Part 3

Quantitative Oncology

Chapter 18

Cancer bioinformatics

John N. Weinstein, MD, PhD

Overview

Bioinformatics is a rapidly developing scientific field in which computational methods are applied to the analysis and interpretation of biological data, usually at the cell or molecular level and usually in the form of large, multivariate datasets. In the context of cancer, the most frequent scenario is molecular profiling at the DNA, RNA, protein, and/or metabolite level for basic understanding of the biology, for identification of potential therapeutic targets, and/or for clinical prediction. The new massively-parallel sequencing technologies are generating a data deluge—literally quadrillions of numbers in all—that strain the capacity of our hardware, software, and personnel infrastructures for bioinformatics; hence, the computational aspect of a sequencing project is now generally more expensive and time-consuming than the laboratory work.

Bioinformatic analysis can be hypothesis-generating or hypothesis-testing. When it is hypothesis-generating, the assumption is that one can afford a large number of false-positive findings in order to identify one or a few evocative or useful ones; when it is hypothesis-testing, the full rigor of statistical inference should be applied. A large number of statistical and machine-learning algorithms, scripts, and software packages are now available for the analysis, and options are multiplying rapidly. Because the datasets are often so large, however, an important aspect of bioinformatics is data visualization, for example display of data arrayed along the length of the genome or, most commonly, in the form of a clustered heat map.

Cancer biologists and clinical researchers should preferably take the lead in biological interpretation of the massive datasets, but statistical analysis should be done by (or under the vigilant aegis of) a professional in informatics; when there are more variables (e.g., genes) than cases (e.g., patients), there is a tendency for the untrained to obtain overly optimistic p-values or see false patterns in even randomized datasets. In addition, subtle errors that arise in the unglamorous tasks of data management and pre-processing often lead to misleading or frankly wrong conclusions from the data.

As high-throughput molecular profiling projects have become cheaper and easier, they have been incorporated progressively into the work of individual institutions, both academic and commercial. However, there are also growing numbers of large-scale public projects in the domain. At the level of cell lines, the first was the NCI-60, a panel of 60 human cancer lines used since 1990 by the U.S. National Cancer Institute to screen more than 100,000 chemical compounds plus natural products for anticancer activity. That panel was followed more recently by the Cancer Cell Line Encyclopedia, the Genomics of Drug Sensitivity in Cancer project, and others. At the clinical level, The Cancer Genome Atlas project has been center-stage, profiling more than 10,000 human cancers of 33 different types, and there is an alphabet-soup of acronyms for other such projects that are in progress or on the drawing board. Those projects, which require massive bioinformatics support, have spawned robust communities of bioinformatics expertise and served as testbeds for the development of new algorithms, software, and visualizations.

I can assure you that data processing is a fad that won't last out the year.

– Editor for a major publishing house, 1957

A generation ago, the results of most laboratory studies on cancer could be processed in a simple spreadsheet and the results written into a laboratory notebook. The data were generally analyzed by experimentalists themselves, using very basic statistical algorithms. That landscape shifted progressively with the advent of microarrays in the mid-1990s and then massively parallel “second-generation” (or “next-generation”) sequencing a decade later. At the turn of the millennium, there was a prediction—only half in jest—that most biomedical researchers would soon abandon the wet laboratory and be hunched over their computers, mining the data produced by “biology factories.” That has not happened, of course; small wet laboratories are thriving. But we do see increasing numbers of biology factories, prominent among them the high-throughput sequencing centers. And, overall, the trend toward computation is unmistakable. That trend is largely a result of new, robotically-enhanced technologies that make it faster, cheaper, and more reliable to perform the *laboratory portions* of large-scale molecular profiling projects and screening assays. As a result, large centers and also small laboratories can churn out increasingly robust streams of data. Those trends have conspired to produce massive datasets that often contain many billions or trillions of entries, requiring more complex, larger-scale, often subtler statistical analyses and “biointerpretive” resources.

Just as the ‘Light-Year’ was introduced for astronomical distances too large to be comprehended in miles or kilometers, the ‘Huge’ (Human Genome Equivalent; about 3.3 billion base-pairs) can be defined for genomics. All of Shakespeare's writings (plays, sonnets, and poems) contain a little over 5 million letters, less than 0.002 Huge. Storage, management, transmission, analysis, and interpretation of data are now most often the bottlenecks, not wet-laboratory data generation itself. The data deluge has variously been likened to an avalanche, a flood, a torrent, or a tsunami. Hence the rise and kaleidoscopic advance of bioinformatics, a multidisciplinary field based on statistics, computer science, biology, and medicine—a field crucial to current biomedical research and clinical progress but still in what might be characterized as an awkward adolescent phase.

The aim of this chapter is not to provide a comprehensive treatment of the sprawling, rapidly evolving arena of cancer bioinformatics. That would, in any case be impossible to do at any depth in the space available. Some sub-fields, for example analysis of the metabolome and the structural analysis of proteins and nucleic acids, will, unfortunately, be short-changed.

The aim is also not (with apologies) to give due credit to pioneers in the field or to cite all of the tools and resources that deserve mention. Rather, the aims are (1) to illuminate some generic aspects of cancer bioinformatics in its current and likely future states; (2) to highlight a sample of the statistical algorithms, computational tools, and data resources available; and (3) to showcase some issues that should be borne in mind by the nonspecialist who is trying to navigate the bioinformatics literature, to comprehend what bioinformatician collaborators are doing, or to use bioinformatics in a project for a better understanding of cancer or for the direct benefit of cancer patients and their families.

The definition and scope of bioinformatics

Definition of “bioinformatics”

The term “bioinformatics” is not new. It first appeared in print in 1970 with a very broad meaning,¹ but its definition, as applied currently, is a matter of almost Talmudic debate. Multiple committees, academic

surveys, and publications have struggled with the subject, even attempting to distinguish between “bioinformaticians” and “bioinformaticists”.² For present purposes, an extended definition of bioinformatics attributed to the U.S. National Center for Biotechnology Information (NCBI) will suffice: *“Bioinformatics is the field of science in which biology, computer science, and information technology merge into a single discipline. There are three important sub-disciplines within bioinformatics: the development of new algorithms and statistics with which to assess relationships among members of large data sets; the analysis and interpretation of various types of data including nucleotide and amino acid sequences, protein domains, and protein structures; and the development and implementation of tools that enable efficient access and management of different types of information.”*

There can be no definitive line of demarcation between bioinformatics and related or overlapping disciplines such as computational biology and medical informatics. Computational biology *“involves the development and application of data-analytical and theoretical methods, mathematical modeling and computational simulation techniques to the study of biological, behavioral, and social systems.”*³ It includes, but extends far beyond, the focus on biological molecules characteristic of bioinformatics. Medical informatics has been defined as *“the field of information science concerned with the analysis and dissemination of medical data through the application of computers to various aspects of health care and medicine.”*⁴ Medical informatics is closely tied to the practical needs of clinical research and clinical practice, whereas bioinformatics is more closely allied with pre-clinical research. However, the two meet—and should synergize—in such projects as biomarker-driven clinical trials.

In the end, a word means what we collectively choose it to mean, and the best way to get a feel for the extent of the field is to list some key words associated with it. As per the famous dictum of U.S. Supreme Court Justice Potter Stewart, “I know it when I see it.” The ingredients of most bioinformatics projects include biological molecules, large databases, multivariate statistical analysis, high-performance computing, graphical visualization of the molecular data, and biological or biomedical interpretation. Typical sources of data for bioinformatic analysis include microarrays, DNA sequencing, RNA sequencing, mass spectrometry of proteins and metabolites, histopathological descriptors, and clinical records. Some of the salient datasets originate within studies being conducted in particular laboratories, but large, publicly available databases and search resources are playing ever-larger roles.

Questions typically addressed by bioinformatic analysis and interpretation

Questions addressed by bioinformatic analysis relate to biological mechanisms, pathways, networks, biomarkers and biosignatures, macromolecular structures, subsetting of cancer types, early detection, and prediction of clinical outcome variables such as risk, survival, metastasis, response to therapy, and recurrence. The paradigmatic bioinformatics project—the type that will be cited throughout this chapter—involves the design, statistical analysis, and biological interpretation of molecular profiles. [Figure 1](#) shows a schematic view of the specimen and information flows in a generic sequencing project whose aim is to identify mutational and/or DNA copy number aberrations as possible biomarkers. The data from such studies can also be used to subset cancers or to make direct comparisons such as tumor versus paired normal tissue, tumor type versus tumor type, responder versus nonresponder, metastatic versus nonmetastatic, or primary versus recurrent cancer.

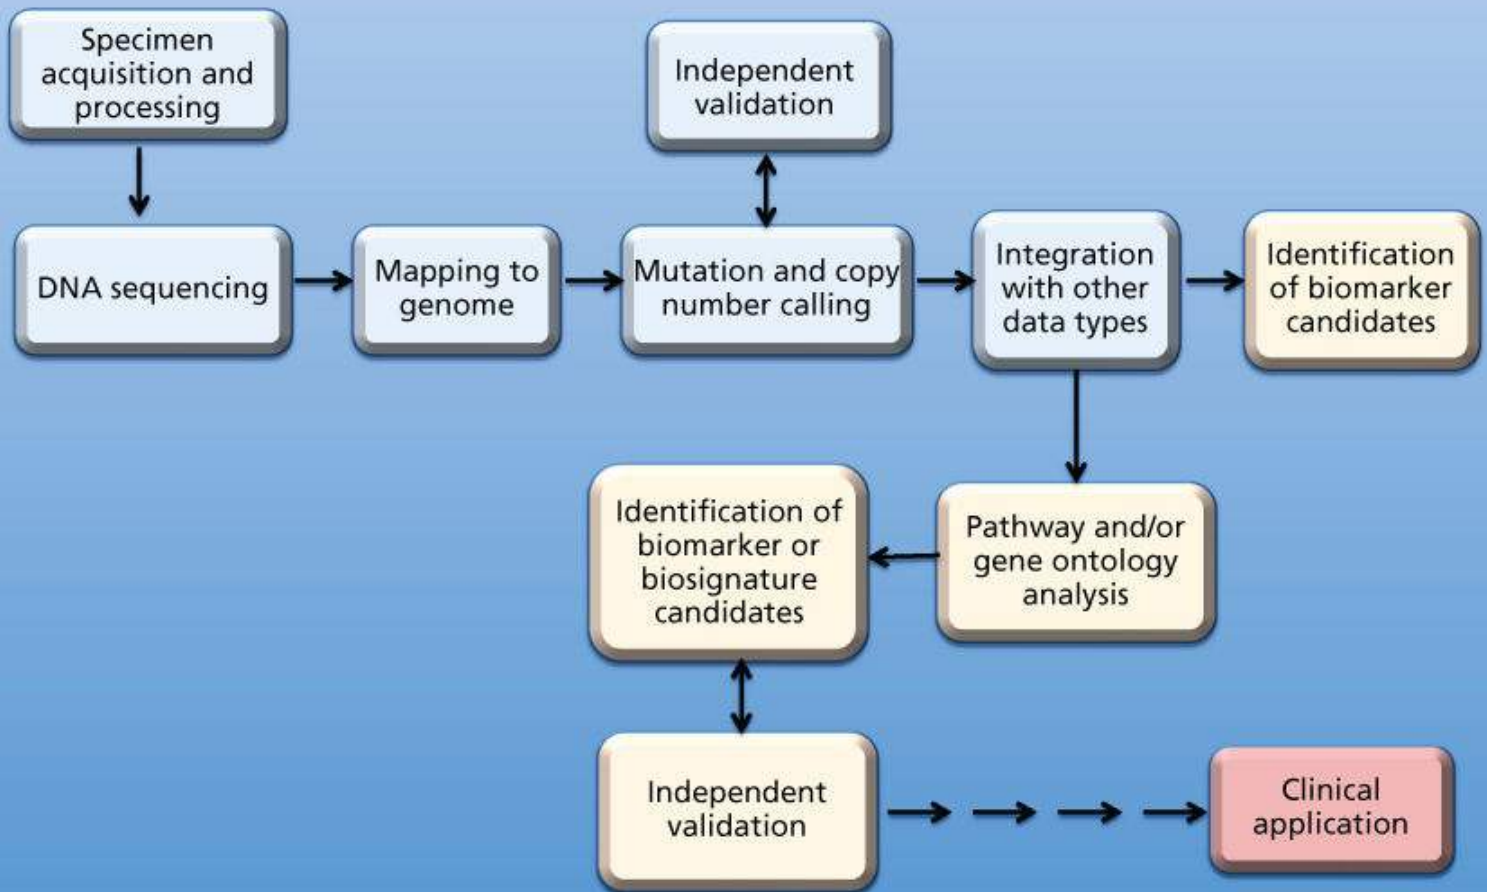

Figure 1 Schematic view of specimen and information flows for sequencing of cancers to identify mutations and/or copy number aberrations as possible biomarkers for clinical application. Amber boxes indicate downstream “biointerpretive” aspects of the pipeline. As indicated by the multiple arrows, many hurdles (scientific, technical, logistical, ethical, and regulatory) must be overcome before possible clinical application. Analogous schematics can be drawn for other data types at the DNA, RNA, protein, and metabolomic levels (including studies based on microarrays, rather than sequencing).

One frequent aim has been the identification of “prognostic” biomarkers for survival, time to recurrence, or metastasis. However, the interest in such biomarkers has been declining, in part because they do not specify a therapy and in part because the landscape of cancer therapy is changing so rapidly that natural history of the disease has lost much of its meaning. Instead, the focus has turned to “predictive” biomarkers. The term is curiously non-specific, and its etymology is unclear, but it has gained currency for molecular markers that predict which subpopulations of patients will respond to a particular therapy. An allied concept is that of the “actionable” biomarker. An actionable, predictive biomarker may be a target for therapy or it may simply be correlated with response. Historically, bioinformatic analysis has identified associations and correlations more often than it has identified causal relationships, but “bioperturbing” technologies such as siRNA, shRNA, CRISPR, and consequent synthetic lethal pharmacological screens are producing large datasets with immediate causal implications.

The analog (microarray) to digital (sequencing) transition

We are witnessing a transition from the primacy of microarrays (fundamentally analog technologies) to the primacy of DNA and RNA sequencing (fundamentally digital technologies). The digital revolution took hold in computing, then in television, in watches, in cameras and cars, and now in biomedical research. DNA and RNA sequencing provide more precise, incisive, and extensive information about the molecular profiles of cancers than could be obtained from microarrays. For example, sequencing the mixture of mRNAs in a tumor (RNA-seq) can yield information on mRNA splicing, mRNA editing, clonal heterogeneity and evolution, viral insertion, fusion gene expression, and allelic components of the overall expression level. In contrast, expression microarrays generally indicate only the relative amounts of the mRNA species present in a sample. However, the transition is not without its growing pains. As of 2015, sequencing is still generally more expensive than gene expression microarrays. And massively-parallel second-generation sequencing currently challenges the bioinformatics community at the levels of hardware, software, and “wetware” (i.e., personnel).

Hardware challenges

Moore's law⁵ is familiar. It relates to the number of transistors that can be crammed into unit surface area on a very large integrated circuit. That number has increased in a remarkably consistent way, two-fold every other year since the 1960s. As a consequence, and because the speed of transistors has increased, the cost of computing power has been cut in half every 18 months. However, the Moore's law decrease has not kept up with the decline in sequencing cost, which was cut 1,000-fold (from about \$10 million per human genome to about \$10 thousand) in the 4 years from late 2007 to late 2011 as second-generation sequencing became available ([Figure 2](#)). The decline in price has slowed dramatically since that time as we await cost-effectiveness of “third-generation” sequencing technologies such as those based on single-molecule sequencing. Nonetheless, even our high-performance computer clusters with large amounts of memory and thousands of CPUs operating 24 hours a day are often saturated with genomic calculations, principally sequence alignments to the genome. The computational demands are so great that heat dissipation and the availability of electricity are often limiting. Some large data centers require their own power stations. Also a big-data problem, it can take prohibitively long to transmit large numbers of sequences and associated annotations from place to place, even along high-speed lines. Cloud computing will help with our limitations of electrical power and storage space, but one must still get the large amounts of data to and from the cloud. Increasingly, computational tools are being brought to the data, rather than the reverse.

Cost per genome

Figure 2 Cost per genome for human whole-genome sequencing. The figure shows an inflection point in late 2007 as massively-parallel sequencing came into practice. We are awaiting the maturation and cost-effectiveness of “third-generation” technologies, principally based on sequencing of single molecules. Source: genome.gov/sequencingcosts (The National Human Genome Research Institute).

Less familiar but an even more serious problem is Kryder's law,⁶ analogous to Moore's law but for the cost of data storage, rather than computing power. An original version of Kryder's law in 2004 predicted that the cost would decrease by about two-fold every 6 months. In 2009, the projection was scaled down to a cost decrease of 40% per year, but the actual rate of decrease from 2009 through 2014 was only 15% per year. The storage space needed for a standard whole-genome BAM file (binary alignment map file/sequence) with 30-fold average coverage of the genome is “only” about 100 gigabytes, but to identify mutations in minority clones within a tumor can require genome coverage redundancies in the hundreds (if they can be identified at all). The storage space required can be reduced by coding only differences from a reference standard, but the reduction is limited by the need to record quality-control information and other types of annotations. Even large institutions are running out of storage space. It may be less expensive to re-sequence samples than to store sequencing data from them over time.

However, there are new possibilities for mass storage on the horizon, paradoxically including DNA itself. DNA may be the most compact storage medium in prospect. A single gram of DNA could encode about 700,000 gigabytes of data (roughly 7,000 whole-genome BAM files). One team has encoded all of Shakespeare's sonnets in DNA and another has encoded an entire book—with an intrinsic error rate of only two per million bits, far better than magnetic hard drives or human proof-readers can achieve.⁷ They

then replicated the DNA to produce 70 billion copies of the book—enough for each person in the world to own 10 copies (without taking up space on their bookshelves). Under the right storage conditions, DNA can remain stable, potentially for hundreds of thousands of years, even at room temperature. If you were faced with the challenge of passing knowledge down to future civilizations, DNA storage would be your best bet. The technology for getting information into and out of DNA is far too expensive for large-scale use at this time, but the price is decreasing rapidly.

Software challenges

Creative ideas are flowing through the field of bioinformatics software development. Many hundreds of capable software packages are being developed and deployed, some of them commercial but most of them academically developed, open-source, and publicly available. The range of choices for any given computational function is almost paralyzing. One result is fragmentation of the community of users, who, for the most part, have not yet coalesced around particular algorithms, software, or websites. Among bioinformaticians, the “not-invented-here” syndrome often applies. As a consequence, Bioinformatics is a classic Tower of Babel in which software packages usually fail to communicate nicely with each other. Various annotation schemes and data formats remain mutually incompatible, despite major international efforts at standardization.

Particularly in terms of sequencing, there are algorithmic challenges of major import.⁸ If the massively-parallel sequencing technologies and the data from them were truly digital, one should be able to identify with certainty whether there is or is not a mutation at a given DNA base-pair. However, that is not the case, as indicated in [Figure 3](#), which shows a Venn diagram for the consistency of somatic mutation calls on the same sequencing data by three major sequencing centers. The differences are considerable, perhaps in part because of clonal heterogeneity, low percentage of tumor cells, poor coverage in some regions of the genome, and/or degradation of the DNA. An additional reason is probabilistic. If each of two callers were 99.999% accurate in identifying mutation at a given base-pair in a genome of three billion bases, then they would still disagree on tens of thousands of calls. Important calls, for example calls of driver mutations and other cancer biomarkers, must be validated by an independent technology. Three such strategies are (1) validation of DNA and RNA calls against each other for the same samples, (2) use of a consensus of calls by different sequencing centers,⁹ and (3) follow up with a different technology such as polymerase chain reaction focused on particular bases.

Figure 3 Venn diagram of the somatic point mutations detected by three different mutations callers circa 2013 on 20 TCGA endometrial tumor-normal exome-seq pairs. The differences for point mutations would be smaller now, but an analogous diagram for indels or structural variants would still show considerable lack of concordance. From⁹

Wetware challenges

At the present time, personnel (wetware) and expertise are even more seriously limiting than the hardware or software issues. Bioinformatics is highly multidisciplinary, at the interface of computer science, statistics, biology, and medicine. There are not many individuals with expertise in all of those disciplines to operate across the interfaces among them. Despite stereotyped pipelines for some parts of the necessary analyses—generally the steps from raw data to mapped sequence—bioinformatics projects usually require customization of analyses and the efforts of a multidisciplinary team.

The bioinformatics components of a typical large molecular profiling project can be divided roughly into data management, statistical analysis, and biointerpretation. Data management sounds mundane, but for a project that includes data from multiple molecular technologies and clinical data sources, it can be challenging in the extreme. When the Hubble telescope was launched in 1990, it was initially crippled by a 1.3-mm error in its mirror because a custom “null corrector” was substituted for the conventional one during final testing. In 1999, the Mars Climate Orbiter was lost because computer software produced output in pound-seconds instead of newton-seconds (metric units); the orbiter's incorrect trajectory brought it too close to Mars, and it disintegrated in the atmosphere. Analogous data mismatch problems are endemic to bioinformatics. Missing or carelessly composed annotations often result in puzzlement or wrong conclusions about the exact meaning of a data field.

Roles in the multidisciplinary bioinformatics team: an opinion

Statistical analysis of highly multivariate data, unlike that of the simple laboratory experiment, generally calls for specialist expertise in computational analysis. The biomedical researcher should be *involved* in the statistical analysis, equipped with a basic understanding of the methods employed and the potential pitfalls. He or she should be prepared to provide the analyst with (1) questions to be asked of the data, (2) biomedical domain information, and (3) information on idiosyncrasies of the technologies and experimental design that may affect analysis. If a data analyst is not given those types of information, he or

she will often generate the right answer to the wrong question or an answer based on incorrect premises. It is dangerous, however, for those untrained in statistics to perform the data management tasks and statistical analyses alone or without very close supervision. Experience has shown a remarkable tendency for the untrained to make mistakes, generally mistakes of over-optimism.¹⁰ They often achieve apparently positive, even ground-breaking, results that later prove to be meaningless. “Unnatural selection” plays a role in that phenomenon; there is a human tendency, reinforced by wishful thinking, to do analyses different ways until one of them gives the desired result. There is also a remarkable, highly tuned tendency for the human mind to find patterns in data where none exist. The analogy of allowing a statistician to perform brain surgery (or a brain surgeon to perform statistical analyses) overstates the case, but not dramatically so.

