatment may lead to orgasms without erection or ejaculation, weakened orgasmic sensation, inability to reach orgasm (central nervous system damage) ⁶⁶	Relearn how to reach orgasm, or intensify sensations, use of vibrators or erotica ⁸⁰	Treatment of hypogonadism or hyperprolactinemia, change medications that can interfere with orgasm ^{80, 81}
Premature ejaculation	Erectile dysfunction can be misperceived as premature ejaculation if need prolonged stimulation to get an erection and then ejaculate quickly	Sex therapy techniques such as stop-start or squeeze ⁸⁰	Oral medication, though not very effective; ⁸⁰ treatment for erectile dysfunction may correct problem ⁸⁰
Penile curvature	Cancer treatment can create penile curvature, understand timeline of pain with erection and changes in curvature ⁸²	Counseling about depression and body image issues	Use medical treatments to reduce curvature; surgical correction of curvature with or without penile prosthesis ⁸²
Pain during sex	Causes of genital pain during sex and interference with sex from chronic	Sensate focus exercises or mindfulness to focus on sexual pleasure and away	Treat chronic nongenital pain with medication or other modalities; medical treatments

	nongenital pain	from pain ⁸³	for pain at orgasm or testicular pain ^{84, 85}
Incontinence during sex	If has stoma, consult with specialty nurse on minimizing interference with sex; urinary incontinence common after radical prostatectomy	Counsel on coping with incontinence during sex, use of mattress pads and other aids	Oral medications or penile tension loop to prevent urinary leakage during sex; ⁸⁶ collagen injections; ⁸⁷ surgery to insert artificial sphincter; ⁸⁸ control of fecal incontinence using diet and medication ⁸⁹
Female low desire	Understanding that problem often multifactorial, not simply hormonal ⁹⁰	Help with poor body image, relationship conflict, coping with history of traumatic sexual experience, ⁴⁷ coping with chronic fatigue and life stress	Treatment for pain that may lead to avoidance of sex; ^{67, 74} changing medications that may contribute; ⁹⁰ androgen replacement rarely helpful and may increase breast cancer risk ⁹¹
Vulvovaginal dryness and pain with sex	Vulvovaginal atrophy is common after normal menopause and more severe after some cancer treatments ^{67, 74}	Counseling on medical treatment options and on better sexual stimulation and communication to maximize sexual arousal, positions for penetration that may help avoid pain ^{67, 80, 92}	Regular use of vaginal moisturizers and water- or silicone-based lubricants during sexual activity; ^{67, 74} use of graduated vaginal dilators; ^{59, 93} low-dose vaginal estrogen if cancer is not hormone sensitive; ⁹⁴ ospemifene ⁹⁵
Difficulty reaching orgasm	Women normally reach orgasm more easily with clitoral stimulation, genetic contribution to ease of reaching orgasm ⁹⁶	Training on reaching orgasm with self-stimulation or vibrator; transition to partner sex ⁹⁷	Change in medications that can interfere with orgasm ^{81, 97}
Incontinence during sex	If has stoma, consult with specialty nurse on minimizing interference with sex; urinary incontinence commonly interferes with sex; ⁹⁸ fecal incontinence frequent after pelvic radiation ⁹⁹	Behavioral bladder training and pelvic floor therapy ¹⁰⁰	Use of oral medications ¹⁰¹ or bulking agents ¹⁰² to prevent urinary leakage; sacral neuromodulation for neurogenic or overactive bladders; ¹⁰³ control of fecal incontinence using diet and medication ^{89, 99}

Unfortunately, specialty clinics that include a psychologist and physician providing integrative treatment are rare even at comprehensive cancer centers. Mental health professionals trained in psychooncology typically lack expertise in treating sexual dysfunction. Most sex therapists have little knowledge about cancer and its treatments.

Psychosocial factors and management

In addition to the psychosocial factors already mentioned, a clinician should also assess the influence of culture,²⁵ sexual orientation,^{75, 76} ethnicity,^{107–109} and religion on sexual issues. Good treatment outcomes are unlikely if interventions are incompatible with patients' sexual attitudes.

Survivorship and follow-up

Continued assessment of sexual problems and referral for treatment is important during survivorship, particularly given the long-term nature of cancer-related sexual dysfunction.

Unmet needs, future directions, and conclusions

Although sexual problems have often been dismissed as an unfortunate, but minor side effect of cancer treatment, they affect 25–50% of cancer survivors and have negative impacts on quality of life. Improvements are needed in the availability of cost-effective solutions for assessment, patient education, and multidisciplinary care. For patients with reasonable levels of literacy, education and self-help tools can be provided in high-quality, online interventions.^{72, 74} Patients from underserved communities may need additional guidance from peer counselors¹⁰⁸ or patient navigators. When first-line interventions do not resolve sexual problems, a stepped care approach can be used to refer patients for more intensive treatment.

Chapter 138

Endocrine complications and paraneoplastic syndromes

Sai-Ching Jim Yeung, MD, PhD, FACP ■ Robert F. Gagel, MD

Overview

Transformation of normal cells results in activation and/or suppression of a number of hormonally active genes. This chapter outlines the several clinical endocrine paraneoplastic syndromes and their appropriate management. Treatment of cancer results in a number of endocrine or metabolic manifestations, most of which are related to hormone deficiency or drug-related toxicity. The introduction of targeted therapy that disrupts signaling pathways and immunotherapy, contrary to expectations, has actually increased the number of endocrine manifestations. This chapter will chronicle the major new endocrine toxicities in addition to those observed with older cytotoxic chemotherapies and radiation.

Introduction

This chapter is divided into two major sections. The first focuses on endocrine complications in cancer patients and the second on endocrine paraneoplastic syndromes. Cancer and its treatment can lead to endocrine dysfunction or clinical and laboratory abnormalities that obscure or mimic endocrine diseases. Paraneoplastic syndromes are a group of diverse clinical syndromes seen in cancer patients caused by circulating biologic/humoral factors that include hormones, immunoglobulins, cytokines, and other agents.

Endocrine complications

Hypothalamic–pituitary dysfunction

Radiotherapy is a common cause of hypothalamic–pituitary dysfunction in cancer patients. There is no strong direct evidence to implicate chemotherapy as a cause of permanent dysfunction of the anterior pituitary, although some of the newer targeted therapies may affect pituitary function. Metastasis to the hypothalamic region or the pituitary gland is uncommon,¹ and clinical manifestations of endocrine dysfunction because of metastatic disease in this region are rare. However, benign tumors such as pituitary tumors and craniopharyngiomas frequently affect this anatomic region and cause endocrine dysfunction. The introduction of immunotherapy by immune checkpoint blockade [anti-CTLA4 antibodies (ipilimumab and tremelimumab) and anti-PD-1 antibody (nivolumab)] has been associated with development of autoimmune hypophysitis that requires hormonal replacement (corticosteroids or thyroid hormone) in 2–3% of treated patients.

Development of radiation-induced hypothalamic dysfunction is insidious; hormonal deficiency can manifest years after radiation. In general, the rapidity of onset and severity of dysfunction depend on the total dose of radiation and the rate of delivery. The sequence and frequency of dysfunction among the axes of hypothalamic–pituitary functions vary. The somatotrophic axis is the most susceptible, while the

thyrotropic axis is the least susceptible ([Figure 1](#)).^{2–5} The diagnosis of hypothalamic–pituitary dysfunction requires vigilance of the physician because most presenting symptoms (e.g., fatigue and weakness) are nonspecific and attributable to other causes common among cancer patients. A diagnostic screen for hypothalamic/pituitary dysfunction may include serum growth hormone (GH) and insulin-like growth factor-1 (IGF-1) measurement and evaluation for gonadal failure. Signs of overt hypopituitarism include hypoglycemia, hypotension, and hypothermia.

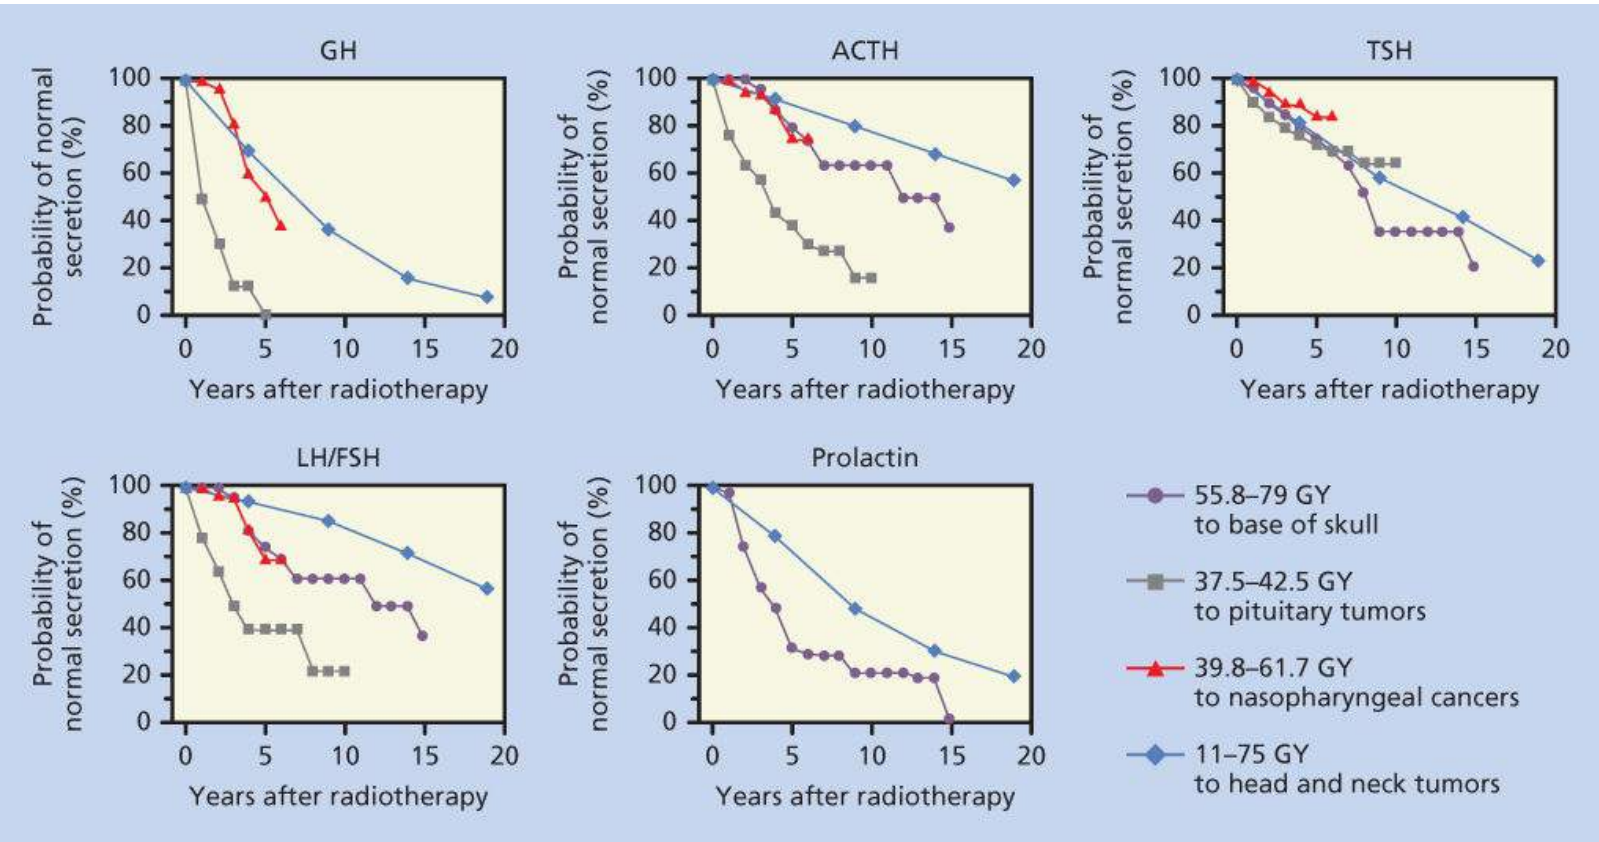

Figure 1 Probability of normal pituitary hormone secretion over time after radiation exposure to the hypothalamic–pituitary areas. Data from four studies were replotted on this single figure. The first set of values (*closed circle*) are from Pai et al.,³ where the patient received 55.8–79 Gy to the base of the skull. The second set of values (*solid square*) are from Shalet et al.,⁸³ where patients with pituitary tumors were treated with 37.5–42.5 Gy. The third series (*open triangle*), from Lam et al.,² shows the effect of radiation treatment for nasopharyngeal carcinoma with 39.8–61.7 Gy. The final series (*open diamond*) represents data from Samaan et al.,⁴ in which 11–75 Gy was administered to treat head and neck tumors.

In children and adolescents, evaluation of sexual development is a useful diagnostic tool. Staging sexual development according to Tanner's criteria, menstrual history in girls and penile/testicular size in boys should be evaluated. In children who have had cranial irradiation, height and weight should be measured every 6 months. In children treated with spinal and craniospinal irradiation, local rather than general growth abnormalities may be present and, if so, require specific evaluation. Foot size is a reliable indicator of growth that can be easily measured. Deviation from normal growth curves should be evaluated for GH deficiency, hypothyroidism, and adrenal insufficiency. If the initial evaluation of GH, IGF-1, thyrotropin (TSH) and free thyroxine (T₄) levels, and radiographic bone age reveal abnormality, then detailed dynamic testing to evaluate the hypothalamic/pituitary axes should be performed ([Table 1](#)).

Table 1 Dynamic testing of the hypothalamic/pituitary axes

Test	Dose/sampling	Contraindications
------	---------------	-------------------

Growth hormone axis

Insulin hypoglycemia	0.075–0.1 U regular insulin/kg IV to achieve glucose \leq 40 mg/dL. Sample for glucose and GH at 0, 30, 45, 60, and 90 min	Coronary heart disease or seizures
Arginine	0.5 g/kg (up to 30 g) IV over 30 min. Sample for GH at 0, 30, 60, 90, and 120 min	Liver disease or renal disease
L-Dopa	500 mg by mouth. Sample for GH at 0, 30, 60, 90, and 120 min	Systolic blood pressure $<$ 100 mm Hg or age $>$ 60 years
Arginine and GHRH	Arginine dose as above. GHRH 1 μ g/kg IV push. Sample for GH at 0, 30, 60, 90, and 120 min	Liver disease or renal disease
Clonidine stimulation protocol	Clonidine 0.15 mg/m ² by mouth. Collect GH samples at baseline, 30, 60, 90, and 120 min	
Growth hormone-releasing hormone (GHRH) stimulation protocol	GHRH at 1.0 μ g/kg body weight IV push. Collect GH samples at baseline, 15, 30, 45, 60, 90, and 120 min	
Growth hormone suppression test	The test should be performed after an overnight fast with the patient maintained at bed rest. The patient should drink a solution of 100 g glucose. Collect GH samples at baseline, 60, and 120 min	

Adrenal axis

ACTH stimulation test, 1-h	Synthetic ACTH 1–24 1 or 250 μ g IM or IV. Draw blood for cortisol at 30 and 60 min after injection	
ACTH stimulation test, 48-h	Beginning at 9 a.m., obtain baseline 24-h urine for 17-hydroxycorticosteroids (17-OHCS) and creatinine. Collect 24-h urine as on day 1. Beginning at 9 a.m., start IV and give 250 μ g synthetic ACTH 1–24 in 250 mL normal saline over 8 h every 8 h for 48 h. Alternatively, 40 IU of depot formulation of purified bovine ACTH in gelatin IM every 12 h for 48 h. Repeat 24-h urine as on days 1 and 2 Days 4 and 5: Collect 24-h urine as on previous days	
Corticotropin-releasing hormone (CRH) stimulation test	Fast for at least 4 h before the test. Human CRH at 1.0 μ g/kg IV bolus over 30 s. Blood samples should be collected at 15 and 1 min before CRH administration and at 15, 30, 45, 60, 90, and 120 min after for measurements of cortisol and ACTH	
Low-dose dexamethasone	Dexamethasone 1.0 mg (adult) or 20 μ g/kg (children) PO between 11 p.m. and midnight. Serum cortisol is collected at 8–9 a.m. the	

test, overnight	next morning. A cortisol level <1.8 µg/dL essentially excludes Cushing syndrome	
Low-dose dexamethasone test, 48-h	Serum cortisol is collected at 8–9 a.m. Dexamethasone 0.5 mg (adult) or 10 µg/kg (children) PO immediately after the cortisol is drawn and again every 6 h for 48 h. A second plasma cortisol is drawn at 9 a.m., 6 h after the last dexamethasone dose. Serum cortisol concentrations <1.8 µg/dL exclude Cushing syndrome	
High-dose dexamethasone test, 48-h	Serum cortisol is collected at 9 a.m. Dexamethasone is administered (2.0 mg; 50 µg/kg in children) every 6 h for 48 h. A second plasma cortisol is drawn at 9 a.m., 6 h after the last dexamethasone dose. Patients with functional adrenal adenomas show no suppression of cortisol levels in the 48-h sample relative to the initial (baseline) sample. Seventy-eight percent of patients with pituitary source of excess ACTH showed >50% suppression of plasma cortisol, while only 11% of patients with an ectopic source of excess ACTH had a >50% suppression	
Comprehensive, 6-day, low-/high-dose dexamethasone test	This protocol incorporates the low- and high-dose dexamethasone tests in succession. 24-h urinary free cortisol and/or 17-hydroxycorticosteroid (17-OHCS) measurement can help verify the results of serum cortisol and ACTH	
Gonadotropin-releasing hormone (GnRH) stimulation test	GnRH 100 µg IV. A sample for serum LH should be collected at baseline and 40 min after GnRH administration	
Metyrapone stimulation (overnight) test	At 11 p.m., metyrapone 30 mg/kg (maximum 3 g) PO with a snack. On the following morning, at 8 a.m., measure serum cortisol and 11-deoxycortisol	

GH = growth hormone; GNRH = growth hormone-releasing hormone; IV = intravenous; IM = intramuscular; PO = by mouth.

In adults who have received cranial or head and neck irradiation, detection of hypothalamic–pituitary abnormalities is more challenging. One strategy to detect hypothalamic–pituitary abnormalities in adults consists of routine screening for GH deficiency and gonadal failure. It is recommended that measurements of IGF-1 and testosterone levels in males and documentation of menstrual history in females be obtained annually for 5 years, and then at 5-year intervals for another 10 years. Any abnormalities noted on the screening tests should be pursued with further dynamic testing to evaluate all the axes of hypothalamic–pituitary functions.

Immunotherapy-induced hypophysitis

The development of immunotherapeutic approaches to treat melanoma and a growing list of other malignancies has resulted in a number of bystander effects. Prominent among these side effects is immunotherapy-induced hypophysitis (IH). In the phase III clinical trial of ipilimumab, 2.3% of patients developed symptoms of IH and evidence of hormonal deficiency including glucocorticoid, thyroid, gonadal, and GH deficiency, necessitating long-term replacement therapy. The pituitary-related events

were grade 3 or 4 in 1.9% of these patients, necessitating urgent treatment or hospitalization. The onset of pituitary failure ranged from 11 to 19 weeks, following initiation of ipilimumab therapy. Common presenting complaints include headache, mental status alterations, abdominal pain, modified bowel habits, and hypotension; it is often difficult to distinguish IH from brain metastasis or symptoms associated with widespread metastatic disease. This difficulty suggests that clinicians initiating therapy with immunotherapy agents should obtain baseline thyroid (free T₄ and TSH), adrenal (ACTH, adrenocorticotrophic hormone and 8 a.m. serum cortisol), gonadal [luteinizing hormone (LH), follicle-stimulating hormone, and estradiol in females or testosterone in males], and growth-related hormones (GH and IGF-1) as baseline before initiating therapy. These measurements should be repeated if a patient develops symptoms suggestive of endocrine deficiency or acute symptoms of hypophysitis (headache and visual disturbance). In patients with symptoms or physical findings consistent with IH, an MRI (magnetic resonance imaging) of the pituitary gland and repeat hormone testing as described above should be performed together with dynamic testing of the adrenal endocrine axis (e.g., low-dose cosyntropin stimulation test). A recent report highlighting a larger experience in a single center indicates that IH is observed not only with anti-CTLA4 agents (ipilimumab and tremelimumab),⁶ but also with an anti-PD1 agent (nivolumab). In a report describing 968 patients treated with these agents for melanoma, prostate cancer, and renal cell carcinoma at a single center, 2.7% (27 subjects) had one or two hormonal deficiencies together with either pituitary enlargement in MRI scans or headache.⁶ In these 27 patients, central adrenal deficiency was identified in 77%, central hypothyroidism in 89%, and central hypogonadism in 79%. An abnormality of the pituitary gland was found by MRI in 85%.⁶ After a median follow-up period of 17 months (range: 1–76), none of the patients recovered normal adrenocortical function, whereas 12–13% recovered thyroid or gonadal function. Clearly, this is a significant and evolving issue; it is unclear at this time whether combinatorial therapy with two or more immunotherapeutic agents, currently under development, will be associated with higher incidence and/or severity of toxicity.

Thyroid disorders

Thyroid disorders and abnormalities in thyroid function are commonly associated with cancer and its therapy.

Serum thyroid hormone-binding protein abnormalities

The levels of thyroid hormone-binding proteins [thyroxine-binding globulin (TBG), prealbumin, and albumin] can be modified by sex hormone levels and nutritional factors; abnormalities of both are encountered frequently in cancer patients. Several chemotherapy drugs affect thyroid function test results. L-Asparaginase appears to reversibly inhibit synthesis of albumin and TBG, resulting in low total thyroxine (T₄), but normal free T₄ levels.⁷ The combination of podophyllin and alkylating agents has also been reported to decrease TBG.⁸ Both 5-fluorouracil⁹ and mitotane¹⁰ increase the total T₄ and triiodothyronine (T₃) levels without suppressing TSH, suggesting that these drugs increase thyroid hormone-binding capacity in the serum.

Euthyroid sick syndrome

Alterations in thyroid hormone metabolism occur in patients with cancer and other serious systemic illnesses.¹¹ Low serum T₃ levels, which may be found in up to 70% of moderately to seriously ill cancer patients, are caused by a decrease in the extrathyroidal conversion of T₄ to T₃. Serum concentrations of

free T₄ are usually normal or high, while concentrations of free T₃ are below normal or low. The patients are clinically euthyroid, and serum TSH level and TRH stimulation test results are normal.

In most patients with euthyroid sick syndrome, T₃, T₄, and TSH levels are normal. Clinical manifestations of hypothyroidism are usually absent, but assessment may be confounded by obtundation, edema, and hypothermia that may accompany severe illness. Low free T₄ levels in the context of euthyroid sick syndrome usually indicate a grave prognosis, with a mortality rate of more than 50%. Although it is generally accepted that thyroid hormone therapy has no benefit, in practice it is sometimes difficult to differentiate between the euthyroid sick syndrome and secondary hypothyroidism. Judicious replacement of T₄ at physiologic levels in these uncommon patients may be appropriate if there are no contraindications (e.g., active ischemic heart disease).

Hypothyroidism

Thyroidectomy

Thyroidectomy may be performed for a variety of oncologic reasons in the management of thyroid cancer, head and neck cancer, or thyroid metastasis. Thyroid replacement is needed in this group of patients. In thyroid cancer patients, supraphysiologic doses of thyroid hormone are adjusted to suppress TSH without overt hyperthyroid symptoms. In others, the dose of thyroid hormone should be adjusted to keep TSH in the normal range.

Radiation

Irradiation is an important cause of hypothyroidism [primary (thyroid), secondary (pituitary), and tertiary (hypothalamic)]. Radiation-induced primary hypothyroidism is caused by thyroid cell destruction, inhibition of cell division, vascular damage, and possibly an immune-mediated phenomenon. Factors that increase the risk of developing primary hypothyroidism include a high radiation dose to the vicinity of the thyroid gland, duration since therapy, lack of shielding of the thyroid during therapy, and combined irradiation and surgical treatments.¹²

The incidences of hypothyroidism after radiation therapy for various cancers and conditions are tabulated in [Table 2](#).^{4, 12–22} A relationship between radiation dose and the prevalence of hypothyroidism is based on studies of patients with Hodgkin disease.^{15, 18} Long-term follow-up of patients treated with low-dose radiotherapy suggests that the threshold for causing clinically evident hypothyroidism is approximately 10 Gy. For Hodgkin-disease patients who received >30 Gy, the actuarial risk of hypothyroidism was up to 45%, 20 years after irradiation.¹⁵ Patients with frank or subclinical hypothyroidism should receive thyroid hormone-replacement therapy.

Table 2 Incidence of hypothyroidism (including compensated hypothyroidism) after radiotherapy.^a

Type of malignancy or conditions	Radiation dose	% with hypothyroidism
Hodgkin disease	30–60 Gy	30–50
Head and neck cancer	40–72 Gy	25–50
Lymphoma	20–40 Gy (median 36 Gy)	30–42
Breast carcinoma	?	15–21
Total-body irradiation in BMT	13.75–15 Gy	15–43

Chemotherapy

The diagnosis of hypothyroidism in 14% of BMT (bone marrow transplantation) patients who received chemotherapy but did not receive total-body irradiation²³ suggests a causal relation between hypothyroidism and high-dose combination cytotoxic chemotherapy. This notion is also supported by studies that showed an increased incidence of primary hypothyroidism in patients treated with multiple combination drug regimens^{24, 25} with or without radiation.²⁴ L-Asparaginase, in addition to inhibition of TBG synthesis discussed above, may also inhibit TSH synthesis reversibly and lead to temporary hypothyroidism with decreased free T₄ levels.²⁶

Thyroid dysfunction is a recognized side effect of cytokine treatments. Treatment with interleukin-2 produces thyroid dysfunction in approximately 20–35% of patients.²⁷ These patients have hypothyroidism, hyperthyroidism, or hyperthyroidism followed by hypothyroidism.²⁸ Approximately 10% of interferon-treated patients develop primary hypothyroidism.²⁹ Pituitary enlargement secondary to interferon-induced hypothyroidism has also been reported.³⁰ Patients with antithyroid antibodies before therapy are at higher risk of cytokine-induced thyroid dysfunction.

Retinoid X receptor (RXR) ligands may be used in the treatment of certain malignancies such as cutaneous T-cell lymphoma. Bexarotene (a RXR-selective ligand) caused secondary hypothyroidism dose-dependently.³¹ A single dose can rapidly suppress TSH in healthy subjects.³² In addition to suppressing transcription of TSH by an RXR-mediated thyroid hormone-independent mechanism, bexarotene also increases metabolic clearance of thyroid hormones by a nondeiodinase-mediated pathway.³³

Tyrosine kinase inhibitors

The rapid introduction of small organic molecules that inhibit kinase activity (tyrosine kinase inhibitors, TKIs) into cancer therapy over the past decade has led to the recognition that many of these agents affect thyroid function in profound ways. The first mechanism is a direct effect of these agents on thyroid function. A number of TKIs target receptor tyrosine kinases with well-defined functions in the thyroid gland including the vascular endothelial growth factor receptor, the epidermal growth factor receptor, RET, KIT, and MET. Other agents target downstream signaling pathways such as RAF, PI3K, and mTOR. These signaling pathways are operative in the thyroid and important for normal thyroid cell growth and function. It is not surprising that disruption of these pathways has effects on thyroid cell growth and death and thyroid hormone synthesis. Indeed hypothyroidism occurs at significant incidence rates with a number of agents: sunitinib, 7–85%; pazopanib, 12%; nilotinib, 22%; axitinib, 20–100%; cabozantinib, 15%; sorafenib, 8–39%; dasatinib, 50%; and imatinib, 0–25%.³⁴ Routine measurement of thyroid function (free T₄ and TSH) at regular intervals during the first year of therapy with one of these agents seems prudent as it is often difficult to differentiate nonspecific side effects of TKI therapy from primary hypothyroidism or effects of metastatic cancer.

There is a second mechanism for development of hypothyroidism in patients treated with specific TKIs for metastatic thyroid carcinoma who have also undergone total thyroidectomy. Specific agents approved (vandetanib, cabozantinib, sorafenib, and lenvatinib) or studied (pazopanib, motesanib, and sunitinib) for treatment of differentiated or medullary thyroid carcinoma cause an elevation of the serum TSH

concentration and low serum T₄ levels with high percent incidences: vandetanib, 49%; cabozantinib, 57%; sorafenib, 41%; and lenvatinib, 57%. As each of these agents causes diarrhea and malabsorption, one presumed mechanism for this effect is reduced absorption of thyroid hormone, although effects on thyroid hormone metabolism have not been excluded. Increasing the thyroid hormone dosages by as much as one-third generally resolves the problem. It is important to note that there may also be malabsorption of calcium, magnesium, and vitamin D, causing worsening hypocalcemia or hypomagnesemia in patients with mild thyroidectomy-associated hypoparathyroidism.³⁵ Routine measurement of free T₄ and TSH should be incorporated into management as more than 50% of these patient will require a dose modification of thyroid hormone (as well as magnesium, calcium, and vitamin D supplementation). It is important to note that primary hypothyroidism, hypocalcemia, or hypomagnesemia can be readily treated, and their appearance, if addressed promptly, should not limit the use of the TKIs. However, in patients with hypothyroidism, hypocalcemia, or hypomagnesemia, all of which can prolong the QT interval, it may be necessary to withhold TKIs that prolong QT interval, that is, vandetanib,³⁵ lenvatinib,³⁶ and sorafenib in patients with QT prolongation until the QT abnormalities are resolved.

¹³¹I-containing compounds

The use of ¹³¹I for treatment of thyroid cancer requires a high serum TSH level. High TSH level is achieved by either withholding thyroid hormone replacement or increasingly by administration of recombinant human TSH. The use of ¹³¹I-containing compounds in the treatment of other tumors may result in hypothyroidism. For instance, using high-dose (100–1000 mCi) [¹³¹I]-metaiodobenzylguanidine to treat unresectable pheochromocytoma may result in primary hypothyroidism.³⁷

Metastasis to the thyroid

Hypothyroidism secondary to metastatic infiltration and replacement of the thyroid by cancer is extremely rare.

Screening

Children who have received either head and neck or cranial irradiation should have a free T₄ and a TSH measurement annually for 5 years, and every 2 years thereafter. Early detection of abnormal T₄ and TSH levels will permit medical intervention before hypothyroidism adversely affects physical and intellectual development and growth. In adults, neck irradiation for treatment of lymphoma and various head and neck tumors is associated with a high incidence of primary hypothyroidism. Patients who have received irradiation should have free T₄ and TSH levels measured annually for 5 years, and then every other year for 10 years, and thereafter every 5 years for another 10 years. Once hypothyroidism is diagnosed, the patient should receive thyroid hormone-replacement therapy.

Hyperthyroidism

Radiation-induced painless thyroiditis with hyperthyroxinemia is an uncommon side effect of external-beam radiotherapy to the head and neck area. Transient hyperthyroidism may occur as a result of inflammation and destruction of thyroid tissue with release of thyroglobulin (containing T₄ and T₃), and is usually followed by hypothyroidism. Transient hyperthyroidism has been reported after mantle radiotherapy in Hodgkin disease patients, and occurs usually within 18 months of treatment.³⁸ A low uptake of radioiodine in most of these cases suggests a diagnosis of silent thyroiditis, but some have Graves' disease. In one series of Hodgkin disease patient treated with radiation, the risk of Graves'

disease in these patients was estimated to be at least 7.2 times that in a healthy population.¹⁵

Ophthalmopathy similar to that in Graves' disease has been reported within 18–84 months of high-dose radiotherapy to the neck for lymphoma, breast cancer, and nasopharyngeal or laryngeal cancer. Ophthalmopathy may occur without hyperthyroidism and in the absence of the human leukocyte antigen-B8.³⁹ This suggests that radiation-induced thyroid injury may induce an autoimmune process that is similar to Graves' disease.

There have also been examples of TKI-associated hyperthyroidism, including two deaths (sorafenib and sunitinib associated).⁴⁰ The presumed mechanism of hyperthyroidism is thyroiditis. Patients with severe hyperthyroidism should be treated aggressively for thyroid storm; consideration should be given to holding TKI therapy until the patient is stabilized in such cases.³⁴

Thyroid nodules and cancers

Low-dose radiation increases the risk of thyroid nodules and cancer. The association between thyroid cancer and low-dose irradiation has been extensively examined,⁴¹ and is discussed in the chapter about thyroid cancer (see 81).

Energy balance and glucose metabolism

Obesity and metabolic syndrome

Cancer treatments may lead to obesity and the metabolic syndrome.^{42–44} The metabolic syndrome is a cluster of abnormalities consisting of central obesity, dyslipidemia, hyperglycemia, and hypertension that increases the risk of type 2 diabetes and cardiovascular disease. Obesity is a modifiable risk factor for carcinogenesis as well as cancer progression. The mechanisms by which obesity promotes cancer include: hyperinsulinemia due to insulin resistance, high IGF-1, adipokines, low adiponectin, increased production of estrogens by adipose tissue, and increased inflammation. Obesity in cancer survivors may place them at increased risk for poor disease outcomes.^{42, 45, 46} Obesity increases the risk of colorectal and genitourinary second primary cancers.⁴⁷ Although low levels of physical activity in cancer survivors can contribute to obesity, the pathophysiologic basis of the weight gain is unclear. As obesity is an adverse prognostic factor for many cancers and is a modifiable risk factor, secondary obesity after cancer treatment needs to be addressed.

Diabetes mellitus

Diabetes mellitus type 2 (DM2) is associated with an elevated risk of pancreatic, liver, colon, gastric, breast, and endometrial cancer.^{48–53} Extensive epidemiologic data suggest important roles of diabetes in carcinogenesis^{48–53} and cancer survival.⁵⁴ The strongest association is perhaps with pancreatic cancer.^{55–59} Apart from the frequently coexisting obesity, the mechanisms by which diabetes promotes cancer include: hyperinsulinemia, high IGF-1, and hyperglycemia. Hyperglycemia per se has a promoting effect on cancer proliferation. In male, cancer survivors with a fasting serum glucose concentration ≥ 126 mg/dL had a higher relative risk for hepatopancreatobiliary second primary cancer.⁴⁷ Evidence-based guidelines for the management of DM2 in cancer patients to optimize patient survival are lacking.

The administration of glucocorticoids (e.g., in combination therapy regimens, for edema of brain metastasis, for prevention of transplant rejection, for graft-versus-host disease in BMT, and for nausea/vomiting) is probably the most common cause of diabetes mellitus in cancer patients. Therefore, patients who receive glucocorticoids must be periodically screened for diabetes with evaluation of

fasting glucose levels during therapy. Treatment with streptozocin⁶⁰ or L-asparaginase⁶¹ may result in insulin-deficient diabetes mellitus. Although there is no evidence of a delayed onset of diabetes mellitus following treatment with streptozocin, follow-up has been limited and short term. For long-term survivors treated with streptozocin, periodic screening for delayed development of diabetes mellitus may be indicated. Diabetes mellitus may also develop as a consequence of serious pancreatitis secondary to treatment with L-asparaginase. Immunotherapy for cancer using cytokines such as interleukin-2 and interferons may cause toxicity to pancreatic β cells and lead to insulin-dependent diabetes.⁶² Tacrolimus, an immunosuppressive agent used to prevent graft-versus-host disease in BMT, also increases the incidence of diabetes, perhaps by damaging pancreatic β cells.⁶³ Patients who received allogeneic BMT are likely to be receiving both glucocorticoids, cyclosporine A and tacrolimus, and are particularly at risk for developing diabetes mellitus.⁶⁴ Management of the blood glucose levels would depend on the severity of the blood glucose level abnormality and on the underlying pathophysiologic mechanism of the increase in blood sugar. In general, insulin will be needed in patients who are insulin deficient.

Metabolic bone diseases

Osteoporosis

Four groups of adult patients are at particular risk for accelerated bone loss and osteoporosis: (i) patients with lymphoma, myeloma, or leukemia; (ii) women with breast cancer treated with cytotoxic chemotherapy frequently undergo an early menopause⁶⁵ and cannot receive estrogen-replacement therapy; (iii) postmenopausal women with estrogen-receptor positive breast cancer; and (iv) men with prostate cancer who are on antiandrogenic therapy and made hypogonadal. Normal bone remodeling involves a delicate balance between bone formation by osteoblasts and bone resorption by osteoclasts. Antineoplastic therapy is toxic to osteoblast function and decreases bone formation. Production by the tumor of hormonally active substances [e.g., parathyroid hormone-related protein (PTHrP), lymphotoxin, interleukin-1, and interleukin-6] may contribute to bone loss. In most cases, it is not clear whether bone loss is caused by antineoplastic therapy or by the underlying disease process and its effects (including cachexia, malnutrition, poor calcium and vitamin D intake, or a combination of these). In patients with breast or prostate cancer, sex steroid hormone deficiency induced by therapy is the most important cause of bone loss. Bone loss is prominent in patients with several disorders (myeloma, leukemia, and lymphoma), affecting the hematopoietic cells, perhaps because of cytokine production and an intimate relationship of hematopoietic cells with bone-forming cells or the use of high-dose or prolonged therapy with glucocorticoids.

A number of drugs can induce osteoporosis.⁶⁶ In cancer patients, glucocorticoids, methotrexate, and cytotoxic drugs that cause renal loss of calcium, magnesium, or phosphorus (e.g., platinum compounds, cyclophosphamide, and ifosfamide) have significant impact on bone density. Osteoporosis (generalized or localized) is observed in children receiving methotrexate therapy for acute lymphoblastic leukemia (ALL).⁶⁷ The osteoporosis improves significantly after cessation of methotrexate therapy. Longitudinal study of ALL patients showed that the leukemic process, high-dose glucocorticoids, and hypomagnesemia (owing to renal wastage following cyclical glucocorticoid and nephrotoxic chemotherapy or antiinfective agents) contributed to the impairment of calcium and vitamin D metabolism and decrease in bone mass at different stages of the treatment process.⁶⁸ Adjuvant chemotherapy for breast cancer (usually involving 5-fluorouracil, cyclophosphamide, and doxorubicin or methotrexate) is associated with low bone mass in premenopausal patients.⁶⁹ Bone loss during chemotherapy is substantial and may lead to increased risk of fracture. Posttreatment hypogonadism appears to be a major factor in these adult women with

osteoporosis. While tamoxifen has a slight protective effect on bone loss, the opposite is true for aromatase inhibitors. BMT usually involves treatment with high-dose cytotoxic drug, glucocorticoids, and immunosuppressive agents. In 24 patients who underwent BMT with high-dose chemotherapy, profound effects on bone biomarkers were observed.⁷⁰

Prompt investigation of gonadal dysfunction in cancer survivors and prompt replacement of gonadal steroids (in the absence of contraindications) in young hypogonadal men or women are recommended to decrease the risk of future bone fractures. The bone mass of long-term cancer survivors should be assessed when the patient is about 30 years old, the age at which most people have attained peak bone mass.⁷¹ If bone mass is normal, no further evaluation is needed beyond the usual recommendations for prevention of osteoporosis. If it is abnormal (more than 2 standard deviations below normal), the patient should be referred for evaluation of the multiple reversible causes of osteoporosis.