Bioinformatic analysis, visualization, and interpretation

[Table 1](#) lists some molecular data types and phenomena that can be significant in the analysis of cancers, often for early detection or for prediction of cancer risk, diagnosis, prognosis, response to treatment, recurrence, or metastasis. The “omic” terminology sometimes seems strained, but it is compact, convenient, and etymologically justified. The suffix “-ome” is from the Greek for an “abstract entity, group, or mass,” so omics is the study of entities in aggregate.¹¹ (A curiosity: we have genetics for the single-gene counterpart of genomics but not protetics for the single-gene counterpart of proteomics or metaboletics for the single-compound counterpart of metabolomics.)

[Table 1](#) A potpourri of bioinformatic data types, phenomena, and data sources

Data types	Immunomic
Genomic—germline, somatic (DNA level)	Epitope-mapping
Single-nucleotide variation (SNV)	Immune cell profiling
Insertion/Deletion (Indel)	Immune regulatory network modeling
Copy number variation	
Loss of heterozygosity (LOH)	Connectomic
Translocation	Co-occurring and mutually exclusive elements
Repeat element	Hub nodes
Functional motif	Random vs. scale-free properties
Domain structure	Disassortivity
Fusion gene	Pathological
Viral insertion	Classification, subclassification
Pseudogene	Grade
	Percent tumor cells
Epigenomic	Clonal heterogeneity (microscopic, macroscopic)
DNA methylation (CpG island)	Marker studies (by immunohistochemistry, in situ hybridization, etc.)
DNA methylation (non-CpG island)	
DNA modification (other)	

Histone modification (acetylation, methylation, etc.)	Clinical
Transcriptomic (RNA level)	Survival
mRNA expression	Disease-free survival
microRNA expression	Time to Relapse
long non-coding RNA expression	Response to therapy
Transcript splice variation	Data sources
RNA editing	Bulk measurement
Allele-specific indices	Whole exome sequencing (WES)
	Whole genome sequencing (WGS)
Proteomic	Bisulfite sequencing
Protein expression	Low-coverage copy number sequencing
Post-translational modification	Reverse-phase protein arrays
Protein complexes and interactions	Mass spectrometry
	Antibody arrays
Metabolomic	Nucleic acid microarrays
Metabolite flux	Single-cell measurement
Metabolite expression level	Single-cell sequencing (DNA, RNA)
Targeted identification (MRM)	Flow cytometry (fluorescence, mass-tagging)
Chromosomic	Clinical
Transcription factor target	Medical records
Histone modifier target	Clinical trials
Replication start site and kinetics	
Transcription start site and kinetics	Other
Accessibility of chromosome location	siRNA, shRNA
Microsatellite instability (MSI)	CRISPR
Chromosomal instability (CIN)	Mass spectrometry
3D chromosomal arrangement	Microdissection, tumor disaggregation
Long-range genomic regulation	Microscopy
Choreography of mitosis and meiosis	Imaging
Pharmacomic	Circulating exosomes, tumor cells (CTC)
Response to treatment	
Natural and acquired resistance	

In biointerpretation and medical interpretation, to the contrary, the biomedical researcher should preferably take the lead on the basis of specific domain expertise and general knowledge of cancer biology. Every basic, translational, or clinical cancer researcher should be able to use a selection of the available tools of biointerpretation to explore the genes, pathways, networks, cell biological entities, and clinical correlates that come into focus on the basis of large-scale molecular datasets. Training researchers in the use of such tools can be considered a primary responsibility of the bioinformatician. The bioinformatician should be prepared to explain the essence of statistical or machine-learning algorithms that he or she is using and to do so in visual, nonmathematical terms. That is *always* possible to do. However, the bioinformatician is likely to have the broader knowledge necessary for selection of the optimal tools and data resources for a project and can do the programming that is often necessary to customize an algorithm or a graphical visualization of the data.

Many of the statistical principles, algorithms, and software used in the field are agnostic to the type of data, but each type has its own peculiarities that require customized attention. Issues like background level, normalization, filtering for variation, distributional properties, thresholds, and representation as continuous or dichotomized values all require careful attention. Poor choices of procedure in those matters can lead to fundamentally wrong results in the analysis. In fact, the most important and most challenging, often unresolvable problems in bioinformatics arise from the most mundane, least glamorous tasks: pre-processing of the data to minimize noise without eliminating signal. Also important, there is a tremendous loss of opportunity and a real danger of uncorrected or uncorrectable error if the datasets and analytical procedures used on them cannot be reproduced months or years later for cross-checking and independent analysis.

“Data integration” is a term that rolls easily off the tongue, but it hides an entire field of intensive study. There are many methods for making disparate data types commensurate with each other and therefore able to be integrated, but none of them are totally satisfactory. [Table 2](#) lists a small sample of the many web-based tools that are available and widely used for analysis, visualization, integration, and interpretation of bioinformatic data.

Table 2 A sample of web-based bioinformatics tools and data resources useful in bioinformatics

The UCSC Genome Browser ¹² —Offers interactive online access to a database of genomic sequences and rich annotation data for a wide variety of organisms. Genome sequence is displayed horizontally, accompanied by a set of annotation tracks (which can be user-selected). For example, there are tracks that give the locations of predicted genes, transcription factor targets, DNA repeat elements, microRNAs, and cross-species comparative genomic information. There is an associated Cancer Genomics Browser for displaying and analyzing cancer genomic data along with associated clinical data ¹³ (http://genome.ucsc.edu/).
The cBioportal ¹⁴ —A resource for intuitive, interactive exploration of multiple cancer genomic datasets and correlative information from many different public molecular profiling projects, including TCGA (http://www.cbioportal.org/).
Cytoscape—A flexible open source software platform for analyzing, visualizing, and annotating complex interaction networks. (http://www.cytoscape.org/)
Bioconductor—An extensive open-source, open-development collection of programs (934 of them as of March 2015), mostly written in R, for analysis, graphical visualization, and annotation of bioinformatic data ¹⁵ (http://www.bioconductor.org).

Ingenuity pathway analysis—Integrated analysis of pathway, regulatory, and disease data (available in public and commercial versions) (<http://www.ingenuity.com>).

Pathway studio—A resource of molecular interactions and associated tools, based in part on natural language processing of biological and medical literature (commercial product) (<http://www.elsevier.com/solutions/pathway-studio>).

Oncomine—An integrated collection of hundreds of public microarray gene expression studies on cancers, with associated tools for meta-analysis of the data, for example to identify tumor subtypes, biomarkers, and therapeutic targets (available in public and commercial versions)¹⁶ (<http://www.lifetechnologies.com/us/en/home/life-science/cancer-research/cancer-genomics/cancer-genomics-data-analysis-compendia-bioscience/oncomine-cancer-genomics-data-analysis-tools/oncomine-gene-browser.html>)).

The Gene Ontology (GO)¹⁷—Product of an international initiative to unify the annotations of genes and gene products by imposing a controlled vocabulary and hierarchical structure of categories (or terms). Formally, the structure is an “acyclic graph” in which each category in the hierarchy can have more than one parent category. There are three independent ontologies: biological process, molecular function, and cellular component. GO is frequently used to identify categories that are relatively enriched with overexpressed or under-expressed genes in a comparison of two gene expression profiles. The many tools for statistical assessment of the enrichment include AmiGo, David, GoMiner, and OBO-Edit (<http://geneontology.org/>).

Compendium of TCGA Next-Generation Clustered Heat Maps (NG-CHMs)—CHMs are the graphical visualizations ubiquitous in bioinformatics for identifying patterns in molecular profile databases. However, they are generally static images. NG-CHMs are highly interactive versions in which one can zoom and navigate using a Google-Maps-like technology; link out to pertinent public data resources including pathway programs, the UCSC Genome Browser, and the cBio Portal; re-color the map on the fly; access a statistical toolbox for detailed analysis of the data; produce high-resolution graphics; and store all metadata necessary to reproduce the map months or years later (<http://bioinformatics.mdanderson.org/main/TCGA/NGCHM>).

The Cancer Genome Atlas (TCGA) Data Portal—A primary source for access to non-restricted TCGA data (<http://cancergenome.nih.gov>).

The Cancer Proteome Atlas (TCPA) Portal—A collection of proteomic databases and tools for analysis and visualization of proteomic data, principally but not exclusively from TCGA (<http://cancergenome.nih.gov>).

Firehose—An analysis infrastructure that coordinates the flow of gigabyte- or terabyte-scale datasets through dozens of analysis algorithms for cancer genome projects including TCGA. An add-on, Nozzle, provides user-friendly formats for the results (<http://gdac.broadinstitute.org>).

Regulome Explorer—A suite of tools for exploration and visualization of large complex datasets, featuring a machine-learning algorithm (random forest) plus a circular ideogram layout, a linear multi-track browser, and 2D plots (<http://explorer.cancerregulome.org>).

Paradigm—A program that infers patient-specific genetic activities on the basis of curated pathway interactions among genes. It incorporates multiple types of omic data on tumor samples and predicts a pathway's activity level based on probabilistic inference (<http://sbenz.github.com/Paradigm>).¹⁸ A related program, Paradigm-Shift (<http://github.org/paradigmshift>) uses a belief-propagation algorithm to infer gene activity from gene expression and copy number data in the context of a set of pathway interactions.

NCI Genomic Data Commons—Comprehensive computational infrastructure under development to store and harmonize genomic data on cancer generated through NCI-funded research programs.

GenBank—The NIH/NLM genetic sequence database, an annotated collection of all publicly available DNA sequences (<http://www.ncbi.nlm.nih.gov/genbank>).

GEO (Gene Expression Omnibus)—A functional genomics data repository of curated microarray- and sequence-based gene expression datasets (<http://www.ncbi.nlm.nih.gov/geo>).

Cancer Genomics Hub (CGHub)—A secure repository for storing, cataloging, and accessing cancer genome sequences, alignments, and mutation information (including restricted-access personally identifiable data) from The Cancer Genome Atlas consortium and related projects. (<https://cghub.ucsc.edu/>).

Visual pattern recognition is a strength of humans, and even the mathematically talented can generally interpret patterns in data better if they are visual. Accordingly, a large number of graphical representations are central tools in bioinformatics. Hierarchical cluster analysis is the data-mining method most frequently used. It builds trees of similarity and difference analogous to those in phylogenetics. For example, a typical gene expression profiling study across a set of patients' samples produces a rectangular matrix of values in which each column represents a patient, each row represents a gene, and each entry in the matrix is the expression level of a gene in a particular patient's tumor. The patients can be clustered to show patterns of similarity and difference in their profiles, and the genes can be clustered to show the similarities and differences in their patterns across the patient samples.

Clustered heat maps (CHMs)

Clustered Heat Maps (CHMs) are the most frequently used graphics for summarizing patterns in bioinformatic data. Hierarchical clustering in *both* horizontal and vertical directions serves to illuminate patterns in the data. CHMs were introduced into bioinformatics in the early 1990s (see¹⁹), and they have since become the ubiquitous graphic for visualizing patterns in omic data. They have appeared in many thousands of publications. The first CHM known to have influenced medical practice (in 1993) is shown in [Figure 4](#). It reflects drug activity correlations in a study of platinum-containing compounds in the NCI-60 anti-cancer cell line screen. It tipped the balance in favor of clinical development of oxaliplatin, now a standard agent for treatment of colorectal cancer.

Figure 4 Drug versus drug clustered heat map for the activity of platinum-containing compounds against the NCI-60 panel of human cancer cell lines. Drugs are listed on both axes in the same clustered order, hence the heat map is symmetrical around the diagonal. Red indicates high correlation of activity profiles, blue indicates low correlation. The data define 12 families (which are highly correlated with the chemical structures of the compounds). Cluster #4 drugs, which consisted entirely of diaminocyclohexyl derivatives, including oxaliplatin, were selectively active against colorectal cell lines. That information tipped the balance for clinical development of oxaliplatin, now a standard agent for treatment of colorectal cancers (due to T Fojo, T Myers, JN Weinstein).

Hypothesis-generating and hypothesis-driven research

Through most of its history, biology was predominantly an observational science. Darwin formulated his hypothesis about natural selection by unbiased observation of the Galapagos finches and other archipelago species, not by experimenting on them. By the middle of the 20th century, however, the dominant research paradigm in biology had shifted to tightly-focused, hypothesis-driven experiments. Taking a lesson from the concept in physics of a critical experiment, *patterns* of experimental result in biology were relegated to the background. In the 1990s, with the maturation of microarrays and other high-throughput molecular technologies, the balance shifted again—toward a synergistic relationship between hypothesis-driven experiments and hypothesis-generating omic research. Announcement in 2000 of the draft human genome sequence solidified that trend, serving as motivation and justification for additional large-scale molecular profiling programs such as The Cancer Genome Atlas (TCGA) and International Cancer Genome Consortium (ICGC) projects. As noted in the introduction, the trend toward

high-throughput omic research was responsible for the emergence of bioinformatics as a prominent player in biomedical science.

The multiple-hypothesis testing trap

This is the most common error in bioinformatic analysis made by those without training in statistics. When mining large molecular or clinical databases for biomarkers, p-values < 0.05 are not hard to find. Consider, for example, a database of 20,000 gene expression values generated by microarray or by RNA sequencing for tumors from 50 patients who responded to a particular drug and 50 who did not respond. If the aim is to discover a gene whose expression in the tumor is positively correlated with response to the drug (therefore a potential predictive biomarker), then $\sim 20,000$ different hypotheses are being tested in parallel, one for each gene. As the p-value (for rejection of the null hypothesis that there is *no* difference) will be less than 0.05 about one in 20 times, even if the data are simply random, there will appear to be about 1,000 potential biomarkers just by chance. More subtle versions of the multiple-hypothesis problem occur, for example, any time multiple statistical algorithms, subsets of genes, or subsets of sample are analyzed. If one tries five different algorithms before finding one that yields a p-value less than 0.05, then the p-value is misleading because it was chosen among the five possibilities. Conceptually the simplest, but overly conservative, remedy is the Bonferroni correction in which the critical p-value (e.g., 0.05) is divided by the number of independent hypotheses to get a corrected critical value. For 20,000 genes, viewed as independent, that would be $p = 0.05/20,000 = 2.5 \times 10^{-6}$ before one would accept the p-value as statistically significant. Most popular for the corrections are algorithms based on false discovery rate (FDR), the fraction of apparently positive results (i.e., apparent rejections of the null hypothesis) that are expected actually to be *false* positives. The statistical nuances are complex, and dozens of different algorithms for the correction have been proposed.²⁰ A popular approach in bioinformatics is the Statistical Analysis of Microarrays (SAM) algorithm, which takes correlation structures in the data into account.²¹

The multiple-hypothesis problem brings into sharp focus the important difference between *hypothesis generation* and *hypothesis testing* in bioinformatics. For the latter, the strict rules of statistical inference must be observed or the results will be incorrect. For example, about 1,000 genes in the above case would spuriously be identified as biomarkers if the investigator were simply mining for genes with uncorrected $p < 0.05$. However, if the investigator started, before looking at the data, with a single-minded focus on one single gene out of the 20,000, then the critical level for that gene would be $p = 0.05$, regardless of how many other genes were present in the dataset.

Hypothesis generation would consist of asking for each gene whether it is a plausible enough candidate biomarker to warrant further study. The FDR provides a metric of that plausibility. One can list the genes in order of their FDR values, from lowest to highest, and keep as candidates all of the genes at the top of the list, extending as far down the list as desired. There is a tendency to select an FDR cutoff of 0.05 by analogy with the usual p-value criterion, but that may be too conservative. How often in biology or medical science do we expect to be correct 19 out of 20 times? As a practical matter, the number of candidates accepted as positive should depend on a balance between the “cost” of independently validating a candidate and the “cost” of missing a *true* positive. If the validation step is a simple assay, one can afford many false positives; if the next step is major surgery, then few if any false positives can be tolerated. The issue of false positives, true positive, and “positive predictive values” is familiar from many areas of public health and clinical practice, for example in the controversies over PSA screening. The issues arise repeatedly throughout bioinformatic analysis. It is, therefore, important that anyone doing a statistical analysis know the question being asked, the reason why it is being asked, and the cost/benefit

ratio of follow-up.

Analysis and biointerpretation in major molecular profiling projects

Large-scale molecular profiling projects have provided important arenas for application of bioinformatics and also rich testbeds for innovation in the field. [Table 3](#) lists some of the more prominent large, publicly sponsored molecular profiling projects. The first waves of large-scale projects have focused on cancer cell lines and bulk samples of primary tumors paired with blood or normal tissue controls. However, additional projects are asking, or will be asking, incisive questions based on microdissection, single-cell sequencing,³⁹ archived formalin-fixed paraffin-embedded samples, pre-treatment/post-treatment pairs, primary tumor/metastasis pairs, comparison of samples from different parts of the same primary tumor, comparison of different metastases from the same patient, primary/recurrent pairs, and samples from responders and non-responders. Those next waves of projects make use of many of the current algorithms and programs for data analysis and interpretation, but they are also motivating the development of novel bioinformatics tools. For example, single-cell sequencing, particularly at the DNA level, imposes a new set of requirements as well as providing a new set of opportunities for incisive analysis. Because recurrent tumors can reflect clones that were minor in the primary but important for choice of therapy, the logistical, fiscal, and ethical barriers to re-biopsy will probably continue to decrease for more and more tumor types and clinical contexts.

Table 3 Some major molecular profiling projects on human cancers, normal tissues, and cell lines

Cultured cancer cells
The NCI-60—A panel of 60 human cell lines used since 1990 by the NCI to screen >100,000 chemical compounds plus large numbers of natural products for anticancer activity. ²² This was the first large public project to link pharmacology to multi-faceted molecular profiling of diverse cancer cells. One byproduct was development of new tools for bioinformatics including the clustered heat map ¹⁹ and other statistical and machine-learning innovations. ²³ The NCI-60 provided a template for the design of CCLE, GDSC, and it informed the design of TCGA (see below). The project is continuing (data at http://discover.nci.nih.gov/cellminer/home.do).
The Cancer Cell Line Encyclopedia (CCLE)—Gene expression, DNA copy number, and sequencing data on 947 diverse human cancer cell lines, with metabolic inhibition assays of 24 anticancer drugs in 479 of the lines. Naïve Bayes and elastic net algorithms were used to predict response profiles on the basis of cell lineage, genetic defects, and gene expression. ²⁴ The project is continuing (http://www.broadinstitute.org/ccle).
The Genomics of Drug Sensitivity in Cancer (GDSC)—Point mutations, indels, microsatellite instability, DNA rearrangements, and gene expression for 639 diverse human cancer cell lines, with metabolic inhibition assays of 130 anticancer gents on 275–507 cell lines per agent. Elastic net regression was used to predict drug sensitivity from the molecular profiles. ²⁵ The project is continuing (http://www.cancerrxgene.org/).
Clinical tumors and tissues
The Human Genome Project—Planning began in 1986, ²⁶ and articles announcing the draft sequence were published in 2001. ^{27, 28} Surprisingly to many investigators at the time, bioinformatic analysis showed that there are only about 23,000 human genes, not the >50,000 expected. The sequence was pronounced 99%

complete in 2004,²⁹ but a major pain for bioinformatics is the necessity of updates in software and databases to keep in sync with continuing refinements of the reference sequence, now in its 38th version (<http://www.cancerrxgene.org/>).

The International HapMap Project—Initiated in 2002 to define common DNA sequence variations among subsets of the human population. Unrelated individuals are ~99.9% identical in sequence, but the remaining sequence and copy number polymorphisms are both useful and a nuisance for bioinformatic analysis³⁰ (<http://hapmap.ncbi.nlm.nih.gov/>).

The Cancer Genome Atlas (TCGA)—Initiated in 2005 for molecular profiling of 10,000 human cancers of 25 types at the genomic, epigenomic, transcriptomic, pathologic, and clinical levels. The first project, published in 2008, was on glioblastoma.³¹ More than 10,000 tumors in all from 33 cancer types have been profiled, more than meeting the initial goals. A “Pan-Cancer” project^{32, 33} summarized similarities and differences among the first 12 tumor types studied. It addressed (1) the commonality of particular functional themes (e.g., driver mutations, aberrant pathways, and drug resistance genes) across multiple tumor types, and (2) the extent to which tumor types can be subdivided into finer and finer categories in ways that may lead to more precise, targeted clinical management. TCGA originally focused on DNA and RNA profiles, but protein studies by reverse-phase protein array (RPPA) and mass spectrometry were later added.^{34, 35} A comprehensive Pan-Cancer analysis covering all 33 TCGA tumor types is scheduled for completion in 2016 (<http://cancergenome.nih.gov/>).

The International Cancer Genome Consortium (ICGC)³⁶—Launched in 2008 for molecular profiling of 50 diverse human cancer types in a manner similar to the profiling in TCGA. The TCGA Research Network and ICGC are collaborating on whole-genome sequencing and analysis of diverse cancers from 2,000 patients (<https://icgc.org/>).

The Adjuvant Lung Cancer Enrichment Marker Identification and Sequencing Trials (ALCHEMIST)—Launched in 2014 by the NCI's National Clinical Trials Network to identify early-stage lung cancer patients with tumors that have genetic changes (EGFR mutations or ALK rearrangements) to evaluate drug treatments targeted against those changes (<http://www.cancer.gov/types/lung/research/alchemist>).

The Exceptional Responders Initiative—Launched by the NCI in 2014 to explore the molecular underpinnings of exceptional responses to treatment. The primary technologies to be used are whole exome- and mRNA sequencing (<http://www.nih.gov/news/health/sep2014/nci-24.htm>).

Genotype-Tissue Expression Project (GTEx)—Initiated in 2006 by the National Human Genome Research Institute to assess the correlation between genotype and expression levels in multiple normal tissues from up to 900 volunteer cadaver-donors—to serve as an aid to genome-wide association studies and as a base of normal background data for studies of cancer and other diseases (<http://www.gtexportal.org/home/>).

1000 Genomes Project—Launched in 2008 as an international effort to establish the most detailed catalogue available on human germline genomic variation³⁷ (<http://www.gtexportal.org/home>).