A key point in the management of the osteoporosis syndrome in cancer patients is the use of bone mineral density measurement (e.g., by dual-energy X-ray absorptiometry) to assess fracture risk and to monitor the effects of therapy. This measurement should be performed early in the course of management of the malignancy so that appropriate preventive measures can be implemented. The oncologist who is prescribing medications that are likely to decrease bone mass should consider active use of bisphosphonates (e.g., alendronate, risedronate, ibandronate, or zoledronate), calcitonin, selective estrogen-receptor modulators (SERMs), or denosumab, in addition to a daily intake of 1200–1500 mg elemental calcium and vitamin D supplementation. Bisphosphonates and denosumab are effective therapies for prevention of bone loss. While osteoporosis in children with leukemia will frequently reverse because the children are in the formative years of bone development, in adults more active measures such as bisphosphonate or teriparatide therapy to prevent bone loss should be considered, rather than waiting for the development of a fracture syndrome.

Another key point is correction of abnormal mineral and vitamin D metabolism by dietary supplements. Nutritional deficiency in teenagers and young adults results in lower bone mass. Treatment of hypocalcemia, hypomagnesemia, and vitamin D deficiency is integral to the successful therapy of osteoporosis in cancer patients. Recent studies document that clinically relevant vitamin D deficiency is present in 50% of the normal population; the percentage is almost certainly higher in patients undergoing cancer therapy.

Osteomalacia

Osteomalacia, a condition characterized by unmineralized bone matrix, is a rare complication of chemotherapy, but should be considered in osteopenic patients and those with osteomalacic clinical syndrome (bone pain and proximal myopathy). The most common cause is a decrease in the serum calcium and/or phosphorus concentrations caused by nutritional deficiency and renal wasting of phosphorus and calcium. Patients who have received chemotherapeutic agents that cause hypophosphatemia, hypomagnesemia, or hypocalcemia are particularly at risk. Investigation of the levels of serum ionized calcium, phosphorus, magnesium, and vitamin D metabolites should be included in the initial evaluation. Appropriate replacement therapy of these vitamins and minerals should be instituted once deficiencies have been identified. Other contributing factors include systemic acidosis and drugs such as anticonvulsants and aluminum.⁶⁶ Tumor-induced osteomalacia will be addressed in the section that follows discussing paraneoplastic syndromes.

Ifosfamide causes tubular damage leading to renal phosphate wasting, hypophosphatemia, and rickets/osteomalacia.⁷² The toxic effects of ifosfamide on renal tubular function include Fanconi

syndrome in adults and children. Tubular damage is seen most commonly when ifosfamide is administered in doses of 50 g/m² or more, or when it is used in combination with cisplatin.⁷³ Rickets is reported most commonly in children. Estramustine, used in the treatment of prostate cancer, has been reported to increase bone resorption and at the same time cause hypocalcemia, hypophosphatemia, and secondary hyperparathyroidism.⁷⁴

Adrenal diseases

Adrenal metastasis

Hematogenous metastasis to the adrenal glands is common, exceeded in frequency only by hematogenous metastasis to the lung, liver, and bone.⁷⁵ Autopsies have documented that 9–27% of patients who died from malignant illness had adrenal metastasis, with bilateral involvement in one-half to two-thirds of patients with adrenal metastasis.

The presence of adrenal metastasis may have important implications for diagnostic and therapeutic planning. When patients with cancer have an adrenal mass but no evidence of metastasis elsewhere, it is important to determine whether this mass represents a metastatic tumor or a separate, unrelated adrenal lesion. Recent advances in imaging techniques have allowed the identification of adrenal lesions antemortem as part of the tumor-staging evaluation. The location of the adrenal glands in the perinephric fat allows the detection of almost all normal glands and contour-deforming masses as small as 5–10 mm. Computed tomography (CT) has a sensitivity and specificity in the detection of adrenal masses. Characteristics on CT examination that suggest adrenal metastasis rather than primary adrenal disease include heterogeneity, contrast enhancement, bilaterality, and size >3 cm.⁷⁶

Without other evidence of metastatic disease, whether the adrenal mass is actually a metastatic tumor is critical information in determining the appropriate therapy for the cancer. Evaluation of a patient who has a malignant adrenal mass should include a history and physical examination to elicit evidence of adrenal insufficiency, Cushing syndrome, mineralocorticoid excess, or pheochromocytoma. Biochemical assessment should include a short ACTH stimulation test with measurements of serum cortisol to rule out adrenal insufficiency. A 24-h urine collection should be obtained to measure urinary free cortisol, aldosterone, catecholamines, and metanephrines. Pheochromocytoma must be excluded, especially if there is hypertension, or an operative procedure of any type is contemplated. It has been reported that one-half of the patients who had a clinically unsuspected pheochromocytoma had clinical deterioration or even death immediately following a non-adrenal-related surgical procedure.⁷⁷

If the biochemical assessment for pheochromocytoma is negative, CT-guided fine-needle aspiration should be considered. This procedure has a sensitivity of 85% in detecting cancer.⁷⁸ MRI may be helpful in the diagnosis of pheochromocytoma. Functional scintigraphy using ¹³¹I-6-iodomethyl-19-*nor*-cholesterol (NP-59) may be used in conjunction with CT and MRI to aid in the diagnosis of a unilateral adrenal mass >2 cm.⁷⁹

Adrenal insufficiency

Despite the relatively high prevalence of adrenal infiltration by many common cancers, clinically evident adrenal hypofunction occurs infrequently, except when both adrenal glands are affected by metastatic disease.⁸⁰ It is estimated that more than 80% of adrenal tissue must be destroyed before corticosteroid production, under both basal and stress conditions, is impaired.⁸¹ Because the clinical manifestations of adrenal insufficiency are nonspecific and overlap findings in cancer patients, a high index of suspicion is

required to detect this treatable condition. The cachexia and weakness seen in patients with adrenal insufficiency can mimic the general wasting seen in patients with extensive metastatic disease. Electrolyte abnormalities can easily be explained by poor intake, malnutrition, side effects of chemotherapeutic agents, or paraneoplastic syndromes. Adrenal insufficiency may develop gradually and therefore be confused with cancer-associated cachexia.

Approximately 20–30% of the patients with bilateral adrenal metastasis will develop adrenal insufficiency.⁸⁰ These patients should all be evaluated by the ACTH stimulation test with serum cortisol measurements and should receive glucocorticoid- and mineralocorticoid-replacement therapy when adrenal insufficiency is suspected and until normal adrenal function is documented. Patients who are stable should receive 20 mg of hydrocortisone in the morning and 10 mg in the early afternoon. In the event of circulatory instability, sepsis, emergency surgery, or other major complications, stress dosages of parenteral glucocorticoid should be given (e.g., hydrocortisone succinate 100 mg intravenously every 8 h).

Other causes of primary adrenal insufficiency in cancer patients include autoimmune adrenalitis, adrenal hemorrhage, and granulomatous diseases. Many cancer patients may be immunocompromised. For example, patients with leukemia or lymphoma or patients who have undergone BMT are immunosuppressed. In these patients, infection of the adrenal glands by cytomegalovirus, mycobacteria, or fungi may lead to adrenal insufficiency.

Adrenal insufficiency may be drug induced. Etomidate,⁸⁰ a common intravenous anesthetic, and ketoconazole, an antifungal drug, both inhibit the production of cytochrome P450-dependent enzymes in the glucocorticoid synthetic pathway. Aminoglutethimide and metyrapone are drugs that inhibit enzymes in steroidogenesis, and may cause adrenal insufficiency when used in the treatment of prostate, breast, and adrenocortical cancers. Mitotane, structurally related to the insecticide dichlorodiphenyltrichloroethane (DDT), has selective toxicity for adrenocortical cells. Adrenal insufficiency is commonly observed when mitotane is administered in doses necessary to treat adrenocortical cancer; glucocorticoid replacement therapy is mandatory in such patients.¹⁰ Increased protein binding is observed in mitotane-treated patients, and may lead to an increased daily requirement of glucocorticoids during replacement therapy. Suramin, recently proposed as an anticancer agent based on its activity against the tumor growth factors, may also cause adrenal insufficiency.

Secondary adrenal insufficiency because of metastasis to the pituitary or hypothalamus may also occur. The most common cause of secondary adrenal hypofunction, however, is exogenous glucocorticoid therapy that suppresses hypothalamic–pituitary adrenal function. A prolonged course of therapy may lead to hypothalamic–pituitary suppression lasting for many months. Short periods of steroid therapy (i.e., 1, 2, or 4 weeks) in patients with leukemia and lymphoma suppress adrenal function for 2–4 days in most patients, and for longer in some patients. In patients who have received glucocorticoids for more than 2 weeks, a tapering period of 10–14 days should be considered. This is especially true for chemotherapy regimens that included high-dose glucocorticoids such as those used in the treatment of acute leukemia and lymphoma. In addition, patients who have been treated within the past year with prolonged glucocorticoid courses should receive stress dosages of glucocorticoid if acute medical or surgical complications occur (e.g., neutropenic fever with hypotension and acute typhlitis). Irradiation of the hypothalamic–pituitary region causes ACTH deficiency and secondary adrenal insufficiency in 19–42% of treated patients ([Figure 1](#)). Several diagnostic approaches have been used to evaluate secondary adrenal insufficiency, including basal 8 a.m. serum cortisol measurements and dynamic tests with 1 µg of synthetic ACTH_(1–24), insulin-induced hypoglycemia, or metyrapone. The effects of immunotherapy on pituitary ACTH production were discussed earlier in this chapter.

Disorders of growth hormone secretion and growth

Childhood cancer or its treatment commonly impairs growth. Medulloblastoma and ALL, common childhood malignancies, are frequently treated with cranial or craniospinal irradiation and/or chemotherapy. Close to 40% of adult survivors of childhood brain cancer are below the tenth population percentile for height, and the risk factors for short stature are young age at diagnosis and radiation treatment affecting the hypothalamic–pituitary axis.⁸² GH deficiency and damage to the osseous growth plates are two common mechanisms of growth retardation.

Cranial irradiation may cause hypothalamic or pituitary dysfunction. The hypothalamus appears to be more radiosensitive than does the pituitary gland and may be damaged by lower radiation doses (<40 Gy). Higher doses (>40 Gy) are likely to damage both hypothalamic and pituitary function. Deficiency of one or more pituitary hormones following irradiation of the hypothalamic/pituitary area occurs in almost 100% of patients 5 years after irradiation ([Figure 1](#)).

GH deficiency is the most frequently noted and often the first pituitary manifestation to arise after cranial irradiation. Isolated GH deficiency following irradiation is common, and the effects are dose related. At lower doses (20–24 Gy), the only effect may be an altered GH secretory pattern and subnormal response to insulin-induced hypoglycemia. With intermediate and higher doses, the GH response to the stimulatory effect of arginine is impaired, and the frequency and amplitude of pulsatile GH secretion are decreased.⁵ At doses up to 30 Gy, abnormal GH secretion and growth retardation are observed in more than 35% of patients, necessitating GH treatment.⁸³

In addition to growth retardation caused by GH deficiency, craniospinal or spinal irradiation for hematologic malignancy or central nervous system tumors and total-body irradiation before BMT may cause two other effects. First, irradiation affects the growth plates in vertebral bodies and in the pelvis and decreases vertebral growth. Second, irradiation causes resistance to GH or IGFs.

Children treated with chemotherapy for malignancy frequently have a period of reduced growth velocity, followed by a “catch-up” growth phase. Systemic illness seems to be the most important component of growth retardation in these children, although chemotherapy may play a significant role. Both growth velocity and height are lower in children who are treated with higher doses of chemotherapy and for a longer duration with combination chemotherapy than in those who receive regular therapy or less-intensive chemotherapy. If there is no catch-up growth after 1.5–2 years, it is important to exclude GH deficiency.

In adults, GH deficiency is thought to cause decreased bone and muscle mass, lower exercise capacity, increased adipose tissue, fatigue, a poor sense of well-being, impaired myocardial function, and increased cardiovascular risks. GH replacement may be indicated to improve the patients' quality of life and sense of well being,⁸⁴ but the concern over IGF-1-induced reactivation of malignant disease should be factored into the decision.

Disorders of electrolyte/mineral metabolism

Hyponatremia

Risk factors for hyponatremia include treatment-induced nausea and vomiting, certain chemotherapy agents, hydration with hypotonic fluid, pain, opiates, and stress (both physical and psychological). In a prospective study of in-patient cancer patients, the incidence of hyponatremia is 3.7% with sodium depletion and syndrome of inappropriate antidiuretic hormone (SIADH), each accounting for about one-

third of all causes.⁸⁵ SIADH is characterized by low serum osmolality and inappropriately high urine osmolality in the absence of diuretics, heart failure, cirrhosis, adrenal insufficiency, and hypothyroidism. In cancer patients, SIADH may be caused by vasopressin secreted by tumors [e.g., up to 15% of small-cell lung cancers (SCLCs)], abnormal secretory stimuli (e.g., intrathoracic infection and positive pressure ventilation), or cytotoxicity affecting paraventricular and supraoptic neurons. It is also possible that chemotherapy-induced lysis of vasopressin-containing cancer cells leads to or worsens SIADH. Drug-induced renal salt wasting or tumor-induced salt wasting (mediated by atrial natriuretic peptide)⁸⁶ can also cause hyponatremia, hypoosmolality, elevated urinary sodium, and urinary osmolality. These SIADH-like syndromes are difficult to distinguish from SIADH when signs and symptoms of fluid volume depletion are subtle or absent. Nonetheless, there are convincing reports that provide evidence of chemotherapy-induced hypothalamic or pituitary damage in the context of SIADH. There are at least seven reports associating vincristine with SIADH, and some of these reports document inappropriately high serum levels of vasopressin.⁸⁷ Vinblastine has also been reported to cause severe hyponatremia and SIADH.⁸⁷ The presumed mechanism of vinca alkaloid-induced SIADH is paraventricular or supraoptic cell microtubular damage.

Cyclophosphamide therapy has been associated with hyponatremia and SIADH. Autopsy findings in a case of fatal hyponatremia induced by cyclophosphamide (1800 mg/m²) suggest that cyclophosphamide directly affects the hypothalamus.⁸⁸ Those findings included infundibular necrosis, decreased intraaxonal secretory granules, and depletion of posterior pituitary vasopressin. Patients treated with lower doses of cyclophosphamide also develop hyponatremia, hypotonicity, urinary hypertonicity, and increased plasma vasopressin levels. Damage to the renal tubules and resulting defects in salt and water transport may be the major cause of hyponatremia associated with low-dose cyclophosphamide therapy.⁸⁹

There are many reports of cisplatin-induced hyponatremia caused by renal salt wasting.⁹⁰ Several reports claim that cisplatin induces SIADH. The mechanism of cisplatin-induced hyponatremia is unclear, but it has been suggested that renal toxic effects of cisplatin, that is, decreased papillary solute content and maximal urinary osmolality are the major factors, rather than a direct effect of cisplatin on vasopressin secretion. In a majority of the patients who have elevated vasopressin levels, the vasopressin levels became suppressed after correction of hypovolemia.⁹⁰ Therefore, the stimulus for vasopressin release in these patients was probably hypovolemia caused by renal salt wasting.

[Figure 2](#) outlines the algorithm for evaluation and treatment of hyponatremia. For hypovolemia and sodium loss, fluid and sodium replacement is the primary treatment. The AVP-receptor antagonists directly block the binding of AVP with its receptors. In clinical trials, conivaptan, lixivaptan, tolvaptan, and satavaptan effectively correct hyponatremia associated with SIADH, cirrhosis, or congestive heart failure, and this new class of drugs are likely to be useful for cancer-related hyponatremia.⁹¹

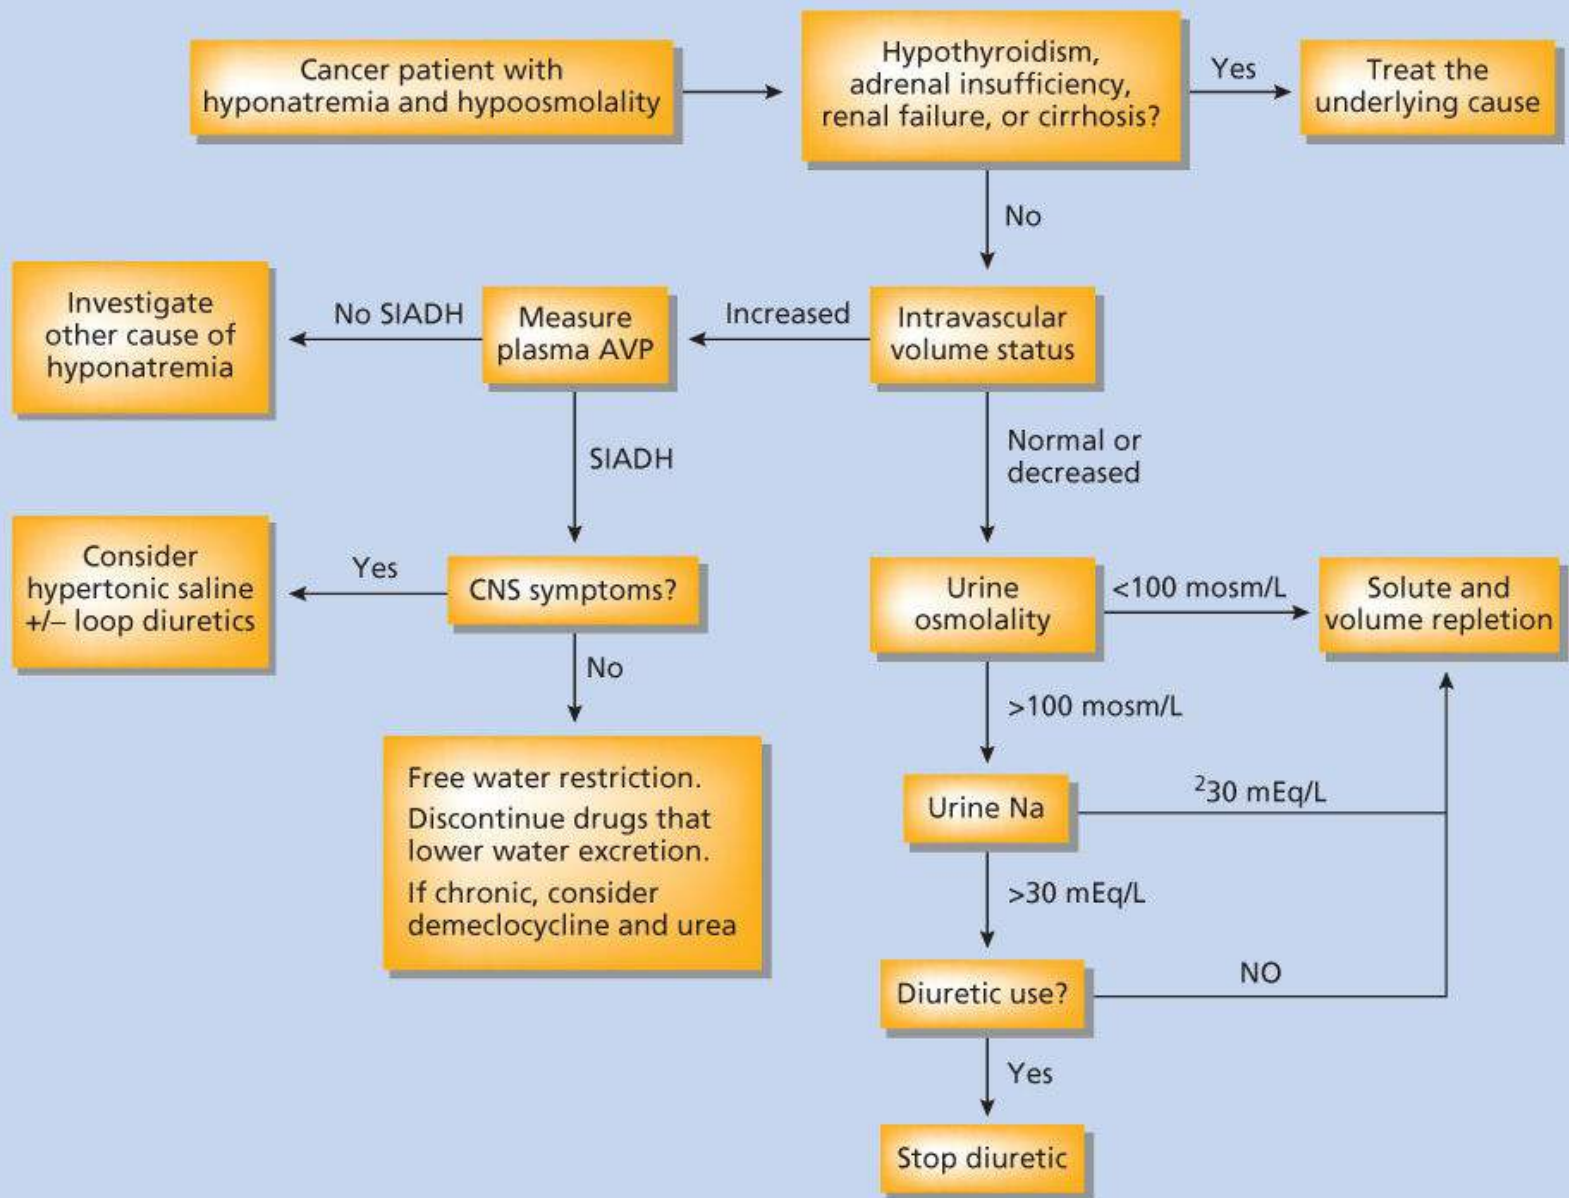

Figure 2 Approach to evaluation of hyponatremia in a cancer patient.

Hypernatremia

Hypernatremia secondary to central diabetes insipidus occurs frequently as a complication of neurosurgery or destruction by the tumor of the anterior pituitary or the related hypothalamic nuclei. Nephrogenic diabetes insipidus can result from the effects of ifosfamide or streptozocin on tubular reabsorption of water. Ifosfamide has broad nephrotoxic effects, although tubular damage predominates. Distal tubular defects develop in about half of patients treated with ifosfamide. However, frank nephrogenic diabetes insipidus leading to hypernatremia is not common.⁹² Streptozocin is another nephrotoxic drug; in addition to causing glomerular defects (proteinuria) and tubular defects (Fanconi syndrome), streptozocin therapy has been reported to cause nephrogenic diabetes insipidus.⁹³

Hypocalcemia

Hypocalcemia may be one of the features of tumor lysis syndrome. Hypocalcemia can also be caused by primary hypoparathyroidism after surgical procedures in the neck that sacrificed or damaged the parathyroid glands (e.g., total laryngectomy and total thyroidectomy). Hypocalcemia is also a common complication of chemotherapy.⁸⁷ Hypocalcemia has been reported in 6–20% of cisplatin-treated patients.

Effects of cisplatin on renal tubular function, magnesium metabolism, bone resorption, and vitamin D metabolism may explain the hypocalcemia. Profound hypomagnesemia causes a decrease in the secretion of parathyroid hormone and a reduction in the calcium-mobilizing effects of parathyroid hormone. Hypomagnesemia also inhibits formation of 1,25-dihydroxy vitamin D₃ (1,25-dihydroxycholecalciferol). Cisplatin may inhibit the mitochondrial function in the kidneys and thereby inhibits conversion of 25-hydroxycholecalciferol to 1,25-dihydroxy cholecalciferol by the enzyme 1- α -hydroxylase. In addition, cisplatin may have a direct inhibitory effect on bone resorption. Carboplatin therapy, similar to cisplatin therapy, is associated with a 16–31% incidence of hypocalcemia. Dactinomycin is another antitumor antibiotic that blocks DNA-directed RNA synthesis, causing hypocalcemia in animals. Dactinomycin also abolishes the calcium-mobilizing effect of thyroid hormone, presumably by interfering with osteoclast-mediated bone resorption. Asymptomatic hypomagnesemia, hypocalcemia, and hypoparathyroidism have also been reported in patients treated with a combination of doxorubicin and cytarabine.

Hypercalcemia

The incidence of hypercalcemia in cancer patients is approximately 1%.⁹⁴ Hypercalcemia in cancer patients is a poor prognostic sign associated with a shortened survival. The paraneoplastic syndrome of hypercalcemia of malignancy is discussed under the section titled “Endocrine Paraneoplastic Syndromes (‘Ectopic’ Hormone Production).” No chemotherapy has been identified as a cause of hypercalcemia. However, there is a clear association between low-dose (usually 2–7.5 Gy) external-beam irradiation of the head and neck area and subsequent development of primary hyperparathyroidism. There is a 2.5- to 3-fold increase in the incidence of primary hyperparathyroidism after low-dose irradiation of the neck.⁹⁵ Among patients who developed primary hyperparathyroidism, 14–30% had prior exposure to radiation. The interval from irradiation to development of hyperparathyroidism ranges from 29 to 47 years. Primary hyperparathyroidism also develop in the context of multiple endocrine neoplasia, types 1 and 2. Surgery is the principal treatment for primary hyperparathyroidism. Removal of adenoma is usually curative, but in the context of MEN1, the surgical procedure of choice is 3.5-gland parathyroidectomy.⁹⁶

Hypomagnesemia

Cisplatin causes morphologic changes and necrosis in the proximal tubule, an important site of magnesium reabsorption. Hypomagnesemia occurs in approximately 90% of patients treated with cisplatin,⁹⁷ and 10% of the hypomagnesemic patients have symptoms of muscle weakness, tremors, and dizziness. Vigorous hydration and the use of osmotic diuretics such as mannitol may prevent renal failure, but has little effect on renal magnesium wasting. Hypomagnesemia may persist long after cessation of cisplatin therapy. There are no large series in the literature addressing the incidence of hypomagnesemia, but the information from the manufacturer indicates that 60% of those taking cisplatin may be affected. Hypomagnesemia also occurs in patients who receive cyclophosphamide and carboplatin.

Disorders of lipid metabolism

Short-term lipid abnormalities caused by cancer therapy are generally of little clinical significance. However, major abnormalities can lead to acute complications. Interferons and vitamin A derivatives can cause significant increases in triglycerides that can lead to pancreatitis. Interferons cause hypertriglyceridemia by increasing hepatic and peripheral fatty acid production⁹⁸ and by suppressing hepatic triglyceride lipase.⁹⁹ Long-term treatment with interferon- α_2 causes hypertriglyceridemia in approximately one-third of patients, most of whom had previous serum lipid abnormalities. Serum triglyceride levels of more than 1000 mg/dL are not unusual. In a case report, a therapeutic effect of diet

and gemfibrozil was observed in the presence of continued interferon- α therapy.¹⁰⁰ All-*trans*-retinoic acid (tretinoin) and other derivatives, for example, 13-*cis*-retinoic acid (isotretinoin), have been used in the treatment of several malignancies, most notably head and neck cancers and acute promyelocytic leukemia. The effects on lipid metabolism are well characterized, although the mechanism of development of lipid abnormalities is less clear. These abnormalities include hypertriglyceridemia caused by elevated very low-density lipoprotein levels, and hypercholesterolemia caused by increased low-density lipoprotein level. Retinoid-induced hypertriglyceridemia can cause stroke and pancreatitis. Hyperlipidemia associated with retinoid therapy has been treated with gemfibrozil or fish oil.

Sexual dysfunction

Radiation treatment to the head may cause a broad spectrum of hypothalamic–pituitary abnormalities ([Figure 1](#)). The resultant thyroid, GH, or adrenal deficiency may indirectly affect reproductive function. Sexual function is directly affected by hyperprolactinemia or gonadotropin deficiency, commonly observed in patients treated with <40 Gy of cranial irradiation.

Hyperprolactinemia occurs commonly (up to 50% incidence within 2 years) following head and neck irradiation with a median hypothalamic–pituitary radiation exposure of 50–57 Gy.⁴ Radiation damage to the hypothalamus leading to a loss of the normal inhibition of prolactin secretion is the proposed mechanism of hyperprolactinemia. Hyperprolactinemia inhibits the secretion of gonadotropin by the pituitary and decreases the responsiveness of the pituitary to gonadotropin-releasing hormone (GnRH), thereby causing secondary hypogonadism. Treatment with dopamine agonists (bromocriptine and cabergoline) inhibits prolactin secretion, and it may be reasonable to proceed with a therapeutic trial if other anterior pituitary functions are normal.

Gonadotropin deficiency occurs commonly (up to 61%) in patients treated with irradiation for brain tumors.¹⁰¹ In children, delayed puberty, absent menarche, and inadequate sexual development are significant problems related to gonadotropin deficiency. Early or even precocious puberty has been reported in patients treated with combined chemotherapy and cranial irradiation for ALL¹⁰² or brain tumor.¹⁰³ This phenomenon occurs more frequently in female patients. Concomitant GH deficiency is frequently noted, although its role in the development of precocious puberty is unclear.

In adults, gonadotropin deficiency may cause sex hormone deficiency and sexual dysfunction. Sex hormone deficiency may alter libido and adversely affect bone and lipid metabolism. Sexual dysfunction and impotence need to be evaluated and appropriately treated. [Figure 3](#) outlines a diagnostic algorithm for the evaluation of hypogonadism.

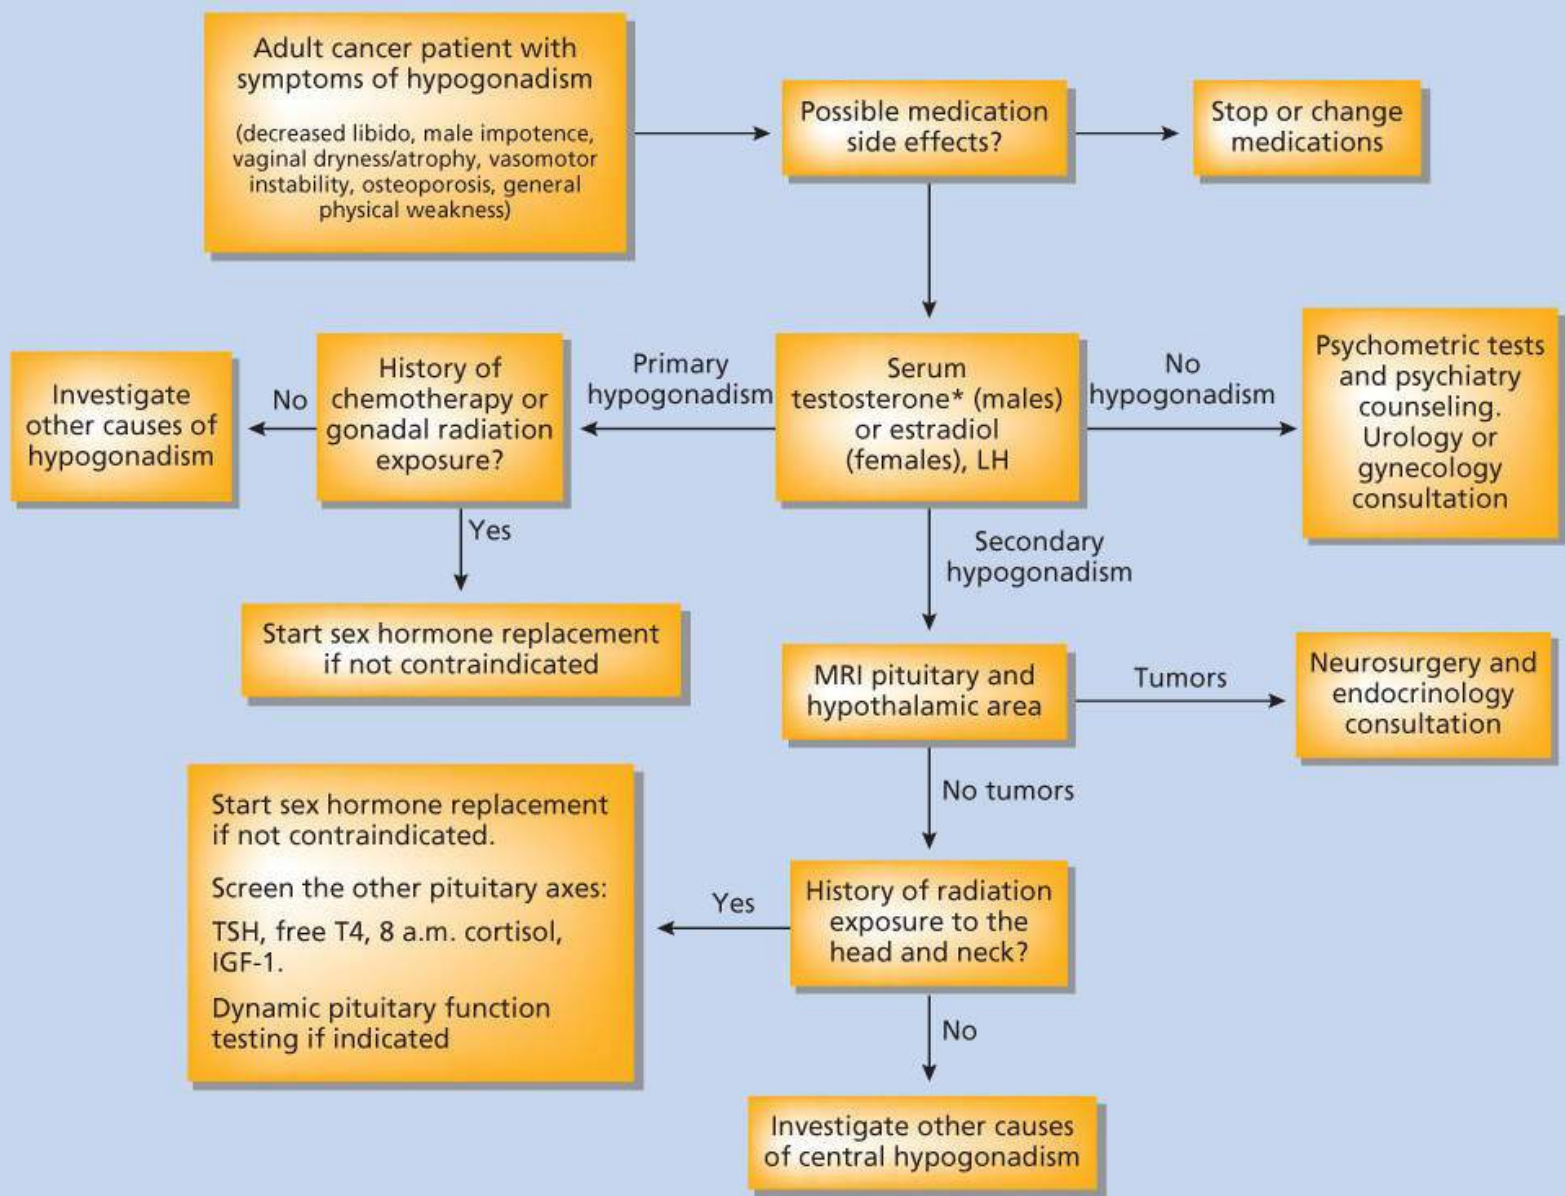

Figure 3 Approach to evaluation of hypogonadism in a cancer patient.

Gonadal complications and dysfunction caused by anticancer therapy have been reviewed.⁸⁷

Endocrine paraneoplastic syndromes (“ectopic” hormone production)

Among the more interesting and protean manifestations of cancer is the production of hormonal substances that produce unique clinical syndromes. These syndromes can be classified broadly into several different types. The first is the production of a hormonal substance by a cell type that normally produces the hormone. Examples include parathyroid hormone production by a parathyroid cancer, production of calcitonin by medullary thyroid carcinoma, and serotonin by carcinoid tumors. In each of these examples a malignancy of a differentiated cell type continues to produce its normal product, but does so in a manner that is largely independent of the normal regulatory processes. These clinical syndromes are discussed in the relevant chapters in this text that discuss these malignancies. The second type, to be discussed in detail here, is the “ectopic” production of a hormone by a cell type that does not normally produce the hormonal substance or produces it normally at very low levels. In some examples, the cell may have

produced the hormonal product at an earlier stage in its development. An example of this is PTHrP production by a squamous cell carcinoma. PTHrP is normally expressed in differentiating squamous cells, but is not expressed or is expressed at low levels in differentiated squamous epithelium.¹⁰⁴ Another example of “ectopic” hormone production occurs in a hormone-producing cell whose machinery has been co-opted to produce another hormone. An example of this is the production of ACTH by a wide spectrum of neuroendocrine tumor types, small-cell carcinoma of the lung being one example.

Production of peptides by neuroendocrine tumors comprises the most common of the “ectopic” hormone syndromes. Neuroendocrine cells are dispersed throughout nearly all organs. Prominent are lung, gastrointestinal tract, pancreas, thyroid gland, adrenal medulla, breast, prostate, and skin. The list of hormones produced by tumors derived from members of this group of neuroendocrine cells includes ACTH, calcitonin, vasoactive intestinal peptide (VIP), bombesin, growth hormone-releasing hormone (GHRH), pancreatic polypeptide, corticotropin-releasing hormone (CRH), neurotensin, somatostatin (SRIH), and other small peptides.

Defined clinical syndromes

There are clearly defined clinical ectopic hormone syndromes that occur with some frequency. Their recognition may help in the definition of the cancer type and lead to appropriate management approaches. In addition, these syndromes are a major cause of morbidity and mortality; treatment approaches are available for many of these syndromes and can improve both quality and duration of survival.

Ectopic ACTH production

Inappropriate secretion of ACTH, although uncommon, is an important cause of morbidity and mortality in certain types of malignancies. There are at least two different mechanisms: ectopic ACTH production or ectopic production of CRH, the hypothalamic peptide that normally stimulates ACTH synthesis and release.

The most common cause of ectopic ACTH production is the expression of proopiomelanocortin (POMC) by a tumor. Posttranslational processing of POMC normally proceeds down one of two mutually exclusive pathways.¹⁰⁵ The POMC precursor can be cleaved in two different ways to produce peptides with very different biologic activities. The pathway that leads to ACTH production and Cushing syndrome is one in which POMC is cleaved to produce big melanocyte-stimulating hormone and ACTH. Fortunately for cancer patients, the enzymes that cleave POMC to produce ACTH are expressed uncommonly outside of the normal pituitary gland. Most malignant tumors expressing the POMC gene produce peptides that cause no identifiable clinical syndrome. The most common tumor type that overexpresses POMC and the proteolytic enzymes that cleave it to produce ACTH is SCLC, although a broader spectrum of tumors including pulmonary carcinoid, medullary thyroid carcinoma, islet cell malignancy, pheochromocytoma, and occasional ganglioneuromas will produce this hormone. Cushing syndrome produced by “ectopic” production of ACTH is characterized by adrenal cortical hyperplasia and hypercortisolism.¹⁰⁶

The second cause of excessive ACTH production is tumor production of CRH.¹⁰⁷ Ectopic production of this peptide causes a clinical syndrome characterized by pituitary corticotrope hyperplasia leading to adrenal cortical hyperplasia and Cushing syndrome. Identification of excessive CRH production requires that the clinician consider this possibility and measure CRH in blood. Neoplasms that can produce CRH include medullary thyroid carcinoma, paragangliomas, prostate cancer, and islet cell neoplasms. There are examples of cancers that produce both ACTH and CRH.