The Encyclopedia of DNA Elements (ENCODE)—An international consortium launched by the NHGRI as a follow-up to the Human Genome Project. Its ultimate aim was to identify all functional elements in the human genome, particularly those not located in RNA-coding regions.³⁸ (<https://www.encodeproject.org>).

The Therapeutically Applicable Research to Generate Effective Treatments (TARGET)—Multi-institutional molecular profiling of genetic changes (gene expression, DNA copy number, DNA methylation, and microRNA expression) that affect the initiation, progression, and response of pediatric

[Figure 5](#) shows schematically the flows of tissue and information in the most prominent molecular profiling project to date, TCGA. Over 50 Tissue Source Sites provided paired tumor and normal samples (blood and/or tumor-adjacent “normal” tissue) plus information on the pathology and clinical history for 33 tumor types. Analysis of the samples by a panel of pathologists with specialist expertise in the particular tumor type has proved critical. The samples were processed in the Biospecimen Core Resource to produce DNA, RNA, and protein preparations, which were then profiled (principally by microarray or sequencing) in the Genome Sequencing and Genome Characterization Centers. Data generation was completed in 2015, but data analysis and interpretation will be the work of many years. The Data Coordinating Center organized and further quality-controlled the data, then made “non-restricted” datasets publicly available as soon as feasible on the TCGA Data Portal. “Restricted” data—those types that might be sufficient to identify an individual patient—are accessible only to researchers who have gone through a registration and vetting process to ensure confidentiality and appropriate use. Raw DNA and RNA sequences, for example, are restricted because they are considered personally identifiable. Central to analysis and interpretation are the seven designated Genome Data Analysis Centers (GDACs), which have matured as a TCGA community of shared, progressively more sophisticated bioinformatic expertise.

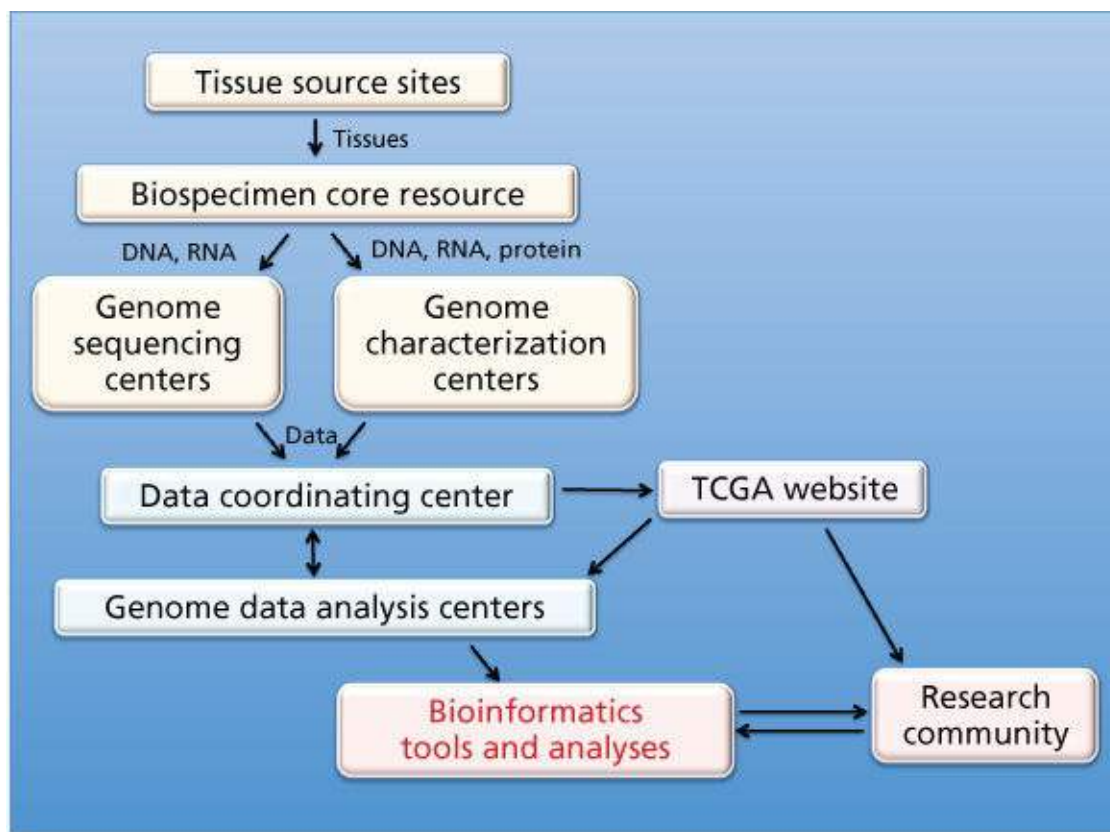

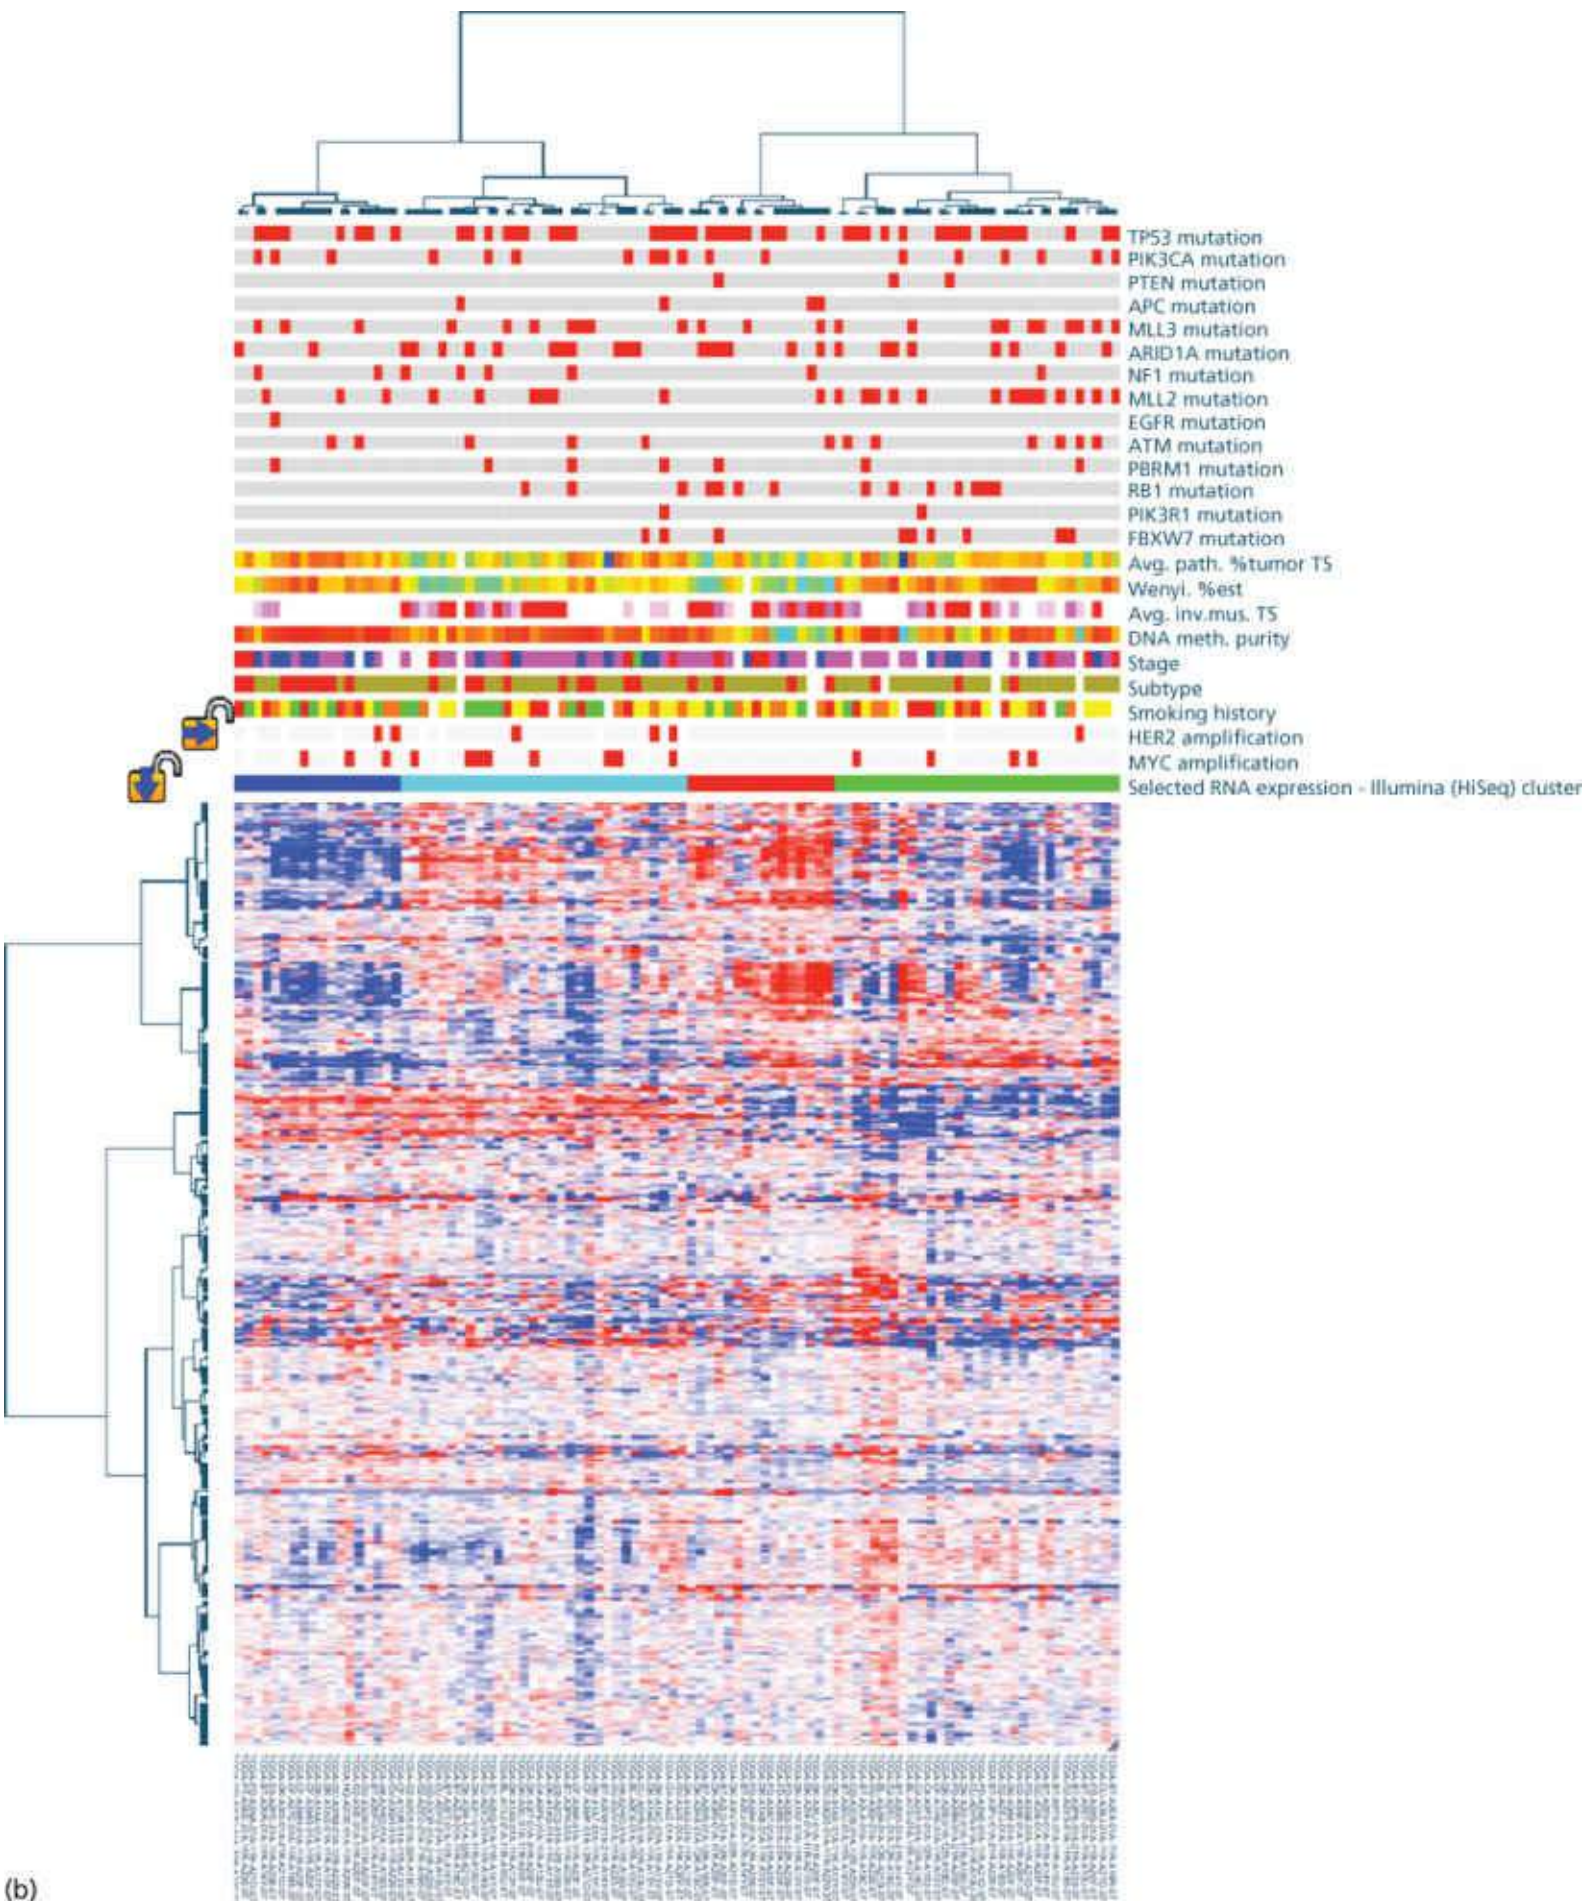

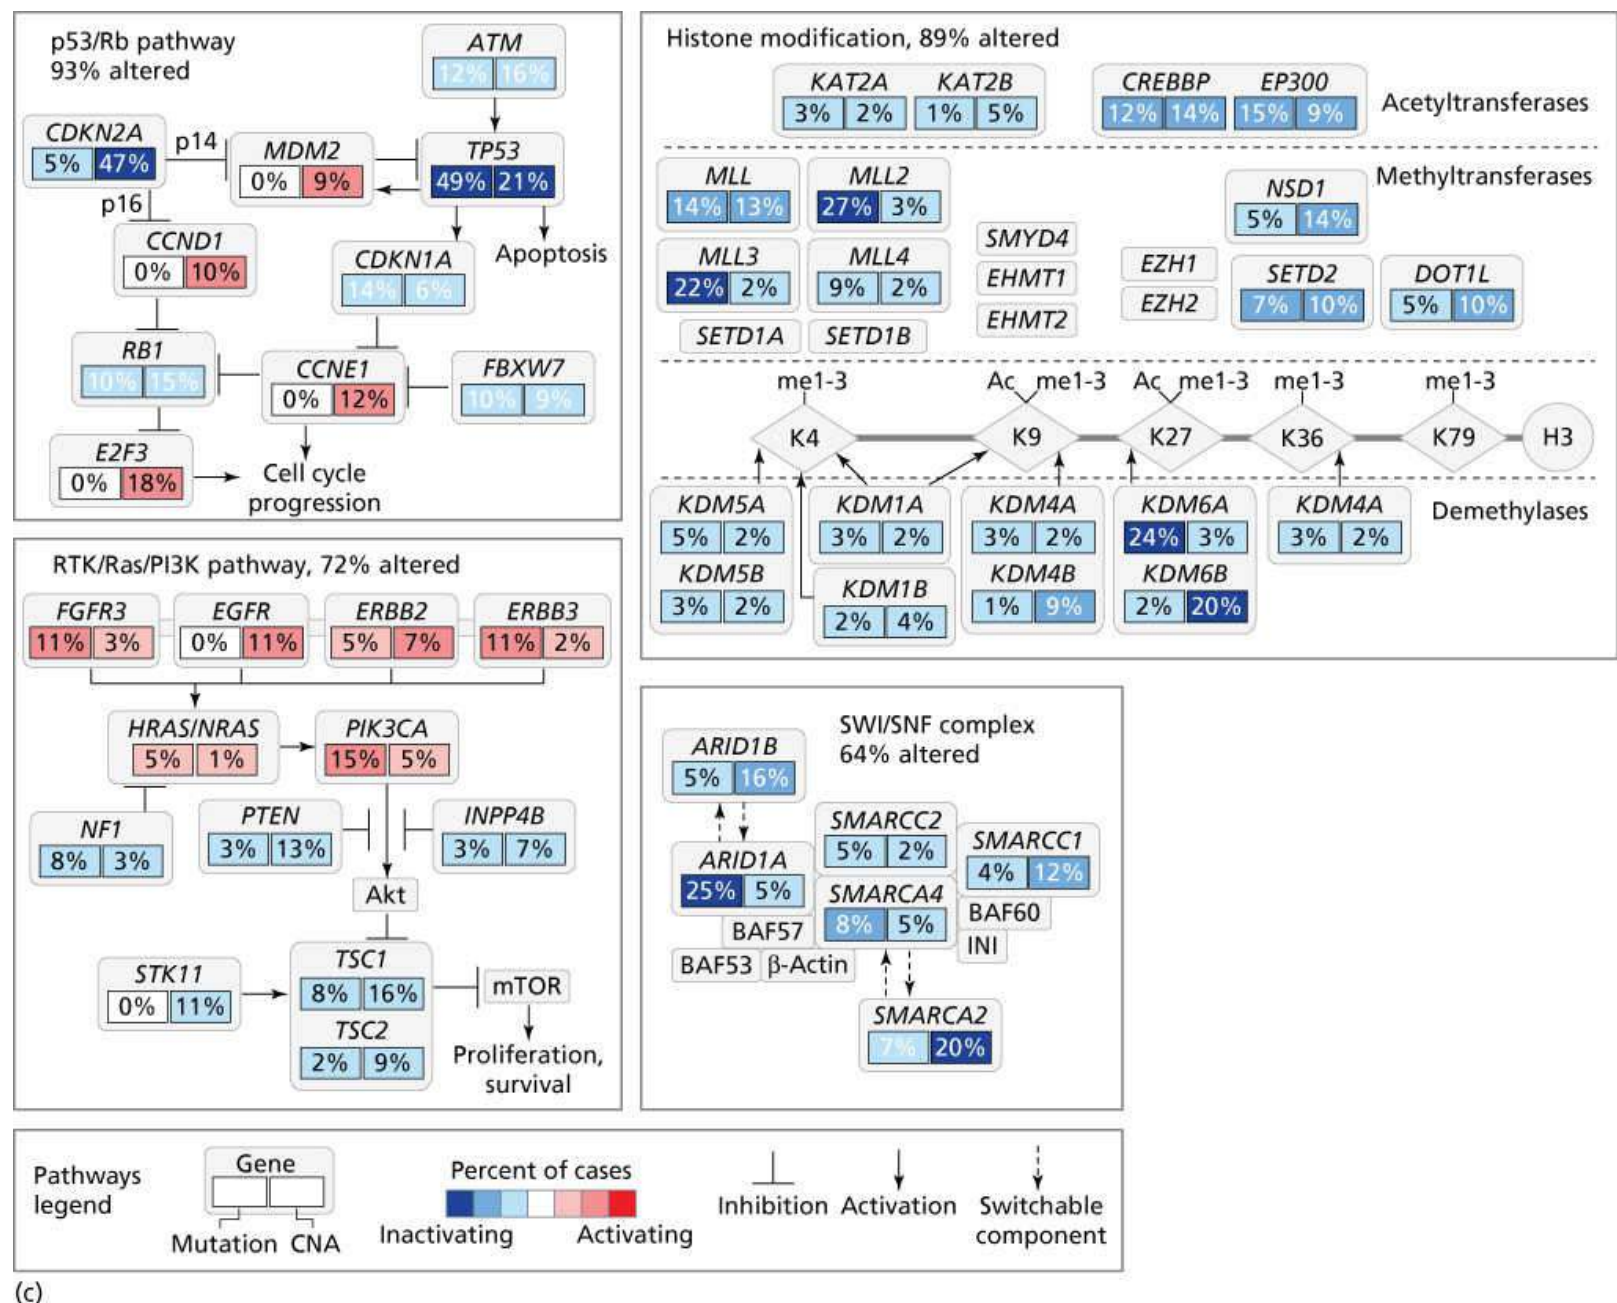

Figure 5 Simplified generic view of the flow of samples and information in The Cancer Genome Atlas program. Tumor plus normal blood and/or “normal tumor-adjacent tissue” specimens were collected with consent by tissue source sites and handled according to defined protocols for submission to the project. The Biospecimen Core Resource vetted the specimens and accompanying clinical data, generated DNA, RNA, and protein samples, quality-controlled the samples, and sent them to the Genome Sequencing and Genome Characterization Centers. Those Centers profiled the samples by sequencing, microarray analysis, or other technologies and sent the data to the Data Coordinating Center. As soon as feasible, non-restricted forms of the data were made public on TCGA's website for use by the research community, including TCGA's Genome Data Analysis Centers. Omitted here for simplicity are many additional components of the information flow such as the Broad Institute's Firehose, which performs and presents large numbers of analyses on the data; Sage Bionetics' Synapse, which provides an environment and tools that facilitate wide collaborative use of the data; Memorial Sloan-Kettering's cBio, which presents the data in a form accessible to nonspecialists; and MD Anderson's compendia of clustered heat maps for pattern recognition in the DNA, RNA, and protein datasets. Also not shown are the expert reviews of clinical data and pathology.

A major spin-off of TCGA has been the coalescence of a large bioinformatics community around the disease-specific and Pan-Cancer Analysis Working Groups (PCAWGs). Each Analysis Working Group (AWG) represents a self-assembled aggregate of the multidisciplinary expertise required for data analysis and biological/medical interpretation. At the center are the GDACs, but many other individuals and institutions join in. Because everyone in an AWG is drilling down into the same datasets and data types, the result is a powerfully creative environment for development of new, innovative tools for analysis, visualization, and interpretation. [Figure 6](#) is based on TCGA's multifaceted Urothelial Bladder Cancer profiling. [Figure 6a](#) shows a compact graphical visualization of the DNA-sequencing data, [Figure 6b](#) shows an interactive “next-generation” CHM for the RNA expression levels, and [Figure 6c](#) shows a particular representation of key pathways.

(c)

Figure 6 Data visualizations in TCGA's Urothelial Bladder Cancer Project. Source: The Cancer Genome Atlas Research Network 2014.⁴⁰ Tumor specimens from 131 patients were included in the analyses. **Panel A:** A compact visualization of mutation profiles across the bladder cancer specimens for genes scored by the MutSig 1.5 algorithm as significantly mutated (due to J. Kim, A. Cherniack, G. Getz, D. Kwiatkowski). **Panel B:** An interactive Next-Generation Clustered Heat Map representation of the mRNA expression data. Genes are on the vertical axis; patient specimens are on the horizontal axis (due to B. Broom, R. Akbani, D. Kane, M. Ryan, C. Wakefield, J. Weinstein). **Panel C:** Representation of four pathways found to be altered at the DNA level in urothelial bladder cancer. Somatic mutations and copy number alterations (CNAs) were found in the p53/Rb pathway, RTK/RAS/PI(3)K pathway, histone modification system, and SWI/SNF complex. Red, activating genetic alterations; blue, inactivating genetic alterations. Percentages shown denote activation or inactivation of at least one allele (due to C. Creighton, D. Kwiatkowski, L Donehower, P Laird).

TCGA was originally designed as a series of disease-focused projects, but similarities and differences in profile across tumor types, as identified by the PCAWGs, have proved extraordinarily valuable. [Figure 7](#) represents the Pan-Cancer project schematically as a 3D matrix of results.

Figure 7 Representation of the Pan-Cancer TCGA project as a 3-dimensional matrix in which the axes are tumor type, data type, and gene or locus. Source: The Cancer Genome Atlas Research Network 2013.³²

Statistical methods and associated pitfalls

Table 4 is a list, by no means comprehensive, of statistical and machine-learning algorithms commonly used in bioinformatics. The descriptions in the table are intended to give the reader a general sense of how the algorithm can be used in bioinformatics, rather than to be rigorous or complete for the statistically trained. In this section, two of the most common will be considered in somewhat more detail with the principal aim of pointing out limitations and frequent errors in their use or interpretation in bioinformatics. Even the simplest univariate statistics can frequently be misused or misleading. The descriptions here, as in **Table 4**, will focus on issues that should be considered by biologists and clinical researchers, ignoring many of the complexities that a biostatistician would want to consider.

Table 4 A sample of statistical algorithms commonly used in bioinformatics

Univariate analysis
t-test (unpaired): A statistical examination of two sample means. A two-sample t-test examines whether two samples are different and is commonly used when the variances of two normal distributions are unknown and when an experiment uses a small sample size.
t-test (paired): A version of the t-test in which samples are paired (e.g., with tumor specimens before

and after treatment)
Permutation t-test: A version of the t-test applicable without assuming normal distribution (but assuming that the distributions of the two samples are the same). Almost all “parametric” statistical tests (i.e., ones in which the reference distributions are obtained from a theoretical probability distribution, e.g. normal distribution) have non-parametric equivalents in which the p-value is obtained by permuting the samples in an appropriate way.
Wilcoxon signed-rank test: Non-parametric equivalent of the paired t-test (based on ranks so normality not necessary)
Wilcoxon rank-sum (Mann–Whitney) test: Non-parametric equivalent of the unpaired t-test (based on ranks so normality not necessary).
<i>Multivariate analysis</i>
Analysis of variance (ANOVA): Various forms of ANOVA extend the t-test to situations in which multiple variables are involved and normal distribution is assumed (e.g., multiple characteristics of more than two types of tumor specimens are being compared).
Multivariate analysis of variance (MANOVA): Like ANOVA but taking into account the interactions (dependencies) among variables.
Cross-validation: Useful in predicting an outcome (e.g., survival) on the basis of expression of one or more genes in a set of samples. A predictive model is trained on, say 90%, of the patients and then tested on the other 10%. Different sets of 10% are then left out iteratively in order to pile up statistics on the model's success on patient samples it has not “seen” during the particular round of training and testing. However, if the model is “tweaked” in any way to optimize it on the basis of the cross-validation, it must then be validated against a separate set of samples to avoid overly optimistic conclusions about the algorithm. For most purposes, the model must be validated using an independent dataset anyway.
Bootstrap: Finds statistical confidence limits for a calculated statistic (e.g., a Pearson or Spearman correlation coefficient between two patients' tumors based on similarities and differences in their expression patterns across N genes). To proceed, we select <i>with replacement</i> a random sample of size N from the set of genes to produce a “pseudo-sample” of N values, then calculate the Pearson correlation coefficient for that sample. We do that many times, say 10,000 times, to build a histogram of estimates of the Pearson correlation coefficient and pick 95% confidence limits on the basis of that histogram. Because the sampling is done with replacement, any given gene may appear in a given sample 0, 1, 2, 3, or more times (according to the Poisson distribution with a mean of 1).
ROC (Receiver-Operator Characteristic): A plot of sensitivity versus 1-specificity that indicates the performance of a binary classifier (for example expression of a particular gene as a predictor of recurrence) as the discrimination threshold of expression is varied from low to high. The area under the ROC curve is directly related to the (non-parametric) Wilcoxon rank sum test.
Hierarchical cluster analysis: The clustering brings similar profiles (e.g., across tumor specimens or across genes) together in a tree-like structure to illuminate patterns of similarity and difference among them. Clustering (supervised or unsupervised) is often used to define subcategories of tumor types.
Fisher's exact test: A permutation test for the independence of variables in a contingency table. For example, if each patient in a clinical trial is labeled as a responder or non-responder to a treatment and labeled as wild-type or mutant with respect to a particular gene, the results of the study can be expressed in a 2×2 contingency table. Fisher's exact test (one- or two-tailed) gives a p-value for the null hypothesis that the gene's status has no effect on response. The word “exact” indicates that the p-value is

accurate for even very small sample sizes. The test can be extended to larger (i.e., $m \times n$) contingency tables.

Bayesian methods: Statistical methods that assign probabilities or distributions to (a posteriori) outcomes or parameters based on a priori experience or best guesses specified before the data are analyzed. Bayes' theorem is then applied to revise the a posteriori probabilities. Bayesian methods differ in concept from the more common “frequentist” ones. An example is a multi-arm, biomarker-driven clinical trial in which accumulating experience is used to reassess the likelihood that a particular biomarker predicts response—and then using that information to put more patients on the arm with the most promising biomarker-predicted therapy.

Student's t-test

Student's t-test was not so named because it is geared to the needs of neophyte trainees. Rather, it was introduced in 1908 by a brewery chemist/academic who published it under the pen name “Student” because company policy forbade publication. The t-test is used in cancer bioinformatics, for example, to assess whether the mean expression of a gene in blood or tumor differs between treated and untreated patients. If treated and untreated samples are from the same patient, the paired t-test (which has more statistical power) can be invoked. Every bench biologist is intimately familiar with the t-test, but two limitations deserve note because they are ignored with regularity:

- The t-test statistic (paired or unpaired) can always be calculated for sets of specimens, but, if the sample size is not large, a correct p-value can be calculated only if both sets of sample values are approximately normally distributed. An extension of the original Student's t-test permits the standard deviations of the two groups to be different, but the distributions must still be normal for calculation of a correct p-value. The problem is that data encountered in bioinformatics are rarely normally distributed, so t-test p-values are often misleading. Microarray data, for example, are generally log-transformed before analysis in a vain attempt to make their data distributions more nearly normal. The usual result, however, is that noisy low-expression data points are given *too much* weight in the subsequent analysis, often seriously distorting the results obtained. The only satisfactory procedure is to filter out the low-noisy, low-amplitude data. But exactly how to do that without throwing out too much of the data or introducing bias can be an extremely complex challenge.
- The p-value can also be misleading if the samples are not independent of each other in the necessary sense. A common mistake is to consider technical replicates (say, triplicates in an assay) as independent. If, for example, an assay measures a gene's expression before and after treatment in triplicate samples from 10 patients, the number of actual samples in each group will be 30. However, if the variation in expression among *patients* is much greater than the variation among *replicates* from the same patient (and that will usually be the case), there will actually be only 10 independent values for treated patients and 10 for untreated. The statistical power of the t-test is dependent on N, the number of samples. Hence, if $N = 30$ is inserted into the standard formula, the p-value calculated will be too optimistic; the null hypothesis that the treatment had no effect may be rejected spuriously.

Wilcoxon rank-sum test and Wilcoxon signed-rank test

The Wilcoxon rank-sum test and Wilcoxon signed-rank test are the non-parametric equivalents of the t-test and paired t-test, respectively. That is, they perform analogous functions but based on rank-ordering of the data points, not the actual numerical distributions. Hence, they are not dependent on the assumption of normal distribution. However, they do generally assume independence, so they are subject to the same

issue as noted above for t-tests with replicates. They have somewhat less statistical power than the equivalent t-test when the samples are indeed normal, but they are less sensitive to outliers and other types of non-normality. They are less likely to be misleading. But there are prices to be paid for the choice. Imagine that the expression levels for a gene in one set of specimens range from 1 to 2 units, and those for the same gene in the other set of specimens differs dramatically from those of the first set, ranging from 101 to 102 units. The non-parametric tests will give the same answers as if the second set's values ranged from 2.1 to 2.2 units, i.e., differing only slightly from those of the first set. Only the ranks count, so very large differences have no more influence than relatively small ones. Hence, the t-statistic may provide a metric more reflective of the reality, even if the associated p-value is unreliable. It is always advisable to consider the *actual* values and differences in addition to p-values or quantities related to the p-values; *statistical* significance does not imply *biological* significance.

The *t*-test and its nonparametric and permutation-based equivalents are among the simplest statistical tests one can encounter in bioinformatics. They are much simpler in principle and in practice than the multivariate and machine-learning analyses. Nonetheless, the foregoing examples indicate the gross mistakes that can be made in using them and the advisability of professional expertise for the statistical analysis of most data in bioinformatics.

Chapter 19

Systems biology and genomics

Saima Hassan, MD, PhD, FRCSC ■ Laura M. Heiser, PhD ■ Joe W. Gray, Ph.D.

Overview

Cancers are complex, adaptive systems comprised of cancer cells, the proximal and distal cells, and soluble and insoluble proteins that influence the behavior of the cancer cells. Features pertaining to the cancer are referred to as intrinsic to the cancer and those comprising the proximal and distal microenvironments are referred to as extrinsic to the cancer. Genomics studies seek to develop comprehensive cellular and molecular profiles of cancers and cancer systems biology studies seek to develop the experimental and theoretical methods needed to understand how the components work together to determine cancer function. The overall goal of these efforts is to develop the ability to predict the behavior of cancers—including progression and response to therapy—from measurements of the intrinsic and extrinsic molecular and cellular components of the cancers. Here, we review recent progress in international efforts to measure the genomic, epigenomic, and proteomic features (aka omic features) of major tumor types. We summarize work on establishing associations between omic features and cancer behavior. Finally, we summarize the computational and experimental models that are currently being used to understand and manipulate the behavior of complex cancer systems.

Introduction

Studies of the behavior of biological systems have traditionally been reductionist, focusing on specific genes or pathways. Today, efforts to generate molecular profiles of cancers are well established, momentum is building to establish associations between features and biomedical behavior, and efforts to establish mechanistic theoretical models are beginning. Systems biology approaches to cancer include studies of the intrinsic molecular features of cancer cells, as well as studies of how signals from the extrinsic microenvironment influence cancer cell signaling and phenotypic response ([Figure 1](#)).

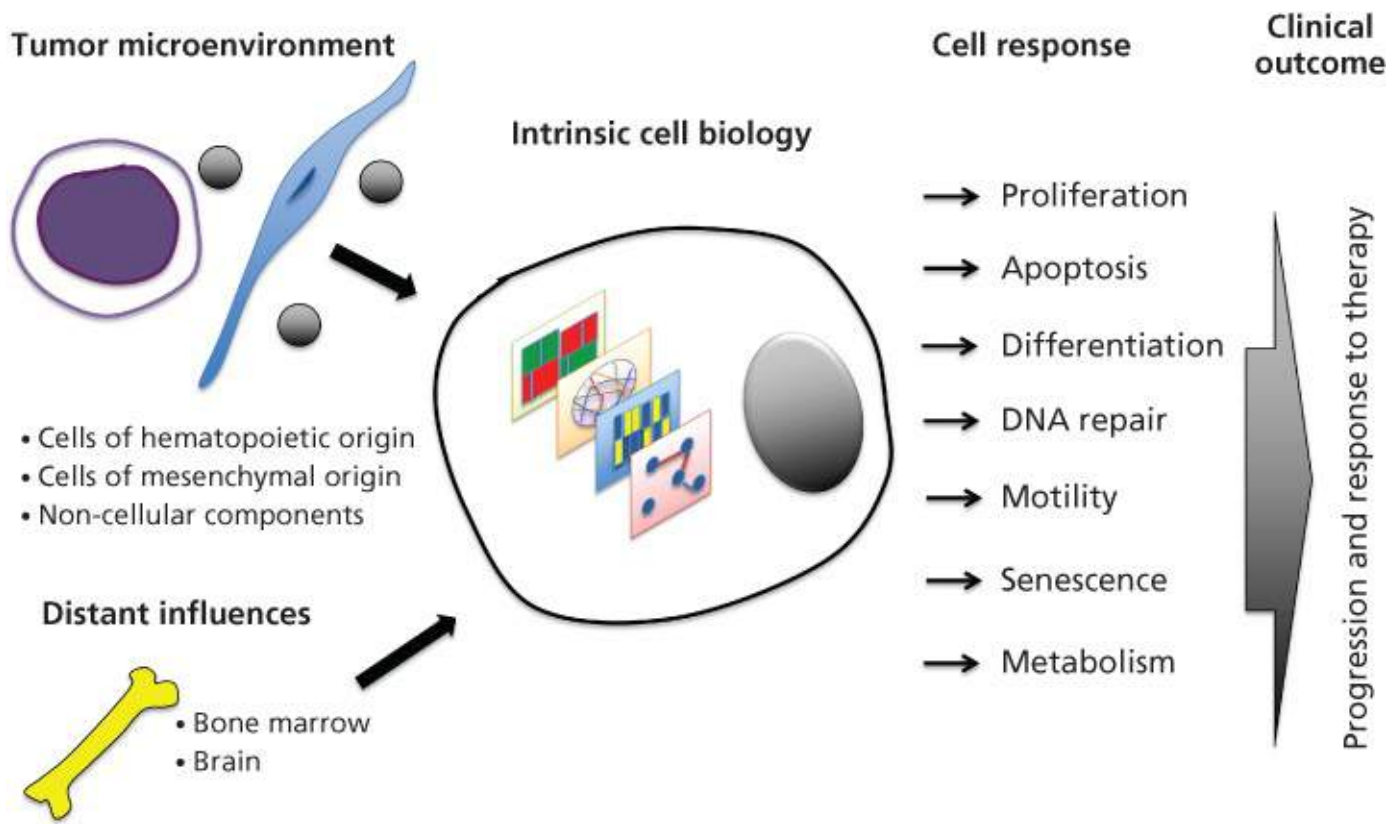

Figure 1 A schematic illustration of the influence of extrinsic and intrinsic systems biology upon cellular function with the potential to identify progression and response to therapy in patients. The extrinsic systems biology component consists of the tumor microenvironment including cells of hematopoietic origin, mesenchymal origin, and noncellular components, in addition to distant influences, from the bone marrow and other multiple organs. Together, with a systems biology approach, cellular function can be studied using various endpoints, including cellular proliferation, apoptosis, differentiation, DNA repair, motility, senescence, and metabolism. Our laboratory is striving to combine these endpoints to better understand tumor progression and response to therapy in the laboratory, and how this may correlate to patients in the clinic.

Intrinsic cancer systems biology, the study of malignant cells that comprise the tumor mass, has evolved with advancements in genomic and epigenomic profiling technologies. These technologies produce comprehensive measurements of the genomic aberrations, and transcriptional and proteomic levels that comprise individual tumors. Several recent studies have identified recurrent events that define cancer subsets, have led to a better understanding of cancer heterogeneity, have identified prognostic subgroups and predictors of response to therapy, and have facilitated discovery of novel therapeutic targets.^{1, 2}

Extrinsic systems biology focuses on understanding external signals that alter the behavior of tumor cells. Extrinsic signals may come from microenvironments in close proximity to the tumor cells (e.g., invading immune cells, cancer-associated fibroblasts (CAFs), and vascular endothelial cells)³ as well as from distal organs, especially the brain.^{4, 5} Several recent observations point to the clinical importance of the tumor microenvironment (TME): stromal components can predict outcome,⁶ the TME can mediate therapeutic response and resistance,⁷ and the immune microenvironment has been shown to mediate tumorigenesis, disease progression,⁸ and therapeutic response.^{9–11}

Together, intrinsic and extrinsic systems biology approaches strive to enable an all-encompassing understanding of the cancer cell and its interactions with its environments. This chapter will discuss both intrinsic and extrinsic systems biology. The intrinsic systems biology section will focus on the clinical impact of high-throughput genomics and the use of cancer cell lines as predictive models of therapeutic

response in patients. The extrinsic systems biology section will discuss its different constituents, the clinical significance, and how the microenvironment can be incorporated into preclinical models.

Key Points

Potential of omics

- TCGA studies have used patient samples to identify new tumor classifications that have prognostic significance and novel therapeutic targets
- Panels of cancer cell lines have been used to identify gene signatures that are predictive of therapeutic response and present in patient samples
- Data analytical tools are being developed and validated in order to integrate different “omic” data types

Intrinsic systems biology and genomics in cancer

Since the mapping of the human genome, numerous technological advancements have enabled the “omics” era in which high-throughput profiling efforts provide comprehensive assessment of changes in DNA, RNA, and protein level in tumors and associated stroma that occur during cancer genesis, progression and response to therapy.¹² Much work today is aimed at developing strategies to use these data to improve the clinical management of cancer. The bottleneck now lies in data processing and interpretation.¹³ Removing the bottleneck will require novel bioinformatic approaches that can effectively identify actionable molecular events and druggable therapeutic targets. Although the robustness of platforms and validation of gene signatures are some of the major concerns regarding their clinical utility,^{14, 15} there are multiple pragmatic issues that must be addressed to better integrate genomic platforms into the clinic. For example, next-generation tumor banks now require greater infrastructure with a larger team of health-care providers that acquire and manage relevant tissue and associated clinical metadata.¹⁶ Tissues for study include surgical specimens, tissue biopsies, and blood samples, each requiring different standard operating protocols and sample preparation techniques.¹⁶ Nonetheless, several institutions have been using genomic platforms to guide clinical trials or in clinical contexts, particularly for diseases where there is little evidence supporting current management practices such as tumors of unknown origin.^{12, 17, 18}

This section is divided into three parts: (1) Genomic analyses of patient samples to provide a better understanding of cancer biology and help fuel future clinical trials. (2) Preclinical models to select cancer subtypes that will better respond to therapy. (3) Bioinformatics approaches to integrate the different genomic platforms.

High-throughput genomics

High-resolution genome analysis techniques are being used in international cancer genome analysis efforts to catalog aberrations driving the pathophysiology of nearly all major cancer types. Together, The Cancer Genome Atlas¹⁹ (TCGA, <http://cancergenome.nih.gov/>) project and the International Cancer Genome Consortium^{20, 21} (ICGC, <http://www.icgc.org/>) have assessed aberrations in over 12,000 samples in 55 separate tumor lineages.²² The broad goal of these efforts is to improve the prevention, diagnosis, and

treatment of cancer patients.¹⁹ In these projects, patient samples have been profiled on multiple platforms that examined whole-genomes and whole-exomes,^{23–26} mRNA, DNA methylation,²⁷ miRNA,^{28, 29} and protein and phosphoprotein levels.³⁰ Results for several cancers are already publically available^{25, 31–33} and several recent papers have described integrative analyses of the characteristics of a dozen human cancer types.^{34–36} Genome aberrations³⁷ found to be important in human cancers include (1) somatic changes in DNA copy number that increase or decrease the levels of important coding and noncoding RNA transcripts; (2) somatic mutations that alter gene expression, protein structure, and protein stability and/or change the way transcripts are spliced, (3) structural changes that change transcript levels by altering gene-promoter associations or create new fusion genes,^{38, 39} and (4) epigenomic modifications that alter gene expression.^{40, 41}

Analysis of these rich datasets has yielded clinically relevant insights into how we may better treat different cancers. For example, urothelial bladder cancers were found to be enriched in mutations in chromatin-regulatory genes, suggesting the potential use of therapeutic agents that target chromatin modifications.²³ Half of the high-grade serous ovarian cancers analyzed were found to be defective in homologous recombination, increasing their likelihood to be more susceptible to poly (ADP-ribose) polymerase (PARP) inhibitors.²⁵ Classification systems are now emerging that stratify tumors into biologically distinct subtypes and are demonstrating greater prognostic and predictive significance in comparison to the commonly used histologic classifications. Illustrative classification systems are now emerging for cancers of the breast,^{42, 43} colon,⁴⁴ pancreas,⁴⁵ ovary,²⁵ lung,⁴⁶ and gastric cancer.²⁴ The METABRIC cohort is a particularly well-developed cohort comprised of nearly 2000 breast tumors that were profiled to assess changes in copy number and gene expression.⁴⁹ Analysis of the copy number profiles identified 10 breast cancer subpopulations, each with a unique spectrum of alterations and disease-specific survival rate.

Our understanding of the molecular landscape of breast cancer is particularly advanced. A key observation from the TCGA breast cancer study³³ is that there are a few common mutations that occur in >5% of tumors (e.g., TP53, PIK3CA, CDH1, MLL3, GATA3, and MED12) and hundreds more that occur in <1% of breast cancers. The genomic aberrations in an individual tumor are comprised of a mix of “driver” and “passenger” aberrations. Driver aberrations are selected during tumor progression because they enable one or more aspects of the cancer pathophysiology that allow initiation, progression, and determination of cancer behavior, including response to therapy.⁴⁸ Passenger aberrations do not contribute to cancer pathophysiology but arise by chance during progression in a genomically unstable tumor.