Patients with ectopic ACTH syndrome may present with clinical features of Cushing syndrome—easy bruising, centripetal obesity, muscle wasting, hypertension, diabetes, and metabolic alkalosis predominate. Alternatively, patients with rapidly growing SCLC may present with a clinical syndrome characterized by cachexia, muscle atrophy, profound hypokalemic metabolic alkalosis, and hypertension without the other clinical findings of Cushing syndrome.

The hallmark of ectopic ACTH syndrome is the finding of an elevated plasma ACTH concentration. However, in the differential diagnosis of hypercortisolism in a cancer patient with an elevated plasma ACTH concentration, one should also consider an ACTH producing pituitary tumor.¹⁰⁸ Differentiation between pituitary ACTH production (a primary pituitary tumor) and ectopic tumor production of ACTH or ectopic CRH production, mimicking a pituitary tumor, is among the most difficult diagnostic workups in the discipline of endocrinology. There are numerous examples where failure to correctly differentiate between ectopic ACTH production and a pituitary tumor producing ACTH has led to incorrect treatment.¹⁰⁹ In some cases, such as ectopic ACTH production by a SCLC, the clinical syndrome (hypokalemia, metabolic alkalosis, hypertension, exceedingly high plasma cortisol levels, and a rapidly growing tumor) will lead to a straightforward diagnosis.¹¹⁰ In other cases, particularly those with tumors that have not been associated with frequent ectopic ACTH production, the diagnosis can be challenging and require the assistance of an endocrinologist experienced in this area and with full access to the spectrum of interventional radiologic techniques used to differentiate pituitary from nonpituitary sources of ACTH.

The diagnostic evaluation begins with the measurement of plasma ACTH in a patient with hypercorticism ([Figure 4](#)). A plasma ACTH concentration >100 pg/mL should prompt investigation for an ectopic source of ACTH.¹¹¹ In patients with an ACTH value below 10 pg/mL (collected under appropriate conditions to prevent degradation of ACTH), a primary adrenocortical source of cortisol (adrenal adenoma or carcinoma) should be considered. The majority of patients will fall into the range of ACTH values between 10 and 100 pg/mL. The major differential diagnostic possibilities in these patients include a central (pituitary) or peripheral (ectopic) source of ACTH, with production of ectopic CRH by a tumor a rare possibility. Differentiation between central and peripheral sources of ACTH is accomplished by several approaches. The identification of a pituitary tumor by MRI provides a presumptive diagnosis of a pituitary source, although pituitary tumors that are nonfunctional or produce another hormonal product occur with some frequency. For this reason, petrosal venous sinus sampling is often employed and permits differentiation between a central (pituitary) and peripheral (ectopic) source of ACTH.¹¹² The diagnosis of ectopic CRH production can only be made by suspecting this diagnosis and measuring the plasma concentration of this peptide. It is also possible to use other approaches to diagnose ectopic ACTH syndrome. ACTH production from a tumor is not generally suppressed by a high dose of dexamethasone. In patients with an ACTH >10 pg/mL, administration of a single 8 mg oral dose of dexamethasone at 11:00 p.m. followed with measurement of serum cortisol level at 8:00 a.m. permits differentiation between central and peripheral sources.¹⁰⁶ In pituitary Cushing syndrome, dexamethasone will generally suppress ACTH by 50%, whereas ACTH production by an ectopic source will generally not be suppressed. False-positive or false-negative results occur with each of these testing procedures.

Figure 4 Differential diagnosis of adrenocorticotropin (ACTH)-dependent Cushing syndrome. It is difficult to differentiate between a pituitary (a) and ectopic (b) source of ACTH, the most common causes of ACTH-dependent Cushing syndrome. To differentiate with certainty, placement of catheters in veins draining the pituitary gland (inferior petrosal sinuses) combined with stimulation by exogenous corticotropin-releasing hormone permits differentiation with certainty (discussed in text). Ectopic corticotropin-releasing hormone (CRH) production by a tumor results in increased ACTH production by the pituitary gland (c). It is difficult to differentiate between ectopic CRH production and pituitary-dependent Cushing syndrome, necessitating the measurement of CRH in peripheral blood to make the diagnosis with certainty. Malignant tumors occasionally produce both CRH and ACTH, further complicating the diagnostic evaluation (not shown).

Surgical removal or treatment of a malignant tumor with chemotherapeutic agents is the primary therapy for an ACTH- or CRH-producing tumor. Any electrolyte abnormalities, diabetes mellitus, or hypertension should be corrected before a planned surgical procedure. Patients with long-standing Cushing syndrome and elevated plasma cortisol values have higher morbidity and mortality postoperatively. Preoperative treatment options include metyrapone (1–4 g/day orally), aminoglutethimide (250 mg orally four times per day with upward titration), or ketoconazole (200–400 mg twice a day orally).^{113, 114} Parenteral etomidate, used for sedation and induction of anesthesia, rapidly inhibits cortisol synthesis at subhypnotic concentrations.¹¹⁵ It is titrated from 0.3 to 4 mg/kg/h to normalize serum cortisol measurements and has been used to rapidly reverse hypercortisolism in a small number of patients. Replacement glucocorticoid therapy is needed when pharmacologic inhibitors of cortisol production are used to prevent adrenal insufficiency. If surgical removal of an ACTH- or CRH-producing tumor is not possible or inadvisable, chronic therapy with inhibitors of cortisol synthesis may be required. Alternatively, laparoscopic adrenalectomy with subsequent replacement of corticosteroids provides a rapid and generally safe approach to management of hypercortisolism. The development of retroperitoneal laparoscopic adrenalectomy during the past decade provides a rapid and safe technique to remove the adrenal glands. This technique is probably underutilized as a therapeutic strategy for management of ectopic ACTH

syndrome.

Patients with rapidly progressive SCLC and ectopic ACTH syndrome form a unique subset of patients because of the need to initiate chemotherapy on a timely basis. Unfortunately, these patients are also highly susceptible to opportunistic infections, and initiation of therapy will often lead to death or serious morbidity related to infection.¹¹⁶ The central dilemma in these patients is that a period of 1–2 weeks may be required for pharmacologic inhibitors of cortisol synthesis to normalize the serum cortisol (and a longer period may be required for normalization of immunity), a delay in the initiation of chemotherapy that is generally deemed unacceptable from an oncologic perspective. Retroperitoneal laparoscopic adrenalectomy, a straightforward and well-tolerated technique following normalization of electrolyte abnormalities and hypertension, may provide a strategy for rapid normalization of excessive cortisol secretion. Prophylactic therapy for opportunistic infections caused by pneumocystis carinii or fungi should be considered if chemotherapy is initiated shortly after normalization of the serum cortisol.

Hypercalcemia caused by malignancy

Hypercalcemia is a common and serious cause of morbidity and mortality in cancer patients.

The most common causes of hypercalcemia in patients with cancer are PTHrP-mediated hypercalcemia, increased production of the active metabolite of vitamin D, calcitriol or 1,25 dihydroxy vitamin D₃, and localized osteolytic hypercalcemia.^{117, 118} Ectopic production of PTH is a rare cause of cancer-associated hypercalcemia. Other common causes of hypercalcemia, most notably primary hyperparathyroidism, should be considered in the cancer patient with hypercalcemia. Measurement of serum intact parathyroid hormone (iPTH) permits differentiation between hyperparathyroidism and a number of other causes of hypercalcemia. The combination of hypercalcemia and an elevated parathyroid hormone level combined with increased urinary calcium excretion provides reasonable evidence for primary hyperparathyroidism. Suppression of the iPTH below the normal range is found in PTHrp or calcitriol-mediated hypercalcemia. Other less-common causes of hypercalcemia in cancer will be discussed below.

Parathyroid hormone-related protein

PTHrP is a small peptide in which 8 of the first 16 amino acids are identical to PTH. This small peptide causes hypercalcemia by binding to the PTH receptor and activating the expression of an osteoblast-specific cell surface protein, RANK ligand (RANKL). Interaction between RANKL and the RANK receptor on the osteoclast precursor causes increased osteoclast differentiation, bone resorption, and hypercalcemia. Other PTH-like actions of PTHrp include hypophosphatemia and increased urinary calcium excretion. PTHrp-mediated hypercalcemia is characterized by a suppressed iPTH level and a low or normal calcitriol level. This contrasts with the finding of elevated iPTH and calcitriol levels in primary hyperparathyroidism. PTHrP production is found commonly in squamous cell carcinomas; other tumors that produce it include: breast, neuroendocrine, renal, melanoma, and prostate tumors.

Calcitriol production by malignant tumors

Lymphoma commonly produces calcitriol, leading to increased gastrointestinal absorption of calcium. Lymphomatous tissue, such as granulomatous tissue seen in sarcoid, berylliosis, silicone-induced granulomatous, tuberculosis, and fungal infection, expresses 1 α -hydroxylase, the enzyme that converts 25-hydroxy vitamin D₃ to calcitriol. Clinical studies show that a high percentage of lymphoma patients have hypercalciuria at the time of diagnosis; a smaller percentage have frank hypercalcemia.¹¹⁹ The characteristic clinical features of hypercalcemia in the context of lymphoma include a suppressed serum iPTH, a normal or slightly increased phosphorus level (caused by the suppression of PTH),

hypercalciuria, absence of bone metastasis, and an elevated serum calcitriol level in approximately one-half of hypercalcemic patients.¹¹⁹

Localized osteolytic bone resorption causing hypercalcemia

Certain malignancies metastasize to bone frequently, and some cause hypercalcemia. Hypercalcemia associated with breast cancer and myeloma is common. In contrast, prostate cancer, despite its more frequent presence in bone, rarely produces hypercalcemia. Malignancies that cause hypercalcemia produce cytokines, PTHrP, or other factors that stimulate increased bone resorption.^{117, 118} Perhaps, the best characterized is the production of PTHrP by breast carcinoma cells. There is compelling evidence in animal models that PTHrP production by breast cancer cells stimulates osteoclastic resorption and release of transforming growth factor (TGF)- β from normal bone. In this animal model, TGF- β release from bone stimulates proliferation of breast carcinoma growth, setting up a loop in which PTHrP production not only stimulates increased osteoclastic resorption, but also accelerates growth of adjacent breast cancer.^{120, 121} Indeed, this thought process led to an examination of and subsequent approval of bisphosphonates and denosumab, classes of drugs that inhibit osteoclast bone resorption, for prevention of cancer metastasis.^{122, 123}

In multiple myeloma, several factors contribute to localized osteolysis. Increased expression of RANKL causing localized osteoclast proliferation appears to be the most important cause. Other factors that may contribute to osteoclast proliferation in myeloma are interleukin-6 and macrophage inflammatory protein 1 α .¹¹⁸

Impact of malignancy-related hypercalcemia

Severe hypercalcemia in the context of hypercalcemia is associated with a shortened life span. The average survival for patients with severe and unresponsive hypercalcemia can be measured in weeks to months. The causes of death include complications of hypercalcemia (coma and renal failure) and progression of tumor. The development of hypercalcemia is often, although not always, an indicator of tumor progression in the face of adequate therapy. As it is not always possible to predict which patients will respond to oncologic therapy, it is important to treat hypercalcemia in all newly diagnosed patients with cancer. Whether to continue to treat recurrent and/or refractory hypercalcemia is a decision that should be based on response of the causative tumor to oncologic therapy and the overall prognosis of the patient. Severe hypercalcemia frequently causes depression of cerebral function or coma, a clinical situation that may reduce suffering in a dying patient.

Therapy of hypercalcemia

Dehydration is a common finding in hypercalcemic patients. Increased urine excretion of calcium causes a concentrating defect, leading to increased fluid loss. Initial management should focus on the reversal of dehydration by infusion of a solution of normal saline at rates between 100 and 300 mL/h. Hydration will commonly lower the serum calcium by 10–40% over a period of 6–12 h. Patients with severe hypercalcemia, defined as a serum calcium concentration >13 mg/dL (3.25 mmol/L), an alteration of mental status, or evidence of renal dysfunction attributable to hypercalcemia should be treated with either intravenous pamidronate (60–90 mg over 4 h) or zoledronate (4 mg over 30 min),¹²⁴ glucocorticoids (40–60 mg/day prednisone equivalent), or gallium nitrate (200 mg/m²/day, infused daily for 7 days).^{125, 126} Salmon calcitonin may lower the serum calcium concentration by 1–2 mg/dL early in the treatment course, but is rarely effective long term. These drugs are sometimes used in combination or sequentially in a patient who is poorly responsive. Glucocorticoids, which inhibit calcium absorption, are most commonly

used as primary therapy for lymphoma, whereas bisphosphonate therapy is more likely to be effective in hypercalcemia associated with solid tumors. Zoledronate is generally more effective than pamidronate because of its increased potency.¹²⁷ Use of bisphosphonates for long-term treatment of bone metastasis has been associated with development of osteonecrosis of the jaw in 1–2.5% of treated patients. This has not been an issue in patients treated short term for hypercalcemia associated with malignancy.

A monoclonal antibody directed against RANKL (denosumab) prevents its interaction with the RANK receptor on osteoclast precursors, thereby reducing osteoclast-mediated bone resorption.¹²⁸ Denosumab is an effective inhibitor of bone resorption, and recent clinical studies have established its efficacy in patients with hypercalcemia and bone metastasis, particularly those patients who have become unresponsive to bisphosphonate therapy.¹²⁸

Human chorionic gonadotropin

Human chorionic gonadotropin (HCG) is formed from two different protein subunits encoded by separate genes. The first is the α subunit that is shared by all members of the pituitary class of glycoprotein hormones including HCG, LH, follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH). The second, the β subunit, is unique for each of these hormones. Production of HCG is found in trophoblastic tumors (choriocarcinomas, testicular embryonal carcinomas, and seminomas) and, uncommonly, in tumors of the lung and pancreas. In younger children, precocious puberty, caused by HCG stimulation of ovarian function, is seen. In adult males, gynecomastia is a common occurrence. Hyperthyroidism may develop from an interaction of HCG with the thyroid-stimulating hormone receptor (TSHR), particularly when β -HCG is expressed at high levels.

Removal or effective therapy for the underlying tumor is the most effective therapy for clinical syndromes caused by excessive β -HCG production. Hyperthyroidism can be treated short term with thionamide therapy if there is belief that chemotherapy or other strategies to treat the underlying malignancy are likely to be effective. In patients with less-responsive tumors, thyroidectomy or radioactive iodine may be required.

Hypoglycemia

Tumor-induced hypoglycemia is an uncommon but challenging cause of morbidity for cancer patients. Three different clinical syndromes have been identified. First, insulin can be produced by islet cell malignancy. Islet cell tumors commonly produce low levels of insulin that are clinically insignificant until large tumor burdens, most commonly in the form of hepatic metastasis, develop. A second cause is insufficient gluconeogenesis, seen in patients with near complete replacement of hepatic parenchyma by tumor, interfering with or eliminating glucose production. The third form is caused by increased concentrations of insulin-like growth factor II (IGF-II), a peptide that activates the insulin receptor. This syndrome is most commonly seen in patients with fibrosarcomas, hemangiopericytomas, or hepatomas. In these patients IGF-II levels are most commonly elevated, the result of a failure of insulin-like growth factor binding protein 3 (IGFBP3) and acid labile subunit to form a complex capable of binding IGF-II efficiently. The elevated circulating IGF-II activates the insulin receptor and causes hypoglycemia.^{129–131}

The most common presentation for each of these clinical syndromes is fasting hypoglycemia, and patients are most likely to develop symptoms during normal periods of fasting, particularly during nocturnal hours. Measurement of a plasma insulin, proinsulin, and C-peptide during a period of hypoglycemia is the most important diagnostic tool for separating the first clinical type (insulin production) from the second (replacement of liver by tumor) and third (IGF-II) types. The findings of elevated insulin, proinsulin, and C-peptide in the face of hypoglycemia (and the absence of any drugs that might stimulate insulin release

from normal pancreas) make a compelling case for unregulated insulin production as a cause of the hypoglycemia. In contrast, insulin, proinsulin, and C-peptide levels will be low in tumor replacement of the liver or IGF-II-mediated hypoglycemia. Laboratory findings in IGF-II-mediated hypoglycemia include an elevated serum IGF-II, low or normal insulin, proinsulin, and C-peptide measurements, low IGF-I levels, and generally normal IGFBP3 or acid labile subunit measurements in the context of a large sarcoma or retroperitoneal tumor.

Surgical excision or antineoplastic therapy to reduce tumor mass is effective in insulin or IGF-II-mediated hypoglycemia; there is little effective therapy for hepatic replacement by tumor other than providing glucose. Hypoglycemia is treated with frequent meals. Patients may remain symptom-free by being awakened for caloric intake during nocturnal hours. A continuous infusion of 20% dextrose through a central venous line may be required to maintain normal blood glucose in patients, particularly those with hepatic replacement by tumors. Glucagon infusion (0.5–2 mg/h) to stimulate hepatic gluconeogenesis is also an effective therapy for patients with insulin-producing tumors or those with IGF-II-mediated hypoglycemia. It is important to document a response to glucagon (1 mg subcutaneously with measurement of plasma glucose at 30 and 60 min following injection) before trying this therapeutic approach. Glucagon can be administered in small volumes (1–5 mL over 24 h), making it possible to use small infusion pumps.¹³² Patients treated with glucagon may develop the characteristic rash associated with glucagonoma, necessitating discontinuance of this treatment modality. Other therapies that have been applied with periodic success include recombinant GH (3–6 µg/kg subcutaneously daily) or glucocorticoids (20–40 mg prednisone equivalents per day). Octreotide or lanreotide have been used in patients with insulin-producing islet cell tumors, generally without success. The lack of success may relate to the fact that SRIH analogs currently available are more effective for inhibiting glucagon than insulin secretion. Diazoxide (3–8 mg/kg/day in 2–3 divided doses) has been used successfully to inhibit insulin secretion, but causes fluid retention, thereby limiting its usefulness at effective doses.

Hypoglycemia may also occur in patients with lactic acidosis in the context of end-stage leukemia or lymphoma. This clinical syndrome occurs in patients with end-stage or extensive disease and leukemic/lymphomatous involvement of the liver. It is hypothesized that lactic acid production by tumor cells exceeds the ability of the liver to clear it. The etiology of the hypoglycemia is unclear, but may result from impaired hepatic gluconeogenesis.¹³³

Syndrome of inappropriate antidiuretic hormone

SIADH was discussed earlier (see the section titled “Disorders of Electrolyte/Mineral Metabolism: Hyponatremia”) as a side effect of cancer therapy. In addition, approximately 15% of SCLC, 1% of other lung cancers, and 3% of squamous cell head and neck cancers produce vasopressin in an unregulated manner, leading to hyponatremia, hypoosmolality, increased urine sodium excretion, and an inappropriately high urine osmolality relative to the plasma tonicity.¹³⁴ In addition, other benign or malignant neoplasms that include primary brain tumors, hematologic neoplasms, skin tumors, and gastrointestinal, gynecologic, breast, and prostate cancers, and sarcomas can produce this clinical syndrome.

Most patients who develop this syndrome are asymptomatic. In cases where the serum sodium concentration falls <120 mEq/L, altered mental status and seizures may develop. In particular, women of reproductive age who develop hyponatremia may develop profound cerebral degeneration. Fluid restriction can be used effectively for short-term management, but treatment with demeclocycline (150–300 mg/day), an agent that inhibits the effects of vasopressin on the kidney, is preferable for long-term treatment. Vasopressin receptor antagonists, conivaptan, lixivaptan, tolvaptan, and satavaptan, have

shown efficacy in clinical trials and at least one, conivaptan, is currently FDA-approved in the United States in an intravenous form (20 mg intravenously over 30 min, followed by 20 mg over 24 h). Tolvaptan (15–60 mg/day) is approved for oral use. Both of these agents are highly effective and it is important to monitor the serum sodium concentration carefully after initiation of therapy.

A consideration in the long-term use of demeclocycline and the V2 receptor antagonists is the cost of therapy. In a patient with a serum sodium concentration <120 mEq/L, use of intravenous conivaptan results in improvement or normalization of the serum sodium over a 24–48 h period and may be most appropriate in this emergent situation; demeclocycline effects are seen over several days. For longer-term therapy, particularly when it is not possible to reduce tumor mass, consideration should be given to the less-expensive demeclocycline, which is generally well tolerated and effective.

Other ectopic hormone syndromes

Tumor-induced osteomalacia

Severe hypophosphatemia caused by renal phosphate wasting is the hallmark of tumor-induced osteomalacia. This clinical syndrome is characterized by osteomalacia, caused by inadequate mineralization of osteoid, and moderate to severe proximal myopathy.¹³⁵ Tumors that produce this clinical syndrome include mesenchymal tumors (osteoblastomas, giant cell osteosarcomas, hemangiopericytomas, hemangiomas, and nonossifying fibromas)¹³⁶ and, rarely, malignant tumors such as prostate or lung cancer. There is compelling evidence that fibroblast growth factor-23, a member of the fibroblast growth factor family that is mutated in autosomal dominant osteomalacia,¹³⁷ is overexpressed by some neoplasms causing tumor-induced osteomalacia.¹³⁸ Oral or intravenous supplementation of phosphate combined with vitamin D therapy is generally effective for eradicating or improving clinical symptoms. Complete surgical removal of the tumor is generally curative.

Erythropoietin, thrombopoietin, leukopoietin, or colony-stimulating factor production

Polycythemia caused by ectopic erythropoietin production is a rare clinical syndrome. It is found in cerebellar hemangioblastoma, uterine fibroids, pheochromocytomas, and renal cell, ovarian, and hepatic cancers.^{139, 140} Treatment can include surgical or chemotherapy reduction of tumor mass or phlebotomy. Other less well-defined syndromes include production of thrombopoietin, leukopoietin, or colony-stimulating factor by some tumors. These conditions are treated by appropriate chemotherapy to reduce its size or by surgical removal.

Renin production

Production of renin by renal (Wilms tumor, renal cell carcinoma, or hemangiopericytoma), lung (SCLC and adenocarcinoma), hepatic, pancreatic, or ovarian carcinomas can produce a clinical syndrome characterized by hypertension, hypokalemia, and evidence of increased aldosterone production.¹⁴¹ Therapy with spironolactone, angiotensin-converting enzyme inhibitors, or angiotensin receptor antagonists may lower the blood pressure and normalize electrolyte abnormalities in patients in whom the tumor cannot be resected.

Growth hormone and prolactin

Acromegaly is a condition characterized by elevated GH and IGF-1 values, most commonly caused by a pituitary tumor. There are uncommon examples of GH production by lung and gastric adenocarcinomas. Ectopic production of GHRH, the hypothalamic peptide that normally regulates GH production by the

pituitary,¹⁴² has been demonstrated for islet cell tumors, bronchogenic carcinoids, and SCLC. It is unlikely that treatment with SRIH analogs, one of the mainstay therapies for pituitary tumors producing GH, will be effective. However, the GH antagonist, pegvisomant, is likely to be effective for treatment of GH excess. Ectopic prolactin production is found rarely in gonadoblastoma,¹⁴³ lymphoma,¹⁴¹ leukemia,¹⁴⁴ and colorectal cancer.¹⁴⁵ The clinical syndrome includes galactorrhea and amenorrhea in women and hypogonadism and gynecomastia in men. Dopamine agonists (bromocriptine, quinagolide, or cabergoline), effective for treatment of pituitary prolactinomas, are generally ineffective for treatment of ectopic prolactin production.

Chapter 139

Infections in patients with cancer

Lior Nesher, MD ■ Kenneth V. I. Rolston, MD, FACP

Overview

Patients with cancer have an increased risk of developing infections, owing both to their underlying disease and its treatment. This risk appears to be greatest in patients with hematologic malignancies and in hematopoietic cell transplant recipients. This is due primarily to the development of various immunologic defects such as neutropenia and impaired cellular and/or humoral immunity, each associated with a unique spectrum of infection. Newer therapeutic modalities for the treatment of some cancers are changing the spectrum of infections as are the increasing use of catheters and other medical devices. While bacterial infections are documented most often, opportunistic fungal and viral infections are being encountered with increasing frequency. The morbidity and mortality of infections in cancer patients is generally greater than in the general population. Thus, early diagnosis and the prompt administration of appropriate therapy are of paramount importance. Antimicrobial resistance among these pathogens has become a worldwide problem, which can only be partially tackled by the development of novel agents. Consequently, the importance of conducting frequent epidemiologic surveillance in order to detect local epidemiologic shifts and of infection prevention, infection control, and antimicrobial stewardship cannot be emphasized enough. The number of cancer survivors is steadily increasing. Many of these patients remain immunosuppressed for substantial periods of time. Keeping these survivors healthy and infection free will continue to be a challenge for years to come.

Infection remains a common problem in patients with cancer. The frequency and nature of infection depend on the type of underlying neoplastic disease.¹ Multiple episodes of infection are not uncommon. Neutropenia, impaired cellular or humoral immunity, the use of catheters and other medical devices, splenectomy, surgery, radiation, nutritional status, and local factors such as obstruction increase the susceptibility of these patients to infection. Each risk factor is associated with a unique set of infections, although there is some overlap. Multiple factors often exist in the same patient. [Table 1](#) lists defects in host defense mechanisms and the infections associated with those defects.

Table 1 Defects in host defense mechanisms and common infections associated with malignant diseases

Disease	Prominent defect	Predominant infections
Acute leukemia, aplastic anemia	Prolonged neutropenia	Gram-positive cocci, Gram-negative bacilli, fungi (<i>Candida</i> , <i>Aspergillus</i> , <i>Zygomycetes</i> , <i>Fusarium</i> , <i>Trichosporon</i>)
Hairy cell leukemia	Neutropenia, impaired lymphocyte function	Gram-negative bacilli, Gram-positive cocci, mycobacteria (including nontuberculous)
Chronic lymphocytic leukemia, multiple myeloma	hypogammaglobulinemia (impaired humoral immunity)	Encapsulated organisms, <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Neisseria meningitides</i>
Hodgkin disease	Impaired T-lymphocyte response	<i>Pneumocystis jiroveci</i> , <i>Cryptococcus</i> spp., mycobacteria, <i>Toxoplasma</i> , <i>Listeria monocytogenes</i> , <i>Cryptosporidium</i> , <i>Candida</i> , CMV
Hematopoietic stem cell transplant recipients	Neutropenia, impaired cellular and humoral immunity	Gram-positive cocci, Gram-negative bacilli, cytomegalovirus, <i>Candida</i> , <i>Aspergillus</i> , herpes viruses (HSV, VZV, CMV)
Breast cancer	Tissue necrosis, radiation damage, foreign bodies	Gram-positive cocci, Gram-negative bacilli, anaerobes (polymicrobial infections common)
Lung cancer	Local obstruction, tissue necrosis	Gram-positive cocci, Gram-negative bacilli, anaerobes (polymicrobial infections common)
Gynecologic malignancy	Local obstruction, tissue necrosis	Mixed aerobic and anaerobic enteric flora including <i>Enterococcus</i> spp. (polymicrobial infections common)

Infections primarily associated with neutropenia

Types of febrile episodes

A specific causative pathogen is identified in about 20–25% of febrile episodes in neutropenic patients (microbiologically documented infections). An additional 20–25% of episodes have identifiable sites of infection (e.g., pneumonia, cellulitis, and enterocolitis) but have negative cultures (clinically documented infections). Approximately 40–45% have neither an obvious clinical focus of infection nor positive cultures, and are referred to as episodes of unexplained fever ([Figure 1](#)). The majority of these are presumed to be due to an occult infection and respond to antibiotic therapy. Fewer than 5% of febrile episodes are due to non-infectious causes such as transfusion reactions, tumor fever, or drug fever.^{2, 3}

Figure 1 Types of febrile episodes in patients with neutropenia.

Sites of infection

The most common sites of infection encountered in neutropenic patients are the respiratory tract followed by the bloodstream (including central line-associated bloodstream infection-CLABSI), the urinary tract, skin and skin structure infections (SSSIs), and infections originating from the oro-pharynx and the gastrointestinal tract ([Figure 2](#)). Less frequent but clinically important sites include the central nervous system, bones, joints, and end organs such as the liver and spleen. Most microbiologically documented infections are caused by the patient's own microflora with a minority being acquired from exogenous sources/environmental exposure.

Figure 2 Common sites of infection in patients with neutropenia.

Infections primarily associated with impaired cellular and humoral immunity

Defects in cell-mediated immunity are common in patients with hematologic malignancies including malignant lymphomas, in allogeneic hematopoietic cell transplant (HCT) recipients, in recipients of high-dose corticosteroid therapy, and in patients treated with newer modalities (nucleoside analogs, monoclonal antibodies, and temozolomide) and result in an increase in infections caused by bacterial pathogens such as *Legionella* spp., *Salmonella* spp., *Nocardia* spp., *Listeria monocytogenes*, and *Rhodococcus equi*.^{4–6} Mycobacterial infections (*Mycobacterium tuberculosis* and nontuberculous mycobacteria) are also relatively common in such patients. *Aspergillus* spp., *Pneumocystis jiroveci*, and the endemic fungi (*Cryptococcus neoformans*, *Histoplasma capsulatum*, and *Coccidioides immitis*) cause most of the fungal infections in this setting.^{7,8} Viral infections are predominantly caused by the herpes group of viruses with cytomegalovirus (CMV) being the most frequent. The community respiratory viruses are important causes of morbidity and mortality in allogeneic HCT recipients. Parasitic infections such as toxoplasmosis, strongyloidosis, and babesiosis are also seen more frequently in patients with impaired cellular or humoral immunity.^{9–11} In patients with impaired humoral immunity, infections caused by encapsulated organisms such as *Streptococcus pneumoniae* and *Haemophilus influenzae* are common.

Infections in patients with solid tumors

Patients with solid tumors who are not significantly immunosuppressed also develop infections frequently. Risk factors include neutropenia that is generally short lived, disruption of normal anatomic barriers (skin and mucosal surfaces), obstruction caused by bulky or rapidly expanding tumors, radiation

damage, surgical procedures, and the presence of various medical devices. The common sites of infection seen in patients with various solid tumors are summarized in [Table 2](#). The site of infection depends on the location and size of the tumor or the site and nature of the medical device, radiation, or surgical procedure. Surgical site infections and catheter-related infections are caused most often by organisms colonizing the skin, although opportunistic pathogens such as *Pseudomonas aeruginosa* and other Gram-negative bacilli are beginning to emerge in this setting.¹² Removal of the offending device and complete or partial relief of obstruction are important aspects of the management of infections in patients with solid tumors. If this is not feasible, prolonged suppressive therapy might be necessary.

Table 2 Common infections in patients with solid tumors

Tumor location	Infection site or type
Breast	Wound infection; cellulitis or lymphangitis related to axillary node dissection; mastitis; breast abscess; bacteremia
Central nervous system (brain, meninges)	Wound infection; epidural/subdural infection; brain abscess; meningitis/ventriculitis; proximal and distal end-shunt-related infections; aspiration pneumonia; urinary tract infection; bacteremia
Genitourinary and prostate	Cystitis; urethritis; acute/chronic pyelonephritis ± bacteremia; catheter-related complicated urinary tract infection (nephrostomy/stents); wound infection; acute/chronic prostatitis; epididymitis, orchitis; pelvic abscess
Hepatobiliary-pancreatic	Wound infection; peritonitis; ascending cholangitis ± bacteremia; hepatic, pancreatic, or subdiaphragmatic abscess
Head and neck	Cellulitis; wound infection; deep facial space infection; mastoiditis/osteomyelitis; sinusitis; aspiration pneumonia; bacteremia; suppurative intracranial phlebitis; meningitis; brain abscess; retropharyngeal and paravertebral abscesses
Musculoskeletal (muscles, bones, joints)	Wound infections; pyomyositis; lymphangitis; bursitis; synovitis; septic arthritis; osteomyelitis; wound infection; prosthesis-related infections; bacteremia
Upper gastrointestinal	Esophagitis; tracheoesophageal fistula with pneumonitis/lung abscess; gastric perforation and abscess; feeding tube-related infections; mediastinitis/osteomyelitis
Lower gastrointestinal	Wound infection; intra-abdominal or pelvic abscess; peritonitis (perforation); enterocolitis; urinary tract infection; perianal/perirectal infection; sacral/coccygeal osteomyelitis

Spectrum of infection

Bacterial infections

Currently, Gram-positive organisms cause ~50% of bacterial infections in neutropenic patients ([Table 3](#)). Gram-negative bacilli account for ~18%, and a substantial proportion, especially deep tissue infections, is polymicrobial.^{13–16} Bacteria commonly isolated from neutropenic patients are depicted in [Table 4](#). Geographic and institutional variations do exist.¹⁷ Consequently, clinicians should consider local epidemiology and resistance patterns when initiating empiric antibiotic therapy.

Table 3 Bacterial infection in 2223 febrile episodes in neutropenic patients

Infection type ^a	2002–2003		2012–2013	
	No.	%	No.	%
Microbiologically documented	262	26	321	26
Gram-positive	134	51	163	51
Gram-negative	51	20	55	17
Polymicrobial	71	27	92	29
Anaerobic	6	2	11	3
Clinically documented	210	21	298	24
Unexplained fever	521	53	611	50

^a These data are derived from surveys conducted at the University of Texas MD Anderson Cancer Center, Houston, Texas, USA.

Table 4 Common infectious agents in patients with cancer

Neutropenia
Bacteria
Gram-positive organisms
Coagulase-negative staphylococci
<i>Staphylococcus aureus</i> (including MRSA)
<i>Enterococcus</i> spp. (including VRE)
Viridans group streptococci
Gram-negative organisms
<i>Escherichia coli</i>
<i>Klebsiella pneumoniae</i>
<i>Pseudomonas aeruginosa</i>
Other <i>Enterobacteriaceae</i>
<i>Stenotrophomonas maltophilia</i>
Fungi
<i>Candida</i> spp.
<i>Aspergillus</i> spp.
<i>Zygomycetes</i>
<i>Fusarium</i> spp.
Cellular immune dysfunction
Bacteria
<i>Listeria monocytogenes</i>
<i>Rhodococcus equi</i>
<i>Salmonella</i> spp.

Mycobacteria
<i>Nocardia</i> spp.
<i>Legionella</i> spp.
Fungi
<i>Aspergillus</i> spp.
<i>Cryptococcus</i> spp.
<i>Histoplasma capsulatum</i>
<i>Coccidioides immitis</i>
<i>Pneumocystis jiroveci</i>
Protozoa
<i>Toxoplasma gondii</i>
Helminth
<i>Strongyloides stercoralis</i>
Viruses
Cytomegalovirus
Herpes simplex virus I and II
Varicella-zoster virus
Epstein–Barr virus
Humoral immune dysfunction
<i>Streptococcus pneumoniae</i>
<i>Haemophilus influenzae</i>

Gram-positive bacteria

Coagulase-negative staphylococci (CoNS) are isolated most often and predominantly cause CLABSI.¹⁸ *Staphylococcus lugdunensis* is a more virulent species and needs more aggressive management.^{19, 20} *Staphylococcus aureus* is often associated with deep-seated infections (deep abscesses and endocarditis), and all patients with *S. aureus* bacteremia should be evaluated for such foci.²¹ Other sites of infection include SSSIs, pneumonia, bone and joint infections, and septic thrombophlebitis. Of concern is the increasing rate of methicillin resistance among *S. aureus* isolates, which is now >50% at many centers.²² Many of these isolates have developed tolerance or reduced susceptibility to vancomycin (referred to as the MIC creep), thereby reducing the efficacy of this agent.^{23–27} Alternative therapeutic agents include daptomycin, telavancin, dalbavancin, oritavancin, linezolid, tedizolid, and ceftaroline.^{28–30}

Viridans group streptococci (VGS) are encountered often in patients with acute leukemia undergoing intensive chemotherapy and in allogeneic HCT recipients.^{31, 32} Risk factors include chemotherapy with agents that induce severe oral mucositis, prophylaxis with fluoroquinolones that can promote the selection of these organisms, and treatment of chemotherapy-induced gastritis with antacids or histamine type 2 (H2) antagonists.^{33, 34} *Streptococcus mitis* is the predominant species. Bacteremia is the most common manifestation. Some patients develop a rapidly progressive disseminated infection involving the bloodstream, lungs, central nervous system, and skin ([Figure 3](#)). This is associated with 25–35%

mortality despite aggressive therapy.³⁵ Of concern are reports that 20–60% of VGS are penicillin resistant at some institutions.^{31, 36} Beta-hemolytic streptococci also cause infections in neutropenic patients, but less often than VGS.³⁷

Figure 3 Invasive infection caused by α -hemolytic (viridans) streptococci. Note the hemorrhagic nature of the lesions in this patient with thrombocytopenia.

The enterococci colonize the lower intestinal tract.^{38, 39} Common sites of infection are the bloodstream, urinary tract, and intra-abdominal infections. *Enterococcus faecalis* is the predominant species accounting for 60–70% of isolates. Most *E. faecalis* strains are susceptible to penicillin, ampicillin, and vancomycin although these agents may lack bactericidal activity. Consequently, combinations of these agents with aminoglycosides are recommended for serious enterococcal infections. *Enterococcus faecium* isolates often express high-level resistance to the aminoglycosides, ampicillin, and vancomycin-resistant enterococcus (VRE). Risk factors for infection with VRE include intestinal colonization and the use of antimicrobial agents with significant activity against anaerobes (metronidazole, clindamycin, and imipenem).⁴⁰ The administration of vancomycin (both oral and parenteral) is also a risk factor. Established therapeutic options for VRE include linezolid, daptomycin, oritavancin, and quinupristin/dalfopristin.^{41–43} Combination therapy may be necessary. Less common but important Gram-positive pathogens include *Bacillus* spp., *Corynebacterium* spp., *Micrococcus* spp., and *Stomatococcus mucilaginosus*.^{44, 45} Nocardiosis is caused by several *Nocardia* spp. (*Nocardia asteroides* complex, *Nocardia brasiliensis*, and *Nocardia otitidiscaviarum*). The most common sites of infection are the lungs (70%) and soft tissue sites (16%).⁴⁶ Establishing a specific microbiologic diagnosis is of paramount importance as the differential diagnosis is wide. Trimethoprim/sulfamethoxazole remains the backbone of therapy although it is often combined with the carbapenems, tetracyclines, or aminoglycosides. *L. monocytogenes* is primarily acquired by the consumption of raw milk or products (cheese) made from raw milk. Bacteremia (75%) and meningoencephalitis (20%) are the most common manifestations.⁴⁷

Immunoglobulins play an important role in the immune systems response to various infections by either opsonization or complement activation. Impaired humoral immunity leads to increased susceptibility to infections caused by *S. pneumoniae* and other encapsulated organisms.³⁷ The widespread use of the

conjugate pneumococcal vaccine has led to a reduction in the frequency of pneumococcal disease especially in pediatric populations.

Gram-negative bacteria

The intestinal tract serves as an important source of infection in neutropenic patients with the predominant pathogens being enteric Gram-negative bacilli. *Escherichia coli*, *Klebsiella* spp., and *P. aeruginosa* remain the three primary pathogens.^{13, 48} Other Enterobacteriaceae (*Citrobacter* spp., *Enterobacter* spp., *Proteus* spp., and *Serratia* spp.) are less common. Despite a decline in the frequency of Gram-negative infections due to antibacterial prophylaxis, the proportion caused by non-fermentative Gram-negative bacilli (NFGNB) such as *P. aeruginosa*, *Stenotrophomonas maltophilia*, and *Acinetobacter* spp. has increased.⁴⁹ *P. aeruginosa* is the most frequently isolated and the most virulent NFGNB and causes between 15% and 20% of Gram-negative infections. It is also the most common Gram-negative organism isolated from polymicrobial infections.¹⁶ Infections caused by *S. maltophilia* are being documented more often in patients with hematologic malignancies and in HCT recipients.^{50, 51} The switch from trimethoprim/sulfamethoxazole (TMP/SMX), which is active against *S. maltophilia*, to the fluoroquinolones, which generally are not, as preferred agents for prophylaxis, may account for this increase. Other infrequent but important NFGNB include *Achromobacter* spp., *Alcaligenes* spp., and non-aeruginosa pseudomonads such as *Pseudomonas putida* and *Pseudomonas fluorescens*. Bacteremia is the most common site of infection followed by pneumonia and urinary tract infection. Fever is often the only manifestation of infection. Other manifestations such as ecthyma gangrenosum are uncommon ([Figure 4](#)). Polymicrobial infections and infections that are complicated by deep tissue involvement (pneumonia, neutropenic enterocolitis (NEC), and perirectal infections) are associated with greater morbidity and mortality.^{16, 52} The emergence of resistance to β -lactam agents and carbapenems is of great concern.^{53–55} Some organisms, especially *P. aeruginosa* and *Acinetobacter* spp., have become multi-drug resistant.^{56, 57} Very few options to treat such organisms (colistin, tigecycline, and combination regimens) currently exist, and very few novel agents are in the developmental pipeline.^{58, 59} Many institutions now conduct surveillance studies in high-risk patients looking for fecal colonization with VRE, *P. aeruginosa*, extended spectrum beta-lactamase (ESBL) producers, and carbapenem-resistant *Enterobacteriaceae* (CRE), because positive surveillance cultures often predict subsequent infection.^{60–63}

Figure 4 Multiple skin lesions (ecthyma gangrenosum) in a patient with *Pseudomonas aeruginosa* bacteremia.

Impaired cellular immunity is a risk factor for legionellosis. The most common *Legionella* species

causing infection is *Legionella pneumophila*. Hospital water systems often harbor *Legionella* spp. and many cases of hospital-acquired legionellosis can be traced to such sources.⁶⁴ Pneumonia is the most common manifestation. The detection of urinary antigens or recovery of the organisms on special media is required to make a specific diagnosis. The fluoroquinolones and macrolides are used most often for treatment and there appears to be no advantage to using them in combination. Non-typhoidal *Salmonella* and *Campylobacter* spp. infections are also seen with increased frequency in patients with impaired cellular immunity.⁶⁵

Cell-mediated immunity plays an essential role in the control of mycobacterial infections. The association of tuberculosis and Hodgkin's disease or hairy cell leukemia has been well established.⁶⁶ Tuberculosis can precede the diagnosis of these malignancies, occur concomitantly, or develop during or after their treatment. Pulmonary infection that produces fever, cough, and weight loss is common. Diffuse pulmonary infiltrates with or without mediastinal enlargement are the most common radiographic findings. Nontuberculous mycobacterial infections are less common.^{67, 68} They produce pulmonary infections, lymphadenitis, SSSIs, catheter-related infections, and disseminated disease. The species isolated most often are *Mycobacterium avium-intracellulare*, *Mycobacterium abscessus*, *Mycobacterium chelonae*, *Mycobacterium fortuitum*, *Mycobacterium kansasii*, and *Mycobacterium marinum*. Prolonged, multiple drug therapy is usually administered for progressive infection.⁶⁹

Anaerobes

Anaerobes are frequently involved in deep-seated, polymicrobial infections such as abdominal/pelvic abscesses, NEC, peri-rectal infections, complicated SSSIs, and pneumonia.^{52, 70} The organisms isolated most often include *Peptococcus* spp., *Fusobacterium nucleatum*, *Bacteroides* spp., and *Prevotella* spp.⁷¹ *Clostridium difficile* infection (CDI) is the leading infectious cause of diarrhea in cancer patients in whom there is increased severity of illness, higher mortality, and an increased risk of relapse and complications. Newer diagnostic tests are available including polymerase chain reaction (PCR)-based assays.⁷² Metronidazole is now considered inferior to vancomycin for the treatment of CDI.⁷³ Agents such as rifaximin and nitazoxanide have been used with limited success.^{74–76} Fidaxomicin is an oral macrocyclic antibiotic that has been recently approved by the FDA for the treatment of CDI in adults, especially those individuals at greatest risk for relapse.^{77, 78} Fecal transplants have also been used successfully in this setting and appear to be promising.⁷⁹ Preventive measures include strict enforcements of infection control practices, appropriate antimicrobial usage, and improved environment cleaning methods.

Fungal infections

Prolonged neutropenia (>7 to 10 days) is a key risk factor for the development of invasive fungal infections (IFIs). The most common causes of IFIs in neutropenic patients are *Candida* spp. and *Aspergillus* spp.⁸⁰ The epidemiology of IFIs has changed substantially over the past 10–15 years.^{81, 82} Before the availability of agents such as fluconazole, invasive candidiasis was quite common with *Candida albicans* being the predominant species. The routine use of azole prophylaxis has led to a decrease in the frequency of candidiasis with manifestations such as oro-pharyngeal candidiasis (thrush), esophagitis, and chronic systemic (hepatosplenic) candidiasis becoming almost of historical interest. Candidemia, often catheter-related, is now the most common manifestation, with the alimentary tract being the predominant portal of entry. Recent studies have demonstrated a major shift from *C. albicans* to non-*albicans Candida* spp. (*Candida glabrata*, *Candida tropicalis*, *Candida krusei*, and *Candida*

There are no characteristic physical signs and symptoms of disseminated candidiasis. Often, the only indication is persistent fever and a gradual worsening of the patient's clinical condition. Some patients have ocular infection causing blurred vision, pain, scotomata, or loss of visual acuity. Nearly 10% of patients develop characteristic erythematous macronodular skin lesions ([Figure 5](#)). A chronic form of *Candida* infection known as chronic disseminated candidiasis has been described, usually after neutrophil recovery. Patients remain febrile and debilitated with substantial weight loss. Symptoms including right upper quadrant or shoulder pain may appear. Alkaline phosphatase levels are usually elevated. Hepatosplenomegaly may be detected. Imaging of the liver and spleen reveals multiple lesions. Approximately 90% of the patients respond to appropriate antifungal therapy.⁶² This type of infection has virtually disappeared from institutions where azoles or echinocandins are used for antifungal prophylaxis. Treatment should be guided by *in vitro* antifungal susceptibility data.⁸⁵ Breakthrough *C. parapsilosis* fungemia may develop during echinocandin therapy, as may *C. glabrata* infection during azole therapy. Echinocandin resistance among *C. glabrata* isolates appears to be increasing.⁸⁶ *C. krusei* isolates are resistant to fluconazole. The mortality associated with systemic candida infections is ~40%. Guidelines for the management of candidiasis have been published by various societies.^{87–90}

Figure 5 Characteristic macronodular cutaneous lesions in a patient with acute leukemia and disseminated *Candida krusei* infection.

Aspergillosis is also frequent in patients with persistent neutropenia. Other risk factors include prolonged high-dose corticosteroid therapy, graft-versus-host disease (GVHD), repeated cycles of neutropenia, respiratory viral infections, and advanced age.⁹¹ The most common pathogen is *Aspergillus fumigatus*.⁹² Infection is usually acquired by inhalation of spores. Outbreaks of aspergillosis associated with construction within or adjacent to the hospital have occurred. More than 70% of infections involve the lungs (IPA, invasive pulmonary aspergillosis), and approximately 35% of patients have hematogenous dissemination to other organs.⁹³ Often, the only evidence of infection is prolonged fever with pulmonary infiltrates that fail to respond to antibacterial therapy. High-resolution CT scanning of the lung is helpful in the early diagnosis of aspergillosis.^{94, 95} Characteristic findings in early stage disease are multiple nodules with a halo of surrounding ground-glass attenuation that represents hemorrhage surrounding a region of pulmonary infarction ([Figure 6](#)).^{94–96} As healing occurs, the infarcted tissue becomes necrotic and retracts from the viable tissue leaving an air crescent. *Aspergillus* sino-orbital infection is being diagnosed with increasing frequency in patients with acute leukemia and in HCT recipients, accounting for at least 15% of cases of aspergillosis ([Figure 7](#)). Infections may erode through the base of the skull and invade the brain or cause destruction of the paranasal and facial structures and the eye. A localized form of aspergillosis has been described in association with intravascular catheters.⁹⁷ *Aspergillus* spores

may be deposited at the time of insertion or may be impregnated in materials used for catheter dressings. These infections are potentially serious because they can disseminate.^{97, 98} Skin lesions, manifested as sharply defined black eschars, occur in about 5% of patients with disseminated infection. Voriconazole is the preferred agent for the treatment of invasive or disseminated aspergillosis. Posaconazole and lipid preparations of amphotericin B are used more often for salvage therapy or when voriconazole intolerance occurs. Combination therapy with a triazole and an echinocandin may be useful for salvage therapy of invasive aspergillosis.^{85, 90, 99, 100} A recent randomized trial has shown higher survival in patients with invasive aspergillosis treated with voriconazole and anidulafungin than those treated with voriconazole monotherapy.¹⁰¹

Figure 6 Rounded pulmonary lesions with surrounding halo, compatible with invasive pulmonary aspergillosis.

Figure 7 Pansinusitis caused by *Aspergillus* spp. in an allogeneic bone marrow transplant recipient with persistent fever.

Cryptococcosis is caused by two sibling species, *C. neoformans* and *Cryptococcus gatti*. The primary site of infection is the lung, which follows the inhalation of spores. Dissemination usually involves the central nervous system (meningoencephalitis and cryptococcoma). Fever and meningeal symptoms are common. Cerebrospinal fluid (CSF) abnormalities include raised opening pressure, lymphocytosis, elevated proteins, and low glucose levels. Cryptococcal antigen is also detected in the CSF and serum in most cases. Induction therapy with amphotericin B or its lipid formulations plus 5-fluorocytosine followed by maintenance therapy with fluconazole is the current standard of care.¹⁰² Histoplasmosis and infections caused by other endemic fungi are less common.⁸ They usually cause pulmonary, CNS, or disseminated infection and should be considered in the differential diagnosis in endemic areas. Pneumonia caused by *P. jiroveci* has traditionally been associated with impaired cellular immunity, which results in the reactivation of dormant infection.^{103, 104} The clinical presentation is usually subacute. Clinical features include fever, a non-productive cough, and progressive dyspnea. The most common CT findings are diffuse bilateral ground glass pulmonary infiltrates with apical predominance and peripheral sparing.¹⁰⁵ The diagnosis is often made by demonstrating the organisms on respiratory specimens including biopsy tissue using stains such as methenamine silver or toluidine blue ([Figure 8](#)). Staining methods have been supplanted by sensitive molecular techniques including semi-quantitative or quantitative PCR.^{106, 107} High-dose TMP/SMX remains the agent of choice for prophylaxis and treatment. Alternative agents include pentamidine, atovaquone, clindamycin plus primaquine, and dapsone plus trimethoprim.¹⁰⁸

Figure 8 Gomori methenamine silver (GMS) stain from a bronchoalveolar lavage specimen demonstrating multiple organisms in a patient with *Pneumocystis carinii* pneumonia.

Other opportunistic fungi

Mucormycosis (zygomycosis) is still relatively uncommon with the most common pathogens being *Rhizopus* spp., *Mucor* spp., *Lichtheimia* (formerly *Absidia*) *corymbifera*, *Rhizomucor* spp., and *Cunninghamella bertholletiae*. Invasive pulmonary infection is the most common form of infection. Some patients develop sinopulmonary, rhinocerebral, gastrointestinal, cutaneous, or disseminated infection.^{109, 110} The clinical presentation of mucormycosis is often indistinguishable from aspergillosis. Mucormycosis should be considered in patients who are immunosuppressed and who develop sinusitis or IFI after prolonged exposure to voriconazole, which is not active against these organisms.^{111–113} Early diagnosis and administration of antifungal therapy is critical along with surgical debridement of infected tissue. Control of underlying diseases and reversal of risk factors when feasible is also of paramount importance.^{85, 114} Amphotericin B products and posaconazole are the only antifungal agents with reliable activity against Mucorales.¹¹⁵ Isavuconazole has also just been approved for the treatment of mucormycosis. Lipid preparations of amphotericin B are preferred for initial therapy, and there is some evidence to suggest that combining these preparations with an echinocandin might be beneficial.¹¹⁶ Therapy is often switched to posaconazole when feasible. *Trichosporon beigelii* can cause disseminated infection particularly in patients with severe neutropenia. A variety of skin lesions have been described and occur in approximately 30% of patients. Portals of entry include the gastrointestinal tract, respiratory tract, and intravenous catheter sites. *Fusarium* spp. have emerged as significant pathogens in patients with neutropenia.¹¹⁷ Localized infections of the lung, sinuses, and skin occur, but most patients have disseminated infection. Cutaneous and subcutaneous skin lesions are frequent.¹¹⁸ Similarly to *Aspergillus* spp., these organisms invade blood vessels, causing thrombosis and infarction. Usually *Fusarium* spp. can be isolated readily from blood culture or tissue specimens. It may be difficult to distinguish *Fusarium* from some other fungi on histopathologic examination. Recovery from this infection depends on resolution of neutropenia, and currently available antifungal agents are at best only marginally effective.^{119, 120}

Various other fungi cause significant infection in neutropenic patients. These organisms include *Blastoschizomyces capitatus*, *Scedosporium* spp., *Geotrichum candidum*, and *Malassezia furfur*.¹²¹ The majority of patients who are infected have hematologic neoplasms, especially acute leukemia.¹²²

Viral infections

Viral infections are uncommon in patients with neutropenia unless they are HCT recipients. Herpes viruses are identified most frequently, especially herpes simplex viruses (HSV), varicella-zoster virus (VZV), and CMV. Most adults are HSV seropositive, and reactivation can occur in ~60–80% of patients undergoing HCT or intensive chemotherapy for hematologic malignancies. Reactivation generally occurs while patients are still severely neutropenic with oral mucositis/ulceration being the most common manifestation. Esophagitis indistinguishable from *Candida* esophagitis occurs occasionally. Encephalitis and dissemination are uncommon. HSV prophylaxis is recommended in patients undergoing HCT or remission induction therapy for leukemia.¹²³ Reactivation of latent VZV also occurs and prophylaxis to prevent recurrence of VZV infection in seropositive patients is recommended for the first year following allogeneic HCT.^{124, 125} Community respiratory viruses, including RSV, influenza A and B viruses, parainfluenza viruses, human metapneumovirus, human coronaviruses, and human rhinoviruses, are common among HCT recipients and patients with acute leukemia in whom upper respiratory tract infection can progress to pneumonitis, which is associated with substantial morbidity and mortality.¹²⁶ Testing for respiratory viruses is recommended in high-risk patients. Specimens include nasopharyngeal swabs, washes, or aspirates, tracheal aspirates, and bronchoalveolar lavage specimens. Optimum treatment for most of these viral infections, except for influenza viruses, remains to be determined. Ribavirin therapy for upper respiratory infection with RSV deters progression to pneumonia and may improve overall outcome in HCT recipients.¹²⁷

Reactivation of EBV may occur after HCT or following chemotherapy with purine analogs such as fludarabine. EBV infection may be responsible for Richter transformation or development of Hodgkin disease in patients with chronic lymphocytic leukemia. In recipients of HCT or solid-organ transplants, uncontrolled proliferation of EBV infected B cells may occur, producing post-transplant lymphoproliferative disorders (PTLDs). In younger patients, a mononucleosis-like syndrome is a common presentation. Fever, sore throat, and lymphadenopathy are typical findings. Dissemination can occur from localized nodular lesions and can be fulminant and rapidly fatal. It is important to monitor high-risk patients (umbilical cord blood transplants, haploidentical transplants, and T-cell-depleted transplants) for EBV DNA viral load using PCR assays. Rituximab is recommended for preemptive therapy or the treatment of PTLD.^{128, 129}

HHV-6 is being recognized as an important pathogen in HCT recipients.^{130, 131} Serologic reactivation accompanied by specific manifestations, including fever, rash, pneumonitis, hepatitis, myelosuppression, and neurologic dysfunction, have been described in recipients of bone marrow, kidney, and liver transplants. HHV-6 viremia is not necessarily associated with increased mortality, and routine screening is not necessary.^{132, 133} Ganciclovir and foscarnet inhibit viral replication, and therapy with these agents may be useful in patients with severe infections. Immunotherapeutic prevention and treatment strategies are being developed.^{134, 135}

CMV infection occurs frequently in immunocompromised patients, especially those with impaired cellular immunity. It is a common complication in patients undergoing allogeneic HCT and has a negative impact on overall survival after transplantation.¹³⁶ CMV seropositivity in HCT recipients is a major risk factor. Without prophylaxis, 50–80% of seropositive patients undergoing HCT reactivate latent infection. CMV seropositivity, in both the HCT recipient and the donor, has an impact on the subsequent development of CMV end organ disease.¹³⁷ Other risk factors for CMV infection include total body irradiation, umbilical cord blood transplantation, the use of T-cell-depleted stem cells, treatment with purine analogs (fludarabine and cladribine), and monoclonal antibodies against CD20 (rituximab), CD52

(alemtuzumab), GVHD, and advanced age.¹³⁸ CMV pneumonia is the most common manifestation ([Figure 9](#)). Other manifestations include retinitis, esophagitis, enteritis, hepatitis, myocarditis, and encephalitis. In addition to end organ disease, CMV infection has been associated with GVHD and secondary bacterial and fungal infections. Early detection of CMV infection is of paramount importance, in order to deploy preventive measures. These measures consist of CMV prophylaxis that has now fallen out of favor when compared to preemptive therapy. The preemptive strategy consists of the administration of antiviral therapy (ganciclovir and foscarnet), which is initiated upon detection of CMV, using either the phosphoprotein 65 (pp 65) antigenemia assay or the PCR assay. Viral load-based, risk-adapted, preemptive treatment strategies have successfully prevented CMV disease, with a very low incidence of breakthrough disease.¹³⁹ Unfortunately, the treatment of established end organ disease, especially pneumonia is not very satisfactory. Currently available systemic antiviral agents include ganciclovir, foscarnet, cidofovir, and leflunomide in addition to some novel agents such as letermovir and brincidofovir that are in the developmental pipeline.^{140, 141}

Figure 9 Computerized tomography scan of an allogeneic HCT recipient with CMV pneumonitis, showing diffuse bilateral pulmonary infiltrates.

Varicella has been recognized as a serious infection in children undergoing cancer chemotherapy. Nearly 30% of children receiving cancer chemotherapy develop serious complications during varicella infection, with around 7% fatality rate. Characteristic manifestations of varicella include a generalized vesicular rash and fever. Lesions appear initially on the face and scalp and subsequently spread to the trunk and extremities. New lesions continue to appear as older lesions crust. Infection may be unduly prolonged in patients with cancer. The vesicles become hemorrhagic and necrotic in patients with thrombocytopenia. Around 10% of children develop a bacterial superinfection. Disseminated visceral infection may result in widespread pneumonia and focal necrosis of the liver, pancreas, or adrenal glands.

Herpes zoster occurs most often in patients with lymphoproliferative disorders. The infection is characterized by a unilateral vesicular rash in the distribution of one or two adjacent sensory dermatomes ([Figure 10](#)). Occasionally, patients develop a generalized varicelliform eruption. The rash is accompanied by pain (zoster-associated pain) that can last for several weeks or months. Cutaneous dissemination of herpes zoster occurs in approximately 35% of patients with cancer, as compared with only 4% of those without cancer. Therapy with adrenal corticosteroids, radiation, or antitumor agents

facilitates dissemination.

Figure 10 Typical vesicular rash caused by varicellazoster virus. Note the dermatomal distribution and the hemorrhagic nature of lesions in this patient with thrombocytopenia.

Laboratory confirmation of the diagnosis is generally not required. VZV can be recovered from the vesicular fluid for a few days after the onset of the eruption. Cultures are positive 30–60% of the time. Detection of VZV antigens in skin scrapings using fluorescence microscopy and detection of VZV DNA, in the CSF or other tissues, using PCR, are more rapid and sensitive diagnostic techniques.

Therapy of VZV infection shortens viral shedding, accelerates healing of lesions, and reduces the frequency of visceral disease. Oral valacyclovir and famciclovir are better absorbed and more effective than acyclovir. Severe infections such as meningoencephalitis and pneumonitis require intravenous acyclovir therapy. Therapy with foscarnet or combination therapy with foscarnet and acyclovir should be considered for patients who fail to respond to acyclovir alone. Varicella-zoster immune globulin must be given within 96 h of exposure to be effective. Varicella vaccine is available for universal immunization and postexposure prophylaxis.^{142, 143} The vaccine is safe, immunogenic, and effective in leukemic children at risk for serious disease, if chemotherapy is interrupted for 1 week before and after administration; approximately 50% developed a mild rash. A 1-week course of antiviral therapy following exposure may be useful for patients who are at risk.¹⁴⁴ A heat-treated vaccine has been shown to be safe and immunogenic in immunocompromised adults.¹⁴⁵

Hepatitis viruses

Hepatitis B virus (HBV) reactivation occurs primarily in patients receiving anti-CD20 agents (rituximab and ofatumumab) and in HCT recipients with clinical manifestations ranging from asymptomatic elevation of hepatic enzymes to fulminant hepatic failure and death. The risk of reactivation is higher with chronic HBV infection (positive HBsAg) than in individuals with resolved infection (positive HBsAb and negative HBsAg). Diagnostic tools such as quantitative HBV DNA measurements and newer antiviral agents (entecavir, lamivudine, and tenofovir) have improved the detection of HBV reactivation and the treatment of reactivated infection. Universal screening of cancer patients for HBV versus risk-based screening remains a matter of debate. Many societies including ASCO and NCCN currently recommend risk-based screening for patients who will be receiving immunosuppressive therapy including anti-CD20

therapy.^{146, 147} Hepatitis C virus (HCV) causes chronic infection in more than three million individuals in the United States and is a major risk factor for the development of liver cancer. HCV reactivation has been described primarily among patients with hematologic malignancies and recipients of rituximab therapy.¹⁴⁸ However, reactivation occurs less frequently than with HBV, and the role of screening cancer patients for HCV has not yet been established.^{149, 150}

Other infections

Toxoplasmosis is one of the most common parasitic infestations in man. Disseminated disease generally occurs in immunocompromised individuals with the CNS, heart, and lungs being involved most often.¹⁵¹ Computerized tomography (CT) or magnetic resonance imaging (MRI) of the brain reveals multiple hypodense lesions, often with moderate contrast ring enhancement. The diagnosis can be confirmed by serologic testing or biopsy, if feasible. Specific therapy consists of pyrimethamine plus sulfadiazine or spiramycin. Alternative agents such as clindamycin, atovaquone, and TMP/SMX have also been used for treatment and/or prophylaxis.¹⁵² *Strongyloides stercoralis* is a soil transmitted helminth and lymphoma is the most common malignancy associated with strongyloidiasis. Many infestations are asymptomatic and some produce only eosinophilia.¹⁵³ Common clinical features include fever and gastrointestinal symptoms such as diarrhea and abdominal pain/cramping. Immunosuppression often induced by corticosteroids can trigger the development of hyperinfection or dissemination.^{10, 154} Pulmonary infiltrates and pleural effusions that are often hemorrhagic can develop, followed by respiratory insufficiency/failure. Polymicrobial bacteremia caused by enteric Gram-negative bacilli and anaerobes is not uncommon. Diagnostic tests include demonstration of the organisms in stool and respiratory specimens, and serological enzyme-linked immunosorbent assay (ELISA) methods. Ivermectin is the therapeutic agent of choice. Screening of high-risk patients (allogeneic HCT recipients and corticosteroid usage) is recommended especially in endemic areas.¹⁵⁵

Special situations

Abdominal infections

An acute abdomen is one of the most difficult problems that physicians caring for patients with cancer encounter.¹⁵⁶ Causes of acute abdomen include appendicitis, cholecystitis, diverticulitis, peritonitis, abdominal abscesses, splenic infarcts, NEC, and tumor lysis/perforation. Patients usually have abdominal pain, distention, guarding, rebound, and diminished or absent bowel sounds. These signs/symptoms may be blunted in neutropenic patients and those receiving immunosuppressive agents. Supportive measures, antibiotics, and occasional surgical intervention are needed for management.

NEC is seen primarily in patients with hematologic malignancies but is now being seen with increasing frequency in patients with solid tumors due to the use of agents such as the taxanes, which produce severe intestinal mucositis.⁵² Common presenting features include fever, abdominal pain or cramping, distention, and diarrhea. Complications include bacteremia that is often polymicrobial, hemorrhage, bowel wall perforation, and abscess formation. The disease may be limited to the cecum (typhlitis), but usually involves the entire lower intestinal tract. Radiographic examination (preferably CT) usually reveals evidence of a paralytic ileus with lack of bowel gas in the right lower quadrant, minimal distention of the terminal ileum, and >4 mm thickening of the bowel wall, which is considered a hallmark of NEC. Initial management is supportive and includes bowel rest, intravenous fluids, correction of cytopathies and coagulopathies, and broad-spectrum antibiotics that include coverage for *P. aeruginosa* and anaerobes.

Surgical intervention may be necessary to manage complications such as hemorrhage or bowel perforation.

Perianal infections

Perianal infections are estimated to occur in 6% of patients with hematologic neoplasms. More than 90% of patients are neutropenic.¹⁵⁷ The major presenting symptom is pain that is aggravated by defecation. Erythematous, indurated, or ulcerated lesions with extensive tissue necrosis and sloughing extending into the rectum are common. The infection often occurs at a site of a fissure or hemorrhoid. Most of these infections are caused by aerobic Gram-negative bacilli, especially *P. aeruginosa* and *E. coli*. Therapy includes general measures such as sitz baths, warm compresses, stool softeners, analgesics, along with broad-spectrum antibiotics. Empiric antifungal therapy is not recommended. Abscesses, if present, should be drained.¹⁵⁸ Resolution of infection often depends on recovery of the neutrophil count. Patients with hematologic diseases who recover from perianal infections caused by hemorrhoids or anal fissures should undergo surgical correction when feasible, to avoid recurrent infections.

Catheter-related infections

Central line-related bloodstream infections have become relatively common.¹⁵⁹ The majority of these infections are caused by *Staphylococcus* spp. and other Gram-positive organisms that colonize the skin, *P. aeruginosa*, *Enterobacteriaceae*, *S. maltophilia*, and *Candida* spp. Quantitative blood cultures and time to positivity help establish the diagnosis of CLABSI, although neither method is foolproof.^{160–164} Sequential time to positivity can also be a predictor of outcome and prognosis.¹⁶⁵ Some episodes, especially those caused by CoNS can be successfully treated without the removal of the catheter.¹⁶⁶ However, catheter removal is usually necessary for CLABSI caused by *S. aureus*, *Acinetobacter*, *Pseudomonas* spp., *S. maltophilia*, *Candida* spp., and non-tuberculous mycobacteria. In addition, if there are signs of localized infection at the catheter insertion site, or if fever or bacteremia persists despite adequate therapy, catheters must always be removed.¹⁶⁰ Antimicrobial lock therapy may be useful particularly if catheter removal is not feasible. The most serious complications of CLABSI are septic thrombophlebitis and endocarditis. Antimicrobial impregnated catheters have been shown to reduce the frequency of catheter-associated infections.^{159, 167}

Therapy of infections in patients with neutropenia

Initial patient evaluation

Febrile neutropenic patients should receive prompt, empiric, broad-spectrum antimicrobial therapy generally via the intravenous route and at maximal therapeutic doses.¹⁶⁸ Pretreatment evaluation should be performed as expeditiously as possible, as a delay in instituting empiric therapy can result in diminished response rates.¹⁶⁹ Pertinent historical information should be obtained, and a thorough physical examination should be performed. Particular attention should be paid to sites that are frequently infected or serve as foci for the dissemination of infection. These include the oro-pharynx, lower esophagus, perineum, paranasal sinuses, fingernails, and skin including the armpits, groin, and vascular catheter insertion sites. Cultures from all appropriate sites (blood, urine, and throat) should be obtained. In patients with central venous catheters cultures from a peripheral site and from all lumens of the catheter

should be obtained.^{170, 171} Neutropenic patients with pneumonia may have normal appearing radiographs. CT scans of the chest and paranasal sinuses should be performed if these sites are potential sources of infection. Complete blood counts and determinations of baseline values for renal and hepatic function should be obtained. Finally, risk assessment should be performed in order to determine whether the patient requires hospitalization or not.¹⁷² Low-risk febrile neutropenic patients can be treated with outpatient parenteral or oral antibiotic regimens if the infrastructure for out-patient management of such patients is in place.^{173–175} All other patients should receive hospital-based therapy. Outpatient therapy can be administered after a short period of hospitalization or for the entire febrile episode.^{176–179} It has been shown to be safe and effective in both adults and children.^{180–182} Outpatient therapy is associated with substantial cost savings, a lower incidence of superinfections with resistant nosocomial pathogens, and improved quality of life for patients and convenience for their families and caregivers.^{173, 183} Various societies including the Infectious Diseases Society of America, the National Comprehensive Cancer Network, and the American Society of Clinical Oncology have published recent guidelines for the management of infections in patients with cancer, which include algorithms for outpatient therapy in low-risk patients.^{168, 184, 185}

Initial antibiotic therapy

The empiric regimen should be based on local epidemiologic and resistance patterns and should provide potent coverage against Gram-negative organisms including *P. aeruginosa* and Gram-positive pathogens. This is usually achieved by administering either a single broad-spectrum agent (monotherapy) or antibiotic combinations.^{168, 185} [Tables 5](#) and [6](#) list the common antibiotic agents and regimens used in this setting. No single regimen is optimal and various factors dictate the choice of one regimen over another. Monotherapy with agents such as the Group 2 carbapenems, cefepime, and piperacillin/tazobactam is considered appropriate for up to 60% of febrile neutropenic episode especially if no obvious focus of infection can be identified.¹⁶⁸ If resistant Gram-positive infections are likely (e.g., in patients colonized with MRSA (methicillin-resistant *Staphylococcus aureus*) or VRE), a combination of these agents with vancomycin, linezolid, or daptomycin is considered appropriate. However, studies have shown that the addition of these agents after a resistant Gram-positive infection has been identified just as effective as empiric usage. Vancomycin may no longer be adequate at some institutions owing to changing susceptibilities, and alternative agents such as daptomycin, dalbavancin, and telavancin may be considered, although clinical experience with these agents in neutropenic patients is limited.^{23, 27–29} Combinations of antipseudomonal beta-lactams and aminoglycosides are generally used to try and provide synergistic bactericidal activity against Gram-negative pathogens such as *P. aeruginosa*. Agents with potent anaerobic activity should be administered when anaerobic infections (e.g., perirectal infections and NEC) are likely or have been documented. The initial regimen may need to be altered during the course of the febrile episode, depending on the susceptibility of microorganisms isolated from clinical specimens, the development of bacterial, fungal, or viral superinfections, or lack of apparent efficacy after administration of the regimen for 3 days. Consequently, all patients need to be carefully monitored for response, toxicity, and the development of other complications, and appropriate changes should be made if the clinical situation or microbiologic data indicate the need.¹⁸⁶ Initial empiric therapy is usually associated with response rates of 65–85% (higher in low-risk patients).¹⁸⁰ A substantial proportion of patients will respond after modification of the initial regimen including the addition of antifungal therapy after 5–7 days.¹⁶⁸

Table 5 Common empiric antibiotic regimens for febrile neutropenic patients

<i>Regimens for low-risk patients</i>	
→ Oral	
Quinolone + amoxicillin/clavulanate	
Quinolone + clindamycin or azithromycin	
Moxifloxacin or levofloxacin (monotherapy)	
→ Parenteral	
Ceftriaxone or ertapenem ± amikacin	
Aztreonam + clindamycin	
Quinolone ± clindamycin	
Ceftazidime or cefepime	
<i>Regimens for moderate to high-risk patients</i>	
Combination regimens	
Aminoglycoside + antipseudomonal penicillin/beta-lactamase inhibitor or cephalosporin or carbapenem, or quinolone (if patient not on quinolone prophylaxis)	
Vancomycin(or linezolid or daptomycin) + antipseudomonal penicillin, or cephalosporin, or carbapenem, or quinolone (if patient not on quinolone prophylaxis)	
Single-agent regimens (monotherapy)	
Extended-spectrum cephalosporin (cefepime)	
Carbapenems (imipenem, meropenem, or doripenem, but not ertapenem)	
Antipseudomonal penicillin/beta-lactamase inhibitor (piperacillin/tazobactam)	

Table 6 Antimicrobial agents commonly used in patients with neutropenia

<i>Aminoglycosides</i>	
Amikacin	5 mg/kg q8 h or 15–20 g/kg/day (single daily dose)
<i>Antipseudomonal penicillins + β-lactamase inhibitor</i>	
Piperacillin + tazobactam	3.375 g q6 h, IV
<i>Extended-spectrum cephalosporins</i>	
Cefepime	1–2 g q8 h, IV
<i>Carbapenem</i>	
Imipenem/cilastatin	500 mg q6 h, IV
Meropenem	1 g q8 h, IV
<i>Monobactam</i>	
Aztreonam	1.5–2.0 g q6–8 h, IV
<i>Quinolones</i>	
Ciprofloxacin	200–400 mg q8h ^a
Levofloxacin	500 or 750 mg q24 h ^a

Moxifloxacin	400 mg q24 h ^a
<i>Others</i>	
Vancomycin	1 g q12 h, IV (monitor levels) target trough 15–20
Trimethoprim-sulfamethoxazole	2.0–20.0 mg/kg/day (trimethoprim) IV q6 h ^a
Metronidazole	500 mg IV q6–8 h ^a
Linezolid	600 mg IV q12 h ^a
Daptomycin	6–8 mg/kg/day
Tigecycline	Initial loading dose 100 mg, then 50 mg IV q12 h
<i>Antifungal agents</i>	
<i>Azoles:</i>	
Fluconazole	200–800 mg q24 h ^a
Itraconazole	200 mg q12 h ^a
Voriconazole	6 mg/kg loading dose q12 × 2 doses, then 4 mg/kg q12 h ^a
Posaconazole	Suspension 200 mg q 8 h with food, tablets/IV 300 mg q 12 h × 2, then 300 mg q24 h ^a
Isavuconazole	iv/po loading dose of 200 mg q 8h x 6 doses, then 200 mg q24h
<i>Echinocandins:</i>	
Caspofungin	70 mg day 1, then 50 mg q24 h
Micafungin	100 mg q24 h
Anidaulafungin	200 mg day 1, then 100 mg q24 h
<i>Polyenes:</i>	
Amphotericin B deoxycholate	0.3–1 mg/kg/day once daily
Amphotericin B liposomal (ambisome)	1–10 mg/kg/day once daily
Amphotericin B lipid complex (abelcet)	5 mg/kg/day once daily
<i>Anti viral agents</i>	
Acyclovir	5–12 mg/kg q8 h ^a
Valacyclovir	1 g q8 h
Ganciclovir	5 mg/kg q 12 h
Valganciclovir	Oral 900 mg q12 h
Foscarnet	90 mg/kg q12 h
Cidofovir	5 mg/kg IV once a week, must be given with probenecid 3 g before infusion and 1 g 2&8 h post infusion
Ribavirin	Oral 10–20 mg/kg q 8 h, available in inhalation, note drug is cytotoxic and

Abbreviations: IV, intravenously; PO, orally.

^a Preparations are available for both intravenous and oral administrations, check dosing for each specific preparation.

Duration of therapy

Some authorities recommend continuation of antibiotic therapy in patients with documented infections until recovery of the neutrophil count (i.e., an absolute neutrophil count >500 cells for two consecutive days). This approach is expensive and may not be needed in many patients. It actually represents broad-spectrum prophylaxis after resolution of infection in many patients. This may result in an increased number of resistant superinfections requiring further modifications of antibacterial therapy and/or the addition of antifungal therapy, and adds to the overall cost of therapy. Another approach is to continue antibiotics until all sites of infection have resolved, the causative pathogen, if isolated, has been eradicated, and the patient has been treated for a minimum of 7 days and has remained free of significant symptoms or signs of infection for at least 4 days. This is indeed the case in most patients with unexplained fever. Antibiotic therapy may be discontinued safely at this point despite the persistence of neutropenia. This approach is less expensive and may be associated with fewer superinfections.

Persistent fever

Patients who remain febrile despite antibacterial and antifungal therapies pose a difficult challenge. These patients may have bacterial infections that are resistant to therapy or infections by other pathogens (viruses and parasites). Drug-related fever or tumor fever may also be present. Aggressive, often invasive, diagnostic maneuvers are sometimes necessary in order to make a specific diagnosis and provide specific therapy to such patients. In patients unable to tolerate invasive diagnostic procedures, continuation of the empiric antibacterial and antifungal regimens and the addition of empiric antiviral or antiparasitic therapy might be necessary.

Other therapeutic modalities

Nearly 15–25% of infections occurring in patients with neutropenia fail to respond to appropriate antimicrobial therapy. In most cases, profound neutropenia persists. The availability of the hematopoietic growth factors has rekindled interest because the administration of granulocyte colony-stimulating factor (G-CSF) to donors increases the number of neutrophils that can be collected.^{187–189} Preliminary clinical studies suggest that this approach to white blood cell collection has produced therapeutic benefit in selected recipients.^{190, 191}

The administration of hematopoietic growth factors to patients receiving cancer chemotherapy reduces the severity and duration of neutropenia and, hence, the frequency of infectious complications. Guidelines for this use of these agents have been prepared by the American Society of Clinical Oncology.¹⁹² The efficacy of these factors as adjuncts to antibiotic therapy for patients who are neutropenic after they have become infected has not been clearly established. It is reasonable to administer these agents to patients with neutrophil counts <500/mm³ who develop pneumonia, septic shock, sepsis syndrome, or fungal infection, because these patients have a poor prognosis without recovery of their neutrophils. These agents should also be considered for patients with documented infections who are failing to respond to appropriate therapy after 24–48 h. The role of granulocyte colony-stimulating factors appears to be expanding.¹⁹³ IFN- γ may be beneficial for some bacterial or fungal infections that are not responding to appropriate

Infection prevention

Suppression of the endogenous microflora, from which most infections arise, is usually achieved using antimicrobial prophylaxis (bacterial, fungal, viral, or protozoal) during the periods of risk. The acquisition of new organisms is accomplished by various techniques, including strict infection control, the use of well-cooked foods, which reduces contamination with Gram-negative bacteria, and various isolation techniques or protected environments.