Recent analyses of glioblastoma have illustrated the strong interplay between the genome and treatment. The initial TCGA studies^{31, 50} demonstrated a link between MGMT promoter methylation and a hypermutator phenotype consequent to mismatch repair deficiency in temozolomide-treated glioblastomas. Johnson et al.⁵¹ performed exome sequencing for initial and recurrent low-grade gliomas. Of 10 tumors treated with adjuvant temozolomide, 6 were hypermutated when they recurred and carried driver mutations involving the AKT-mTOR pathways. This suggests a role for therapeutic agents that target the AKT-mTOR pathways in patients with recurrent low-grade gliomas previously treated with temozolomide. In many cases, the genome landscapes of the recurrent tumors were dramatically different than those of the primary tumor, illustrating the need for longitudinal following of patients during treatment.

A pan-cancer approach was launched in 2012 to analyze genomic aberrations among the panel of TCGA cancers³⁶ with the goal of identifying genomic features common to multiple cancer types. Initial studies have focused on 13 cancers.^{52, 53} Integrative analysis of genomic and proteomic platforms identified novel

cancer subtypes that were associated with survival.³⁴ Interestingly, the pan-cancer approach to proteomic profiling revealed an elevated expression of HER2 in several cancers, including endometrial cancer, bladder cancer, and lung adenocarcinoma.³⁰ Because endometrial cancer has a higher expression of HER2 in comparison to breast cancer, this suggests that anti-HER2 agents, such as T-DM1, may be effective in treating endometrial cancer.³⁰ The pan-cancer approach lends itself to basket-style clinical trials, which are guided by specific molecular aberrations across different tumor types, as opposed to the traditional clinical trial designs that use large populations based on histologic classifications.⁵⁴

Organization of these large-scale data for convenient visual and computational analyss is critical to enable community-wide. Useful tools for this are now emerging, and several of the most popular are listed in [Table 1](#).

Gene signatures—prognostic and predictive biomarkers of response

Tissue histology and locally invasive properties are still commonly used as surrogate markers for distant metastatic spread and indicators of outcome. However, in the last decade, conventional classification strategies have been supplemented by omic-based strategies. These efforts began in 1999 with the demonstration that gene expression analysis could be used to distinguish between acute myeloid leukemia and acute lymphoblastic leukemia.⁵⁵ This was quickly followed by an analysis of gene expression in breast cancer that identified intrinsic breast cancer subtypes, designated as hormone receptor-positive luminal A and luminal B, HER2-enriched, basal-like, and normal-like.⁵⁶ The classification of these subtypes was validated in several independent cohorts and was found to have strong prognostic significance.⁵⁶

Several efforts are now underway to use this information to develop clinically validated prognostic signatures. In breast cancer, for example, van't Veer et al.⁵⁷ identified a 70-gene signature that could predict recurrence in a select group of younger patients with early breast cancers. This signature, now marketed by Agendia BV as MammaPrint, was validated in independent cohorts and outperformed Adjuvant! Online software in clinicopathologic risk assessment.^{58, 59} Although smaller retrospective studies have demonstrated the use of MammaPrint as a prognostic marker,^{59, 60} no prospective data is yet available that demonstrates its benefit in the adjuvant setting. Another test, marketed by Genomic Health as OncotypeDx, was developed in 2004 using an RT-PCR assay on RNA extracted from formalin-fixed paraffin-embedded tumor blocks. This 21-gene assay was tested retrospectively in two clinical trials, and was found to have prognostic significance. It is now widely used in the clinic to inform patients with estrogenreceptor-positive and early breast cancer of their risk of distant recurrence and potential benefit

from chemotherapy.^{61, 62} Several competing prognostic and predictive gene expression signatures have been published^{63, 64} including a 17-gene signature for estrogen receptor-positive, node-negative breast cancer,⁶⁵ a 50-gene PAM50 risk of recurrence signature,⁶⁶ and a 44-gene Rotterdam signature.⁶⁷

Not surprisingly, cancer subtype signatures are being developed for a growing number of other cancers. In colon cancer, for example, three unique gene signatures have been identified: Oncotype Dx colon cancer assay (Genomic Health, Inc.), ColoPrint (Agendia), and ColDx (Almac).⁷¹ Although these tests have been shown to be independent prognostic biomarkers, their predictive value is still unknown.⁷² In a positive move, academic efforts are now underway to reconcile diverse colorectal cancer classification schemes-based gene expression signatures.⁴⁴ For example, gene expression analysis identified basal-like and luminal subtypes associated with overall and disease-specific survival.⁷³ A pancreatic cancer classifier has been reported that identified three subtypes of pancreatic ductal adenocarcinoma that demonstrated a differential prognosis response to therapy.⁴⁵ Importantly, an ongoing community-wide classification effort is now underway that is attempting to integrate genomic and proteomic profiles to identify subtypes that transcend tumor origin. A recent report from this group defined a unified classification of tumors into 11 major subtypes.³⁴ This approach will become more powerful as additional tumor types are added to the analysis.

Experimental models of patient tumors for pharmacogenomics studies

Identification of molecular features that are causally related to clinical outcomes such as cancer progression or response to therapy requires experimental models in which cells carrying aberrant genes and networks can be manipulated. Collections of cell lines derived from patient tumors are widely used as laboratory models of cancer.⁷⁴ Cell lines are an attractive model system for studying cell-intrinsic biology for several reasons, including that they are: (1) a renewable resource; (2) can be manipulated in the laboratory setting; (3) are amenable to genomic profiling; and (4) can be used to assess therapeutic responses can be quickly assessed.^{74, 75} Although the first tumor-derived cell lines were established in the 1950s, their use as an experimental tool gained traction with the development of the National Cancer Institute 60 (NCI60) platform.^{76, 77} The NCI60 consists of 60 human tumor cell lines, representing nine cancer types, and has been used to screen over 100,000 compounds for therapeutic efficacy.⁷⁸ Analysis of these data with the COMPARE algorithm has provided a quantitative method for identifying associations between molecular features of cells and sensitivity to particular compounds.⁷⁸

Since the demonstration of the utility of the NCI60, several other groups have developed panels of cancer cell lines, including pan-cancer^{79–81} and tissue-specific collections (e.g., breast,⁸² lung,^{83, 84} and melanoma⁸⁵). One of the most well-developed panels, comprised of ~70 breast cancer cell lines, has been used to assess gene function and to identify mechanisms of therapeutic response and resistance.^{82, 86, 87} Recently, very large cell line collections representing multiple tumor types have been used to identify associations between molecular features and response to molecular perturbants across tumor types.^{80, 81, 88} Comparison of the genomic and epigenomic features of cell lines with those measured from primary tumors showed that the cell lines mirror many aspects of "omic" diversity in primary tumors that are likely to influence therapeutic response. Cell line and tumor similarities include: (1) recurrent copy number changes and mutations,^{82, 86, 89} (2) transcriptional subtypes,^{86, 89} and (3) pathway activity.⁸⁶ However, there are significant exceptions. For example, cell lines grown on plastic have been reported to change epigenomic status⁹⁰ and some cell lines fail to retain genomic aberrations that were present in the tumors from which they were derived. Glioblastoma is a notable example of the latter, as cells grown on plastic usually fail to retain a region of amplification involving the EGFR oncogene that is frequently

present in primary tumors.⁹¹

In breast cancer, analysis of correlations between drug sensitivity and molecular features revealed that approximately 30% of the compounds tested are associated with subtype or genome copy number aberration,⁸⁶ and robust integrated predictive signatures of sensitivity can be identified for ~50% of compounds.^{86, 87} Importantly, many of the *in vitro* signatures can be observed in primary patient samples^{80, 81, 87} suggesting that cell line studies may be used to guide the development of signatures that can be used to stratify patients in the clinic. Evidence from other tissue types also supports the notion that cell lines are a powerful system for studying the molecular underpinnings of therapeutic response. For example, *in vitro* model systems accurately recapitulated several clinical observations, including that (1) lung cancers with EGFR mutations respond to gefitinib,⁹² (2) breast cancers with HER2/ERBB2 amplification respond to trastuzumab and/or lapatinib,^{82, 93} and (3) tumors with mutated or amplified BCR-ABL respond to imatinib mesylate.⁹⁴ Of course, cell lines grown on plastic do not model many aspects of human cancers. A particular weakness is that they do not model the impact of the microenvironment on cancer cell behavior. Models that include signals from the microenvironment as covered later in this chapter.

Principles of integrative analysis

Several computational tools have been developed to identify molecular signatures associated with biological behavior. One of the first of these is gene set enrichment analysis (GSEA).⁹⁵ The rationale behind GSEA is to analyze the expression of predefined groups of genes that share a common biological function, chromosomal location, or regulation, to determine whether they show wholesale differences in gene expression between comparator populations. For example, GSEA analysis identified the RAS, NGF, and IGF1 pathways as differentially expressed in TP53 mutant versus TP53 wild-type cancers.⁹⁵

The network analysis tool PARADIGM⁹⁶ was designed to identify pathways whose activities differ between comparator populations. PARADIGM integrates multiple omic data types, including DNA copy number and gene expression, to calculate integrated pathway levels (IPLs) for over 1300 curated signal transduction, transcriptional, and metabolic pathways from publicly available databases (e.g., the NCI Pathway Interaction Database KEGG, Reactome, and BioCarta). These IPLs can then be used to identify subnetworks that differ between comparator populations (e.g., responsive versus resistant tumors). The subnetworks are composed of interlinked *pathway features* (genes, proteins, complexes, families, processes, etc.) that take on activities distinctive in one class of tumors compared to another. For example, PARADIGM analysis of TCGA breast cancer samples identified HIF1- α /ARNT pathway activity as high in basal-like breast cancers, suggesting that these malignancies might be susceptible to angiogenesis inhibitors and/or bioreductive drugs that become activated under hypoxic conditions.³³

One problem with tools that incorporate pathway information is that some genes and networks have been more extensively studied than others, and so there is inherent bias in the resultant pathways. HotNet2 is an algorithm to find aberrant networks using a strategy that tries to avoid curation bias. HotNet2 uses a modified diffusion process and considers the source, or directionality, of heat flow in the identification of subnetworks that reduces the impact of curation bias. This tool was applied in recent pan-cancer network analyses to identify 16 frequently mutated networks that affect well-known cancer phenotypes.⁹⁷

Crowd sourcing to rapidly advance systems biology

Advances in profiling technologies and subsequent generation of large, complex datasets require robust analytical methods to facilitate the conversion of “big data to knowledge” (<http://bd2k.nih.gov/>). This

effort is still in its infancy; many competing methods are being developed so it is difficult to determine which perform best. One novel approach to identify effective algorithms is using crowd-sourced community-wide challenges. The DREAM project (<http://dreamchallenges.org>) is one example of the power of this approach. DREAM brings communities of researchers together to address complex problems in systems biology, while also developing methods for identifying the most effective novel algorithms. A key aspect of these challenges is to eliminate the “self-assessment trap” in which data generation, data analysis, and model validation are combined within the same study.⁹⁸ Moreover, the advancements that arise through these collaborative efforts come at a much more rapid pace than can be achieved through traditional single-team research approaches.

Two recent DREAM challenges demonstrate the power of this crowd-sourcing approach. In the NCI-DREAM7 challenge, unpublished drug sensitivity measurements along with transcriptional and proteomic profiles for a panel of breast cancer cell lines were made freely available to the scientific community.⁹⁹ Over 40 international groups developed predictors of drug response using a broad range of machine learning and statistical algorithms. A meta-analysis of all methods demonstrated that modeling nonlinear relationships and incorporating existing knowledge are essential features for generating robust predictive biomarkers. Another DREAM challenge sought to assess the ability of computational strategies to predict breast cancer survival from clinical features, gene expression, and copy number profiles in breast cancer.¹⁰⁰ This challenge used data from the METABRIC breast cancer cohort,⁴⁹ and in multiple rounds of blinded evaluations, assessed the performance of more than 1400 models. It showed that the best-performing modeling strategy significantly outperformed a benchmark first-generation 70-gene risk predictor.⁵⁸ Interestingly, this study also demonstrated the “wisdom of the crowd” as the aggregation of the predictions from all the models performed as well or better than the best model. These results demonstrate the power of crowd sourcing to advance algorithm development and identify clinically relevant biomarkers.

Key Points

The tumor microenvironment (TME)

- The TME is comprised of multiple cellular and noncellular components
- The TME composition influences cancer progression and patient outcome
- The TME is implicated in therapeutic response and resistance
- Preclinical modeling of TME is challenging but now amenable to high-throughput platforms
- Patient-derived xenografts can predict response to therapy and can potentially be used alongside clinical trials

Tumor microenvironment

Constituents of the tumor microenvironment

There are different ways of categorizing the TME,⁷ and one approach divides the TME into three main groups: cells of hematopoietic origin, cells of mesenchymal origin, and noncellular components.¹⁰¹ Cells

of hematopoietic origin populate two cell lymphoid and myeloid lineages. The lymphoid cell lineage consists of T cells, B cells, and natural killer cells, whereas the myeloid cell lineage consists of macrophages, neutrophils, and myeloid-derived suppressor cells. Cells of mesenchymal origin include fibroblasts, myofibroblasts, mesenchymal stem cells, adipocytes, and endothelial cells. The two major components of this group are CAFs and endothelial cells. CAFs are fibroblasts that have been co-opted by the tumor to promote tumor growth, angiogenesis, and distant metastasis.^{102, 103} Endothelial cells and pericytes have also been shown to play an important role in vessel growth formation needed for tumor progression.¹⁰⁴ The most important player of the noncellular group is the extracellular matrix (ECM). The ECM can be further subdivided in two parts: the basement membrane, which consists of type IV collagen, laminin, and fibronectin, and the interstitial matrix, which is made up of fibrillar collagens, proteoglycans, and glycoproteins. The ECM has been shown to play roles in maintaining tissue architecture, cell invasion, tumor progression, and angiogenesis.¹⁰⁵

Tumor microenvironment and the hallmarks of cancer

Hanahan and Weinberg¹⁰⁶ defined six essential capabilities, termed the hallmarks of cancer, that are essential for tumor growth. These include (1) evading apoptosis, (2) self-sufficiency in growth signals, (3) insensitivity to anti-growth signals, (4) tissue invasion and metastasis, (5) limitless replicative potential, and (6) sustained angiogenesis. Eleven years later, an update of these six hallmarks was published, with recognition of the TME as an important player in tumor growth, and the addition of two hallmarks: reprogramming of energy metabolism and evading immune destruction. However, categorizing the cancer hallmarks into two distinct categories of origin—tumor cell and TME—is an artificial classification, as the majority of the cancer hallmarks (7/8) are in fact a product of the cross-talk between stromal and cancer cells.¹⁰⁷

Role of tumor microenvironment in modulating therapeutic response and predicting recurrence and survival

The TME can serve as a mediator of either response or resistance to therapeutic agents. One classic example is that of vessel normalization, wherein tumor vasculature can be manipulated to improve delivery of chemotherapy.^{7, 108} Vasculature associated with tumors is abnormal and consists of immature vessels with increased permeability as well as compromised ability to deliver nutrients and therapeutics. The administration of anti-angiogenic therapy leads to pruning of immature vessels, resulting in a “normalized vasculature” that allows for more effective delivery of chemotherapy agents.¹⁰⁸ Furthermore, the TME may serve as a predictive biomarker of localized and long-term response to therapy. For example, melanoma has a distinct type of metastasis called in-transit disease, wherein patients develop locoregional metastases in the skin and subcutaneous tissues more than 2 cm from the primary lesion but not beyond the regional nodal basin. One of the treatments for this type of disease is intralesional injection of interleukin (IL)-2, which can be administered in the office. One of our co-authors (SH) studied the immune response at the site of disease, from tissue biopsies 6–8 weeks post-treatment and found that patients who developed a pathologic complete response to treatment demonstrated an increased peritumoral infiltrate of CD8+ T cells and an improved overall survival. This is suggestive, along with other studies, that a localized response in the TME can be an important factor in mediating a systemic response, which in turn can impact overall survival.^{109, 110}

Resistance to therapy can either be an innate process, mediated by intrinsic properties of the TME, or an acquired process, which is an adaptive host response to therapeutic intervention.^{7, 111} Several mechanisms

have been proposed to explain intrinsic resistance to therapy, including survival signals from protective niches in the TME, impaired drug delivery from vascular impairments and leakage, paracrine signaling with secretion of chemokines from stromal cells, and immunosuppression.^{7, 112} Immune responses are important factors in mediating acquired therapeutic resistance. Resistance to paclitaxel has been shown to result in part by enhanced expression of IL-34, colony-stimulating factor (CSF)-1, and macrophage infiltration.¹¹³ Indeed, a monoclonal antibody has been identified, RG7155 (Roche), which targets macrophages and CSF-1 receptor activation, and has demonstrated response in patients with diffuse-type giant-cell tumors.¹¹⁴ Other mechanisms that have been implicated in acquired resistance include the induction of senescence-associated secretory phenotype and changes in cell differentiation.⁷

Studies of the TME have yielded predictive markers of local recurrence in mouse models and prognostic markers in patients. An inflammatory signature has been identified, which was associated with recurrence of clinically detectable disease but not advanced recurrent disease. This inflammatory signature was characterized by an increase in serum concentrations of IL-6 and vascular endothelial growth factor (VEGF). The progression of minimal residual disease to a recurrence occurred through an evasion of the immune response by the cancer cells.^{115, 116} Park et al. established the importance of the TME as a prognostic marker in breast cancer.⁶ They used laser capture microdissection to isolate stromal cells from the primary tumor of patients. A gene signature derived from the stroma was found to be a strong prognostic marker of overall survival and relapse-free survival. Immune cells were an important component of this gene signature, with the good-outcome patients demonstrating an enrichment of T-cell and NK-cell markers, suggesting a T_H1-type immune response. The prognostic significance of the amount of stroma within the primary tumor, termed tumor-stroma ratio has also been demonstrated in colon cancer and breast cancer.¹¹⁷ Furthermore, the prognostic value of immune cells has since been demonstrated in breast cancer and colon cancer.^{118–121} A stromal lymphocytic infiltrate was found to be an independent prognostic marker associated for overall survival in two randomized controlled trials with triple negative breast cancer patients.¹²⁰ In colon cancer, a score that measures the presence of certain lymphocyte populations, termed Immunoscore, was shown to be a stronger prognostic marker than current AJCC (American Joint Committee on Cancer) prognostic markers, including T stage (tumor depth) and N stage (nodal involvement).¹²² Interestingly, the Immunoscore may have great potential in patients with localized colorectal cancer with no detectable spread or lymph node involvement on pathology of imaging, of which 25% of such patients go on to develop recurrence.¹²³ In two independent cohorts, Immunoscore was able to identify a group of patients that were at higher risk of developing recurrence and may have otherwise benefited from adjuvant therapy.^{123, 124} Given the prognostic significance of stromal gene signatures, it is important to consider the composition and extent of the stroma in tumor samples when tumor-derived gene signatures are being generated.¹²⁵

Modeling the tumor microenvironment

The majority of pharmacologic agents targeting aspects of the microenvironment suggested by laboratory studies have not been successful in clinical trials.^{126, 127} This may be due to intrinsic tumor factors or limitations associated with preclinical models. A common criticism about preclinical models is that cancer cell lines alone do not encompass the complexity inherent to heterotypic signaling associated with cancer cells and their microenvironment. [Table 2](#) summarizes a few of the chemosensitivity models that have been proposed to better model the complex interactions between the tumor and its microenvironment.

Table 2 Summary of advantages and disadvantages of several pre-clinical chemosensitivity models

Model	Advantages	Disadvantages
Cell lines	<ul style="list-style-type: none"> • Unlimited source of self-replicating material • Easy to use • Amenable to high-throughput screening 	<ul style="list-style-type: none"> • Generated from more aggressive tumors • Do not model the complex paracrine and endocrine influences upon tumor growth
2-Dimensional	<ul style="list-style-type: none"> • Easy to use • Amenable to high-throughput screening 	<ul style="list-style-type: none"> • Differences in cell morphology, polarity, receptor expression, oncogene expression, between 2D monolayers and <i>in vivo</i>¹²⁸
3-Dimensional	<ul style="list-style-type: none"> • 3D spheroids may better model the hypoxic core and drug diffusion found in solid tumors • Differential response to therapy in comparison to 2D models 	<ul style="list-style-type: none"> • May be variability in cell size and shape • May require more specialized equipment and cost • More labor-intensive • If using matrigel, need to take into account lot-to-lot variability¹²⁹
Microenvironment microarray	<ul style="list-style-type: none"> • Amenable to high-throughput screening • Influence of different microenvironment proteins upon therapeutic response and resistance 	<ul style="list-style-type: none"> • Difficult to model tumor heterogeneity • Statistical analytical approaches are being developed¹³⁰ • Validation still required¹³⁰
Mouse models	<ul style="list-style-type: none"> • Can be used to test therapeutic response upon primary tumor growth and distant metastasis • Both transgenic mice and xenografts can be used to observe response alongside clinical trials^{131, 132} 	<ul style="list-style-type: none"> • Difficult to use on a larger scale to test multiple therapeutic compounds
Xenografts	<ul style="list-style-type: none"> • Easier to use, as cancer cell lines can either be easily injected or transplanted 	<ul style="list-style-type: none"> • Use immunodeficient mice and cancer cell lines that often represent more aggressive tumors
Transgenic	<ul style="list-style-type: none"> • Can better model human tumor progression¹³³ 	<ul style="list-style-type: none"> • Difficult to use in the preclinical setting as the age of mice need to be synchronized in order to administer treatment to similar sized-tumors

Patient-derived xenografts	<ul style="list-style-type: none"> • Renewable tissue resource^{134, 135} • Similar genomic properties as in patient tumors¹³¹ • Therapeutic response in PDX models is similar to clinical outcome achieved in patients¹³¹ 	<ul style="list-style-type: none"> • Requires set-up to acquire patient samples and to grow tumors in mice • Requires immunodeficient mice¹³¹ • Engraftment failure can be high and time to treatment long in some tumor types¹³¹
----------------------------	---	--

Two-dimensional (2D) models in which cancer cells are grown as monolayers on plastic are commonly used to assess therapeutic response.¹²⁸ These 2D models have been instrumental in driving the development of many therapeutic agents that are currently used in the clinic. Several approaches have been developed to add microenvironmental signaling. One approach employs 2D co-cultures in which cancer cell lines are grown together with stromal cells. Co-culture models have identified changes in tumor genotype, phenotype, and response to therapy that result from interaction with microenvironmental signals.^{136, 137} Alternately, cells can be grown on substrates comprised of soluble and insoluble proteins from the diverse microenvironments to which cancer cells are known to spread. This can be accomplished efficiently by arranging microarrays comprised of thousands of individual array elements carrying one or more microenvironment proteins. These are referred to hereafter as microenvironmental microarrays (MEArrays). MEArrays are produced by printing combinations of ECM, growth factors, and other proteins onto substrata as ~200 μm diameter spots that support cell adhesion and growth. Live cells are then added and grown to assess the impact on growth of the proteins.^{130, 138} Cells grown on MEArray can also be treated with therapeutic compounds to assess the impact of the microenvironmental proteins on therapeutic response. Typically, cells that are grown are immunofluorescently stained using an affinity reagent that report on cancer-related phenotypes (e.g., proliferation, apoptosis, differentiation status, and senescence) of interest and then quantified using high-content imaging^{130, 139} ([Figure 2](#)).

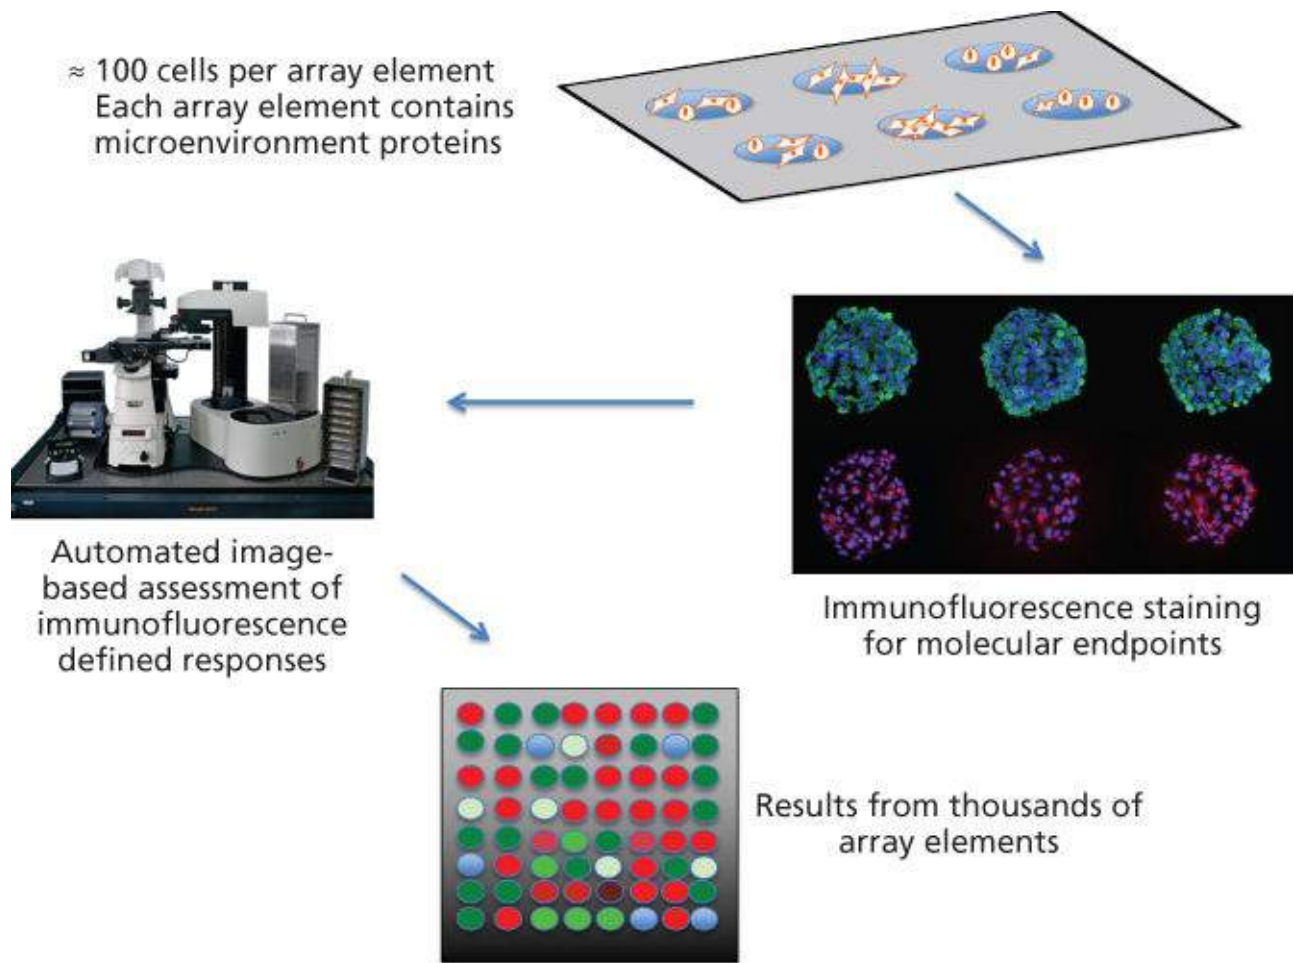

Figure 2 Schematic illustration of the use of microenvironment microarrays to assess the impact of diverse microenvironments on cancer cell growth. Several thousand microenvironmental proteins printed as ~250 micrometer diameter spots host the growth of cancer cells. Changes in immunofluorescence staining pattern induced by the microenvironmental proteins are recorded using fluorescence image analysis.

Three-dimensional (3D) culture methods establish cells in 3D environments comprised of extracellular proteins and sometimes other cell types.^{7, 128, 140} Matrix components such as matrices (e.g., matrigel) or scaffolds (e.g., collagen, laminin, and alginate) can be added to 3D models in order to better model tissue architecture. Isolated from mouse sarcoma cells, matrigel is a basement membrane-derived hydrogel that has been commonly used in cancer models and shown to support tumor growth and angiogenesis.^{141, 142} However, one of the challenges in the use of matrigel is its relatively undefined molecular composition and high lot-to-lot variability therein.¹²⁹ Microfluidic systems, consisting of 3 connected wells, an inlet reservoir, a cell culture chamber, and an outlet reservoir, have been developed for 2D and 3D models, in addition to high-throughput platforms.¹²⁸ 3D co-culture models have also been developed. One such promising model has demonstrated the formation of larger sized breast tumors within 24 h.¹⁴³ The fidelity with which co-culture models mirror *in vivo* microenvironments is increasing as 3D cell-printing techniques^{144, 145} are used to arrange multiple cell types into laboratory cancer “tissues”.

The importance of the TME has also been well established from mouse models. In xenograft mouse models, cancer cell lines are injected into immunocompromised mice. Metastasis develops infrequently when cell lines are injected subcutaneously ectopic sites. With a favorable microenvironment, tumors grown in orthotopic models tend to grow faster than their ectopic counterparts and have a greater propensity to metastasize.¹⁴⁶ Although xenograft models are useful tools to study tumor growth and metastasis inhibition, they are limited by the immunocompromised status of the host mice and the use of

cell lines that are derived from more aggressive tumors.¹³¹ Efficacy of therapeutic agents in xenograft models has not been shown to correlate well with efficacy in clinical trials.¹⁴⁷ As a result, there has been an effort to develop genetically engineered or transgenic mice as more realistic models. The advantage of this model is that the mice are immunocompetent and tumors progress from preinvasive, invasive, and distant metastasis, in a manner akin to human tumor progression.¹³³ Some transgenic mouse models develop tumors with short latency and have been used as chemosensitivity models.^{127, 132, 148} However, these models are difficult to use on a large scale, owing to the need to synchronize the generation of pups, onset of tumors, and subsequent administration of therapy.¹⁴⁸

More recently, patient-derived xenograft (PDX) models are being used to study therapeutic efficacy. PDXs are established from patient biopsies engrafted into immunocompromised mice.¹³¹ The rate of engraftment is variable ranging from as low as 13%¹⁴⁹ to as high as 71%.¹⁵⁰ PDX models enable transplantability of human tissue from mouse to mouse and are thus a renewable tissue resource.¹³⁴ Whole-genome sequencing has revealed high similarity between PDX tumors and human tumors in terms of copy number and structural variations. PDXs have been used as a model to better understand clonal evolution in the growth of breast cancers.¹⁵¹ PDXs are currently being used to assess chemosensitivity for breast cancer, lung cancer, melanoma, and pancreatic cancer.^{131, 152} Preliminary studies, albeit with a small number of patients, have identified a good correlation with therapeutic response in PDX models and clinical outcome.^{150, 152} Therefore, PDX models are gradually being integrated into the later stages of preclinical development for therapeutic agents. The PDX models are also being considered in co-clinical trials, in which therapeutic agents are tested patients in a clinical trial alongside in mice in order to better understand how best to strategize against therapeutic resistance.¹³¹

Conclusion

The long-term goal of cancer systems biology is to develop the experimental and theoretical methods needed to understand and manipulate the behavior of the complex and adaptive cancers with which we are confronted. This will require that we be able to measure the molecular composition, cellular organization, and anatomic locations of these cancers and that we develop the theoretical framework needed to predict the behavior of cancer cells including the effect of the proximal and distal environmental signals that influence their behavior. International cancer genome efforts are now providing increasingly detailed information about the molecular components of cancers, imaging strategies are emerging that allow assessment of the multiscale organization of cancerous tissues, and increasingly accurate biological models are being developed that enable identification of molecular features that are causally related to cancer cell behavior. It now remains to develop cancer analytics that can be used to predict the behavior of complex adaptive systems so that this information can be used to more accurately predict cancer behavior and to devise more durable treatment strategies.

Summary

Cancer genomics and systems biology studies seek to describe molecular and cellular features that are intrinsic and extrinsic to cancer cells and to interpret the resulting data in ways that allow prediction of the behavior of individual cancers. These studies guide several aspects of precision medicine including prediction of cancer behavior, identification of optimal therapeutic targets, and development of strategies for durable control of individual cancers. International omic analysis

efforts are now yielding comprehensive omic profiles of hundreds to thousands of tumors of most major cancer types and the data are generally available to the scientific community. Computational scientists are making good progress in establishing associations between cancer omic profiles and cancer behavior—especially aspects of cancer progression and response to therapy. Systems biologists are now developing experimental and theoretical strategies to understand and predict the behavior of the complex systems. These studies focus both on the behavior of the cancer cells themselves and the influence of distal and proximal environments on the behavior of the cancer cells. This chapter highlights work in all of these areas and provides illustrative examples of recent progress in each.

Acknowledgments

We would like to thank our funding organizations: for SH, the Canadian Breast Cancer Foundation, the Young Investigator Award of the Conquer Cancer Foundation of ASCO, endowed by the Breast Cancer Research Foundation and Evelyn H. Lauder family, Banting Postdoctoral Fellowship from CIHR, and support from the Ontario Institute for Cancer Research through funding by the Government of Ontario. JG and LH received support from the Susan G. Komen Breast Cancer Foundation, NIH/NCI U54 CA112970 and the Knight Cancer Institute.

Chapter 20

Statistical innovations in cancer research

J. Jack Lee, PhD, MS, DDS ■ Donald A. Berry, PhD

Overview

Cancer research is rapidly changing, with fast-growing numbers of possible cancer targets and cancer drugs to investigate and no end in sight. Advances in genomics, proteomics, and epigenetics provide remarkably detailed profiles of each patient's tumor and, as a result, allow science to consider each patient as unique, with the goal of delivering precision medicine to each patient. The low success rates of late-phase clinical oncology trials and high costs of bringing new drugs to market, however, have necessitated changes in the drug-development process. Statistical innovations can help in the design and conduct of clinical trials to facilitate the discovery and validation of biomarkers and streamline the clinical trial process. The application of Bayesian statistics provides a sound theoretical foundation that can encourage the development of adaptive designs to improve trial flexibility and efficiency while maintaining desirable statistical-operating characteristics.

The principal goals of the innovations presented in this chapter are to (1) use information from clinical trials more efficiently in drawing conclusions about treatment effects, (2) use patient resources more efficiently while treating patients who participate in clinical trials as effectively as possible, and (3) identify better drugs and therapeutic strategies more rapidly, moving them more quickly through the development process. The underlying premise is to exploit all available evidence, placing information gleaned from an ongoing clinical trial into the context of what is already known. The innovations considered are intuitively appealing. However, some are controversial. Some are being used in actual clinical trials while others are still being developed and evaluated for such use.

This chapter addresses two types of innovations. One is a natural extension of the traditional practice of frequentist statistics. The other type is based on a Bayesian statistical philosophy. The Bayesian approach is tailored to real-time learning (as data accrue), and the frequentist approach is tied to particular experiments and to the experiment's design. However, there is substantial overlap between these complementary approaches.

The main topics covered in this chapter include the following. The introduction of basic probability theory and Bayesian approach is explained through examples. Differences between frequentist and Bayesian methods are compared and contrasted. The development of adaptive designs by applying outcome adaptive randomization, predictive probability, interim and extraim analyses, and factorial design is discussed. In addition, hierarchical modeling can be utilized to synthesize information available from the trial as well as external to the trial. Seamless phase I/II and II/III designs can be applied to shorten the drug-development period. Platform designs can be constructed to evaluate many drugs simultaneously. The application of these statistical innovations is illustrated in the BATTLE trials and I-SPY 2 trial. Finally, information on computing resources for the design and implementation of innovative trials is given.

Cancer research (and medical research, in general) is rapidly changing; the number of possible cancer targets and cancer drugs to investigate is growing, with no end in sight. Advances in genomics, proteomics, and epigenetics provide remarkably detailed profiles for each patient's tumor and, as a result, allow science to consider each patient as unique. Modern computing has supported these advances, allowing statisticians to simulate trials with complicated designs and to evaluate design properties such as statistical power and false-positive rate. The basic requirement is that the design be specified prospectively.

The low success rates of late-phase clinical oncology trials^{1–3} and high costs of bringing new drugs to market⁴ have necessitated changes in the drug-development process. Recognizing the need to modernize, the FDA issued its *Critical Path Opportunities Report* in March 2006, identifying biomarker development and streamlining clinical trials as essential changes to be made in this process.⁵ Further guidance was then issued by centers within the FDA: The Center for Devices and Radiological Health (CDRH) published initial guidelines for using Bayesian statistics in medical device clinical trials in 2006 and final guidelines in 2010.⁶ The Center for Biologics Evaluation and Research (CBER) and the Center for Drug Evaluation and Research (CDER) issued a joint guidance document for planning and implementing adaptive designs in clinical trials.⁷ In addition, CDRH released a draft guidance on adaptive designs for medical device clinical studies in 2015.⁸

The principal goals of the innovations presented in this chapter are to (1) use information from clinical trials more efficiently in drawing conclusions about treatment effects, (2) use patient resources more efficiently while treating patients who participate in clinical trials as effectively as possible, and (3) identify better drugs and therapeutic strategies more rapidly, moving them more quickly through the development process. The underlying premise is to exploit all available evidence, placing information gleaned from an ongoing clinical trial into the context of what is already known. The innovations considered are intuitively appealing. However, some are controversial. Some are being used in actual clinical trials while others are still being developed and evaluated for such use.

This chapter addresses two types of innovations. One is a natural extension of the traditional practice of frequentist statistics. The other type is based on a Bayesian statistical philosophy. Readers who are familiar with Bayesian ideas may wish to skip some Bayesian sections. The Bayesian approach is tailored to real-time learning (as data accrue), and the frequentist approach is tied to particular experiments and to the experiment's design. However, there is substantial overlap between these complementary approaches. Much of this chapter's development of clinical trial design employs the Bayesian approach as a tool for finding designs that tend to treat patients in the clinical trial more effectively and that identify better drugs more rapidly. However, the frequentist properties (such as false-positive rate and power) of the design thus derived can always be found, often requiring simulation. Ensuring that a design has prespecified frequentist properties means that the Bayesian approach can be used to design trials with good frequentist properties.

Preliminaries

The basis of all experimentation is comparison. Evaluating an experimental therapy in a clinical trial requires information about the outcomes of the patients had they received some other therapy. The best way to address this issue is to randomize patients to the experimental therapy and to some comparison therapy. Although there are ways to learn without randomizing, there are limitations to approaches that do not employ randomization. Moreover, randomization does not require equal assignment probabilities to the therapeutic strategies, or “arms,” being compared. Unbalanced randomization is possible, either with

fixed ratios or adaptive ratios, that is, such that assignment probabilities depend on data accumulating in the trial. (The latter possibility is the principal focus of this chapter.)

Most clinical trials are conducted in accord with a protocol, which aims to evaluate the treatment effect as a whole.⁹ Protocols may refer to retrospective or sporadic collection of data, but they are usually prospective. Clinical trials are always prospective. A prospective protocol describes how the trial is to be conducted, including how patients will be assigned to a therapy and when the trial will end. Deviations from a protocol may make scientific inferences from the trial difficult or impossible (although they may be necessary at times to avoid exposing participants to unnecessary risks). Valid inference can only be made based on sound statistical theory in properly conducted trials.

Bayesian approach

This section shows how Bayesian learning takes place and how the Bayesian approach relates to the more traditional frequentist approach. It is necessarily superficial. Further reading includes a comprehensive but elementary introduction to Bayesian ideas and methods,¹⁰ discussions of their role in medical research,¹¹ and of clinical trials in particular,^{12–15} and books describing more advanced Bayesian methods.^{16, 17}

Bayesian updating

The defining characteristic of any statistical approach is how it deals with uncertainty. In the Bayesian approach, uncertainty is measured by probability. Any event whose occurrence is unknown has a probability. The frequentist approach uses probabilities as well, but in a more restricted manner, as described hereafter. Examples of probabilities in the Bayesian approach that do not have frequentist counterparts include the following: The probability that the drug is effective, the probability that patient Smith will respond to a particular chemotherapy, and the probability that the future results in the trial will show a statistically significant benefit for a particular therapy.

The Bayesian paradigm is one of learning. As information becomes available, one updates one's knowledge about the unknown aspects of the process that is producing the information. The fundamental tool for learning under uncertainty is Bayes' rule. Bayes' rule relates inverse probabilities. An example that will be familiar to many readers is finding the positive predictive value (PPV) of a diagnostic test: In view of a positive test result, what is the probability that the individual being tested has the disease in question? It can be considered as the “inverse probability” of a positive test given the presence of the disease, which is called the test's sensitivity. PPV also depends on the test's specificity, which is the probability of a negative test, given that the individual does not have the disease. Moreover, PPV depends on the prevalence of the disease in the population. In applying Bayes' rule to statistical inference, the analog of PPV is the “posterior probability” that a hypothesis is true, given the experimental results. The analog of disease prevalence is the “prior probability” that the hypothesis is true.

Consider an overly simplified numerical example, one with only two possible response rates (r): $r = 0.75$ and $r = 0.50$. If you are accustomed to thinking about PPV for diagnostic tests, consider one of these to be that the “patient has the disease” and the other to be that the “patient does not have the disease.” The question is this: Is r equal to 0.75 or 0.50? Before any experimentation, these two possibilities are regarded to be equally likely: $P(r = 0.75) = P(r = 0.50) = 1/2$.

The focus of the Bayesian approach is learning. Probabilities are calculated as new information becomes available, and is taken to be “given.” Statisticians have a notation that facilitates thinking about and

calculating probabilities as new information accrues. They use vertical bars to separate the unknown event of interest from known quantities (or taken to be given): $P(A|B)$ is read “probability of A given B .” Assign R for tumor response and N for nonresponse. Using this notation, for example, $P(R|r = 0.75) = 0.75$. More interesting is the probability of $r = 0.75$, given a tumor response: $P(r = 0.75|R)$. These two expressions are reciprocally inverse, with the roles of the event of interest and the event being assumed. Bayes' rule connects the relationship between these two expressions, namely that the updated (posterior) probability of $r = 0.75$ is as follows:

$$P(r = 0.75|R) = P(R|r = 0.75)P(r = 0.75)/P(R)$$

The denominator on the right-hand side of the equation follows from the law of total probability:

$$\begin{aligned} P(R) &= P(R|r = 0.75)P(r = 0.75) + P(R|r = 0.50)P(r = 0.50) \\ &= (0.75)(1/2) + (0.5)(1/2) = 5/8 \end{aligned}$$

That is, $P(R)$ is the average of the two response rates under consideration, 0.75 and 0.50, where the average is with respect to the corresponding prior probabilities—half each in this example. Substituting the numerical values into Bayes' rule, the posterior probability of $r = 0.75$ is as follows:

$$P(r = 0.75|R) = (0.75)(1/2)/(5/8) = 3/5$$

Therefore, the new evidence boosts the probability of $r = 0.75$ from 1/2 (or 50%) to 60%. As the total probability is 100%, the evidence in a single response lowers the probability of $r = 0.50$ from 50% to 40%.

Consider a second independent observation. The probability of r before this second observation is the posterior probability of the first observation. If the second observation is also a response, then a second application of Bayes' rule applies to give $P(r = 0.75|R, R) = 9/13 = 69\%$, which is a further increase from the previous values of 50% and 60%. On one hand, if the second observation is a nonresponse, then $P(r = 0.75|R, N) = 3/7 = 43\%$, a decrease from 60%. This process can go on indefinitely, updating either after each observation or all at once on the basis of whatever evidence is available. The current probabilities of the various possible values of response rate r can be found at any time. These probabilities depend on the original prior probability and on the intervening observed data. This process of updating and real-time learning is an important advantage of the Bayesian approach to designing and conducting clinical trials.

The example mentioned previously considered only two possible values of r . More realistically, the response rate r may be any number between 0 and 1. The left-hand panel in [Figure 1a](#) shows a constant or flat curve that is a candidate for prior distribution. The flat curve indicates that the probability is spread equally over this range of values of r . This might be termed an “open-minded prior distribution” because the posterior distribution depends almost entirely on the evidence from the experiment at hand. After a single-tumor response, Bayesian updating serves to change the probability distribution to the one shown in the right-hand panel of [Figure 1a](#)—that is, the right-hand panel is the posterior distribution after observing R when the prior distribution is the one shown in the left-hand panel. The shift in the distribution to larger values of r corresponds to the intuitive notion that larger response rates become more likely after observing R . Bayes' rule quantifies this intuition.