Antibacterial prophylaxis

Prophylactic antimicrobial regimens achieve a major reduction in the patients' microbial burden. The quinolones (ciprofloxacin and levofloxacin) are the most commonly used agents for antibacterial prophylaxis resulting in significant reduction in the frequency of Gram-negative infections, but with little impact on the frequency of Gram-positive infections.^{195, 196} Although quinolone prophylaxis is associated with reduced mortality related to Gram-negative infections, and in reduced all cause mortality in some studies, it has also resulted in the emergence of quinolone resistance among enteric Gram-negative bacilli including *E. coli*.^{197–199} Its use remains controversial and it is therefore not recommended for routinely in neutropenic patients, but must be considered only in patients at high risk for bacterial infection, such as those with prolonged periods of neutropenia.^{168, 184, 185} Discontinuation of prophylaxis when indicated is critical. Surveillance for the emergence of resistant organisms is also of utmost importance.^{200, 201}

Antifungal and antiviral prophylaxis

Increasing frequency of IFIs in high-risk patients has led to the use of antifungal prophylaxis.²⁰² Fluconazole (and itraconazole) prophylaxis has been shown to decrease both superficial colonization and systemic *Candida* infections. The selection of resistant species (*C. krusei* and *C. glabratta*) is a potential problem, although these organisms are also seen in “azole naïve” patients. Prophylaxis against molds including *Aspergillus* spp. is less successful although newer agents such as micafungin, voriconazole, and posaconazole with more potent activity against molds than older agents have been evaluated.^{203–205} Increased voriconazole administration has already been associated with the emergence of breakthrough zygomycotic infections, cautioning against the widespread adoption of this strategy. TMP/SMX remains the agent of choice for *P. jiroveci* prophylaxis.¹⁰⁸ Alternative (but less effective agents include pentamidine, dapsone, and atovoquone.

Prophylactic acyclovir has been shown to prevent reactivation of HSV infection in patients undergoing intensive chemotherapy (with or without radiation therapy) before HCT or induction therapy for leukemia or lymphoma. Preemptive therapy (rather than prophylaxis) with ganciclovir or foscarnet is the current recommendation for high-risk patients with positive CMV antigenemia.¹³⁹

Isolation

Reduction of the acquisition of new organisms has been attempted by putting patients at risk into reverse isolation. Patients are also given well-cooked foods and are asked to avoid fresh fruits and vegetables (e.g., tomatoes and salads) that are naturally contaminated with Gram-negative bacilli such as *P. aeruginosa*, *Klebsiella pneumoniae*, and *E. coli*. More elaborate regimens are expensive and time

consuming and have not been shown to be more effective than strict adherence to hand-washing techniques.

Protected environments provide a combination of the two approaches, that is, the use of isolation units to protect the patient against nosocomial contamination plus antibiotic regimens to reduce the patient's endogenous flora. The protected environment generally consists of isolation units, which provide a barrier between the patient and the hospital environment, using aggressive decontamination techniques and filtered air. The patient's food is specially prepared or sterilized to minimize contamination. Disinfection of the patient is achieved using intensive regimens, which include oral nonabsorbable antibiotics. Patients bathe with germicidal soaps and apply topical antibiotic ointments or sprays to areas of heavy microbial contamination.

Because attempts at suppressing the endogenous microflora and those at preventing the acquisition of organisms have not been overwhelmingly successful, other means for infection prevention need to be developed. The hematopoietic growth factors [granulocyte-macrophage (GM)-CSF and G-CSF] have been demonstrated to shorten the duration of neutropenia and to reduce the number of febrile days and of documented infections in selected subpopulations of patients with neutropenia. Current guidelines suggest that the primary use of these agents is not indicated in patients who were previously untreated and receiving most chemotherapy regimens. The secondary administration of growth factors can decrease the probability of febrile neutropenia after a documented occurrence in an earlier cycle. It can also reduce the period of neutropenia and the frequency of infectious complications in patients undergoing high-dose cytotoxic therapy with autologous marrow transplantation.

Antimicrobial stewardship

Antimicrobial resistance results in increased morbidity, mortality, and cost of healthcare. Antimicrobial stewardship has become an essential part of the management of patients with cancer, particularly in an age where the development of novel antimicrobial agents is at a standstill. The major goal of antimicrobial stewardship is to optimize antimicrobial usage while reducing unwanted consequences such as toxicity and the selection of resistant organisms.^{206, 207} Strategies for effective antimicrobial stewardship are listed in [Table 7](#). These strategies are best implemented by an independent, multidisciplinary, antimicrobial stewardship team (MAST).^{208–210}

Table 7 Antimicrobial stewardship strategies

Continuing education for all healthcare providers
Guidelines/pathways for appropriate antimicrobial usage based on local microbiology and susceptibility/resistance
Formulary interventions restricting specific agents
Audits of antimicrobial usage with feedback to prescribers
Introduction of surveillance and decision support programs
Monitoring outcomes (morbidity, mortality, and length of stay) and resistance patterns
Comprehensive infection control program

Perspectives

Infection remains a serious complication for many cancer patients. The spectrum of infection continues to change, and the emergence of multidrug-resistant pathogens has posed serious challenges, especially as new drug development is rather limited. Disseminated fungal infections have become the leading cause of death in patients with hematologic malignancies, and in HCT recipients. Despite some improvements, the early diagnosis and adequate treatment of many IFIs remain unsatisfactory. Viral infections represent a growing threat particularly in patients with hematologic malignancies and HCT recipients. Newly emerging global threats (such as MERS and Ebola) can have a devastating impact on patients with cancer who are immunosuppressed. Reliable methods for the rapid diagnosis of these and other viral infections, and effective means for their prevention and treatment still need to be developed. Parasitic infections remain uncommon except in endemic areas. Although effective therapies are available, toxicity and the need for prolonged maintenance or suppressive therapy can be problematic. The development of risk-assessment strategies has led to the recognition of a “low-risk” subset among patients with neutropenia. Newer treatment strategies such as outpatient oral therapy have resulted in substantial cost savings, reduction in healthcare-associated infections, and improved quality of life. Protected environments, prophylactic programs, infection control strategies, and the CSFs have reduced the risk of infection in patients with cancer. Antimicrobial stewardship may delay the development of resistant organisms. Newer technologic advances should lead to further progress. Nonetheless, the recognition, prevention, diagnosis, and treatment of infections in patients with cancer will continue to challenge us in the foreseeable future, as we work toward the larger goal of eliminating cancer.

Chapter 140

Oncologic emergencies

Sai-Ching Jim Yeung, MD, PhD, FACP ■ Carmen P. Escalante, MD

Overview

Cancer and its treatment can lead to oncologic emergencies. This chapter discusses the approach to acute emergency problems in cancer patients. A list of emergent problems has been selected for focused discussion. Sudden cardiopulmonary arrest is discussed along with special consideration in resuscitation of cancer patients. Arrhythmia, superior vena caval syndrome, pericardial tamponade, and acute hemorrhage are important cardiovascular emergencies. Tumor lysis syndrome can be rapidly fatal, and early recognition and treatment are very important in preventing disastrous outcomes. Pulmonary problems include airway obstruction, pleural effusion, hemoptysis, pneumothorax, and pulmonary embolism. Neurological emergencies include spinal cord compression, brain herniation, and status epilepticus. Neutropenic fever is perhaps the most frequently discussed important topic in oncologic emergency. Other important issues such as perforated viscus, anaphylaxis, and cytokine release syndrome are also discussed. Oncologists and emergency physicians must be aware of these potentially serious acute complications of cancer patients in order to initiate appropriate treatments in a timely manner.

Introduction

An oncologic emergency is an acute condition that is caused by cancer or its treatment and that requires intervention as soon as possible to avoid mortality or severe morbidity. Cancer patients are more likely to require emergency care than noncancer patients. Physical debilitation, altered hemostasis, and impaired immunity due to malignancy or its treatment also make cancer patients vulnerable to accidents and mishaps in everyday life. Because cancer patients have unique concerns and changes in physiological status, emergency care providers need to adapt to their special needs.

The emergency care of cancer patients is evolving into a hybrid discipline—a cross between oncology and emergency medicine. There are many types of problems for which cancer patients present to an emergency care facility, and in-depth discussions would fill volumes.^{1–3} Because of page constraints and coverage of some relevant topics in other chapters of this book, this chapter will cover only selected topics.

Approach to acutely ill cancer patients

Cancer patients often have comorbidities such as coronary heart disease, diabetes mellitus, and chronic obstructive pulmonary disease. Some of these may be attributable to the same risk factors for carcinogenesis (i.e., old age, diet, cigarette smoking, or sedentary lifestyle). Emergency care providers caring must assess the extent of the malignancy, the response to treatment, the overall prognosis, and the patient's and family's wishes in order to formulate an appropriate treatment plan ([Figure 1](#)). The majority

of cancer patients who are approaching their ends of life do not want “heroic” measures, and addressing advance directives and do-not-resuscitate (DNR) orders in a timely manner may improve the quality of life in the weeks before death.⁴

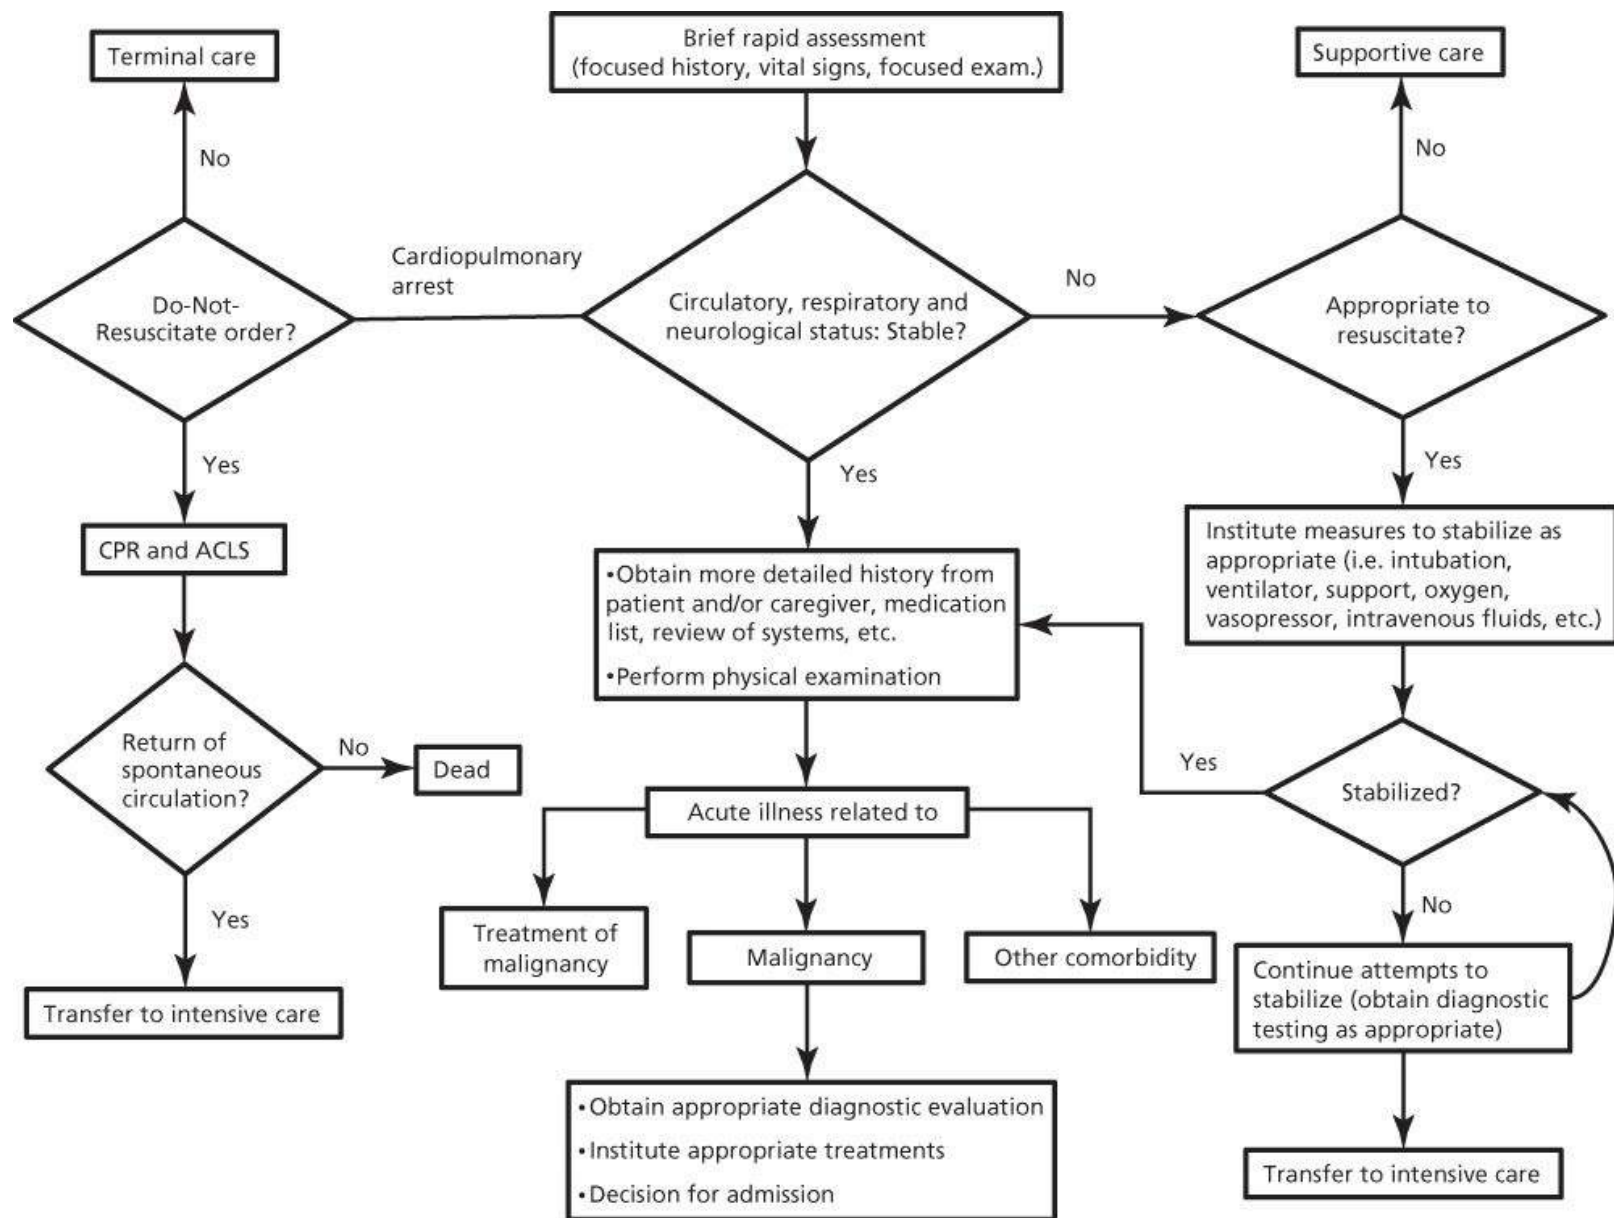

Figure 1 Approach to acutely ill cancer patients.

First, the patient should be rapidly assessed. This assessment should include the chief complaint, a focused history, vital signs, and a quick overall physical assessment. If the patient is unable to relay the history of present illness, a family member, companion, or caregiver may provide pertinent information. Intervention for unstable vital signs should be initiated immediately. In case of cardiopulmonary arrest, appropriate guidelines are followed (<http://www.acls.net/aclsalg.htm>).⁵ Once the patient is stabilized, thorough history and physical examination should be completed. For the majority of cancer patients with emergencies, a comprehensive evaluation is necessary. The emergency may be due to the cancer, cancer treatments, or comorbid conditions, all of which should be considered in the differential diagnosis.

Circulatory oncologic emergencies

Sudden cardiopulmonary arrest

Most deaths are preceded by cardiopulmonary arrest. Resuscitation is more likely to succeed when cardiopulmonary arrest was caused by an acute reversible insult rather than by a steady irreversible decline in bodily functions. The success rate of resuscitation and the hospital discharge rate of resuscitated patients are similar for cancer patients and noncancer patients.⁶ A meta-analysis of inpatient resuscitation (including cancer patients) estimated that the probabilities of successful resuscitation and being discharged alive are about 30% and 12%, respectively.⁷ Similarly, for cancer patients with out-of-hospital arrest who received resuscitation at the Emergency Department of a cancer center, the probabilities of successful resuscitation and being discharged alive are 43% and 17%, respectively.⁸ The mortality rate of cancer patients in intensive care is about 50%, which is similar to that of severely ill non-cancer patients.⁹ If a cancer patient has good performance status and is not expected to die soon, reluctance to resuscitate the patient or admit the patient to intensive care is unjustified. A non-end stage cancer patient in cardiopulmonary arrest should be resuscitated with the same level of intense effort as any noncancer patient. However, when cardiopulmonary arrest occurs as the expected final event, resuscitation is generally futile.

Oncologists should ensure that advance directives (medical power of attorney, living will, and out-of-hospital DNR orders) are discussed with cancer patients and their families. Many informed patients readily sign living wills or appoint health care proxies. Timely recommendation of DNR status may avoid unnecessary trauma to patients, futile efforts, wasted resources, and anguish for family members; this also provides time for open discussion to settle disagreements among the patient and family members.

When a cancer patient presents to a health care facility in impending or full cardiopulmonary arrest, the emergency physician may have never seen the patient before, and assessment of prognosis is difficult and often impossible. The decision to initiate or continue resuscitation should be based on a rapid assessment of the patient's physical condition, a brief history of the events preceding the arrest, and the following factors: (1) duration of arrest, (2) initial cardiac rhythm, (3) rigor mortis or algor mortis, (4) type, stage, and prognosis of cancer, (5) history of cancer treatment and prospects for its success, (6) expressed directives of the patient or family, (7) comorbid conditions, (8) performance status and nutritional status, (9) potential quality of life if the patient survives, and (10) advanced age.

The fact that the patient was transported to an emergency center may indicate that death is unexpected, that the family has not yet accepted the patient's grave prognosis, or that the patient or family is seeking relief of symptoms or suffering at the last moments of life. Demands for resuscitation may be motivated by denial of the terminal condition. A questionnaire-based study has found that most cancer patients want to be resuscitated despite poor survival rates, and that they want themselves and their next of kin to be involved in the decision-making process.¹⁰ In the absence of clear advance directive, resuscitation may be needed to give the family "closure" by knowing that "everything possible has been done." However, resuscitation of patients with advanced refractory malignancies may be inappropriate when it will only prolong pain and suffering.

Special consideration in resuscitation of cancer patients

Most physicians and health care providers follow the resuscitation algorithms outlined in the advanced cardiac life support (ACLS) protocols (<http://www.acls.net/aclsalg.htm>).⁵ However, identification of specific causes of cardiopulmonary arrest may enable physicians to target efforts to reverse or control the specific causes. Carcinoid crisis is a good example of an uncommon but preventable and treatable cause of cardiopulmonary arrest in cancer patients. The crisis may be precipitated by anesthesia, biopsy, surgery, chemotherapy, or adrenergic drugs (e.g., dopamine and epinephrine). Affected patients may

develop refractory hypotension, arrhythmias, and bronchospasm due to massive release of serotonin and other vasoactive peptides from the tumor. Carcinoid crisis can be aborted or treated with octreotide acetate, a somatostatin analog, 150–500 µg intravenously (IV).¹¹ Cardiac tamponade is another example. If a patient has pulseless electrical activity due to tamponade by a malignant pericardial effusion, resuscitation will not succeed until the pressure on the cardiac chambers is relieved by pericardiocentesis.

Causes of cardiac arrest in cancer patients

In the general population, undiagnosed neoplasm is a rare cause of sudden death. In cancer patients, a review of causes of death found that 4% of patients died of cardiac problems and that 90% of these died from atherosclerosis-related ischemic heart disease.¹² Most causes of cardiopulmonary arrests in cancer patients are related to cancer or antineoplastic therapy, rather than primary cardiac disease.

Tumor-related causes

Tumor-related cardiac problems are usually the result of pericardial involvement (e.g., neoplastic pericarditis and cardiac tamponade). Tumors can induce arrhythmias by secretion of hormone mediators (e.g., catecholamines by pheochromocytomas and serotonin by carcinoid tumors) or by direct mechanical irritation of the heart or pericardium. Arrhythmias associated with myocardial tumors, coronary obstruction by tumor, and massive tumor embolization have been reported to cause sudden cardiopulmonary arrest. Cardiac amyloidosis can also lead to intractable congestive heart failure, arrhythmias, conduction disturbances, and sudden death.¹³ Other tumor-related causes of arrest include hemorrhage, loss of ventilatory function, and organ failure.

Systemic therapy-related causes

Antineoplastic agents can cause complications (angina, myocardial infarction, congestive heart failure, hypotension, arrhythmia) leading to cardiopulmonary arrest.¹⁴ Doxorubicin may cause electrocardiographic and rhythm changes (mostly benign) in about 30% of patients¹⁵ and sudden cardiopulmonary arrest in almost 1% of patients.¹⁶ Some drugs (e.g., imatinib, trastuzumab) may interfere with myocardial remodeling after cytotoxic myocardial damage, causing cardiomyopathy and heart failure.¹⁵ High-dose cyclophosphamide may cause ventricular arrhythmia, cardiomyopathy, pericardial effusion, and cardiac arrest.¹⁷ Fluorouracil and capecitabine are associated with acute coronary vasospasm leading to angina and myocardial infarction; they have also been reported to cause acute cardiogenic shock. Hypotension, arrhythmia, and sudden death have been reported with cytokines (interleukin-2 [IL-2], interferons) and monoclonal antibodies.

Radiotherapy-related causes

Radiation can damage the pericardium and heart.¹⁸ Pericarditis may occur shortly or months to years after exposure of the chest to radiation. Radiotherapy can lead to valvular diseases, pericardial effusion, tamponade, pericardial fibrosis, or restrictive cardiomyopathy. The direct toxic effect of radiation can cause electrocardiographic changes, including T-wave abnormalities and atrial arrhythmias. Exposure of the heart to radiation is also associated with coronary artery problems (accelerated atherosclerosis, endarteritis, medial fibrosis, intimal proliferation), leading to myocardial infarction and sudden death.¹⁹

Arrhythmia

Arrhythmia is a common problem in cancer patients that needs emergency care. Sustained arrhythmia can lead to cardiopulmonary arrest and death; otherwise, the symptoms of intermittent arrhythmia can be subtle. The symptoms are primarily due to the hemodynamic effects. Significant signs and symptoms include isolated or recurrent loss of consciousness (syncope), light-headedness (dizziness), palpitation, chest pain, dyspnea, and acute neurologic deficits.

Sustained arrhythmia can be diagnosed electrographically readily. However, arrhythmia is often transient or intermittent, causing difficulty in diagnosis. An electrocardiographic rhythm strip or a brief period of continuous monitoring does not exclude latent and potentially serious rhythm disorders. When symptoms suggest arrhythmia, Holter monitoring for 24–48 h or event recorders (continuous loop, postevent, or real-time continuous) are indicated to capture the arrhythmia. Analysis of cardiac rhythm may be complicated in cancer patients because they often have exaggerated respiratory variations of the electrical axis and changes in mean QRS voltage that can be confused with heart rhythm irregularity. Such changes may be due to pleural or pericardial effusions, pulmonary surgery (pneumonectomy or lobectomy), or radiation-induced lung damage.

Primary arrhythmia

Primary arrhythmia arises from cardiac and pericardial structures. Common causes of primary arrhythmia in all patients include ischemic disease; increased intracardiac pressure and wall stress; congestive, hypertrophic, and infiltrative cardiomyopathy; and fibrosis. In cancer patients, the causes of primary arrhythmia are primary or metastatic intracardiac tumors, amyloid infiltration, myocarditis, pericarditis, pericardial constriction, and cardiomyopathy related to antineoplastic agents (especially anthracyclines and anti-HER2 therapy).¹⁴

Secondary arrhythmia

Secondary arrhythmia arises from toxic reactions to drugs; increased sympathetic states (severe anxiety, hyperthyroidism, pheochromocytomas, carcinoid tumors, etc.); abnormal electrolytes; and radiation-induced heart damage. Some cancer drugs are arrhythmogenic ([Table 1](#)).^{20–24} In addition to chemotherapy, antifungal agents, antiprotozoans, and antibiotics, which are commonly used to treat infectious complications in cancer patients, may prolong the QT interval [listed at <http://www.qtdrugs.org> (Arizona Center for Education and Research on Therapeutics)], potentially leading to arrhythmia.

Table 1 Antineoplastic drugs associated with cardiovascular side effects

	Pulmonary HTN	Systemic HTN	Ischemia	Reduction in LVEF	QT prolongation	VT/Sudden death	Bradycardia
<i>Tyrosine kinase inhibitors</i>							
Imatinib	Reported			0.5–1.7%			
Dasatinib	Reported			2–4%	<1–3%		
Cabozantinib		33%			Mean increase of QTcF by10–15 ms; No QTcF >500 ms		
Lapatinib				1.5–4%	16%		

Erlotinib			2.3%				
Nilotinib	Reported	10–11%			1–10%; QTcF > 500 ms in 1%	Reported	
Pazopanib		40–42%		8–11%	QTcF > 500 ms in 0.2– 2%	Torsades de pointes in <1%	
Sorafenib		9–43%	2.7–3%	12%	No large changes (i.e., <20 ms)		
Sunitinib		5–47%		2.7–27%	Dose- dependent	Torsades de pointes in 0.1%	
Vandetanib		33%			QTcF > 500 ms in 1%	Reported	
<i>Antibodies</i>							
Bevacizumab		4–35%	0.6– 1.5%	1.7–3%			
Trastuzumab		4%		2–28%			
<i>Alkylating agents</i>							
Cisplatin		Reported	Reported	Reported		Reported	
Ifosfamide				17%			
Cyclophosphamide			Reported	7–28%			
Busulfan				Reported			
Mitomycin				Reported			
<i>Anthracyclines/anthraquinones</i>							
Daunorubicin				Reported			
Doxorubicin				3–26% 5% at the cumulative dose of 400–450 mg/m ²		6%	Reported
Idarubicin				5–18%			
Epirubicin				0.9–3.3%			
Mitoxantrone				Reported			
<i>Antimetabolites</i>							
Capecitabine			3–9%	Cardiogenic shock reported		2.1%	

5-Fluorouracil			1–68%	Cardiogenic shock reported			
Gemcitabine							
Cytarabine				Reported			
Clofarabine				27%			
<i>Topoisomerase I inhibitors</i>							
Irinotecan							Reported
<i>Taxanes</i>							
Paclitaxel			<1–5%			0.26%	<0.1–31%
Docetaxel			1.7%	2.3–8%			
<i>Vinca alkaloids</i>							
Vincristine			Reported				
Vinblastine			Reported				
<i>Miscellaneous</i>							
IL-2				Reported		0.2%	
Arsenic trioxide					26%		
Vorinostat					3.5–6%		
Interferon-α			1%	Reported			
Tretinoin (retinoic acid)				Reported			
Bortezomib				2–5%			
Thalidomide							0.12–55%
Pentostatin				Reported			

Abbreviations: AF, atrial fibrillation; HTN, hypertension; LVEF, left ventricular ejection fraction; QTcF, QT interval corrected by Fridericia's formula; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

Treatment of arrhythmia

Treatment of arrhythmia should be based on both urgency and etiology. For hemodynamically stable arrhythmias of secondary origins, the primary treatment should focus on correcting metabolic derangements (particularly potassium, calcium, and magnesium) and discontinuing culprit drugs. Specific treatment to reverse the causative factor should be administered. When treatment aimed at controlling the cardiac rhythm is necessary, standard guidelines for management of arrhythmia may be followed.⁵ Commonly used IV antiarrhythmic drugs are listed in [Table 2](#).

Table 2 Commonly used IV antiarrhythmic drugs

Name	Class	Dose ^a	Indication ^a

Adenosine	Nucleoside	6 mg IV over <3 s followed by NS 20 mL bolus; second dose and third dose of 12 mg 2 min apart as needed	Narrow complex PSVT; PSVT due to AV node or sinus node reentry
Amiodarone	Class III antiarrhythmic	Cardiac arrest: 300 mg IVP; 150 mg IVP q 3–5 min up to 2.2 g/day	
		Stable wide-complex tachycardia: 150 mg IV over 10 min; repeat q 10 min as needed; maintenance infusion 0.5 mg/min; up to 2.2 g/day	Supraventricular or ventricular tachyarrhythmias; control of rapid atrial tachyarrhythmia in patients with low LVEF when digoxin is ineffective
Atropine	Anticholinergic	0.5–1 mg IVP q 3–5 min as needed, up to 0.04 mg/kg	Symptomatic sinus bradycardia; Mobitz type 1 AV block; asystole
Digoxin	Digitalis glycoside	Loading dose: 10–15 µg/kg lean body weight in divided doses	To slow ventricular response in A. fib. or A. flutter; PSVT
Diltiazem	Calcium channel blocker	0.25 mg/kg IV over 2 min; second dose 0.35 mg/kg IV over 2 min in 15 min prn; maintenance: 5–15 mg/h by titration	To slow ventricular response in A. fib. or A. flutter; PSVT; to terminate AV nodal re-entrant tachycardia
Esmolol	β-Blocker	0.5 mg/kg over 1 min; then infuse at 0.05 mg/kg/min; titrate up to maximum of 0.3 mg/kg/min	PSVT, A. fib. or A. flutter; Reduce incidence of VF in MI or USA
Ibutilide	Class III antiarrhythmic	1 mg IV over 10 min; repeat in 10 min prn	SVT including A. fib. A. flutter; effective for conversion of A. fib. flutter of relatively brief duration
Isoproterenol	β-Agonist	Infuse 2–10 µg/min; titrate	Symptomatic bradycardia; torsades de pointes refractory to Mg; β-blocker overdose
Lidocaine	Local anesthetic	1–1.5 mg/kg IVP; repeat 0.5–0.75 mg/kg IVP q 5–10 min up to total of 3 mg/kg prn; maintenance: 30–50 µg/kg/min IV	VT or VF; wide-complex tachycardia; significant ventricular ectopy; torsades de pointes
Metoprolol	β-Blocker	5 mg slow IVP q 5 min up to a total dose of 15 mg	PSVT, A. fib., or A. flutter; Reduce incidence of VF in MI or USA
Procainamide hydrochloride	Class IA antiarrhythmic	20–50 mg/min up to a total dose of 17 mg/kg	Recurrent VF or VT
Propranolol	β-Blocker	0.1 mg/kg slow IVP in three divided doses 2–3 min apart	PSVT, A. fib., or A. flutter; Reduce incidence of VF in MI or USA
Quinidine gluconate	Class IA antiarrhythmic	Intermittent bolus doses of 80 mg every 5–10 min or 10 mg/min IV infusion up to 400 mg	Supraventricular and ventricular arrhythmias

Verapamil	Calcium channel blocker	2.5–5 mg IV over 2 min; repeat q 15–30 min prn up to a total dose of 20 mg	PSVT, A. fib., or A. flutter
-----------	-------------------------	--	------------------------------

Abbreviations: A. fib., atrial fibrillation; A. flutter, atrial flutter; AV, atrioventricular; IV, intravenous; IVP, intravenous push; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NS, normal saline; prn, as needed; PSVT, paroxysmal supraventricular tachycardia; USA, unstable angina; VF, ventricular fibrillation; VT, ventricular tachycardia.

^a Source: From ACLS Provider Manual.⁵

Paroxysmal supraventricular tachycardia (SVT) may be converted back into sinus rhythm in a considerable proportion of cases by vagal maneuvers. Adenosine administered as one or two doses of rapidly injected boluses under electrocardiographic monitoring is frequently effective in restoring sinus heart rhythm. Adenosine is also used to determine the mechanism of the arrhythmia when the diagnosis is unclear on electrocardiograms.

Stable secondary arrhythmia is unlikely to deteriorate into a life-threatening catastrophe. Frequently, secondary arrhythmia presents as ventricular ectopy (sometimes in bigeminy, trigeminy, or other coupled patterns), or supraventricular ectopy (often as intermittent or sustained SVT). Isolated premature ventricular complexes do not require any treatment. Complex forms of ventricular ectopy are often controlled by β -adrenergic blockers. Amiodarone should be considered for patients with a low left ventricular ejection fraction, but with caution for patients with hepatic insufficiency or underlying thyroid diseases. Rarely, amiodarone can cause hypotension, bradycardia, and QT prolongation that may precipitate torsades de pointes. Except for β -adrenergic blockers, many antiarrhythmic drugs, especially types 1A, 1C, and 3, are potentially proarrhythmic.²⁵ Cardiac monitoring during the initiation of antiarrhythmic therapy should be considered because cancer patients may have an increased susceptibility to proarrhythmic effects due to metabolic derangements and concomitant use of other QT-prolonging drugs.

SVT is the most common arrhythmia in cancer patients. Although pharmacological agents are used for sustained SVT with stable hemodynamics, elective synchronized cardioversion under conscious sedation should be considered early and planned appropriately. The initial energy level for synchronized cardioversion recommended by the American Heart Association is 100 J, but an initial shock with an energy level of 200 J has been recommended by others for the conversion of atrial fibrillation.²⁶ Higher energy levels for cardioversion are appropriate when cancer patients have concomitant effusions or are significantly overweight. If sinus rhythm can be restored within 48 h of the onset of SVT, anticoagulation therapy may be avoided. However, the time of onset of arrhythmia is not always clear. Intracardiac thrombosis may be excluded by transesophageal echocardiography. In lack of clear evidence for the time of onset, the patient should be anticoagulated prior to cardioversion.

Arrhythmias of structural origin in cancer patients are more difficult to control than arrhythmias of metabolic etiology. In the emergency setting, the therapeutic goals are stabilization of hemodynamics and respiratory status, discovery of correctable pathologic conditions, and control of symptoms. Depending on the etiology of the arrhythmia, emergent consultation with cardiologists and emergent diagnostic or interventional procedures may be required.

Patients with unstable arrhythmia should be treated with aggressive pharmacological or electrical interventions. The interventions should follow established algorithms such as those by the American Heart Association.²⁷ These interventions include administration of a vasopressor, such as vasopressin or epinephrine (if required); administration of antiarrhythmic drugs such as amiodarone, lidocaine, and

procainamide; electrical cardioversion or defibrillation; airway management; ventilation with oxygen; administration of IV fluid; and chest compression (if required). Emergency treatment of torsades de pointes varies from the standard algorithms for ventricular tachycardia; it entails expedient use of IV magnesium sulfate, electrical overdrive pacing, pharmacological overdrive with isoproterenol, or administration of phenytoin or lidocaine.

Tumor lysis syndrome

Tumor lysis syndrome (TLS) consists of severe hyperphosphatemia, hyperkalemia, hyperuricemia, azotemia, hypocalcemia, and metabolic acidosis (out of proportion to renal insufficiency) due to the massive release of cell contents and degradation products of dead tumor cells into the bloodstream.²⁸ TLS can occur spontaneously, but it usually occurs within 72 h after chemotherapy in patients with leukemia and lymphoma, but new therapeutic regimens may alter the timing of onset. TLS can also occur in patients with nonhematologic malignancies, including small cell carcinomas, nonsmall cell lung cancer, breast cancer, and ovarian cancer.

The symptoms of TLS are nonspecific. Common symptoms include nausea, vomiting, cloudy urine, weakness, fatigue, and arthralgia. Other signs and symptoms related to metabolic and electrolyte abnormalities include neuromuscular irritability, seizures, muscle weakness, and arrhythmia. Arrhythmia may cause sudden death in patients with TLS.²⁹ Precipitation of uric acid in the renal tubules may lead to nephropathy and acute renal failure.³⁰ The acute cause of death in TLS is arrhythmia secondary to severe electrolyte abnormalities (especially hyperkalemia) and renal failure. Early recognition of metabolic abnormalities and prompt treatment can avoid fatal outcomes.

Factors associated with increased risk of TLS include the type of malignancy (e.g., acute lymphocytic leukemia, acute myeloid leukemia with white blood cell count > 75,000/ μ L, Burkitt's lymphoma), responsiveness to therapy, rapid malignant cell turnover, and large tumor burden.³¹ Other risk factors are preexisting renal insufficiency, acute renal failure developing shortly after the treatment, and poor response to hydration. Pretreatment serum lactate dehydrogenase levels, which tend to correlate with tumor bulk in lymphoma or lymphocytic leukemia, can predict the development of posttreatment azotemia, but pretreatment hyperuricemia is not predictive. A predictive scoring system for TLS has been proposed based on data from acute myelocytic leukemia patients undergoing induction therapy.^{32, 33} The score may potentially be used in a risk-based prophylaxis for TLS. Preventive measures should be started early in patients at risk. Aggressive hydration with IV crystalloid fluid up to 3 L/m²/day may maintain a urine output >100 mL/h with or without diuretics. The xanthine oxidase inhibitor allopurinol (100–300 mg/day orally) may prevent severe hyperuricemia. The role of febuxostat, a new xanthine oxidase inhibitor, remains to be studied.

The diagnosis of TLS requires a high level of suspicion because there are few signs or symptoms in the early stage. Routine uric acid and electrolyte screening (including measurement of calcium and phosphorus levels) is indicated in patients with high tumor bulk or hematologic malignancies. The diagnosis of TLS may be based on the Cairo–Bishop definition.^{31, 34} Once diagnosed, patients with severe TLS should have continuous monitoring of hemodynamic and electrocardiographic parameters in intensive care. The allopurinol dose may be increased up to 900 mg/day. Rasburicase, a recombinant urate oxidase that converts uric acid to allantoin, is highly efficacious in reducing uric acid level. Rasburicase (150–200 μ g/kg IV daily or one-time dosing with a rescue dose as needed) may be used to prevent or treat urate nephropathy.³⁵ Increased IV fluid hydration may be coupled with diuresis using loop diuretics (e.g., furosemide, 20–200 mg IV every 4–6 h) and acetazolamide (250–500 mg IV daily).