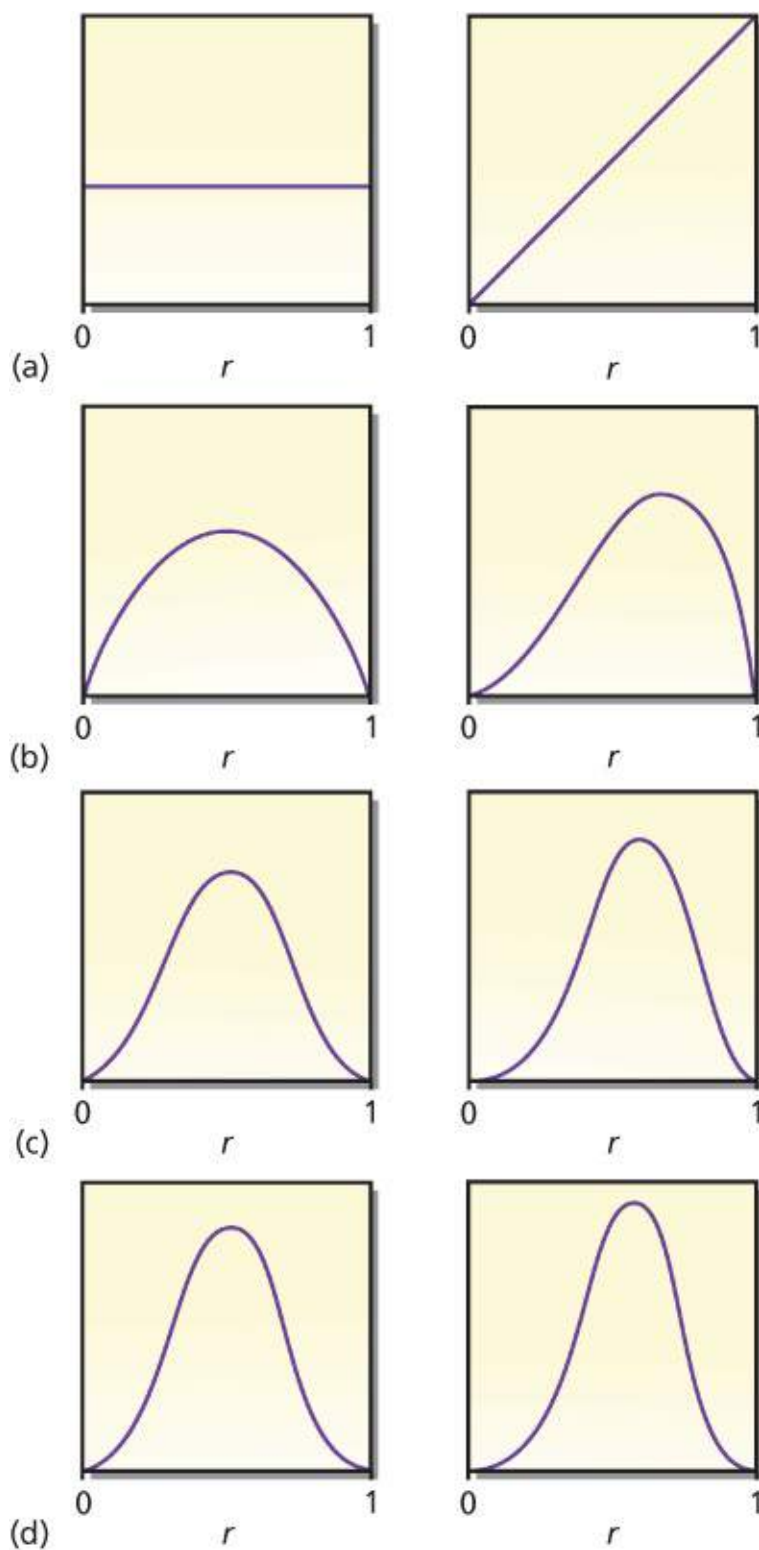

Figure 1 Prior distributions of response rate r . The left-hand panel in each pair is the prior distribution of response rate r . The right-hand panel is the posterior distribution of r after having observed a response in a single patient. The (predictive) probability of a response for each left-hand panel is 0.500, increasing in the right-hand panels to 0.667, 0.600, 0.571, and 0.556 in cases (a), (b), (c), and (d), respectively. Changes are greater and learning is more rapid when the prior distribution reflects greater uncertainty.

There are many candidate prior distributions other than the first one shown in [Figure 1a](#). Three other prior/posterior pairs are shown in [Figure 1b–d](#). The right-hand panel within each pair is the posterior distribution after observing R when the prior distribution is the one shown in the left-hand panel. Moreover, the left-hand curves in [Figure 1b–d](#) are themselves posterior distributions for the right-hand curves in [Figure 1a–c](#), respectively, but in the situation when the observation is an N . Intuitively, after a nonresponse, the concentration of probabilities shifts to smaller values of r . Mathematically, observing R

means to multiply the current distribution by r (the response rate) and renormalize it so that the area under the curve is 1. Similarly, observing an N means to multiply by $(1 - r)$, the rate of nonresponse.

An implication is that moving left to right and top to bottom in [Figure 1](#) corresponds to starting with the prior distribution in the left-hand panel of [Figure 1a](#) and observing RNRNRNR. The eight curves shown in [Figure 1](#) are proportional to the following respective functional forms: 1 , r , $r(1 - r)$, $r^2(1 - r)$, $r^2(1 - r)^2$, $r^3(1 - r)^2$, $r^3(1 - r)^3$, and $r^4(1 - r)^3$. Each observation of response increases the exponent of r by 1, and each observed N increases the exponent of $(1 - r)$ by 1. As is evident in the figure, additional observations lead to narrower distributions. As the number of observations increases, the distribution tends to concentrate about a single point, which is the “true” value of r , the response rate that produces the observations. Free software that provides a visual demonstration of the Bayesian update in the context of the so-called beta-binomial distribution can be downloaded at https://biostatistics.mdanderson.org/SoftwareDownload/SingleSoftware.aspx?Software_Id=96.

The principal message of this section is not the numerical calculation defining the updated distribution, but the fact that updated distributions can be found using the Bayesian approach at any time during a clinical trial.

Prior probabilities

Bayesian updating requires a starting point: a prior distribution of the various parameters. In the example, one must have a probability distribution for response rate r in advance of or separate from the experiment in question. This prior distribution may be subjectively assessed or based explicitly on the results of previous experiments. In some settings, such as some regulatory scenarios, an appropriate default distribution is noninformative or open-minded^{10, 13} in the sense that all possible values of the parameters are assigned the same prior probabilities. The left-hand panel of [Figure 1a](#) is an example.

Noninformative or flat prior distributions limit the benefits of taking a Bayesian approach when they ignore information that is available from outside the experiment. However, the benefit of employing Bayesian updating may be substantial even if one starts with a flat distribution that does not reflect anyone's assessment of the prior information. Flat prior distributions serve some important roles. One is that it may be helpful to distinguish the evidence in the data in the experiment under consideration from that present before the experiment. Another is that the Bayesian conclusions that arise from using flat prior distributions are often the same as the corresponding frequentist conclusions.

Prior distributions are usually based on historical data. Suppose that a similar drug (or the same drug in a possibly different patient population) gave a response rate of 50% in 20 patients: 10 responders and 10 nonresponders. The corresponding likelihood of response rate r (see the section titled “Frequentist/Bayesian Comparison”) is $r^{10}(1 - r)^{10}$. Given that there may be differences between the historical setting and that of the current trial, it would not be reasonable to use this information directly without any modification as a prior distribution for r , but it would be appropriate to somehow exploit this relevant information. One possibility (another is described in the section titled “Hazards over Time”) is to discount the historical evidence as it applies to the context of the current trial. For example, weighing an historical observation as having the information equivalent of 30% of that of a current observation would mean using a prior distribution proportional to $r^3(1 - r)^3$. This is the distribution shown in [Figure 1d](#), left-hand panel.

Robustness

In the presence of enough data, essentially all observers will have similar posterior distributions; this is

robustness. An implication is that the particular prior distribution assumed does not matter much when the sample size is moderate or large. As an example, consider the eight distributions shown in [Figure 1](#) and think of each of them in turn as being the prior distribution of a different person. Parameter r is the response rate to a particular drug. Suppose that 40 patients are treated in a trial and 20 of them respond. Applying the principle of robustness, the eight people in question will come to very nearly the same conclusion about the drug's response rate. The eight posterior distributions are shown in [Figure 2](#). The curves are nearly superposed. The eight 95% probability intervals will also be very similar. The data outweigh any of the prior distributions shown in [Figure 1](#).

Figure 2 Posterior distributions for response rate r based on an experiment with 20 responses and 20 failures. The eight prior distributions considered are the eight distributions shown in [Figure 1](#). Except for proportionality constants, these are 1 , r , $r(1 - r)$, $r^2(1 - r)$, $r^2(1 - r)^2$, $r^3(1 - r)^2$, $r^3(1 - r)^3$, and $r^4(1 - r)^3$. The corresponding posterior distributions are proportional to $r^{20}(1 - r)^{20}$, $r^{21}(1 - r)^{20}$, $r^{21}(1 - r)^{21}$, $r^{22}(1 - r)^{21}$, $r^{22}(1 - r)^{22}$, $r^{23}(1 - r)^{22}$, $r^{23}(1 - r)^{23}$, and $r^{24}(1 - r)^{23}$. These eight posterior distributions are very similar, demonstrating the robustness principle.

If two prior distributions are markedly different and the corresponding information contained in the prior distribution is strong, then robustness still applies, but it could take a good deal of data to bring two disparate distributions close together.

Frequentist/Bayesian comparison

In the frequentist approach, hypotheses and parameters do not have probabilities. Rather, probability assignments apply only to data, with particular values assumed for given unknown parameters in calculating these probabilities. For example, the ubiquitous p -value is the probability of data as or more extreme than the observed data assuming that the null hypothesis is true. In symbols:

- Frequentist p -value: $P(\text{observed or more extreme data} | H_0)$
- Bayesian posterior probability: $P(H_0 | \text{observed data})$

It is easy to confuse these two concepts. A p -value is commonly interpreted as the probability of no effect, and 1 minus the p -value as the probability of an effect. This interpretation is wrong. This is trying to have a Bayesian posterior probability without a prior probability, which is impossible.

There are two important differences between a frequentist p -value and a Bayesian posterior probability. One is the inversion of the conditions: what is assumed in the former has a probability in the latter. The second difference is that p -values include probabilities of results other than those observed in the experiment.

As an example, consider a single-arm phase II trial for testing $H_0: r = 0.5$ versus $H_1: r = 0.75$. Assuming a type I error rate $\alpha = 5\%$, a sample size of $n = 33$ gives 90% power. Suppose that the final results are of 22 responses of 33 patients, the (frequentist) one-sided p -value is the probability of 22 or more responses of the 33 patients, assuming the null hypothesis, $H_0: r = 0.5$. Under this assumption, the probability of observing 22, 23, 24, ... responses is $0.0225 + 0.0108 + 0.0045 + \dots = 0.0401$. As this p -value is less than 5%, observing 22 responses is said to be “statistically significant.”

The Bayesian measure is the posterior probability of the hypothesis that $r = 0.75$ (which is 1 – the probability of $r = 0.5$) given 22 responses out of 33. (As indicated earlier, the Bayesian calculation depends only on the probability of the data actually observed, 22 responses of 33, while the frequentist calculation also includes probabilities of 23, 24, etc., responses.) Using Bayes' rule:

$$P(H_1|22 \text{ of } 33) = P(22 \text{ of } 33|H_1)P(H_1)/P(22 \text{ of } 33)$$

As mentioned in the equation, the denominator follows from the law of total probability assuming H_0 and H_1 being equally likely before observing the data:

$$\begin{aligned} P(22 \text{ of } 33) &= P(22 \text{ of } 33|H_1)P(H_1) + P(22 \text{ of } 33|H_0)P(H_0) \\ &= (0.0823)(0.5) + (0.0225)(0.5) = 0.0524 \end{aligned}$$

Therefore,

$$\begin{aligned} P(H_1|22 \text{ of } 33) &= (0.0823)(0.5)/0.0524 = 0.785 \\ P(H_0|22 \text{ of } 33) &= (0.0225)(0.5)/0.0524 = 0.215 \end{aligned}$$

The calculation considers just two hypotheses, $r = 0.5$ and $r = 0.75$. In considering other values of r , Bayes' rule weighs them by $P(22 \text{ of } 33|r)$, which is called the likelihood function of r . The likelihood function is pictured in [Figure 3](#). It indicates the degree of support for response rate r provided by the observed data. Values of r having the same likelihood are equally supported by the data. Only relative likelihoods matter. For example, conclusions about $r = 0.5$ versus 0.75 depend only on the ratio of their likelihoods, 0.0823 and 0.0225, values that are highlighted in [Figure 3](#). Because $0.0823/0.0225 = 3.66$, the data lend 3.66 times as much support to $r = 0.75$ as they do to $r = 0.5$.

Figure 3 Likelihood of r for 22 responses out of 33 observations. The likelihood is $P(22 \text{ of } 33|r)$, which is proportional to $r^{22}(1 - r)^{11}$. The likelihoods at $r = 0.5$ and 0.75 are highlighted. These values are used in the calculational example in the text.

The conclusions of the two approaches are different conceptually and numerically. In the frequentist approach, the results are statistically significant, with p -value = 0.0401. Some researchers interpret statistical significance to mean that H_0 is unlikely to be true. That is not what it means. It means that the observed data are unlikely when H_0 is true. The Bayesian posterior probability of H_0 directly addresses the question of the probability that H_0 is true. This probability is 0.215. Although smaller than the prior probability of 0.50 (because the data point somewhat more strongly to H_1 than to H_0), it is five times as large as the p -value!

Interval estimates also have different interpretations in the two approaches. In the Bayesian approach, one can find the probability that a parameter lies in any given interval. In the frequentist approach, confidence intervals have a long-run frequency interpretation for fixed and given parameters. So it is not correct to say that a 95% confidence interval has a probability of 95% containing the parameter of interest. Despite the different interpretations, there is a point of agreement between the two approaches. In other words, if the prior distribution is flat (e.g., the left-hand panel of [Figure 1a](#)), then the Bayesian posterior probability of a confidence interval is essentially the same as the frequentist level of confidence. For example, if the prior distribution is flat, then the Bayesian posterior probability, indicating that a parameter lies in its 95% confidence interval, is in fact 95%. For prior distributions that are not flat, the posterior probability of a 95% confidence interval may be greater than or less than 95%. If the historical data upon which the prior distribution is based are consistent with those from the current experiment, then the posterior probability indicating that the parameter is in the 95% confidence interval will be >95%. If the historical data are different from those in the current experiment, then the probability that the 95% confidence interval contains the true parameter will typically be <95%.

Predictive probabilities

The ability to predict the future—with the requisite uncertainty—is important for designing and

monitoring trials. The Bayesian approach allows for calculating probabilities of future results without having to assume that any particular hypothesis is true. The process is straightforward, at least logically if not mathematically. For a specified experimental design, one finds the conditional probabilities of the future data for each parameter value and averages them with respect to the current probabilities of the various parameter values. Predictive probabilities are exploited extensively in this chapter.

Consider the 33-patient trial described earlier. Suppose that the first 16 patients have been treated, with 13 responses and 3 nonresponses. What will be the results after the full complement of 33 patients is available? The number of responses will be between 13 and 30, but not all events are equally likely. In particular, it seems most unlikely that there will be no responses in the next 17 patients after having seen 13 of the first 16 patients, and it is.

It might seem reasonable to use an estimate of r (e.g., the current rate, $13/16 = 0.81$) and calculate the probabilities of the results of the next 17 patients, assuming this value of r , but this could be wrong. Such a calculation incorporates the uncertainty in the future data for the given r , but fails to incorporate uncertainty in r . Bayesian predictive probabilities incorporate both types of uncertainty. [Table 1](#) shows the results, assuming just two values of r , 0.5 and 0.75. The first column (the leftmost column) lists the possible numbers (S) of responses after 33 patients. The second and third columns show the probabilities of the possible values of S for these two values of r . The corresponding probabilities without conditioning on r are shown in the fourth column. This is a weighted average of the second and third columns. The weights are the respective probabilities of the two values of r conditional on having observed 13 responses in the first 16 patients: 0.039 for $r = 0.5$ and 0.961 for $r = 0.75$. The fourth column evinces greater variability (greater standard deviation) than either of the previous two columns. Typically, when all values of r between 0 and 1 are considered (i.e., all values have positive probability), predictive probabilities reflect greater uncertainty about future results than when conditioning on a particular value of r . (The rightmost column of [Table 1](#) is discussed in the next section.)

Table 1 Predictive probabilities of number S of responses after 33 patients, given 13 responses in the first 16 patients

$S(\text{of } 33)$	$P(S r = 0.5)$	$P(S r = 0.75)$	$P(S)$	$P(H1)$
13	0.0000	0.0000	0.0000	0.0002
14	0.0001	0.0000	0.0000	0.0006
15	0.0010	0.0000	0.0000	0.0017
16	0.0052	0.0000	0.0002	0.0050
17	0.0182	0.0000	0.0007	0.0148
18	0.0472	0.0001	0.0019	0.0432
19	0.0944	0.0005	0.0042	0.1192
20	0.1484	0.0025	0.0082	0.2887
21	0.1855	0.0093	0.0162	0.5491
22	0.1855	0.0279	0.0341	0.7851
23	0.1484	0.0668	0.0701	0.9164
24	0.0944	0.1276	0.1263	0.9705
25	0.0472	0.1914	0.1857	0.9900
26	0.0181	0.2209	0.2129	0.9966
27	0.0052	0.1893	0.1820	0.9989
28	0.0010	0.1136	0.1091	0.9996
29	0.0001	0.0426	0.0409	0.9999
30	0.0000	0.0075	0.0072	1.0000

Note: Columns $P(S|r = 0.5)$ and $P(S|r = 0.75)$ assume the indicated value of r in calculating the probability. Column $P(S)$ is the weighted average of the two previous columns, where the respective weights are 0.039 and 0.961. The last column gives $P(H1)$, the probability of $H1$ ($r = 0.75$), given S responses after 33 patients.

For convenience in this example, equal prior probabilities are assumed: $P(H1) = P(H0) = 0.5$. Although there is no vertical bar “|” in these expressions, these probabilities can depend on other available evidence, such as results of earlier clinical and preclinical trials. There may be additional information from biological assessments, such as when considering targeted therapies. These overall conditions are taken to be understood in setting down $P(H0)$ and $P(H1)$.

Bayesian versus frequentist interim analyses

There are numerous commonalties and a few differences between the Bayesian and frequentist approaches. This section addresses a principal difference. In the Bayesian approach, one makes an observation and updates the probabilities of the various hypotheses. This simple process implies a degree of flexibility that is difficult to mimic in the frequentist approach.

Consider the trial design described previously, with $n = 33$ patients and testing $H0: r = 0.5$ versus $H1: r = 0.75$. Observing 22 or more responses will be sufficient to reject $H0$ in favor of $H1$ (with a one-sided 5% type I error rate). However, assigning 33 patients to an experimental therapy without assessing interim results is ethically problematic and would likely be questioned by institutional review boards. If the

results are conclusive (either positive, strongly suggesting $r > 0.5$, or negative, suggesting $r \leq 0.5$) part of the way through the trial, then the trial should be stopped. Suppose that after 16 patients, one finds that 13 respond and 3 do not, from a Bayesian perspective, the updated probability of $H1$ is 96.1% (assuming prior probability $P(H0) = 0.5$).

Whether this probability is “conclusive” is not clear. The decision as to whether to continue a trial is complicated. It depends on the consequences of the trial, given the current results and also given the future results. In the Bayesian approach, the consequences of future results can be weighed by their predictive probabilities; for example, suppose that the impact of the trial depends on whether the posterior probability of $H1$ is $> 95\%$ when the data from the full complement of 33 patients become available, then one can calculate the predictive probability of this event. The rightmost column in [Table 1](#) shows the posterior probability of $H1$ assuming S responses of 33 patients. To achieve $>95\%$ posterior probability requires at least 24 responses in the 33 patients. The probability of this event is the sum of the probabilities for $S \geq 24$ (the fourth column in [Table 1](#)), which is 0.8642. Although the current probability of $H1$ is $> 95\%$, owing to the uncertainty in S and in r , this characteristic will be lost with probability $1 - 0.8642 = 0.1358$. That this has moderate probability indicates the tentative nature of the current conclusion. The possibility that the current conclusion is moderately likely to change can be factored into the decision to continue the trial.

If the predictive probability that the current conclusion will be maintained is sufficiently high, then one may reasonably decide to stop a trial. This is true for both claims of futility and superiority. The possibility of stopping a trial early on the basis of predictive probability should be stated explicitly in the trial's protocol.

The focus of the frequentist perspective is the type I error rate, α . This is the probability of rejecting $H0$ when $H0$ is true, which depends on the trial design. For a fixed sample size of 33 patients, the calculation is straightforward. Rejecting $H0$ for ≥ 22 responses means $\alpha = 0.0401$ (see the previous section). The calculation becomes more complicated when there is a possibility of stopping the trial early. In the example, if the trial is stopped and $H0$ is rejected, when there are 12 or more responses in the first 16 patients, then α is increased because there is additional opportunity for rejecting $H0$. Assuming $r = 0.5$, the probability of rejecting $H0$ is now 0.0640. Because this is greater than 0.05, the convention is to modify the stopping and rejection criteria to reduce α to about 0.05. For example, rejecting only if there are 13 responses or more out of 16 patients treated, or if there are 22 or more responses after 33 patients are treated, gives an overall type I error rate of 0.0450.

It follows that it is more difficult to draw a conclusion of statistical significance when there are interim analyses. The reason is that the type I error rates are calculated assuming that a particular hypothesis (the null hypothesis of no effect) is true. In a sense, an investigator is penalized for interim analyses in the frequentist approach. There are no such penalties for interim analyses in a Bayesian perspective. The reason is that Bayesian probabilities are not conditional on the basis of any particular hypothesis.