Urinary alkalization by sodium bicarbonate or acetate IV infusion to increase the solubility of urate in urine should only be considered in cases of severe hyperuricemia when rasburicase is not available. Frequent electrolyte measurements (every 4–6 h) may be required. Hyperkalemia should be treated with insulin plus dextrose, calcium, and bicarbonate IV along with oral potassium ion-exchange resins (sodium polystyrene sulfonate). In hyperphosphatemic patients with hypocalcemia, the addition of an oral calcium-based compound (e.g., calcium acetate or calcium carbonate) will reduce phosphate absorption and enhance calcium absorption. IV calcium infusion can potentially cause calcium phosphate precipitation in the presence of severe hyperphosphatemia and should be used cautiously. Dialysis may be required for patients with symptomatic hypocalcemia and a serum phosphorus level >3.3 mmol/L (>10.2 mg/dL). Other indications for dialysis include persistent or refractory azotemia, hyperkalemia, hyperuricemia, oliguria, anuria despite diuretic use, acidemia, and volume overload. Prompt dialysis should be instituted with continued monitoring until biochemical abnormalities resolve. Hemodialysis is the most common mode of dialysis; prolonged hemodialysis sessions, continuous arteriovenous hemodialysis, continuous veno-venous hemofiltration, and continuous renal replacement therapy at a high dialysate or replacement fluid flow rate (>3 L/h) are alternative methods.

Pericardial tamponade

Pericardial tamponade occurs when a pericardial effusion impairs hemodynamics. Accumulation of excess fluid in the pericardial space in cancer patients is due to obstruction of lymphatic drainage and/or excess fluid secretion from tumor nodules on pericardial surfaces. Mesothelioma is the most common malignancy that arises from the pericardium. Carcinoma of the lung and malignant thymoma may involve the pericardium by direct extension. More frequently, malignancies arrive at the pericardium by retrograde lymphangitic spread or hematogenous dissemination. Melanoma is the malignancy most likely to metastasize to the heart. Lymphomas, leukemias, and gastrointestinal neoplasms may also cause pericardial effusions.³⁶ Cytologic examination of pericardial fluid reveals metastatic disease in 70–80% of cancer patients with pericardial effusion. Nonmalignant causes of pericardial tamponade include pericardial abscess, *Candida* pericarditis, and complications of central venous catheterization.

Malignant pericardial effusion usually occurs in advanced malignancy and is associated with poor prognosis (median survival time: about 6 months; 1-year survival rate: 28%).³⁷ More than two-thirds of patients with malignant pericardial effusion are asymptomatic. In symptomatic patients, common complaints are shortness of breath, dyspnea on exertion, chest pain, orthopnea, and general weakness. Findings on physical examination may vary from normal to hemodynamic collapse. Tachycardia, hypotension, jugular venous distention, organomegaly, and edema may indicate compromised cardiac output. The classic findings of cardiac tamponade are determined by both the quantity of pericardial fluid and the rapidity of fluid accumulation. Pulsus paradoxus, an exaggeration of the physiological decrease in systolic blood pressure with inspiration, is a classic but nonspecific finding of cardiac tamponade because it is seen also in patients with lung cancer, significant lung disease, or cor pulmonale.

Diagnosis of pericardial tamponade usually requires additional testing. Low QRS voltage and electrical alternans in electrocardiographs are suggestive findings. Chest radiographs may reveal widening of the mediastinum and cardiac silhouette ([Figure 2a, b](#)). Computed tomography (CT) or magnetic resonance (MR) imaging studies frequently detect pericardial effusions as an incidental finding. These studies provide information on the location (loculated or not) and size of pericardial effusions but do not adequately assess the hemodynamic significance. Two-dimensional echocardiography is the most useful test for diagnosing pericardial effusion and evaluating its hemodynamic significance, that is, the presence of cardiac tamponade. Collapse or compression of the right atrium, diastolic collapse of the right

ventricle, and cardiac “rocking” (side-to-side or front-to-back movement) are often observed in cardiac tamponade. Alterations in the respiratory variation of flow across the mitral valve as measured by Doppler shift are also helpful in evaluating the hemodynamics.

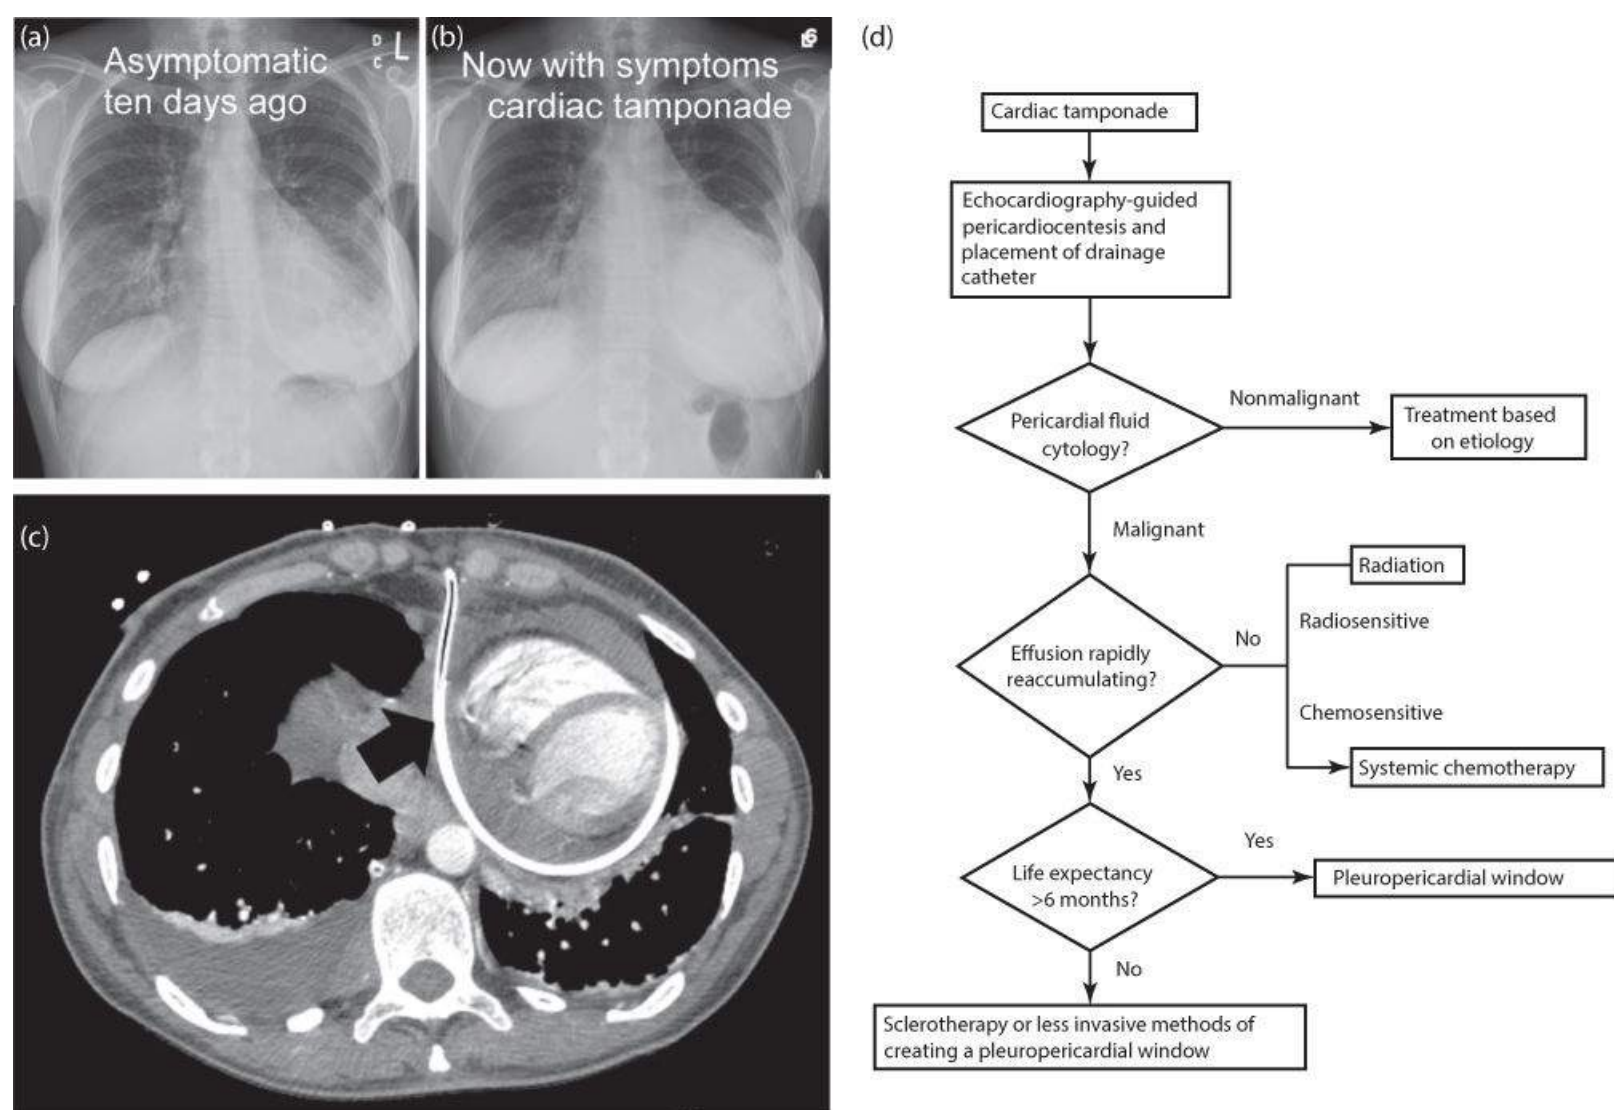

Figure 2 Chest imaging of patients with pericardial tamponade and management algorithm. Widening of mediastinum and cardiac silhouette is evident (b) when compared with a prior chest radiograph (a). Chest CT of a different patient with pericardial tamponade shows the presence of an indwelling drainage catheter (c). An algorithm for management of pericardial effusion is shown (d).

Initial management of malignant pericardial effusion depends on the hemodynamic stability. A scoring system may guide the decision for urgent pericardiocentesis.³⁸ In patients with hemodynamic compromise, ultrasound-guided pericardiocentesis, with placement of a drainage catheter into the pericardial space (Figure 2c), may be performed emergently in the emergency center or intensive care unit (Figure 2d). Complications are rare and may include massive pericardial bleeding and pneumothorax. Pericardial fluid can be drained from the catheter, and the catheter can stay until <50 mL/day of fluid is drained. Fibrinolytic agents may be used to unclog the catheter to facilitate drainage and avoid repeat pericardiocentesis or replacement of the catheter.³⁹ However, pericardial fluid will usually reaccumulate after removal of the catheter.

Long-term management of malignant pericardial effusion focuses on preventing reaccumulation of fluid, which occurs in >50% of patients. Because the long-term survival for most patients with malignant pericardial effusion is limited, an effective therapy with limited discomfort and risk to the patient should be employed. Creation of a pleuropericardial window using a variety of approaches can avoid repeated

pericardiocentesis. This surgical procedure is usually done in an operating room, but it can be performed in a hospital room or intensive care unit using local anesthesia. The use of a percutaneous intrapericardial balloon catheter to create a pleuropericardial window has had some success.⁴⁰ A laparoscopic transdiaphragmatic approach to create a pericardioperitoneal shunt has also been described.⁴¹ In stable patients, systemic chemotherapy, pericardial radioactive colloid, or thoracic external-beam irradiation may be used for tumors that are sensitive to these treatment modalities. Additional radiotherapy should be avoided in patients with significant prior exposure of the heart to radiation. Local application of cytotoxic agents or sclerosing agents to the pericardium can prevent fluid reaccumulation in many patients,⁴² but sclerotherapy can be very painful.

Acute hemorrhage

Acute gastrointestinal bleeding and genitourinary bleeding are discussed in other chapters. Hemoptysis, which can rapidly compromise respiratory function, will be discussed later in this chapter. This section will cover some less frequent but serious bleeding events: carotid arterial rupture, splenic rupture, and retroperitoneal hemorrhage.

The manifestations of acute hemorrhage depend on the rate and the site of bleeding. In most cases, the site of bleeding is obvious, but sometimes bleeding can be internal and difficult to diagnose. Signs and symptoms of hypovolemia and hypoperfusion include tachycardia, hypotension, oliguria, and depressed mental status. Very often, diagnostic imaging studies or procedures, such as CT scans, ultrasonography, arteriography, or endoscopy, are necessary to diagnose internal bleeding.

The primary management objectives for acute hemorrhage are to rapidly identify the bleeding source and achieve hemostasis. In the acute setting, direct pressure to compress the bleeding vessel or site should be applied whenever feasible while the cardiopulmonary status is assessed expeditiously. IV fluid resuscitation is vital in maintaining intravascular volume, cardiac output, and adequate vital organ perfusion. Isotonic crystalloid fluids (normal saline, lactated Ringer's solution, PlasmaLyte, etc.) should be used as first-line agents because colloids (e.g., gelatins, dextrans, hydroxyethyl starches, albumin) have not been proven to improve survival.⁴³ Coagulopathy or thrombocytopenia should be corrected immediately by transfusion of blood products. The decision to transfuse red blood cells depends on the hematocrit, hemodynamic stability, persistence of hemorrhage, estimated blood loss, and comorbid diseases (e.g., coronary artery disease and cerebrovascular disease). Typed and cross-matched red blood cells are preferred, but noncross-matched type-specific blood or type-O blood may have to be used in life-threatening cases. Specific therapeutic procedures to control bleeding, such as embolization, balloon tamponade, or surgery, should be performed in a timely manner.

Carotid artery rupture

Most cases of carotid artery “blowout” occur in patients with head and neck cancers. Carotid blowout syndrome may be caused by direct tumor invasion or erosion into the carotid artery or by complications of cancer treatment, for example, postsurgical wound infection, postradiation necrosis, or orocutaneous fistula. It usually occurs as a sudden and massive arterial spurting. Occasionally, ominous minor and transient bleeding (sentinel bleeds) herald the massive blowout. In some cases, bleeding through a fistula into the esophagus or trachea may manifest as massive hematemesis or hemoptysis. Without prompt management, the patient's condition will rapidly deteriorate to hypotension, hypovolemic shock, loss of consciousness, and death.

Hemostasis is of utmost importance. As neck vessels are accessible to direct manual compression,

continuous firm compression should be applied at the site of the carotid artery rupture until the patient arrives at the operating room for surgical treatment. Crystalloid IV fluid resuscitation, prompt transfusion of blood products, and administration of vasopressors should be performed to maintain perfusion of vital organs. Carotid artery rupture has limited surgical options, and surgical ligation of the bleeding carotid artery is associated with high morbidity (25% of patients have neurologic sequelae) and high mortality (40%).⁴⁴ Endovascular treatment with vessel sacrifice (embolization or balloon occlusion) or stent placement (covered stent) has become major treatment options.^{45, 46}

Splenic rupture

The spleen is fragile and vulnerable to rupture from trauma. In cancer patients, spontaneous splenic rupture is relatively rare and is associated with acute leukemia, non-Hodgkin's lymphoma, chronic myelogenous leukemia, hairy cell leukemia, and Hodgkin's lymphoma. Metastases to the spleen in patients with solid tumors such as gastric, prostate, and lung cancer can also cause rupture. The mechanism of spontaneous splenic rupture is not clear. Minor trauma to the spleen may contribute in some cases. Other contributing factors include splenomegaly, infiltration of the splenic capsule by malignant cells, splenic infarction, thrombocytopenia, coagulopathy, anticoagulation therapy, and disseminated intravascular coagulation.

The typical clinical presentation of splenic rupture involves pain in the left shoulder or abdomen (left upper quadrant), tachycardia, and hypotension. The severity of the signs and symptoms may depend on the extent of bleeding. Diagnostic peritoneal lavage is rarely used in nontraumatic cases; thus, the definitive diagnosis of splenic rupture relies on imaging studies. Contrast-enhanced CT is the diagnostic study of choice; ultrasonography can be performed at bedside for hemodynamically unstable patients to diagnose splenic rupture.⁴⁷

For patients with splenic rupture and hematologic malignancies, prompt splenectomy is necessary because the mortality rate for these patients is extremely high without surgery. In selected patients with contraindications to surgery, selective arterial embolization of the ruptured site may stop the bleeding.⁴⁸ Other supportive treatments are IV fluid, supplemental oxygen, pain medications, blood transfusion, and correction of thrombocytopenia and coagulopathy.

Retroperitoneal hemorrhage

Damage to retroperitoneal organs or structures may cause retroperitoneal hemorrhage. Malignancies rarely cause spontaneous retroperitoneal hemorrhage; in such cases, the culprit is usually renal cell carcinoma or adrenal gland neoplasm (primary or metastatic). Anticoagulation, thrombocytopenia, and coagulopathy are predisposing factors. Retroperitoneal or intraperitoneal invasive procedures and placement of a central venous catheter through a femoral vessel can also cause severe retroperitoneal hemorrhage.

Retroperitoneal hemorrhage causes nonspecific signs and symptoms that vary according to the rate of bleeding and the underlying disease. Patients may present with abdominal pain, a tender mass in the flank, tachycardia, and hypotension. Some may have hematuria or hematochezia if the blood somehow finds its way into the ureter or gastrointestinal tract. It is difficult to establish a diagnosis of retroperitoneal hemorrhage on the basis of clinical findings. Maintaining a high level of clinical suspicion and performing early imaging studies are keys to the successful management of retroperitoneal hemorrhage. CT of the abdomen and pelvis is the noninvasive study most commonly used to diagnose retroperitoneal bleeding ([Figure 3](#)). Bedside ultrasonography may also rapidly diagnose retroperitoneal bleeding.

Figure 3 Retroperitoneal bleeding. The CT scan of the abdomen and pelvis of a thrombocytopenic leukemia patient showed a large inhomogeneous retroperitoneal collection (white arrowheads) consistent with a hematoma in the left psoas muscle displacing bowel loops to the right.

The management of retroperitoneal hemorrhage depends on the severity of bleeding and the underlying cause. After the initial stabilizing treatments for acute hemorrhage, the patient should be monitored closely for hemodynamic stability and continuation of blood loss. In life-threatening situations, most patients require emergent laparotomy to remove the bleeding tumor or organ.⁴⁹ Renal cell carcinomas are often hypervascular, and selective arterial embolization may control the bleeding of a renal lesion. External-beam radiation treatment of a bleeding tumor is another option in hemodynamically stable patients with a relatively stable hematocrit.⁵⁰

Superior vena cava syndrome

Superior vena cava (SVC) syndrome refers to a constellation of signs and symptoms resulting from partial or complete obstruction of blood flow through the SVC to the right atrium. The obstruction may be caused by compression, invasion, thrombosis, or fibrosis of this vessel. Lung cancer is the leading cause of SVC syndrome; non-Hodgkin lymphoma is the second most common cause.^{51, 52} Although Hodgkin lymphoma commonly involves the mediastinum, it rarely causes SVC syndrome. Primary mediastinal malignancies such as thymoma and germ cell tumors account for <2% of SVC syndrome. Breast cancer is the most common metastatic disease that causes SVC syndrome;⁵³ other metastatic cancers include gastrointestinal adenocarcinoma, prostate adenocarcinoma, sarcomas, and melanoma. Nonmalignant causes of SVC syndrome include retrosternal goiter, pyogenic infections, sarcoidosis, teratoma, pleural calcification, silicosis, postradiation fibrosis, chemotherapy-induced fibrosis, constrictive pericarditis, and idiopathic mediastinal fibrosis.⁵² An increasing cause of SVC syndrome in cancer patients is central venous catheter-induced thrombosis.

Obstruction of the SVC causes a rise in venous pressure in the SVC. Collateral venous circulation often

flows through the azygos venous system. Obstruction below or at the entrance of the azygos veins forces blood to travel in the opposite direction down the azygos and chest wall veins to reach the inferior vena cava. SVC obstruction caused by tumors often develops insidiously over weeks. However, thrombosis may cause a rapid onset of obstruction. Sudden SVC obstruction is a true emergency because the rapid elevation of pressure in the SVC causes increased intracranial pressure, resulting in cerebral edema, intracranial thrombosis or bleeding, and death.

Common symptoms of SVC syndrome are a sensation of fullness and pressure in the head, cough, dyspnea, chest pain, and dysphagia. More significant symptoms include visual disturbances, hoarseness, stupor, seizure, and syncope. Typical signs include venous distention of the neck and chest wall, nonpitting edema of the neck, facial edema, facial plethora, tongue edema, proptosis, retinal vessel dilatation, stridor, and upper extremity edema. The signs and symptoms are exacerbated by lowering the upper body relative to the heart (i.e., bending forward, stooping, or lying down).

CT, especially contrast-enhanced spiral CT, is the most useful diagnostic study. It not only reveals the site of obstruction and collateral flow but also differentiates extrinsic compression of SVC by tumor from thrombosis. CT also provides anatomical details about the tumor and its surrounding structures, helping to guide biopsy procedures if a histologic diagnosis of the tumor has not been established previously. CT can also detect other emergent complications—such as proximal airway obstruction and pericardial effusion—that frequently coexist with SVC obstruction. If IV iodine contrast is contraindicated, radionuclide venography and MR imaging are alternatives. 3-D contrast-enhanced MR venography may be superior to CT, digital subtraction angiography, and Doppler ultrasonography in detecting and determining the extent of thrombo-occlusive disease in chest vessels.⁵⁴ Contrast angiography for diagnosis of SVC syndrome is rarely indicated.

An algorithm for SVC syndrome is available (http://www.factsoncancertreatment.org.uk/index.php?option=com_alresource&keyword=S&catid=1&Itemid=107). The method for establishing the histologic cancer diagnosis may depend on the working diagnosis, location of the tumor, physical status of the patient, comorbid conditions, and available expertise of the health care facility. CT-guided needle biopsy is an alternative to surgical biopsy by thoracotomy or mediastinoscopy.⁵⁵ Bronchoscopy may provide the cancer diagnosis in up to 50% of patients with SVC syndrome. If lymph nodes are accessible, excisional biopsy can establish the diagnosis with minimal morbidity. Excisional biopsy is preferred if lymphoma is suspected because the histologic classification of lymphoma is firmly based on lymph node architecture.

In rare emergent situations of impending airway obstruction or increased intracranial pressure, endovascular interventions,⁵⁶ including angioplasty, SVC stenting, and pharmacomechanical thrombolysis, should be employed immediately. Stenting provides rapid symptomatic relief in the majority of patients and improves the quality of life. These stents usually remain patent for the rest of the patient's life.⁵⁷ Some authors recommend stenting as first-line treatment of SVC syndrome.^{57, 58} Stenting may relieve severe symptoms while the histologic diagnosis of the malignancy is being pursued, or when radiation or chemotherapy has failed or not yet taken effect.

Supplemental oxygen, bed rest with upper body elevation, and sedation may help to lessen the symptoms by lowering venous pressure and cardiac output. The use of diuretics may transiently decrease edema, but the efficacy of diuretics has not been proven, and overdiuresis causes dehydration, which should be avoided to minimize the risk of thrombosis. Corticosteroids (e.g., dexamethasone) may be useful in the presence of airway compromise or increased intracranial pressure. Anticoagulation is controversial despite the presence of superimposed thrombosis in up to 50% of SVC syndrome. Anticoagulation and thrombolysis may be beneficial in situations such as indwelling catheter-induced thrombosis or

propagation of the thrombus into the brachiocephalic or subclavian system. However, anticoagulation increases the risk of intracranial bleeding, especially when intracranial pressure is elevated, and may complicate or delay biopsy procedures; therefore, it should be avoided unless a clear indication is identified.

Radiotherapy remains the principal treatment for many patients with malignant SVC syndrome, especially in recurrent disease after chemotherapy or chemo-insensitive tumors such as nonsmall cell lung cancer.⁵⁹ In general, radiotherapy is well tolerated, and SVC syndrome symptoms begin to improve in about 1 week. Radiotherapy is also justified if a histologic diagnosis cannot be established in a timely manner. Chemotherapy is the preferred initial treatment of SVC syndrome caused by chemosensitive tumors such as small cell lung cancer and lymphoma. Most small cell lung cancer patients experience partial or complete resolution of the signs and symptoms within a couple of weeks. Although SVC obstruction recurs in approximately 25% of cases, salvage chemotherapy and/or radiotherapy can achieve prompt resolution of symptoms in most patients. After chemotherapy for lymphoma, local consolidation with radiotherapy may be beneficial in patients with large cell lymphoma and large mediastinal masses. Cancer invasion of SVC is no longer considered unresectable.⁶⁰ Surgical treatment with reconstruction may be indicated for certain tumor types or selected patients.⁶¹

Respiratory oncologic emergencies

Massive hemoptysis

Approximately 5% of hemoptysis episodes are considered massive. The definition of massive hemoptysis ranges from the expectoration of >100 mL of blood in a single episode to >600 mL in 24 h.⁶² Airway bleeding leading to life-threatening airway obstruction, hypotension, aspiration, or anemia is also considered massive hemoptysis. The mortality rate of massive hemoptysis is about 30%, ranging from 5% to 71% depending on the volume of blood expectorated and the rate of bleeding.^{63–67} Other factors associated with mortality include low pulmonary reserve and large amount of blood retained in the lungs.⁶⁴ Death attributable to endobronchial and alveolar hemorrhage is usually due to asphyxiation rather than exsanguination.

The primary causes of massive hemoptysis in cancer patients are malignancy, infection, and hemostatic abnormalities. Bronchogenic carcinoma is the most common cause of massive hemoptysis in cancer patients over 40 years old. About 3% of lung cancer patients have fatal hemoptysis,⁶⁸ which occurs more commonly in necrotic squamous cell carcinoma than other types of lung cancer. Hemoptysis secondary to lung metastases is most commonly associated with melanoma, breast, kidney, laryngeal, and colon cancers. Other tumors, such as esophageal tumors, may cause massive hemoptysis by direct extension to the tracheobronchial tree. In immunocompromised patients (e.g., patients with hematologic malignancies, bone marrow transplantation, or prolonged neutropenia), necrotizing, angioinvasive fungal infections (aspergillosis and mucormycosis) may cause massive pulmonary hemorrhage.⁶⁴ Hemostatic abnormalities such as severe thrombocytopenia and coagulopathy may result from malignancy or its treatments and contribute to hemorrhage. Another factor that can contribute to massive hemoptysis in cancer patients is lung injury by radiation or chemotherapy.

In addition to hemoptysis, symptoms may include dyspnea, hypotension, tachycardia, central cyanosis, clammy skin, or chest pain. Hemodynamic instability may require volume resuscitation. The respiratory status should be initially supported by supplemental oxygen. The American College of Chest Physicians Guidelines recommend securing the airway by endotracheal intubation with a single-lumen tube, and

emergent bronchoscopy to identify the bleeding site for endobronchial interventions such as laser or plasma coagulation and electrocautery.⁶⁹ Endobronchial interventions may also include administration of topical agents (thrombin), iced saline lavage, injection of epinephrine 1:20,000, and tamponade with a balloon catheter. Although rigid bronchoscopes offer improved airway control, ability to suction, and the ability to remove large clots, fiber optic scopes offer improved access and visualization of the distal airways. Other airway management options include unilateral intubation via the bronchoscope or a double-lumen endotracheal tube to isolate the unaffected lung. For massive right-sided pulmonary bleeding, the left main stem bronchus is intubated over the bronchoscope, but unilateral intubation of the right lung in patients with massive left-sided bleeding is not recommended due to the risk of right upper lobe occlusion. For patients bleeding from one lung, lateral decubitus positioning with the affected lung in the dependent position may help to minimize aspiration to the unaffected side. Underlying coagulopathies must be corrected, and cough suppressants may be helpful.

Noe et al. have proposed an algorithm for management of massive hemoptysis, in which CT angiography plays an important role.⁷⁰ Bronchial artery embolization is becoming first-line treatment for massive or recurrent hemoptysis. Together with bronchoscopy and chest X-ray, CT angiography provides information about the tumor, bleeding site, and anatomy of the bronchial and extrabronchial arteries for planning the endovascular intervention. Bronchial artery embolization is safe and effective. Embolization of the bleeding vessel may be performed with Gianturco steel coils, absorbable gelatin pledgets, polyvinyl alcohol foam, or isobutyl-2-cyanoacrylate. Patients in whom embolization fails may benefit from radiotherapy. Emergency lung resection is feasible in selected patients and is generally performed in patients with refractory hemoptysis in whom other treatments have failed or bleeding from the pulmonary vessels.⁷¹

Massive pleural effusion

Approximately 10% of pleural effusions are massive when there is near-complete opacification of the hemithorax on chest X-ray. About two-thirds of massive pleural effusions ([Figure 4](#)) have underlying cancer.⁷² The malignant causes are lung carcinoma (36%), breast carcinoma (25%), lymphoma (10%), and ovarian carcinoma (5%).⁷³ Adenocarcinoma accounts for 79% of lung carcinoma cases that metastasize to the pleura.⁷⁴ In young adults, lymphoma is the most common cause of malignant pleural effusions.⁷⁴ After pneumonia, malignancy is the second leading cause of exudative pleural effusions, and malignancy is the cause of 8–20% of transudative pleural effusions.⁷⁵ Other factors causing pleural effusions include local tumor effects (hilar and mediastinal lymphadenopathy causing impaired lymphatic drainage from the pleural space), systemic tumor effects, hypoalbuminemia, complications of cancer treatment [radiotherapy and chemotherapy (e.g., methotrexate, procarbazine, cyclophosphamide, mitomycin, bleomycin, and IL-1)], and congestive heart failure.

Figure 4 Massive pleural effusion. The CT scan of the chest of a patient with a massive pleural effusion is shown. L, collapsed lung; E, pleural effusion; A, extensive axillary lymphadenopathy.

For some patients, the pleural effusion may be the presenting sign of the malignancy. Common symptoms are cough, dyspnea, and orthopnea, but about one-fourth of malignant pleural effusions are asymptomatic. The presence and severity of these symptoms depend on the volume and the rapidity of fluid accumulation. Fever is occasionally present and may be due to atelectasis or pneumonia. Pleuritic chest pain and pleural friction rubs are not common; when present, they indicate extensive neoplastic involvement of the pleura and chest wall.

A pleural effusion is diagnosed by clinical examination and confirmed with radiography. On examination, patients with pleural effusion exhibit dullness to percussion, decreased breath sounds in the area of the effusion, and decreased diaphragmatic excursion and tactile and vocal fremitus on the affected side. Sometimes crackles may be auscultated immediately above the percussed dullness. Patients with large-volume effusions (>1500 mL) may have an inspiratory lag, contralateral tracheal deviation, and intercostal fullness. The pleural effusion caused by lung carcinoma is generally on the same side as the primary lesion.⁷² The cause of a pleural effusion is generally diagnosed by thoracentesis. Malignant effusions may appear serous, serosanguinous, or bloody. Fluid analysis discriminates between exudative and transudative effusions.⁷⁶ Cytology is more sensitive than percutaneous pleural biopsy to diagnose the cause of the effusion.^{74, 77} Other more invasive diagnostic options include bronchoscopy, pleuroscopy, video-assisted thoracoscopy, and open pleural biopsy.

Treatments are chosen based on severity of symptoms, rate of fluid accumulation, overall prognosis, performance status, and responsiveness of the malignancy to treatment. Massive pleural effusion causing hemodynamic instability, significant dyspnea, hypoxemia, or mediastinal shift should be treated emergently by thoracentesis. However, the benefits of a therapeutic thoracentesis without pleurodesis are usually temporary; in approximately 70% of cases, fluid reaccumulates within 30 days unless effective

systemic chemotherapy is administered. If there is no symptomatic improvement after thoracentesis in cancer patients with a lung trapped by visceral pleura encasement, placement of an indwelling pleural catheter is not indicated.⁷⁸ Otherwise, an indwelling pleural catheter will allow outpatient periodic drainage of pleural fluid to improve symptoms,^{79, 80} particularly dyspnea, and improve quality-adjusted survival.⁸¹ Some patients may also achieve pleurodesis over time. Chemical pleurodesis should be considered in patients with life expectancy of more than a few months and symptomatic relief after thoracentesis. The effective sclerosing agents, with success rates of 72–90%, are doxycycline, minocycline, bleomycin, and talc.^{82, 83} Tube thoracostomy may be indicated depending on clinical and radiographic findings and the biochemical characteristics of the effusion:⁸⁴ empyema, infected pleural fluid as confirmed by culture or microscopy (e.g., Gram stain), or complicated parapneumonic effusions. Patients in whom thoroscopic treatment fails and patients with chronic complicated parapneumonic effusions should be considered for open thoracotomy and decortication.

Acute airway obstruction

Acute airway obstruction usually involves the upper airway. Tumors that obstruct by direct extension are primary tumors of the head and neck (base of tongue, larynx, hypopharynx, thyroid, or trachea) and mediastinum (lung cancer, thymoma). Metastatic tumors that may cause upper airway obstruction are cancers of the breast, esophagus, kidney, colon, melanoma, sarcoma, and mediastinal lymphoma. The mechanisms causing the obstruction include extrinsic compression, tumor encroachment, tumor-associated airway edema, and hemorrhage. Nonmalignant causes include food or foreign body aspiration, severe tracheomalacia, tracheal stenosis or stricture, and airway edema (due to hypersensitivity and infections). Severe drug-induced angioedema may occur with angiotensin-converting enzyme inhibitors and paclitaxel. The most common cause of lower airway obstruction is primary bronchogenic carcinoma. Other rare causes of lower airway obstruction are metastases from cancers of the colon, breast, thyroid and kidney, melanoma, lymphoma, and sarcoma. Patients with carcinoid tumors may experience severe bronchospasm due to release of hormone mediators.

Dyspnea may be the only early symptom of airway obstruction. When dyspnea occurs with exertion, the upper airway diameter is usually decreased to 8 mm, whereas when dyspnea occurs at rest, the airway diameter is usually decreased to 5 mm, often coinciding with the development of stridor. As obstruction progresses, orthopnea, tachycardia, diaphoresis, wheezing, stridor, and intercostal muscle retraction may be noted. Stridor is an ominous finding that may be rapidly followed by cyanosis, obtundation, bradycardia, and death.

The oral cavity should be quickly visualized to exclude foreign body aspiration. In most cases of upper airway obstruction, the clinical examination provides the diagnosis. The clinical examination is often corroborated by direct visualization via either laryngoscopy or bronchoscopy depending on the location of the lesion. For lower airway obstruction, chest radiographs identify the obstruction in 75% of cases. CT of the neck and/or chest is very helpful in diagnosing obstruction by tumors. Edema caused by acute infection in a previously narrowed airway should also be considered in the differential diagnosis.

The management of airway obstruction is to reverse or bypass the obstruction. In addition to supplemental oxygen, supportive therapies may include administration of corticosteroids, inhaled racemic epinephrine, bronchodilators, helium–oxygen mixtures, and antibiotics (if infection is suspected). Laryngoscopy or bronchoscopy may be necessary to guide endotracheal intubation in upper airway obstruction.⁸⁵ Patients with obstructions involving the upper third of the trachea may require a low tracheotomy. Decisions for surgical interventions depend on extent of the malignancy, responsiveness to antineoplastic treatment,

performance status, and comorbid conditions. For central airway obstruction, interventional pulmonary treatments may use rigid or flexible bronchoscopes⁸⁶ and may include placement of tracheobronchial stents, balloon bronchoplasty, laser bronchoscopy, endobronchial argon plasma coagulation, photodynamic therapy, cryosurgery, and brachytherapy. Other treatment options include CT-guided radiofrequency ablation, external-beam radiotherapy, and surgical debulking or resection.

Pneumothorax

Pneumothoraces in cancer patients are iatrogenic or spontaneous. The majority of pneumothoraces treated in hospitals are iatrogenic.⁸⁷ Procedures that may cause a pneumothorax include percutaneous lung biopsy, transbronchial biopsy, insertion of central venous catheters, and insertion of pulmonary artery catheters. Spontaneous pneumothorax is most commonly due to chronic obstructive pulmonary disease. Both primary and metastatic pulmonary neoplasms may also cause pneumothorax. Chemotherapeutic agents associated with pneumothorax include bleomycin, carmustine, and lomustine. Infectious agents associated with pneumothorax include *Staphylococcus*, *Klebsiella*, and *Pseudomonas* species, *Pneumocystis carinii*, and *Mycobacterium* species. Rupture of mycetoma into the pleural space may result in pneumothorax and is associated with *Aspergillus fumigatus* infection, coccidioidomycosis, cryptococcosis, and mucormycosis.

The severity of symptoms at presentation is related to the patient's underlying pulmonary status. Patients may present with respiratory distress, tachypnea, tachycardia, cyanosis, diaphoresis, and agitation. Patients with underlying lung disease often cannot tolerate decreases in vital capacity and have an increased risk for respiratory failure secondary to pneumothorax. Dyspnea is often unrelated to the volume of pneumothorax; however, dyspnea and chest pain are present in almost all cases of significant pneumothorax. The chest pain is frequently acute and pleuritic on the affected side. Cough, hemoptysis, and orthopnea are less frequent.

Small pneumothoraces are usually undetectable on physical examination. Examination usually demonstrates tachycardia, absent tactile fremitus, hyperresonance, and absent or decreased breath sounds on the affected side. Patients with large or tension pneumothoraces may have contralateral deviation of the trachea, asymmetrical hyperexpansion, and decreased movement of the affected hemithorax. Patients with a tension pneumothorax may have elevated central venous, pulmonary artery, and right atrial pressures. Hypotension, severe hypoxemia, and respiratory acidosis occur when increased intrapleural pressure impedes venous return.

The diagnosis of pneumothorax is confirmed when an upright chest radiograph reveals a visceral pleural line with the absence of lung markings beyond the line. For patients with a small pneumothorax, the pleural line may be difficult to discern. Previous work has shown that one-third of pneumothoraces are undetected on semi-erect and supine chest radiographs.⁸⁸ Pleural ultrasonography may be more accurate than chest radiography to diagnose pneumothorax.⁸⁹

Patients with small pneumothoraces may be closely observed with supplemental oxygen and serial chest radiographs 3–6 h after the initial radiograph. If there is no expansion of the pneumothorax, the patient may be discharged from observation with appropriate follow-up instructions and repeat radiograph in 12–48 h.⁹⁰ For symptomatic, rapidly expanding, and moderate to large (>15% of the ipsilateral pleural space) pneumothoraces, catheter aspiration should be done. Outpatient management with small caliber intercostal catheters and Heimlich valves has a success rate of 78%.⁹¹ Failure to re-expand or recurrence following catheter aspiration requires tube thoracostomy. Tube thoracostomy is indicated as initial treatment for traumatic pneumothorax, hemothorax, pneumothorax occupying >15% of the ipsilateral

pleural space with retained secretions, pneumothorax with lung infections on the affected side, and pneumothorax related to mechanical ventilation/barotrauma. Patients with a persistent air leak due to bronchopleural fistula and patients with only partial lung expansion 5–7 days after a tube thoracostomy should be considered for surgical repair. Chemical pleurodesis may be indicated for recurrent pneumothorax.⁹²

Pulmonary embolism

Pulmonary embolism can be difficult to diagnose in cancer patients because the signs and symptoms may be masked by the neoplastic process or complications of cancer treatments. Cancer is an independent risk factor for thromboembolism in addition to other factors such as major trauma/surgery, advanced age, recent myocardial infarction, cerebral vascular accident, immobility, obesity, and history of thrombosis. Compared with patients without malignancies, cancer patients have higher rates of initial thrombosis, thrombosis recurrence, and fatal pulmonary embolism.⁹³ The risk of thromboembolism in cancer patients without other comorbid conditions is 15–20%. Compared with noncancer patients undergoing similar procedures, cancer patients undergoing surgery have two to three times the risk of developing postoperative deep venous thrombosis.⁹⁴

In most cases, symptoms of pulmonary embolism are vague. Dyspnea, pleuritic chest pain, and tachypnea were present in 97% of patients with confirmed pulmonary embolism.^{95, 96} The most common presenting symptom is dyspnea. Frequently, patients also have tachycardia. Massive pulmonary embolism may cause syncope. Angina may occur due to right ventricular ischemia. Hemoptysis may rarely occur due to pulmonary infarction 12–36 h after the embolic event. Deep venous thrombosis in the lower extremities is found in <50% of patients with pulmonary embolism. Sometimes, fever and a pleural rub may also be detected.

Pulse oximetry or arterial blood gases may demonstrate hypoxemia for which supplemental oxygen should be provided. Chest radiography is helpful in excluding other causes of the symptoms, and occasionally may suggest pulmonary embolism by the presence of a Hampton's hump (dome-shaped and pleura-based lung opacity) or Westermark sign (peripheral radiolucency due to decreased blood flow with or without central pulmonary vessel dilatation).

An electrocardiogram commonly shows sinus tachycardia, inverted T waves, or nonspecific ST-T wave abnormalities. Right axis deviation, atrial arrhythmia, right bundle branch block, and P-pulmonale may occur, but the classical S1-Q3-T3 pattern is unusual. In cancer patients, D-dimer has a high negative predictive value and sensitivity for pulmonary embolism, and a normal D-dimer result can exclude pulmonary embolism.⁹⁷ In another study that included cancer patients, a D-dimer concentration >3000 ng/mL is associated with centrally located pulmonary emboli and death within 15 days.⁹⁸

High-resolution CT pulmonary angiography or spiral CT is the first-line diagnostic test ([Figure 5](#)); in case of IV iodine contrast allergy, MR angiography is an alternative. For diagnosis of pulmonary embolism, CT and MR angiographies have a sensitivity and specificity of about 80% and 90%, respectively.^{99, 100} The negative predictive value of CT angiography is 98%.¹⁰¹ The radionuclide ventilation-perfusion (V/Q) scan is second line when CT or MR angiography is contraindicated because of renal dysfunction or hypersensitivity. As emboli in the distal pulmonary vasculature are not reliably detected with CT or MR angiography, patients with strong suspicion of pulmonary embolism but negative findings on either imaging modalities should be considered for contrast pulmonary angiography, the diagnostic gold standard.

Figure 5 Saddle embolus. This CT scan shows a saddle embolus (below the three arrowheads) at the bifurcation into the pulmonary arteries.

Hemodynamically unstable patients should be stabilized by administration of IV fluid and/or inotropic agents as guided by central venous pressure monitoring in intensive care. Oxygen at high concentration via mask or endotracheal tube may be necessary for massive pulmonary embolism. Treatment options for patients with massive pulmonary embolus and hemodynamic instability (i.e., occlusion of >40% of the pulmonary vasculature, right ventricular dysfunction according to echocardiography, and severe hypoxemia) include systemic thrombolysis, catheter-directed thrombolysis, and embolectomy. In pulmonary embolism causing acute right ventricular dysfunction, thrombolytic therapy is associated with decreased all-cause mortality despite increased major bleeding and intracranial hemorrhage.¹⁰² Thrombolysis demands special attention to contraindications related to bleeding risk (especially in the presence of brain metastasis). Due to increased risk for massive bleeding and intracranial hemorrhage but no reduction in mortality, thrombolysis should not be used for most normotensive patients with pulmonary embolism.¹⁰³ Although systemic thrombolysis may be beneficial in massive pulmonary embolism, catheter-directed thrombolysis may cause less major bleeding complications than systemic thrombolysis; the role for catheter-directed thrombolysis remains to be clearly defined.¹⁰⁴ Surgical or catheter embolectomy is reserved for patients in whom other approaches of clot removal have failed.

There are published guidelines for the management of venous thromboembolism in cancer patients.^{105, 106} Low-molecular-weight heparin (LMWH) is recommended for the initial 5–10 days of anticoagulation for cancer patients with newly diagnosed pulmonary embolism and creatinine clearance >30 mL/min. Unfractionated heparin (IV bolus of 80 units/kg followed by continuous infusion at 18 units/kg/h) can be an alternative to LMWH. LMWH has the advantages of not requiring partial thromboplastin time monitoring and IV access. IV unfractionated heparin may be preferred in patients who very probably will need invasive interventions because of its short half-life. IV unfractionated heparin is administered in a bolus injection of 5000–10,000 units, followed by a continuous infusion of 1000–1500 units/h with

adjustments to maintain the activated partial thromboplastin time at 1.5–2.0 times the control value.¹⁰⁷ For long-term (≥ 6 months) anticoagulation, LMWH is preferred over vitamin K antagonists (e.g., warfarin) because it is less likely to interact with other drugs and chemotherapy, needs no monitoring, is associated with fewer recurrence of venous thromboembolism, and may prolong survival of cancer patients.¹⁰⁸ Treatment with vitamin K antagonists to an international normalized ratio between 2 and 3 is an acceptable alternative for long-term therapy when LMWH is not possible. Extending anticoagulation beyond 6 months may be considered for patients with active malignancy until cancer treatment has completed and the malignancy has become inactive.¹⁰⁹ A number of new antithrombotic agents are currently under investigation for applications in cancer patients.¹¹⁰ Their use for either prevention or treatment of pulmonary embolism in cancer patients is not recommended at this time.

Anticoagulation is contraindicated in the presence of active intracranial bleeding, recent surgery, thrombocytopenia (platelet $< 50,000/\mu\text{L}$), or coagulopathy. Inferior vena cava filters may be considered when anticoagulation is contraindicated or when pulmonary embolism recurs or existing thrombus worsens under optimal therapy with LMWH, but end-stage cancer patients may gain little benefit.¹¹¹ Contraindications for anticoagulation should be periodically reassessed so that anticoagulation can resume when it is safe. Filters are not recommended for primary prophylaxis in cancer patients.¹⁰⁵

For patients with primary brain malignancies, anticoagulation is recommended in the same manner as for patients with other cancers. Many cancer patients with pulmonary embolism may be safely treated as outpatients, especially cases of incidental pulmonary embolism, which are clinically unsuspected and are discovered in CT scans ordered for treatment response evaluation or staging.¹¹² As the rates of recurrence, morbidity, and mortality in incidental cases are comparable to symptomatic cases, incidental pulmonary embolism should be treated in the same way with initial and long-term anticoagulant therapy as for symptomatic pulmonary embolism except for peripheral subsegmental emboli that are judged to be highly probable imaging artifacts.^{106, 110, 113}

Neurologic oncologic emergencies

Spinal cord compression

Spinal cord compression occurs in 3–5% of cancer patients and should be considered an emergency because treatment delay may result in irreversible morbidity, including paralysis.¹¹⁴ In 95% of cases, spinal cord compression is caused by metastases involving the vertebral column (70% in the thoracic spine, 20% in the lumbosacral spine, and 10% in the cervical spine). Metastasis to the thoracic vertebrae is likely to cause problems because of the vulnerable local blood supply and the fact that the spinal canal is narrowest here. Spinal cord compression occurs more frequently in patients with lung, breast, unknown primary, prostate, and renal cell cancer than other malignancies.

Back pain is the most common symptom in spinal cord compression, and patients may present with pain localized to the spine or radicular pain due to neural compression. The pain may worsen with movement, recumbence, coughing, sneezing, or straining. Muscle weakness follows pain and may be accompanied by sensory loss. Once symptoms of autonomic dysfunction, urinary retention, and constipation develop, irreversible paralysis rapidly follows. Paralysis and urinary retention before treatment are predictive of poor outcome. Clinical findings include tenderness elicited by palpation over the involved vertebral segments, muscle weakness, abnormal reflexes, and sensory loss in the distribution of the involved spinal segment and below. Leg ataxia may be present prior to muscle weakness. Patients with autonomic dysfunction may have a palpable bladder, an increased postvoid residual urinary volume, or decreased

rectal tone.

Clinical guidelines for diagnosis and management of spinal cord compression are available.^{115, 116} Patients with spinal cord compression often have abnormalities (e.g., bony erosion and pedicle loss, partial or complete vertebral collapse) on plain radiographs of the spine. However, normal spine radiographs do not exclude epidural metastasis. MR tomography of the spine is the best method for evaluating epidural spinal cord compression ([Figure 6](#)). Gadolinium enhancement should be used when there is suspicion of cord compression due to epidural abscess or neurological symptoms due to leptomeningeal metastasis. Gadolinium enhances inflamed tissues and defines anatomic margins. Myelography accompanied by CT may be performed with minimum discomfort. However, when metastatic disease completely blocks the flow of cerebrospinal fluid, myelography does not allow definition of the upper margin of tumor involvement.

Figure 6 Spinal cord compression. Sagittal MRI images of the spine from three different patients demonstrate an intramedullary lesion (*arrowhead*) in low cervical spine (a), compression of the lower portion of the thoracic spinal cord by metastatic disease in the vertebral body (*arrowhead*) (b), and compression of the upper portion of the lumbar spinal cord by an epidural tumor (*arrowhead*) (c).

Treatment of spinal cord compression aims to improve or prevent loss of neurologic function, provide local tumor control, stabilize the spine, and pain control. Analgesics, especially opioids, should be administered promptly and judiciously because inadequate pain control often delays appropriate physical examination and diagnostic imaging study. When spinal cord compression is suspected, corticosteroid therapy should be administered. Dexamethasone is often used as it has good gastrointestinal absorption and a 36-h half-life. It is controversial whether a high-dose (100 mg) IV bolus followed by maintenance doses (usually 16 mg every 6 h) is necessary.¹¹⁷ Low doses (4–10 mg every 6 h) may be just as effective with fewer side effects.^{116, 118} For most patients with spinal cord compression by a radiosensitive malignancy, radiotherapy alone is the standard initial treatment. The outcome of radiotherapy depends on the pretreatment neurologic status and radiosensitivity of the malignancy. Surgical decompression may be appropriate for patients requiring spine stabilization, patients who have had prior radiotherapy in the area of the compression, patients who need tissue for diagnosis, and patients with progression despite appropriate treatment with steroids and radiation, but may not be appropriate for patients with advanced malignancy and a limited life expectancy. A meta-analysis has shown that surgical resection followed by radiotherapy may improve ambulation ability and survival better than radiotherapy alone.¹¹⁹ Chemotherapy may be effective for compression by a chemosensitive malignancy and may also be used in combination with other treatments or sometimes as an alternative when other choices are not appropriate (e.g., high operative risks, or near-maximum radiation doses already delivered to the affected area).

Brain herniation

Patients with possible brain herniation should be rapidly assessed, and those with hemodynamic instability should be stabilized with appropriate therapies.¹²⁰ Symptoms and physical findings suggestive of brain herniation include changes in the level of consciousness, papilledema, pupillary and eye movement irregularities, nausea, vomiting, meningismus, decorticate or decerebrate posturing, and Cushing reflex (hypertension and bradycardia). If there are findings suggestive of herniation or increased intracranial pressure, an imaging study such as a noncontrast CT of the brain should be performed emergently. MR imaging can provide additional diagnostic information after the patient has been stabilized.

On recognition of clinical signs of brain herniation, treatment to decrease intracranial pressure should be instituted immediately, even before brain herniation is documented by imaging studies. Emergency treatments include hyperventilation and administration of mannitol and steroids. Hyperventilation is the most rapid way to decrease intracranial pressure. Sedate, intubate, and ventilate to achieve a PCO_2 of 25–30 mm Hg, which causes cerebral vasoconstriction, decreases cerebral blood volume, and subsequently decreases intracranial pressure. The benefit of hyperventilation is generally short-lived, and equilibration may occur within a few hours. Mannitol 20–25%, a hyperosmotic agent, is effective within minutes of administration and remains effective for several hours by forming an osmotic gradient between the blood and brain to drive water from the brain to the blood. Mannitol 20–25% is administered IV at 0.5–2.0 g/kg over 20–30 min. Additional doses may be necessary if the patient continues to deteriorate. Corticosteroids should be administered and may be helpful especially when herniation is due to vasogenic edema surrounding intracranial metastases.¹²¹ Dexamethasone is commonly administered at an initial bolus dose of 40–100 mg IV, then 40–100 mg/day in divided doses.

Further treatment in intensive care may include IV infusion of hypertonic saline, propofol, and hypothermia.¹²⁰ Neurosurgical intervention such as placement of a ventricular drain or decompressive craniectomy may be necessary if the patient has neurologic deterioration despite appropriate medical management. Treatment should be directed at the underlying cause once intracranial pressure is controlled.

Status epilepticus

Status epilepticus is defined as >5 min of continuous seizure activity or >2 sequential seizures without full recovery between seizures.¹²² It can lead to devastating neurologic and systemic consequences, such as neuronal injury and cell death, neurogenic pulmonary edema, and rhabdomyolysis with renal failure. Tumors in the brain causes about 7% of cases of status epilepticus, and these cases have higher short-term mortality than status epilepticus unrelated to tumors.¹²³

The etiology of seizures in cancer patients may include structural, metabolic, infectious, and treatment-related causes. In a review of 50 cancer patients presenting to an emergency center with seizures, 16% had seizures due to a new structural lesion and 52% had previously documented central nervous system lesions.¹²⁴ Seizures commonly occur in patients with intracranial tumors. The cancers that commonly metastasize to the brain are lung cancer, breast cancer, melanoma, genitourinary malignancies, and gastrointestinal malignancies.

Neurologic function is often suppressed (confused or unresponsive) postictally. Clinical findings after seizure activity may include bruising or tongue bites, signs of urinary or fecal incontinence, and increases in lactic acid and muscle enzyme levels. It is important to determine whether the patient has previously

had seizures and, if so, the type of seizure and medications used for control. The status, extent, and treatment of the malignancy should also be reviewed. If the event precipitating seizure activity cannot easily be determined, a diagnostic workup should be initiated. Evaluation may include measurement of electrolytes, serum glucose, calcium, and magnesium, and hepatic and renal function testing. A complete blood cell count, blood cultures, measurement of electrolytes, urea nitrogen, creatinine, glucose, calcium, magnesium, blood gases, anticonvulsant drug levels (if prescribed), drug screens, and electroencephalography are appropriate. CT brain imaging without IV contrast is necessary.¹²⁵ Lumbar puncture may also be indicated depending on the suspected seizure precipitant, the patient's condition, findings on imaging, and whether convulsions have stopped to allow the procedure to be performed.

When patients present with status epilepticus, airway, breathing, and circulation should be assessed immediately ([Figure 7](#)).^{122, 125} Cardiopulmonary status should be supported and stabilized according to ACLS algorithms. Hypoglycemia as the cause of seizure must be first excluded or diagnosed and treated. Anticonvulsant therapy with an IV benzodiazepine (e.g., lorazepam or midazolam) should be administered to halt seizure activity. Generally, lorazepam (typically 4–8 mg IV) is used because of its rapid onset of action and longer duration of efficacy. After seizure has stopped, an unconscious patient should be placed on his or her side in the recovery position to prevent aspiration. Airway suctioning and supplemental oxygen may be required. Reversible medical causes of seizures should be corrected. These patients will likely not require long-term anticonvulsant therapy. Patients with status epilepticus due to other causes will require prolonged treatment with an anticonvulsant. Some clinicians prefer levetiracetam in cancer patients because it is not metabolized by the liver and has minimal drug interactions with antineoplastic therapy. For patients with continuing seizure activity despite initial anticonvulsant treatment, therapy can be escalated in steps to high-dose anticonvulsant therapy (e.g., pentobarbital, thiopental, propofol, and midazolam) with complete sedation, intubation/ventilator support, and electroencephalography monitoring in intensive care.

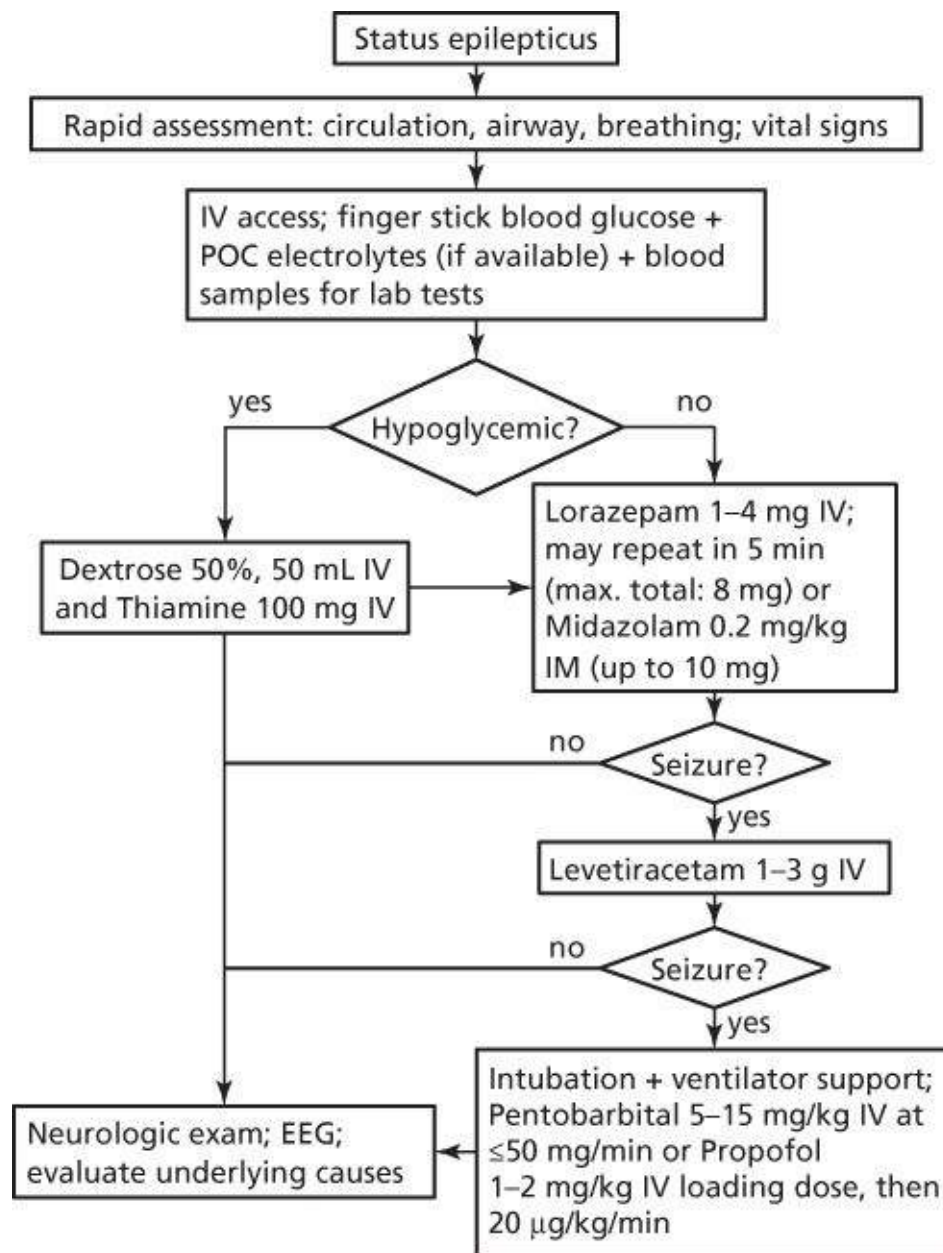

Figure 7 Algorithm for management of status epilepticus adapted for cancer patients. *Abbreviations:* EEG, electroencephalogram; POC, point-of-care bedside testing; IV, intravenous; IM, intramuscular.

Other oncologic emergencies

Perforated bowel

Perforation along the gastrointestinal tract is a serious emergency. In cancer patients, common causes are spontaneous perforation secondary to tumor (primary or metastatic) and iatrogenic perforation secondary to endoscopy or cancer treatment. If the wall of the gastrointestinal tract is significantly infiltrated or replaced by tumor, radiotherapy- or chemotherapy-induced tumor necrosis may lead to bowel perforation. Antiangiogenic therapies such as bevacizumab and small molecule inhibitors such as imatinib and sorafenib have been associated with bowel perforation.¹²⁶ Bowel perforation can be caused by severe infections such as typhlitis and neutropenic enterocolitis.¹²⁷ Severe gastroenteritis due to radiotherapy or chemotherapy may lead to severe bowel dilatation/distention and subsequent perforation. Common causes of bowel perforation unrelated to cancer include appendicitis, diverticulitis, and peptic ulcer disease.

Typically, perforation causes acute pain that prompts emergent evaluation. In cases of cervical esophageal perforation, symptoms at presentation may include neck pain, dysphagia, hoarseness, and subcutaneous emphysema. In thoracic esophageal perforation, upper abdominal rigidity, severe retrosternal chest pain, odynophagia, and hematemesis are common. In gastric perforation, acute onset of severe abdominal pain is usually the first symptom. The pain may be associated with nausea and vomiting, and in about 15% of patients, significant bleeding is present. Referred pain to the shoulders may occur because of irritation of the diaphragm. In cases of free perforation into the peritoneal cavity, abdominal distension and signs of peritonitis (severe rebound abdominal tenderness, guarding/rigidity, and absent bowel sounds) may be present.

Fever and leukocytosis with left shift may be present in patients with peritonitis, mediastinitis, or abscess. However, the white blood cell count should be interpreted in the context of recent chemotherapy or use of neutrophil-stimulating cytokines. Amylase levels may be high in intestinal, esophageal, or gastric perforation, and lipase levels may be high in gastric perforation. In cervical esophageal perforation, a plain radiograph of the neck in the lateral view may show air in the deep cervical tissues. Plain radiographs of the chest are also valuable in esophageal perforation as pneumomediastinum may be evident. Free air detected by plain radiographs (upright chest X-ray or abdominal series with upright or decubitus views) ([Figure 8](#)) can provide evidence of bowel perforation. As for duodenal perforation, plain abdominal radiographs may show air in the retroperitoneal space. Other radiographic signs of perforation include outlining of both sides of the bowel wall by air and visualization of the hepatic ligament. If bowel perforation is highly suspected clinically and the initial studies do not show evidence of perforation, CT scan with oral water-soluble contrast agent (e.g., diatrizoate) is very accurate in diagnosing bowel perforation and can provide detailed information about the location and surrounding anatomy of the perforated structure.

Figure 8 Pneumoperitoneum. A 53-year-old man with multiple myeloma and amyloidosis involving the gastrointestinal tract, undergoing treatment with thalidomide and dexamethasone, presented with acute abdominal pain and abdominal distention. Abdominal radiographs showed intraperitoneal free air (*arrowheads*). Laparotomy revealed bowel perforation secondary to massive colonic distention.

Management of a perforated viscus may be expectant management, expectant management followed by surgery, or immediate surgery. Factors influencing the management are the etiology, size, location and containment of the perforation, the clinical course (development of sepsis), the patient's performance status and quality of life prior to the perforation, the prognosis based on the status of the malignant disease, and comorbid conditions that increase the risk of perioperative mortality. Nonsurgical treatment measures include nasogastric tube suction, administration of broad-spectrum IV antibiotics, IV hydration, parenteral nutrition, and close monitoring.¹²⁸ If the patient's condition deteriorates during expectant treatment, then a decision to operate can be made.

Neutropenic fever

Neutrophils are phagocytic white blood cells that defend the human body against infections. Neutropenia is defined as a neutrophil count of ≤ 1000 cells/ μL , absolute neutropenia as neutrophil ≤ 500 cells/ μL , and profound neutropenia as neutrophil ≤ 100 cells/ μL .¹²⁹ Neutropenia often occurs in cancer patients as a consequence of intensive chemotherapy or the malignancy. Infection is the leading cause of morbidity and mortality in neutropenic patients. Fever [defined as a single oral temperature $>38.3^\circ\text{C}$ (101°F) or $>38.0^\circ\text{C}$ (100.4°F) for >1 h] in a neutropenic cancer patient often resolves after empirical systemic broad-spectrum antibiotics (up to about 60% of cases).¹³⁰ Neutropenic fever is a true medical emergency, and timely administration of antibiotics may prevent sepsis and death.

Neutropenic patients are immunocompromised and lack the ability to mount a full inflammatory response to infections. Therefore, any symptom or sign of infection should be investigated fully.¹³¹ Physical examination should include careful inspection of commonly infected sites such as mouth, pharynx, perineum, eyes, vascular access sites, percutaneous catheter sites, and skin. Initial laboratory evaluation should include: complete blood cell count, serum creatinine, blood urea nitrogen, transaminases, blood cultures from a peripheral vein and vascular access ports or catheters, urinalysis, urine culture. Chest radiography is indicated for patients with respiratory signs or symptoms.

Further evaluation should be guided by physical findings, signs, and symptoms. Lesions on the mucous membranes and the skin can be viral (e.g., herpes simplex and varicella zoster), bacterial (e.g., ecthyma gangrenosum), or fungal (e.g., disseminated candidiasis, aspergillosis, or *Fusarium*) infection. Any site of a localized infection should be pursued with aspiration or biopsy for pathogen identification to guide treatment. Sinus symptoms may be due to bacterial or fungal infections, some of which may be invasive and fatal. Abdominal pain, distention, bloody diarrhea, nausea, and vomiting are typical findings in neutropenic enterocolitis.¹³² In the presence of diarrhea, stool specimens should be evaluated with for *Clostridium difficile* infection by a toxin assay or polymerase chain reaction. Perianal symptoms may suggest the presence of a perianal abscess. The differential diagnosis of pulmonary disease in febrile neutropenic patients is broad: infection (viral, bacterial, fungal, and protozoan), radiation-induced pathologic conditions, chemotherapy-induced side effects, hemorrhage, and infarction. Correlation of pulmonary symptoms and findings on chest radiographs is a clinical challenge in neutropenic patients. Classic methods of sputum evaluation such as direct examination of stained specimens, culture, and testing of antibiotic sensitivities are now complemented by detecting microbial DNA (polymerase chain reaction) and microbial antigens in bodily fluids or tissues. Serologic tests have also been helpful in identifying infections in neutropenic patients. Nevertheless, findings on chest radiography are abnormal in 17–25% of patients with neutropenic fever despite the absence of pulmonary signs or symptoms,¹³³ and lung infiltrate on chest X-ray can predict a complicated clinical course.¹³⁴ Therefore, if a neutropenic patient is being considered for possible outpatient oral antibiotic therapy, a chest X-ray should be obtained to exclude pulmonary infiltrates even in the absence of pulmonary signs or symptoms.¹³¹

About 80% of clinicians prescribe antibiotics according to guidelines for neutropenic fever.¹³⁵ Although guidelines and general statements should be heeded, local epidemiology and clinical practice conditions must also be taken into consideration.¹³⁶ The initial management approach of neutropenic fever should be based on risk with subsequent modification based on clinical response.^{130, 137–139} For low-risk patients [i.e., Multinational Association for Supportive Care in Cancer (MASCC) score ≥ 21 or Talcott group 4] with stable hemodynamics, no comorbidity and low symptom burden, outpatient treatment with oral fluoroquinolone plus amoxicillin/clavulanate (clindamycin if allergic to penicillin) as initial empiric regimen may be appropriate unless a fluoroquinolone has been used for prophylaxis before fever onset.¹⁴⁰

The patients should receive the initial doses of empirical antibiotics within 1 h of triage. Eligibility for outpatient management should be determined by monitoring the patient's condition for at least 4 h. However, successful outpatient management relies on coordination among primary care, oncology and emergency departments to ensure a rapid response and close follow up during the outpatient treatment period as well as effective communication between clinicians and patients and their care takers.¹⁴¹

The standard approach for neutropenic fever is inpatient treatment with IV antibiotics. Factors associated with prolonged hospital stay in adults with neutropenic fever include hematologic malignancies, high-intensity chemotherapy, long duration of neutropenia, and cultures growing Gram-negative multidrug-resistant bacteria.¹⁴² Monotherapy with broad-spectrum β -lactam antibiotics, such as piperacillin-tazobactam, carbapenems or the fourth-generation cephalosporin cefepime, is recommended. Adding other antimicrobials (e.g., aminoglycosides, fluoroquinolones, vancomycin, colistin, daptomycin) to the initial regimen in cases with suspected or known antibiotic resistance or serious infections is also indicated. Empirical coverage for Gram-positive organisms with vancomycin is acceptable if a Gram-positive bacterial infection is suspected or known, for example, cellulitis, central venous catheter-related infection, mucositis, or the use of prophylactic antibiotics against Gram-negative bacteria.¹³⁰ Vancomycin use in neutropenic fever has more than tripled to 55% in 2010 over 10 years.¹³⁵

If a febrile neutropenic patient does not respond to the initial broad-spectrum antibiotic therapy, additional antibiotics or antifungal therapy is recommended. Fluconazole may be used as initial empirical therapy in patients who have not received prior antifungal prophylaxis. Amphotericin B is beneficial for patients with persistent fever during broad-spectrum antibiotic treatment without antifungal prophylaxis, persistent neutropenia for more than 15 days, or a documented fungal infection. *Candida albicans* and nonalbicans *Candida* species are important pathogens in leukemia patients and bone marrow transplant recipients, and *Aspergillus* infection causes significant problems in patients with prolonged and profound neutropenia. Other fungi, such as *Fusarium* and *Trichosporon*, are emerging as important pathogens, perhaps owing to increased prevalence of antifungal prophylaxis.

In high-risk patients, especially leukemic patients, a de-escalation approach may be employed instead of the escalation approach discussed above.¹³⁸ Patients at risk for infection with resistant pathogens (e.g., methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant *Enterococcus*, extended spectrum β -lactamase-producing Gram-negative bacteria, and carbapenemase-producing organisms) and patient with unstable hemodynamics should be treated initially with broad-spectrum antibiotic combinations. Major risk factors for infection with resistant pathogens include prior colonization or infection by resistant organisms and a high local prevalence of resistant pathogens in cultures obtained when fever started in neutropenic patients. De-escalation of antibiotic therapy is based on the culture results and clinical response 72–96 h after initiation of antibiotic therapy.

The adjunct therapy of a myeloid colony-stimulating factor to increase leukocytes in chemotherapy-induced neutropenic fever does not improve overall mortality, although such therapy is associated with shorter durations of fever, neutropenia, and antibiotics use.¹⁴³ Although prophylactic colony-stimulating factors should be considered if the risk of chemotherapy-induced neutropenic fever is >20%, starting these factors after fever onset in a neutropenic patient is generally not recommended.¹³⁰

Anaphylactic reactions to chemotherapy drugs

Anaphylactic reactions to chemotherapy drugs are another important type of emergency in cancer patients. Urticaria and angioedema occur in 90% of anaphylactic reactions. Other manifestations are chest tightness, upper airway obstruction, abdominal pain, bronchospasm, and hypotension. The National

Institute of Allergy and Infectious Diseases and the Food Allergy and Anaphylaxis Network have established diagnostic criteria for anaphylaxis; depending on the probability of allergen exposure, a different number of criteria based on acute onset and involvement of the tegumentary, respiratory, cardiovascular, or gastrointestinal systems are used.¹⁴⁴ Important elements in anaphylaxis treatment are early recognition, airway maintenance, and hemodynamic support ([Table 3](#)).^{145–149} Common chemotherapy drugs that may cause anaphylaxis include: L-asparaginase, taxanes (paclitaxel and docetaxel), etoposide, teniposide, procarbazine, platinum compounds (cisplatin and carboplatin), ifosfamide, cyclophosphamide, anthracyclines (daunorubicin, doxorubicin, and idarubicin).

Table 3 Recommendations for acute management of anaphylaxis in adults

1. Remove the antigen or delay the absorption of the antigen
2. Assess airway; intubate if there is evidence of laryngeal edema or impending severe airway obstruction; in extreme circumstances, when orotracheal intubation or bag/valve/mask ventilation is not effective, cricothyrotomy or catheter jet ventilation may be needed
3. Assess hemodynamics; position the patient supine (or semi-reclining in a position of comfort if dyspneic or vomiting) and elevate the legs
4. Administer epinephrine as first-line treatment
 - In case of a less severe episode: 0.3 mg SQ, 1 mg/mL, repeated at 10- to 20-min intervals
 - In case of a more severe episode: 0.3–0.5 mg IM, 1 mg/mL, repeated at 5- to 10-min intervals
 - In case of shock or airway obstruction: 1 mg/100 mL IV, 0.01–0.02 mg/min, up to a total dose of 0.1 mg
 - In case of persistent shock: may repeat dose or start an IV drip infusing at 2–10 µg/min
 - If patient is over 50 years old or has a history of cardiac problems and life-threatening symptoms exist: test dose of 0.1–0.15 mg SQ or IM
5. Administer IV crystalloid fluid (normal saline or lactated Ringer's solution)
 - In case of hypotension, administer 1 L over 15 min, then reassess; repeat as needed up to 3 L
6. Administer glucocorticoid
 - Methylprednisolone 125 mg IV push; may repeat every 4 h if symptoms persist (alternative: hydrocortisone 500 mg, dexamethasone 20 mg, or other potent corticosteroids)
7. Administer antihistamines (both H1 and H2 blockers)
 - Diphenhydramine 25–50 mg IV or IM; repeat every 2–4 h as needed
 - Cimetidine 300 mg IV or famotidine 20 mg IV
8. Inhaled racemic epinephrine via a nebulizer can reduce laryngeal swelling; β-agonists for bronchospasm and wheezing
9. In case of resistant hypotension,
 - Military antishock trousers, or Trendelenburg's position may be helpful
 - Infuse dopamine 5–20 µg/kg/min IV by titration
 - Administer naloxone 0.4–2.0 mg IV every 2 min (maximum 10 mg)
10. In case of β-blocker-accentuated epinephrine-resistant anaphylaxis
 - Administer glucagon 1–5 mg IV over 2–5 min
 - Administer terbutaline 0.25 mg SQ
 - Administer isoproterenol 2–10 µg/min IV by titration

Abbreviations: IM, intramuscularly; IV, intravenous; SQ, subcutaneously.

Systemic reactions to cytokines and monoclonal antibodies

Biological drugs are protein drugs produced using biotechnology, which include monoclonal antibodies, fusion proteins, and cytokines. Several cytokines (interferons and ILs) and monoclonal antibodies have been approved for the treatment of specific malignancies. A new classification of adverse reactions to biological agents differentiates five types: (α)—reactions due to massive release of cytokines, (β)—hypersensitivity because of an immune reaction against the biological agent, (γ)—immune or cytokine imbalance syndromes manifesting as immunosuppression, autoimmune, or inflammatory diseases, (δ)—symptoms due to cross-reactivity, and (ϵ)—symptoms not directly involving the immune system.¹⁵⁰ The toxic effects associated with cytokines may be serious. Monoclonal antibodies may induce massive release of cytokines, which may lead to fever, rigor, dyspnea, hypoxia, hypotension, or even death. Reactions vary widely from skin reactions to anaphylaxis, and reactions to some of these biological agents have been reviewed.¹⁵¹

Interferon- α

Acute adverse effects of interferon- α (IFN- α) occur during the first 2–8 h, but they rarely limit treatment, and severity lessens with subsequent doses in most patients. Flu-like symptoms, hypotension or hypertension, tachycardia, nausea, and vomiting are common side effects. With chronic administration, fatigue, anorexia, and weight loss can become severe.¹⁴⁸ Mild granulocytopenia develops gradually after the first week. Immune hemolytic anemia and thrombocytopenia are rare. Ischemic colitis, ischemic optic neuropathy, and congestive heart failure have also been reported. Neurologic, behavioral, and cognitive changes may limit treatment. Flu-like side effects may be managed with acetaminophen or nonsteroidal anti-inflammatory drugs. Other supportive care measures may be provided depending on the symptoms.

Interleukin-2

High-dose IL-2 (aldesleukin) is associated with cardiovascular and hemodynamic adverse effects that resemble septic shock.¹⁵² High-dose IV IL-2, which should be given in an inpatient setting, can lead to hypotension, vascular leak syndrome, and respiratory insufficiency. Support of peripheral vascular resistance with vasopressors, endotracheal intubation, and fluid resuscitation may be necessary during therapy. Acute neurologic side effects (psychosis, disorientation, and behavioral changes) may occur and require discontinuation of therapy. Guidelines for administration of high-dose IL-2 have been suggested.¹⁵³ Low-dose IV and subcutaneous IL-2 regimens can be administered in an ambulatory care setting with observation for several hours after administration. Common symptoms include fever, chills, nausea, vomiting, anorexia, malaise, fatigue, myalgia, arthralgia, and pruritus. Prophylaxis includes acetaminophen 650–1000 mg 1 h before therapy and 4 and 8 h later and histamine type 1 and 2 receptor antagonists (e.g., diphenhydramine 50 mg orally 1 h before therapy and 25 mg 4, 8, and 12 h later plus cimetidine 800 mg orally before therapy). Meperidine (25–50 mg IV) may be given as needed for rigor and chills.

Monoclonal antibodies

The list of antibody pharmaceuticals has grown ([Table 4](#)). Immediate reactions appear during the first hour after administration and are heterogeneous in etiology and presentation (nausea, vomiting, skin reactions, respiratory symptoms, and hypotension).¹⁵¹ Some involve release of cytokines (type α); others involve an IgE-mediated hypersensitivity (type β). Anaphylaxis, urticaria, and angioedema can occur.

Patient-related risk factors for having a reaction include the malignancy, concomitant treatments, and current immune status; drug-related factors include the degree of humanization, method of production, glycosylation pattern, and the allergenic potential of the excipients. Delayed hypersensitivity can appear between 2 h and up to 14 days after infusion¹⁵¹ and is often serum sickness-like (e.g., rash, vasculitis, and erythema multiforme).

Table 4 Antibody therapies approved by the US Food and Drug Administration

Pharmaceutical agent	Target antigen	Monoclonal antibody type	Conjugated moiety	Indication	Acute side effect ^a
Alemtuzumab (Campath-1H)	CD52	Humanized	—	B-cell chronic lymphocytic leukemia	Cytopenias, infections, cardiomyopathy
Bevacizumab (Avastin)	VEGF	Humanized	—	Colorectal cancer	Epistaxis, headache, hypertension, rhinitis, back pain, exfoliative dermatitis, taste alteration, rectal bleeding
Brentuximab vedotin (Adcetris)	CD30	Chimeric	Monomethyl auristatin E	Hodgkin lymphoma, anaplastic large cell lymphoma	Cytopenias, peripheral sensory neuropathy, fatigue, upper respiratory tract infection, diarrhea, rash, cough, nausea, and vomiting
Cetuximab (Erbix)	EGFR	Chimeric	—	Colorectal cancer, head and neck cancer	Skin toxicity (acneform rash), interstitial lung disease, infection, diarrhea, nausea, conjunctivitis, pulmonary embolus
Denosumab (Prolia, Xgeva)	RANK ligand	Human	—	Bone metastasis	Hypocalcemia, hypophosphatemia
Gemtuzumab ozogamicin (Mylotarg)	CD33	Humanized	Calicheamicin	CD33-positive acute myeloid leukemia	Cytopenias, infection, bleeding, mucositis, hepatotoxicity
Ibritumomab tiuxetan (Zevalin)	CD20	Murine	Radiolabeled (yttrium-90 or indium-111)	Non-Hodgkin lymphoma	Cytopenias, fatigue, nasopharyngitis, nausea, abdominal pain, cough, diarrhea
Ipilimumab (Yervoy)	CTLA-4	Human	—	Melanoma	Fatigue, diarrhea, pruritus, rash, colitis
Ofatumumab (Arzerra)	CD20	Human	—	Chronic lymphocytic leukemia	Neutropenia
Panitumumab (Vectibix)	EGFR	Human	—	Colorectal cancer	Skin toxicity, paronychia, fatigue, nausea, diarrhea, bowel

					obstruction
Pertuzumab (Perjeta)	HER2	Humanized	—	HER2-positive breast cancer	Diarrhea, alopecia, neutropenia, nausea, fatigue, rash, peripheral neuropathy
Rituximab (Rituxan)	CD20	Monoclonal antibody	—	B-cell non-Hodgkin lymphoma	Infection, cytopenias, hypogammaglobulinemia
Tositumomab (Bexxar)	CD20	Murine	Radiolabeled (I-131)	Non-Hodgkin lymphoma	Cytopenias, infection, hypothyroidism
Trastuzumab (Herceptin)	HER2	Humanized	—	HER2-positive breast cancer	Cytopenias, diarrhea, fatigue, stomatitis, upper respiratory tract infections, mucosal inflammation, nasopharyngitis, dysgeusia

^a In addition to cytokine release syndrome.

Although the incidence rates of reactions vary (e.g., 40% for trastuzumab and 77% for rituximab), the general precaution and treatment of the antibody infusion syndrome are the same. Transient symptoms may be treated and supported similar to anaphylaxis ([Table 3](#)). Prophylactic treatment with acetaminophen and diphenhydramine may attenuate this antibody infusion syndrome. Reactions generally resolve by slowing or interrupting the infusion. After symptoms resolve, infusion may be restarted at 50% of the previous rate.

Part 13

The Future of Oncology

Chapter 141

A vision for twenty-first century healthcare

Leroy Hood, MD, PhD ■ Kristin Brogaard, PhD ■ Nathan D. Price, PhD

Overview

The convergence of system medicine, big data, and patient-activated social networks is leading to a medicine that is predictive, preventive, personalized, and participatory (P4). P4 medicine has two central thrusts—optimizing wellness and demystifying disease. To bring P4 medicine into the healthcare system, we initiated a longitudinal pilot study generating individual data clouds for 108 well people. The integration of the individual data clouds identified “actionable possibilities” that allow individuals to optimize wellness or avoid disease. We believe that this approach will transform healthcare by decreasing costs, increasing quality, and promoting innovation in a new healthcare sector—scientific wellness.

A vision for healthcare

Healthcare is one of the most significant challenges of our time. Costs are rapidly growing worldwide and are not delivering commensurate improvements in health.¹ For example, even though the United States is the biggest healthcare spender in the world, it ranks near the bottom of the top 17 developed nations in survival among those 50 years of age and older.^{1, 2} Moreover, studies on the drivers of health and disease show that approximately 30% is attributable to genetic causes, 60% to environmental and behavior causes, and only about 10% to healthcare itself, with interactions among these factors.³ Thus, the focus of today's healthcare—which is almost entirely on disease—ignores major aspects of the actual drivers of health. This focus is problematic because once biological systems are altered in disease, they often cannot be restored to their fully functional pre-disease state. Clearly, major systemic changes are needed to provide the healthcare we need for the twenty-first century.

Quantifying wellness and demystifying disease

To transform the current healthcare system, we suggest the adoption of two major thrusts—*quantifying wellness* and *demystifying disease* by studying its origins. Wellness is critical to both optimizing human potential (or capital) and providing fundamental insights into disease and disease prevention through its ability to examine the earliest wellness to disease transitions so as to study disease at the point of detectable inception. On the contrary, contemporary healthcare generally analyzes and treats patients only after they become sick.

The key to this transformation is to take a systems biology approach to disease, which leads naturally to systems medicine and its conviction that healthcare of the future must be predictive, preventive, personalized and participatory—P4 medicine. The fundamental question is how to apply P4 medicine to patients and introduce it into the contemporary healthcare landscape.

In this chapter, we outline a powerful new approach to quantifying wellness and minimizing disease that

will serve as a model for transforming healthcare. It will be introduced through an extended, data intense, longitudinal study of 100,000 “well” people. This model will provide the basis for establishing quantitative metrics of wellness and for identifying the transition states from wellness to most common diseases.

The emergence of P4 medicine

As background, we provide a personal view of how this P4 vision of medicine has emerged over the past 40 years, and how its implementation will impact the healthcare system of the twenty-first century.

The early stages

Let us review the state of biomedical research five decades ago. When one of us (Lee Hood) began as an assistant professor at Caltech in 1970, it was obvious that biology and disease were far more complex than most researchers assumed at that time—and that studying biological systems one gene or one protein at a time was not likely to decipher this complexity.⁴ The well-known parable of the elephant and six blind men is apt: each man felt a different part of the elephant (trunk, leg, tusk, etc.) and characterized the elephant by that observation. So, to one person the elephant was like a snake (trunk) while to another it was like a fan (ear) and so forth. Understanding the elephant requires a holistic approach that integrates the data. The study of biology and medicine suffers from analogous complexities, where we measure one or a few genes or proteins and fail to see the whole picture. We need to integrate different global or comprehensive types of biological information to decipher disease complexity. The emergence of this new integrative discipline—now called systems science—has led to the transformation of biology and medicine.

What became obvious in the 1970s was that scientists lacked the approach (systems science), the technologies, and the systems-driven strategies to address biological complexity. During this period, I read Thomas Kuhn's *The Structure of Scientific Revolutions*,⁵ which highlighted the difficulties in catalyzing paradigm changes in physics due to scientists' conservatism and reluctance to move beyond conventional wisdom to think outside the box. It became clear to me that there needed to be paradigm shifts in the field of biology, to move beyond reductionist thinking to a broader systems approach. At that point I made a decision to dedicate my career to deciphering in various ways biological complexity. Most of these efforts were initially viewed with considerable skepticism—as predicted by Kuhn.

Facing these challenges, I participated in five paradigm changes over the next four decades that addressed biological complexity and led to the emergence of systems biology, systems medicine, and the concept of a medicine that was predictive, preventive, personalized, and participatory—P4 medicine.^{6, 7} These paradigm changes were as follows:

1. Bringing *engineering to biology* through the development of six instruments that allowed the reading and writing of DNA and proteins. These instruments introduced the concept of high-throughput biological data generation and its associated big data and analytics.^{8–10}
2. One of these instruments, the automated DNA sequencer, enabled the *Human Genome Project*, which produced a complete list of genes, and by inference proteins—parts lists that made systems science possible.^{9, 11, 12}
3. The emergence of *cross-disciplinary biology*—bringing together biologists, chemists, computer scientists, engineers, mathematicians, physicists, and physicians under one roof—learning one

another's languages and working together in effective teams to enable “big biology” efforts to solve very complex biological problems. This collaborative effort fueled the cycle of biological discovery driving technology that, in turn, drives analytics to understand the mechanisms of biology. Bill Gates played a critical role in catalyzing the shift to cross-disciplinary biology in 1992 by recruiting me to establish the Department of Molecular Biotechnology at the University of Washington Medical School, which pioneered key technologies and analytics in genomics, proteomics, cell sorting, and large-scale DNA synthesis.¹³ This department also produced two of the 16 centers involved in sequencing the human genome.

4. In 2000, I co-founded the Institute of Systems Biology to pioneer *systems science* and its necessary technologies and analytics.^{14, 15} This global systems approach was the key to addressing biological complexity. Its application to disease led to the fifth paradigm change.

5. *Systems medicine and P4 medicine* emerged from the application of systems science to disease.^{16–18} Thus, the first four paradigm changes led to a revolutionary new approach to study disease, wellness, and medicine.

In retrospect, these experiences generated the following useful insights about how to catalyze paradigm changes in modern society:

- New ideas need new organizational structures—each of these five changes required the creation of new organizational entities to serve as their champions. Longstanding bureaucratic cultures can only rarely adopt new ideas as they were honed by outdated needs and experiences of the past, and thus often have trouble adapting to the present, let alone the future.
- If you want to persuade organizations to adopt new ideas, you must engage the organization's leadership. Middle-level managers often fail to understand the paradigm changes as they are mired in day-to-day operations.
- Each of these ideas was initially met with considerable skepticism. Determined optimism is essential for moving ideas forward in the face of widespread resistance.
- Each of these changes fundamentally altered how we viewed and practiced biology and medicine.
- It is essential to bring new ideas to the broader community of biological scientists, and ultimately to the public. At the Institute for Systems Biology (ISB), the Logan Center for Education is committed to bringing modern science to these audiences—and to promoting K-12 science education in this new context.

The book of life—four levels of biological information

These paradigm changes provided the conceptual framework and the tools to understand information in biology in a far more holistic manner than ever before—as four discrete levels of information—DNA, RNA, proteins, and biological networks or systems ([Figure 1](#)). They also demonstrated the need to be able to integrate and model biological information to address its complexity.

Figure 1 A schematic representation of the many different data types that are present in individual data clouds.

The genome can be described as a book containing the digital instructions for life.¹¹ The genome is a four-letter language of DNA (G, C, A, T) and is packaged in 23 pairs of human chromosomes that are present in each of an individual's 10^{13} cells. The human genome (diploid) contains about 6 billion letters or about 6 m of DNA. Since your body contains 10^{13} cells, it has sufficient DNA to reach from the earth to the sun 600 times. The genome is divided into about 20,000 units of information termed genes.

The genes can be read as digital four-letter copies (or transcripts) of the DNA language—these copies are termed RNA. The genes can be modified chemically or through their interactions with proteins, thus modifying their ability to be expressed. These are termed epigenetic modifications. The generation of RNA transcripts for individual genes allows for their differential amplification according to their use needs (up to millions of RNA copies per cell) and it allows the transcripts to be altered chemically to modify their information content. For example, we studied one human gene, neurexin, that had at least 2000 different RNA transcripts—and the fascinating question was how many of these unique transcripts represented different units of information (the others are presumably noise).¹⁹

Most RNA transcripts can be translated by a complex biological machine into proteins, which represent the third level of information. A 20-letter language corresponding to the 20 amino acids encodes proteins. This language directs the folding of each protein into a unique and complex three-dimensional structure that executes the specific functions of life. Proteins may function alone or through interactions with other

proteins and/or informational molecules to create complex molecular machines or biological networks.

Networks, the fourth level of information beyond DNA, RNA, and proteins, arise from interactions between proteins and DNA, RNA, other proteins, and small molecules of life (metabolites) in the context of the various biological networks of life (e.g., gene regulatory networks, protein interaction networks, and metabolic networks). These networks are dynamical, changing over time, and are formed both by the information from their genes and the information from their environment. Thus networks encode the dynamics of life that occur *via* the integration of both genetic and environmental information. Biological networks mediate critical life processes including development, physiology, and aging. Perturbations in biological networks cause human disease.

Classical molecular biology involves the study of life, analyzing one or a few genes or proteins at a time. Systems biology involves analysis of the dynamics of networks in developmental processes, physiological responses, and aging. To facilitate systems analysis of these dynamical networks, it has been critical to begin developing tools that enable the sequence analysis of all genes in the genome; all gene modifications (epigenome); all RNAs (transcriptome); all the proteins in a given cell, organ, or creature (the proteome); and the metabolites present in a given cell, organ, or creature (the metabolome). These collectively are termed “omic” analyses. It is also important to measure at least some higher level physiological and psychological phenotypes.

Today, there are several approaches to understanding biology and medicine. For example, the term genomic medicine is very popular and it addresses the role that the genome plays in disease. In contrast, systems medicine (a systems approach to disease) takes a holistic and integrative approach to the dynamics of life and disease, which includes the genome but also the transcriptomes, epigenomes, proteomes, metabolomes and more complex phenotypes. Systems medicine focuses on understanding the roles that both the genome and the environmental changes play in wellness and disease, in part through a study of its dynamical biological networks.

Systems medicine: a tipping point

Systems medicine has two central features.

First, each individual will have a virtual, personalized, dynamical cloud of billions of data points ([Figure 2](#)). The data are heterogeneous in type and multiscale in dimension. They range from molecular, cellular, and organ data to social networks that link individuals together—and these data are dynamical in that they change with time and environmental perturbations. The ISB is developing the analytical tools to integrate and model these data to identify “actionable possibilities” that will enable each individual to respond to these opportunities in order to optimize their wellness and/or minimize the severity or chances of disease.

Figure 2 A schematic diagram of the “network of networks.” Biological networks can operate at the level of genes, of proteins and other molecules, of cells, of organs, and even of social networks of individuals. In disease, some of these networks are altered to become disease perturbed. The difference between normal and disease-perturbed networks provides insights into disease mechanisms, early diagnosis, and improved identification of drug target candidates.

These big-data clouds present an enormous signal to noise challenge stemming from the inherent variability (noise) in biological information that is irrelevant to the health questions at hand. Thus, systems approaches are critical to mining these large datasets for actionable information, identifying potentially small signals from amidst large amounts of noise.²⁰

Second, dynamical biological networks manage, integrate, and transport biomolecules and associated information in living organisms, and these in turn mediate normal development and physiological responses. These networks become perturbed in disease,^{21, 22} and thus alter the information they process (Figure 3). Assessing the differences between normal and disease-perturbed networks provides deep insights into disease mechanisms, novel diagnostics approaches, and new therapeutic target candidates.

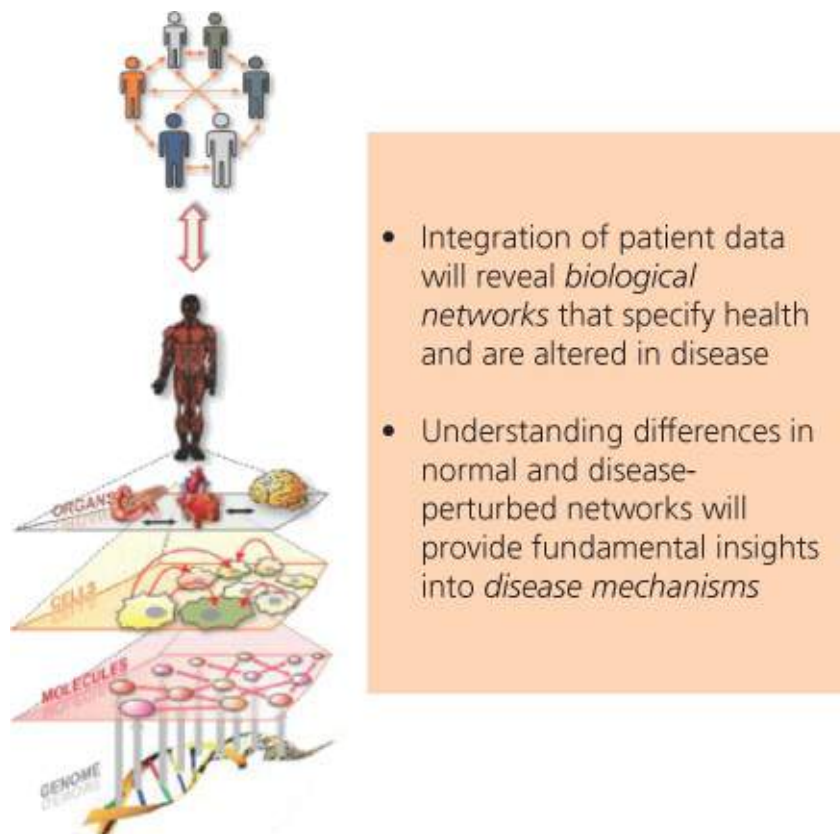

Figure 3 A schematic diagram of the four hierarchical levels of biological information—DNA to RNA to proteins to interactions, networks, and biological systems.

In 2008, ISB initiated a \$100 million partnership with the state of Luxembourg. It provided \$20 million annually to ISB for 5 years to develop the strategies and technologies necessary for the advancement of systems medicine. This funding was flexible, thus allowing the institute to pursue high-risk high-reward strategies. These efforts were extremely successful and led to the development of nine novel technologies and systems-driven strategies that accelerated the enablement of translational medicine, as demonstrated by the following three examples.

- First, we pioneered complete genome sequencing of entire families and this accelerated our ability to identify disease genes.²³ To date, we have analyzed 23 diseases, hundreds of families, and more than 9000 complete human genomes. Most recently, we employed family genome sequencing to identify rare variants in a cluster of genes encoding neural excitability that influence the risk of bipolar disease.²⁴
- Second, we demonstrated that a prion-induced neurodegenerative disease in mice had 10 disease-perturbed biological networks that emerged over the 22-week course of the disease.²⁵ We demonstrated that these networks became disease perturbed at different points during the course of the disease progression. Hence, the earliest changing networks provided insights into early diagnostic possibilities as well as the identification of early therapeutic target candidates. We further demonstrated that the dynamics of these 10 different networks collectively explained virtually every aspect of the pathophysiology of this disease. These results provide fundamental insights into early disease mechanisms, as well as into the later stages of disease progression.
- Third, we used a systems approach to blood protein diagnostics to develop a panel of 13 blood proteins that enabled us to distinguish benign lung nodules from cancerous lung nodules²⁶ via a test that is now clinically available through the ISB spinout company, Integrated Diagnostics. Over-diagnosis of lung cancer from identified nodules is a huge problem, leading to as many as 40% of

surgeries being performed on benign nodules. Thus, broad implementation of this test could save the healthcare system billions of dollars in unnecessary surgeries, in addition to significantly reducing the morbidity and unnecessary risk to the health of the patients. Twelve of these 13 proteins map into three disease-perturbed networks of lung cancer—opening up the possibility for new approaches to identify drug target candidates and blood protein diagnostics that can follow the progression of the disease as a nodule turns from benign to malignant. In this regard, we have also demonstrated (as discussed above) that one could follow brain-specific blood proteins to reveal from the *blood* the progressive disease perturbations of four major networks in prion-induced neurodegeneration, including the first disease-perturbed network.²⁵ Together, these results support the idea that diagnostic biomarkers can be identified for the very earliest stage of the disease and that these biomarkers can follow disease progression.

P4 medicine: a revolution in healthcare

The novel strategies and technologies that resulted from ISB's successful Luxembourg partnership led to the insight that the “new medicine” must be predictive, preventive, personalized, and participatory—P4 medicine. Indeed, P4 medicine emerged from a convergence of three powerful forces in science and technology: (1) systems medicine; (2) big data and analytics; and (3) patient/consumer activated social networks. The four Ps each accurately describe the general features of this “new medicine” and how it differs strikingly from conventional medicine. Distinguishing features of P4 Medicine from contemporary medicine include the following:

- It is proactive, not reactive.
- It focuses on the individual and not averaged patient populations.
- It places a major focus on wellness and not just disease.
- It generates dynamical individual data clouds that can be used to optimize wellness and avoid or eliminate disease.
- It empowers individuals to participate in their own health.

Traditional population-based drug studies are classic examples of how conventional healthcare falls short of P4 medicine. Currently, drug studies include, for example, up to 30,000 patients that are given a drug or placebo; their responses are extrapolated into curves that establish the average responses of the population; and a determination is made on this basis whether the drug works. This approach has significant limitations because each patient is individually unique—with regard to both genetics and environmental exposures. They should never be studied only as averaged populations.

We must study individuals and not populations. Accordingly, P4 medicine would separately analyze the individual data clouds of the 30,000 individuals and then aggregate them into related groups according to the characteristics that are of interest to the physician (e.g., response to a given drug, adverse reaction to a given drug). This view also argues that experiments with single patients ($N = 1$) can be incredibly useful, especially if there are longitudinal measures in place that enable patients in their “well” state to serve as their own control as disease manifests and progresses.

P4 medicine also harnesses the power of patient (consumer)-activated social networks. Individuals will become empowered through networks that communicate and engage them in the opportunities of P4 medicine. Empowered patients will be the driving force for bringing an understanding of the new medicine to physicians and will be the major instigator of change in contemporary healthcare. These

patient-driven social networks also enable patients to participate in crowd sourcing to optimize their own health—by sharing valuable lessons and learning from others' experiences. Ultimately, these networks will be a powerful social force for driving physicians and a conservative healthcare system to accept change.

P4 medicine: quantifying wellness and demystifying disease

P4 medicine has two central thrusts—wellness and disease.^{27–29} Today's healthcare focuses almost entirely on disease and is where the vast majority of society's healthcare dollars are currently spent. However, studies about the drivers of health and disease show that approximately 30% is attributable to genetic causes, 60% to environmental and behavioral causes, and only about 10% to healthcare, with considerable interactions among these factors.³ To catalyze an effective twenty-first century healthcare system we need to more fully address the remaining 90% of the drivers of health. This requires a reorientation toward maintaining and optimizing wellness—and not just reacting to disease once symptoms manifest or become severe. The key to making wellness a credible scientific study is to quantify it. We will outline how this might be done later in this chapter. Our view is that that over the next 10–15 years two separate healthcare industries will emerge—the scientific wellness industry and the disease industry (current healthcare industry). Further, the scientific wellness industry will far exceed the disease industry in market cap during this time. We are now at the earliest stages of the emergence of this transformational science-based wellness industry.

The importance of wellness can be further articulated by the following observation. If the rate of increase in lifespan seen over the past 15 years continues, approximately one half of the children born in 2015 will live to be 100.³⁰ The question arises as to what physical and intellectual condition they will be in during the last 20–30 years of life. Clearly, a move toward wellness is essential for our future.

A pilot wellness program

Once the systems medicine tipping point was reached and P4 medicine delineated, the question arose as to how it might be brought to the current healthcare system. We realized that we needed a compelling pilot program that included all of the principles of the four Ps and that focused on both wellness and disease. We termed this scientific wellness as it employed the dense, dynamic, personal data clouds.

100,000 Person Wellness Project

In 2013, we proposed a systems-based project that included the four Ps, generated dynamical patient data clouds, and focused on the scientific wellness and disease conditions relevant to each individual—namely, a longitudinal, data-rich study of 100,000 well people over a multi-decade timeframe.^{27, 31} We proposed to (1) determine the complete genome sequence of each individual; (2) study blood, saliva, and urine every 3 months to delineate clinical chemistries, 700 metabolites, and about 400 proteins; (3) analyze the gut microbiome every 3 months; and (4) include descriptive assessments of past medical history, current physical and psychological states, and quantified self-measurements (activity, pulse and quality of sleep with a fitbit and blood pressure and weight). The overarching concept is to analyze the individual measurements and to integrate various combinations of these data types into models for each individual that reveal “actionable possibilities” that if acted upon could improve their health or allow them to avoid disease (see below).

As these measurements are assessed over time it could soon become possible to divide the individuals into two groups—first, those who remained well or improved in health and, second, those who transitioned into disease ([Figure 4](#)). From those who remained well, or improved, we can identify metric panels that should allow us to quantify wellness. We are convinced that these metrics will allow us to delineate physical and psychological aspects of wellness. One might imagine that each individual has a conceptual “well of wellness” and we believe that many of us are low down in our wells. Acting on personalized actionable possibilities brings us up toward the top of our wells—optimizing both our physiological and psychological health. How effectively individuals optimize their own wellness is a function of how effectively they respond to their personalized actionable opportunities.

Figure 4 Health status change over time. Individuals can move in a trajectory that leads to maintaining or increasing wellness, or can transition to being less well and into disease. Early detection and actionable possibilities can aid in transitioning individuals from a disease trajectory and into a wellness trajectory as well as optimizing wellness for each individual.

For those who transitioned into disease we could analyze the longitudinal data back to identify the wellness to disease transition point, allowing us to study the earliest perturbations to relevant disease-perturbed biological networks ([Figure 4](#)). These insights would lead to the possibility of understanding the earliest disease mechanisms, of developing pre-symptomatic diagnostic agents and of possibly identifying drug target candidates that could be deployed in preventive medicine to avoid the downstream cascade of negative events leading ultimately to the manifestation of disease. In time, this would make it possible to change individuals early on in the disease trajectory back to the wellness trajectory—and thus save healthcare systems significant dollars. Accordingly, this wellness study not only studies wellness, but it also studies disease at precisely the time medicine should study disease—at its point of inception. Conventional medicine generally studies only sick patients, long after the wellness to disease transition has occurred—an often-ineffective process. Many systems, even after disease is treated, cannot return to their same level of effectiveness from before the disease. The study of wellness will let us both optimize human capital and identify the wellness to disease transitions that will let us terminate disease early and bring individuals back quickly from the disease initiation and back onto their wellness trajectories.

Actionability is a central concept for connecting data to behavior, that is, by identifying items that are actionable; we are not just providing a risk of a negative future event (which has few demonstrated effects on behavior) but rather providing in depth information into what is happening in an individual's body now

and providing a roadmap for what can be done immediately (and consistently over time) to have a material impact on his or her body in the present (which does motivate behavior). The actionable possibilities would be brought to the individuals by coaches who could clearly explain the actionable possibilities and how the individual could respond appropriately to them in the context of their own desires for their health. The coaches would be supported by physicians for clinical advice through the established healthcare system. The coaches are an incredibly important part of this process to aid people in improving their own health.

Importance of data accessibility from the longitudinal 100K Wellness Project

Our view of data accessibility is quite simple. It is essential that all of the patient de-identified data be available to qualified investigators who will mine it for the predictive and preventive medicine of the future.

One's children and grandchildren, accordingly, will be the beneficiaries of the analysis of one's data—each of us individually contribute to the medicine of the future that will improve the health of our children—optimizing wellness and avoiding disease. We would argue that it is one's social obligation to allow their data to be used to invent the future medicine. George Church in his Personalized Genome Project (PGP)³² has made a similar plea. If consumer and patient data are to be made widely available to qualified investigators, two important concerns must be considered.

First, it is essential to have strong security in place to protect the data. Appropriate methods such as encryption are available for protecting the data and must be employed.

Second, there are federal and state laws in place that aim to protect individuals against genetic discrimination, including the Genetic Information Nondiscrimination Act (GINA). GINA prohibits health insurance companies from denying coverage or charging higher premiums solely on the basis of genetic information. GINA also prohibits employers from using genetic information for hiring, firing, promotion, and other employment decisions. There are, however, significant types of discrimination that GINA does not protect against, including discrimination for life insurance, long-term care insurance, and disability insurance. Congress should address these issues by expanding GINA and enacting other relevant legislation to ensure that there is no discrimination on the basis of genetic data.

Scaling up

One of our primary goals was to understand how to scale the wellness program to 100,000 well individuals. Our initial thought was to scale in four tranches—going from 100 to 1000 to 10,000 and finally to 100,000—each over a period of a year or so. However, we had many questions about this strategy:

- What measurements should be made? How often?
- How would we develop all of the analytical tools?
- How much would a project for 100,000 individuals cost?
- How could we scale this project up from 100 to 100,000?

Hundred Person Wellness Project

With these questions in mind, we launched the effort with a 10-month pilot study of 108 individuals (100 Pioneers) in March of 2014 and completed the data gathering at the end of the year. Accordingly, we have gone through three data tranches (every 3 months) and are now in the process of analyzing these data. We discuss here some of the initial striking results that the pilot study generated.

Hundred Pioneer pilot study results

The study required a sophisticated team to manage a host of scientific, logistical, organizational, and participant engagement issues. These included sample collection procedures, decisions about the appropriate assays to include (for discovery as well as clinical utility), sample distribution for analyses (vendors and ISB), the development of analytical tools to integrate and model the Pioneer data to reveal actionable possibilities, the recruitment and training of wellness coaches, and the formation of an MD advisory panel to oversee this process. Of the 108 Pioneers who enrolled in the study, all remained in the study throughout its duration and the majority have expressed interest in continuing the study into its next phase. Seventy percent of our Pioneers were compliant to the coaching recommendations of their actionable possibilities. Our high retention and engagement rates were influenced by three elements: (1) the coach was incredibly effective in explaining each individual's actionable possibilities and in encouraging individuals to act upon them in accordance with their own health objectives; (2) understanding how one's own genes interacted with and impacted other types of data was particularly persuasive in encouraging people to change behavior; and (3) observing the positive (and appropriate) changes in one's data cloud over time in response to specific lifestyle changes was an enormously reinforcing experience.

The first data tranche of clinical chemistries revealed that 91% of the Pioneers had specific nutritional deficiencies and 68% had inflammatory indicators (both correctable). Three Pioneers had extremely high levels of mercury. Two of these ate significant amounts of tuna sushi, while one had mercury arising from old dental fillings. One substituted salmon for tuna sushi and within 2 months his mercury level had dropped by half—and the other two had similar experiences in dealing with their mercury sources.

We had several indications of likely disease transitions. For example, two of the Pioneers were homozygous for the variant that causes hemochromatosis (C282Y). In a small proportion of such individuals, this disorder can lead to high iron and ferritin levels in the blood. High blood iron levels can attack the joints, pancreas, the liver, and/or the heart—potentially leading to arthritis, diabetes, liver cirrhosis/cancer, and/or cardiac decompensation in various combinations. Since this disease often presents with the cardiac complications, individuals may be already chronically ill with diabetes or liver disease before they are diagnosed.

The treatment is simple. Send the individuals with the C282Y mutations to their physician for a work-up for the diagnosis; if indicated, the individual can have regular blood draws until normal iron levels are reached. We identified the two individuals with homozygous C282Y genotypes only with the earliest changes, before any serious tissue damage had been done, thus over time saving the healthcare system significant dollars—by avoiding what could have been chronic hemochromatosis. Further, the children of these individuals are being genetically tested—stopping the progression of an undiagnosed and treatable disease to the next generations.

Using standard cutoff values for fasting serum glucose, we identified 53 of the 108 participants who had fasting glucose in the prediabetic range at baseline (e.g., were prediabetic). After only 5–6 months of

health coaching, seven of these individuals had reverted to normoglycemia and the overall trend in glucose levels in the population was decreasing.

The integration of two or more different data types (e.g., blood, microbiome, genetics, activity) was also informative. For example, using Genome-wide Association Studies (GWAS), we could place the 108 Pioneers into five, low to high risk categories according to their genetic (GWAS) propensity for Crohn's disease. When the bacterial populations in the gut microbiome were compared against these genetic propensities—two strains of more “pathogenic” bacteria increased as the genetic risk for each group of individuals increased. Thus, there is an association between the genetics of Crohn's disease susceptibility and changing microbial populations in the gut microbiome. It is not yet clear what the causal association might be or whether there is a strong actionable possibility here.

What is clear is that every one of the 107 Pioneers had multiple actionable possibilities. There was a remarkable compliance, with more than 70% of the Pioneers acting upon their actionable possibilities. Thus, this program can optimize wellness and/or reduce disease for each individual.

Many participants came to three conclusions as a result of these studies:

- Your genes determine your potential, not your destiny. For many conditions, a change in behavior can address genetic limitations.
- Personalized, comprehensive and real-time data are empowering. With this knowledge, it is easier and more motivating for one to take responsibility for one's health. This is the key to beginning to control healthcare costs.
- Many of the Pioneers are interested in continuing with the next phase of the longitudinal study (which we will outline shortly). This is a measure of how convinced most were that this study had profoundly “changed their lives.”

Benefits of the 100,000 (100K) person and 107 Pioneer wellness studies for healthcare

1. We will create a catalog of actionable possibilities for optimizing wellness and minimizing disease, and for aiding others in launching similar studies. This catalog of exponentially increasing actionable possibilities (analyzing new data identifies new actionable possibilities) will be a central focus of optimizing individual wellness in the future.
2. We will generate the dynamical, personalized data clouds that permit the extraction of individual actionable possibilities, which, if acted upon, allow individuals to optimize wellness and minimize disease.
3. We will generate a multiparameter, biomarker panel for wellness that in time, we believe, will allow us to disentangle the physiological and the psychological components of wellness quantitatively from the blood. It will facilitate individuals moving up their well of wellness to maximize their own human potential.
4. We will delineate the wellness to disease transitions for the common diseases and open the possibilities for early diagnosis followed by early treatment—thus moving individuals quickly from their early disease trajectories back to their wellness trajectories. Analysis of this dataset will thus catalyze opportunities focused on the predictive and preventive aspects of P4 medicine.
5. We will push the development of miniaturized, highly parallelized, microfluidic-based, fully

automated and less costly assays that will eventually be migrated to a smart phone, so that the assays may be done at home and transmitted to analytical centers for evaluation. This will lead to a digitalization of medicine that will catalyze the large cost reductions and democratization of use benefits previously seen in the digitization of communications and IT.

6. We will create a database that will have an enormous amount of information for wellness and for disease transitions. These data will provide the raw material for innovation and the creation of companies in the wellness and the disease transition fields.

7. The 100K Person Wellness Project will help catalyze three major benefits of P4 medicine to the healthcare system: facilitating lower costs, introducing more effective healthcare, and accelerating innovation and company creation.

How do we plan to proceed?

We have two major strategies for moving the 100K Wellness Program forward:

1. ISB plans to push the 100K Wellness Project forward by bringing in partners, both national and international, that will manage smaller groups of Pioneer-like projects on wellness and employ patients that are predisposed to certain diseases to enable us to follow disease transitions more quickly. We have several potential partners in the European Union and are exploring additional possibilities with countries in Asia and the Middle East. These would be academic efforts that could also drive the development of new assays (see above) and analytical tools.
2. We have launched a company, Arivale, which will provide a scientific path to wellness for consumers. Our goal is that this company will, in time, significantly help reduce the cost and improve the efficacy of maintaining or enhancing wellness. We already see this digitization of medicine taking place, through the process of determining how to effectively optimize the types of data that need to be aggregated, and by building out the data analytics capabilities for extracting the actionable knowledge from these data. In the first 6 months of its existence, Arivale without advertising attracted more than 1000 consumers in the Seattle area.

Systems medicine and cancer: a postscript

A reader of this book might ask just what systems medicine (and P4 medicine) might offer cancer. It is clear that the systems approach to cancer has much to offer and we will briefly outline a few examples.

1. Cancers shed rare cells into the blood that can be isolated and characterized, especially with the new techniques of single-cell analysis. These cells may provide new opportunities for early diagnosis, following the progression of the cancer, identifying the recurrence of cancer, and possibly even localizing the distant sites of metastases.
2. One can assess the network dynamics of cancer progression in mouse model systems (as we did for prion-induced neurodegeneration) and gain insights into early disease-perturbed networks, which in turn provide opportunities for developing early diagnostics and potential therapeutic targets to attack cancer at its early inception. We have studies underway in mouse models for glioblastoma with striking results that demonstrate that disease-perturbed networks explain many of the most fundamental properties of cancer.
3. One can develop blood diagnostics for cancer, follow its progression, follow the response to

therapy, identify recurrences, and even identify disease-perturbed networks that provide insights into possible therapeutic drug candidates (see our earlier description of an approach to lung cancer diagnostics).

4. One form of RNA, micro (mi)RNA, plays a very important role in cellular regulation. These miRNAs interact with important regulatory networks and provide yet another systems-driven approach to identifying molecules that could be drug target candidates.

5. A key aspect of future cancer treatment will be triple drug therapies that are initiated at the outset of the treatment of the disease. Cancer and HIV/AIDS (human immunodeficiency virus/acquired immunodeficiency syndrome) are diseases exhibiting excessive mutation rates. Just as triple drug therapy converted HIV/AIDS from a fatal to a chronic disease, triple drug therapy for cancer will have the opportunity to do the same. An understanding and analysis of the disease-perturbed networks of cancer is the key to identifying multiple potential drug target candidates that can act synergistically with one another. Moreover, systems strategies can be deployed to identify appropriate combinations of three or more drugs through combinatorial analyses.

6. The longitudinal study of well people as described above will ultimately allow us to identify the wellness to disease transitions in cancers and begin to investigate early disease-perturbed networks. An understanding of these early transitions will open new possibilities for early diagnostics and therapies.

7. We can apply longitudinal wellness studies to individuals undergoing cancer treatment to optimize their wellness during this difficult process. Wellness is never seriously considered as part of cancer treatment today. Moreover, we can do the same for patients that have already undergone successful (cytotoxic, chemotherapeutic) cancer treatments to once again optimize their wellness.

These are just a few examples of how P4 medicine can address cancer—and we are just at the beginning of imagining all of the P4 opportunities that lie ahead of us for cancer research. The key is to bring P4 medicine into the healthcare systems rapidly so that medicine can begin to exploit these opportunities. A major challenge, quite obviously, is how to bring an understanding of these opportunities to physicians—who often can be quite conservative in their willingness to accept new ideas.

The democratization of wellness and healthcare

Our vision for the future of healthcare is that patients will participate by taking responsibility for their own health, the digitization of medicine, and our more effective understanding of how to use personalized data clouds to optimize wellness and avoid disease that we can substantially reduce the cost of healthcare while enhancing its effectiveness.

We are convinced that this will happen through a focus on wellness and the early identification of disease transitions that can be identified and treated rapidly and effectively. As costs come down and concrete discoveries are made, P4 medicine will be brought not only to the developed world but to the developing world as well. Who would have thought in 1990 that a woman in a rural village in India could make a living for her family using a cell phone? Yet, this is precisely what has happened through the digitization of communications. In a similar manner, the digitization of medicine, together with the other changes noted above, will strikingly reduce the costs of healthcare and that, in turn, will democratize P4 healthcare for the poor as well as the rich. It is difficult to comprehend, within the next decade, how many individuals, rich and poor alike, might be in a position to transform their human potential through optimizing wellness and minimizing disease. These are indeed exciting times for advancing medicine. As we move into the

twenty-first century, medicine will increasingly become predictive, preventive, personalized, and participatory. It will focus on each of us as individuals and optimize our health according to each of our individual and unique characteristics.

Acknowledgments

We thank the individuals in the Pioneer 100 project for their participation in this adventure and the many wonderful team members (too numerous to mention) who have made this project possible. We thank Gretchen Sorensen and Jennifer Lovejoy for many valuable comments on the manuscript. We also thank the Institute for Systems Biology for providing philanthropic support to this project, the Robert Wood Johnson Foundation, and the M.J. Murdock Charitable Trust for grants that helped to partially fund the study.