Although it is not a Bayesian quantity, the type I error rate of any Bayesian design, however complicated, can be evaluated. If the design has interim analyses, then such a calculation incorporates appropriate penalties. This calculation is straightforward in a simple example such as that given earlier. In more complicated settings, it can require Monte Carlo simulations.

A breast cancer trial illustrates some advantages of a Bayesian design.¹⁸ Women with breast cancer who were at least 65 years of age were randomized to receive either standard chemotherapy or capecitabine. The sample size was expected to be 600–1800. After the 600th patient had enrolled in the trial, and following the protocol, predictive probabilities were calculated. Calculations were made of the

predictive probability of statistical significance given the present sample size and with additional patient follow-up at the present sample size. If that achieved a predetermined level, patient accrual would stop, but observations of the existing patients would continue. The predictive probability cutoff point was achieved at the first interim analysis and so accrual stopped (the final sample size was 633). Indeed, the study later showed that the women in this study population who were treated with standard chemotherapy had a lower risk of breast cancer recurrence and death than women treated with capecitabine.¹⁹

Analysis issues

The purpose of this section is to consider two types of analytical issues. The first is an extension of the previous section. The second is unrelated to the first and deals with a particular aspect of survival analysis.

Hierarchical modeling: synthesizing information

When analyzing data from a clinical trial, other information is usually available about the treatment under consideration. This section deals with a method called hierarchical modeling. One of its uses is synthesizing information from different sources. The method applies in many settings, including meta-analysis and incorporating historical information. A hierarchical model is a random-effects model. In a meta-analysis, one level of the experimental unit is the patient (within a trial) and the second level is the trial itself. Hierarchical models also apply for design issues such as combining results across diseases or disease subtypes and for such seemingly disparate issues such as cluster randomization. Design issues for hierarchical modeling are considered in the next section.

Consider a phase II trial in which 21 of 33 patients responded. The one-sided p -value is 0.08 for the null hypothesis $H_0: r = 0.50$, and so the results are not statistically significant at the 5% level. Now consider an earlier phase I trial using the same treatment in which 15 of 20 patients responded. This information seems relevant, even if the population being treated might have been somewhat different and the trial might have been conducted at a different institution. However, it is not obvious how to incorporate the information into an analysis. The frequentist approach is experiment specific, which requires imagining that the two trials are part of some larger experiment. If one assumes that the entire set of data resulted from a single trial involving 53 patients with 36 responses, then from a frequentist perspective this would lead to a p -value of 0.0063, which is highly statistically significant. However, this conclusion is wrong because the assumption is wrong. Moreover, it is not clear how to make it right.

Any Bayesian analysis that assumes the same response rate applies in both trials would be similarly flawed. Response rate r may be reasonably expected to vary from one trial to another. Two response rates for the same therapy may be different even if the eligibility criteria in the two trials are the same. For one thing, the eligibility criteria may be applied differently in the two settings. However, even if the patients accrued are apparently similar, their accruals differ in time and place. Our understanding of cancer and its detection changes over time. Moreover, there are differences in the use of concomitant therapy and variations in the ability to assess clinical and laboratory variables. A way to repair the analysis is to explicitly consider two values of r , say r_1 for the first trial and r_2 for the second.

Recapitulating, there are two extreme assumptions that lead to analyses that are easier to carry out, but both are wrong. One is to assume that r_1 and r_2 are unrelated and to base any inferences about r_2 on the results of the second trial alone. The other is to assume that $r_1 = r_2$ and combine the results in the two trials.

The two r -values may be the same or different. In a Bayesian hierarchical model, both possibilities are allowed, but neither is assumed. In other words, r_1 and r_2 are regarded as having come from a population of r -values. The population may have little variability (homogeneity) or substantial variability (heterogeneity). The observed response rates give information concerning the extent of heterogeneity, with disparate rates suggesting greater heterogeneity. When the observed rates are similar, the precision of estimates of r_1 and r_2 will be greater than when the observed rates are disparate. In the former case, there will be greater “borrowing of strength” across the trials. If it happens that the results of the trials are very different, then there will be little borrowing and the information from any one trial will not apply much beyond that trial.

More generally, there may be any number of related studies or databases that provide supportive information regarding a particular therapeutic effect. The studies may be heterogeneous and may consider different patient populations. The next example is generic but it is more complicated than the previous example because it includes nine studies.²⁰ The only commonalty in the studies is that all addressed the efficacy of the same therapy.

The response rates can take any value between 0 and 1. The number S of responses and sample size n are shown for each study in [Table 2](#) and [Figure 4](#). There are nine response rates, r_1 , r_2 , up to r_9 , one for each study. Each of the nine sample response proportions S/n is an estimate of the corresponding r . There were 106 responses among 150 patients. If all nine of the response rates are assumed to be equal, then the posterior distribution of the common response rate r (assuming a flat prior distribution) is that shown in [Figure 4](#), labeled “pooled analysis.”

Table 2 Numbers of responses S , sample size n , observed response proportions (including its standard error), and adjusted estimates of response rates by study

Study number	Responses S	Sample size n	Observed response proportions (standard error)	Bayes estimate (standard deviation)
1	11	16	0.69 (0.116)	0.69 (0.094)
2	20	20	1.00 (0.000)	0.90 (0.064)
3	4	10	0.40 (0.155)	0.53 (0.121)
4	10	19	0.53 (0.115)	0.57 (0.094)
5	5	14	0.36 (0.128)	0.48 (0.109)
6	36	46	0.78 (0.061)	0.77 (0.058)
7	9	10	0.90 (0.095)	0.80 (0.097)
8	7	9	0.78 (0.139)	0.73 (0.110)
9	4	6	0.67 (0.192)	0.68 (0.125)
Total	106	150	0.71 (0.037)	0.68 (0.064)

Note: The Bayes estimate column is described in the text.

Figure 4 Response comparisons. The dot plot on the r -axis shows the observed response proportions given in [Table 2](#). The areas of the dots are approximately proportional to sample sizes n . The pooled-analysis curve shows the distribution of response rate r assuming no study effect. The hierarchical analysis curve shows the Bayesian estimate of the distribution of response rates allowing for heterogeneity across the various studies.

Even though this pooled analysis is wrong, the overall estimate of 106/150 may be quite reasonable. However, the precision associated with this estimate is too great (equivalently, its standard error is too small). In contrast, the “hierarchical analysis” curve in [Figure 4](#) is a Bayesian estimate of the distribution of the response rates in the population of studies. (This curve is the mean posterior distribution assuming a noninformative prior for the parameters in a particular class of distributions for r -values, called *beta distributions*.) As is typical of hierarchical analyses, this curve shows greater variability than does the analogous curve under the assumption of homogeneity.

In a hierarchical analysis, an individual study's r has a distribution that depends on the data from that study, but it also depends on the data from the other studies. The rightmost column in [Table 2](#) shows the mean of the distribution of each study's response rate. This is also the predictive probability of the response for a future patient in that study. The individual study probabilities are shrunk toward the overall mean. This shrinkage is greater for smaller studies, and for studies with observed proportions further from the overall mean. Hierarchical borrowing is defensible because it does not make the assumption that all studies had the same true response rate, and because the extent of borrowing is determined by the data.

[Figure 5](#) provides a pictorial comparison of the rightmost two columns in [Table 2](#), demonstrating shrinkage. The Bayesian estimates are intermediate between simple pooling (complete shrinkage) and each trial standing alone. The amount of shrinkage—including the two extremes mentioned previously—depends on the prior distribution of the population of trials. This aspect of the prior distribution should be set in advance, or varied to allow for assessing the sensitivity of the overall conclusion.

Figure 5 Observed response proportions compared to the adjusted response rate estimates. Values are given in the two rightmost columns in [Table 2](#). The dot plot on the r -axis shows the observed response proportions, just as in [Figure 4](#). The Bayes estimates assume a hierarchical model and show shrinkage toward the overall mean.

Shrinkage is a consequence of hierarchical modeling. The motivation for such modeling is to use the available information appropriately in improving precision or in decreasing the required sample size. Consider study number 1 in [Table 2](#). Simply pooling the data from the other eight studies would greatly increase the precision of its estimated response rate. For example, the standard error would be reduced from 0.116 to 0.037. However, in view of the possibility of heterogeneity in the studies, such pooling would not be justified. Borrowing hierarchically also strengthens the conclusion, but not as much. The standard deviation of the Bayes estimate is only about 20% smaller, from 0.116 to 0.094. Although smaller than the reduction with unabashed pooling, this reduction implies that >50% savings in sample size is necessary to carry out a clinical trial (in the setting of study number 1 in [Table 2](#)) with the same precision: $(0.116/0.094)^2 - 1 = 52\%$. For example, to achieve the same standard error in a stand-alone study would require 25 as opposed to 16 patients in study number 1 of [Table 2](#).

Patient covariates can be incorporated into a hierarchical analysis, thus adjusting for known differences in the studies but still accounting for unknown effects. In this example and in more complicated hierarchical settings as well,²¹ modeling allows for borrowing from other studies and databases. If the results are consistent across studies, then the amount of borrowing will be greater. If the results are sufficiently different (after accounting for covariates), then this suggests heterogeneity among the studies and there is little borrowing.

Hierarchical modeling in trial design

There are many settings in which trials can be set up to borrow strength from related, but not necessarily identical, experimental units.

Consider designing a trial for a therapy for a disease that has several subtypes, such as several different histologies that exist for one type of tumor. The response rates will likely differ for the different subtypes. The setting is essentially the same as that of the previous section. The focus is then the tumor response rate within the individual subtype. These have a distribution, just as in the previous section. Recognizing the possibility of borrowing across subtypes means greater precision for estimating each individual response rate and therefore that the sample size within each subtype can be smaller.

The extent of borrowing depends on the results, just as in the previous section. In other words, the savings in terms of sample size cannot be predicted with certainty. However, this is not a problem if the interim results can be monitored. The interim results can be used to determine the precision associated with the estimates of the various response rates. If the interim results will not be available when the decision to stop the trial must be made, then the uncertainties regarding heterogeneity across subtypes can be assessed at the trial design stage and the sample size chosen accordingly, recognizing that the eventual precisions cannot be predicted perfectly.

Hazards over time

Time-to-event (TITE) analyses/survival analyses are ubiquitous in cancer research. In this section, we focus on a narrow aspect of survival analysis that enables greater understanding of cancer and its treatment. For illustration, we use data from a clinical trial, protocol 8541 of the Cancer and Leukemia Group B (CALGB).²²

This trial considered three different dose schedules of cyclophosphamide, doxorubicin, and 5-fluorouracil (CAF) in the treatment of node-positive breast cancer: high, moderate, and low. These are, respectively, four cycles of CAF at 600, 60, and 600 mg/m², six cycles at 400, 40, and 400 mg/m², and four cycles at 300, 30, and 300 mg/m². The primary endpoint was disease-free survival, which is shown

in [Figure 6](#) for the three dose groups using Kaplan–Meier plots. We provide no p -values for the comparisons (high vs moderate; high vs low) because the statistical significance is not relevant to our purpose.

Figure 6 Disease-free survival proportions for the three CAF dose groups of CALGB 8541.

Although TITE curves such as those in [Figure 6](#) are standard, they do not tell the whole story regarding any benefit of increasing dose and dose intensity. A clearer picture is contained in hazard plots over time. Hazards are the proportions of events within a particular time period as a fraction of those patients who are at risk at the beginning of the period. For example, suppose that the event is a recurrence and there are 100 patients in a group that are at risk in the first year. If 10 of these patients experience a recurrence of the disease in the first year, then the first-year hazard is 10%. Going into the second year there are 90 patients at risk. If another 18 experience recurrences in the second year, then the second-year hazard is $18/90 = 20\%$. When calculating the hazards from survival plots such as those in [Figure 6](#), one subtracts the current year's survival proportion from the previous year's survival proportion and divides by the previous year's survival proportion. The resulting yearly hazards are shown in [Figure 7](#).

Figure 7 Hazards for the three CAF dose groups of CALGB 8541, derived from [Figure 6](#).

A striking observation from [Figure 7](#) is that the hazards decrease over time (after the second year) for all three treatment arms. This is a reflection of the heterogeneity of this disease. The most aggressive tumors recur early, giving the high hazards evident in the first few years. Once their tumors have recurred, patients are removed from the at-risk population. The remaining tumors are less aggressive and so they recur at a lower rate.

Regarding a treatment arm effect, the apparent benefit of the high-dose schedule is restricted to the first 5 years or so. Actually, the hazard for patients on the high-dose schedule is lower than those of the other two arms in each of the first 6 years. (Although it is not much lower in the last few of these 6 years, and it is not much lower than that of the moderate-dose schedule at any time.) This observation is impressive because each year is like a new study, with previous recurrences not counted when starting a new year.

A final comment regarding hazards relates to the common problem of predicting survival results into the future for patients already accrued to a trial. This differs from the general problem of prediction discussed in “Predictive Probabilities.” Consider [Figure 6](#). Some of the patients have as little as 10 years of follow-up information. As more follow-up information becomes available, there will be no change in these curves before the 10-year time point. However, the curves are subject to change beyond 10 years. Because the focus is on patients for whom the tumor has not yet recurred, the way the curves will change depends on the hazards beyond 10 years. The information available about these hazards is shown in [Figure 7](#). For predicting when and whether a patient's disease will recur, consider hazards 1 year at a time, always building on the patient's current year of follow-up. Each incremental hazard prediction depends on the data for the corresponding year.

Principles of statistical design: decision analysis and factorial experiments

Decision analysis

Clinical practice and clinical research involve making decisions. A list of the possible results, probabilities, and consequences of each decision, pros and cons expressed as utilities, allows for

choosing one decision over another. Predictive probabilities play a central role in the decision-making process, which makes the Bayesian approach ideal. Choosing the trial design and selecting the optimal sample size are decisions that benefit from the use of decision analysis, which is described in greater detail in other references.^{23–32}

Factorial experiments

Most comparative drug trials in oncology test one experimental agent against a control. The patients in both treatment arms may receive additional therapy based on the current standard of care for the type and stage of their cancer, and on their prior treatment. They may have surgery and receive concomitant radiation and other chemotherapy, which may include several drugs. If the experimental drug is shown to be sufficiently effective, then it will be incorporated into the standard therapy. This approach is simple and clean, but it has a number of drawbacks. One is that it is not possible to assess the individual contributions of the various components of polychemotherapy or combination therapy that are developed in this way. Another is that the approach provides a mechanism for adding drugs to standard regimens but not for subtracting them. An experimental agent's effectiveness may or may not require all other components of the standard regimen. Adding an experimental drug to a standard regimen, however, may make other components of the regimen unnecessary. In the latter case, there is no way of identifying these components.

To some extent this conundrum is inevitable. Studying the possible removal of a component of standard chemotherapy is difficult, and for ethical reasons this is so, even if the component has never been proven to contribute to the overall effectiveness of the combination. However, better approaches for developing drugs would alleviate the problem and could lead to more rapid development of better therapies. A fundamental principle of optimal experimental design in statistics is to change the various contributing factors in such a way as to learn efficiently about their impact on outcome. This impact may involve interactions between the factors and it is important to learn about such interactions. What is required is to model relationships and exploit the available data to inform the model.

An alternative to varying one factor at a time in separate studies is using factorial designs.³³ In the simplest example, patients would be assigned to one of four regimens: A alone, B alone, A and B in combination, and neither. (The last of these does not mean “no therapy” because all patients receive standard therapy.) These four possibilities are shown schematically in [Figure 8](#), where “A” means that the patient receives A and “No A” means the patient does not receive A. The factors may be drugs, or other interventions (“A” could be radiation therapy, or surgery before rather than after chemotherapy, or a high dose as opposed to a low dose of a drug). Reading from left to right in [Figure 8](#) may not indicate time. The two drugs may be given concurrently or sequentially, A before B or B before A. Indeed, sequential versus concurrent administration of drugs could be another factor in a factorial design.^{34, 35}

Figure 8 A 2×2 factorial design considering drugs A and B and their combination. There are four possible treatment combinations.

An advantage of factorial designs is that they enable estimating the “main effects” of the individual drugs

and therefore a single trial answers two (or more) questions, while using the same sample size as a two-arm trial. Another advantage is that factorial designs allow for assessing interactions between the factors. For example, comparing the difference between the top two cases in [Figure 8](#) with the difference between the bottom two cases addresses whether the effect of B is the same when it is given with drug A as when it is given without drug A. [Table 3](#) shows the types of interactions that are possible for the four combinations of drugs A and B considered in [Figure 8](#), assuming that the endpoint is the response rate. For negative interactions, the effect of the combination is less than the sum of the individual drug effects. For positive interactions, the effect of the combination is greater than the sum of the individual drug effects.

[Table 3](#) Response rates (%) for the four treatment combinations in a factorial design in which drugs A and B are added to standard therapy (hypothetical effects)

Treatment combination	Neither effective	A effective B not	B effective A not	Additive effects	Negative interaction	Positive interaction (Example I)	Positive interaction (Example II)
A and B	20	30	30	40	30	50	40
A, no B	20	30	20	30	30	30	20
B, no A	20	20	30	30	30	30	20
Neither	20	20	20	20	20	20	20

A limitation of factorial designs is that some treatment combinations may not be ethically or practically possible. For example, one of the combinations in [Figure 8](#) is neither of the two drugs. In some oncology settings it may not be possible to have such a treatment arm. Including only three arms in the trial is better than having only two, but then individual drug effects cannot be assessed and the sample size advantages of the factorial design are lost.

When a two-arm trial is designed to have a particular power, a second factor can be added without increasing the sample size. The power for assessing the interaction between the factors is not as great as for assessing a main effect, but there will be some information about interactions. The sample size can be increased if high power for assessing an interaction is required, but a reasonable and usually a more realistic alternative is to keep the sample size the same and accept modest power for assessing interactions. Learning about interactions is essential, both clinically and scientifically, and interactions cannot be identified from a single two-arm trial. Factorial designs can consider more than two factors and more than two levels per factor. [Figure 9](#) shows a more complicated example, a 2 × 2 × 3 factorial design. Now there are three doses of drug C. Data from every patient contribute in estimating the main effects of A, B, and C separately and so there is no increase in sample size. Estimating three-way interactions has less power than estimating two-way interactions, but the results from the factorial design in [Figure 9](#) will contain some information about the three-way interaction of drugs A, B, and C.

Figure 9 A $2 \times 2 \times 3$ factorial design considering drugs A and B, three levels of drug C, and their combinations. There are 12 possible treatment combinations.

A modification for a large factorial design is to use an adaptive randomization scheme, as discussed in a subsequent section of this chapter. The efficacy and toxicity of the various combinations could be explored using unbalanced assignments, favoring combinations that the accumulating data suggest are promising. If it turns out that one of the drugs is ineffective, whether used with or without the other drugs, it would be dropped.

In many oncology drug settings, toxicity is as important as efficacy. There are ways to incorporate them both in a factorial design. For example, one can establish the notion of *admissible combinations* based on toxicity. This involves allowing only certain of the full factorial combinations at the start of the trial. As experience accrues about toxicity, other combinations become admissible, or the number of admissible combinations shrinks. The assignment to treatment combinations within the set of admissible combinations can be made either randomly or adaptively based on accumulating information about efficacy.

Adaptive designs of clinical trials

The focus of this section is a family of designs that are adaptive or dynamic in the sense that observations made during the trial can affect the subsequent course of the trial. The focus is clinical trials, but the ideas also apply to the preclinical setting.

Designs of clinical trials are usually static in that the sample size and any prescription for assigning treatment, including randomization protocols, are fixed in advance. Results observed during the trial are not used to guide its course. There are exceptions. Some phase II cancer trials have two stages, with stopping after the first stage possible if the results are not sufficiently promising. Moreover, most phase III protocols specify interim analyses that determine whether the trial should be stopped early for sufficiently strong evidence of a difference between competing treatment arms. However, traditional early stopping criteria are very conservative and so few trials stop early.

The simplicity of trials with static designs makes them solid inferential tools. Their sample sizes tend to be large, at least in comparison with the alternatives to be discussed in this section. In addition, they usually consider two therapeutic strategies, or arms, thus enabling straightforward treatment comparisons. That is not to say that static trials always give clear answers as to whether one arm is better than the other,

but only that they usually allow for an unambiguous quantification of the uncertainty regarding whether one arm is better.

Despite their virtues, static trials result in slow and unnecessarily costly drug development. The number of cancer drugs available for development is increasing exponentially. It is inefficient to focus on a single drug when myriad others are sitting on the sidelines waiting to be evaluated. Pharmaceutical companies and medical researchers generally must be able to consider hundreds or thousands of drugs for development at the same time. Static trials inhibit the simultaneous processing of many drugs. Moreover, they cannot efficiently address dose–response questions when many drugs are under consideration. Dynamic designs that are integrated with the drug-development process are necessary for reasonable progress in medical research.

Using an adaptive design means examining the accumulating data periodically, or even continually, with the goal of modifying the trial's design. These modifications depend on what the data show about the unknown hypotheses. Among the modifications possible are stopping early, restricting eligibility criteria, expanding accrual to additional sites or inclusion of certain subgroups of patients, extending accrual beyond the trial's original sample size if its conclusion is still not clear, dropping arms or doses, and adding arms or doses. All of these possibilities are considered in the light of the accumulating information. Adaptive designs also include unbalanced randomization where the degree of imbalance depends on the accumulating data. For example, arms that give more information about the hypothesis in question or that are performing better than other arms can be weighted more heavily.³⁶

Adaptation is not limited to the data accumulating in the trial. Information that is reported from other ongoing trials can also be used. This is easier to implement if one takes a Bayesian approach, possibly using hierarchical modeling as described in the previous section.

Adaptive designs are increasingly being used in cancer trials. This is true for trials sponsored by pharmaceutical companies, and more generally. For example, a variety of trials conducted at The University of Texas MD Anderson Cancer Center are prospectively adaptive.³⁷ Examples of commonly used adaptive designs are given below.

Continual reassessment method (CRM) in phase I trials

The purpose of phase I cancer trials is to identify the maximum-tolerated dose (MTD). Phase I trial designs generally use either a rigid, algorithm-based up-and-down design or an adaptive design that is based on a statistical model. Variants of the so-called 3 + 3 design³⁸ and the accelerated titration design³⁹ are forms of the up-and-down design that are commonly used in phase I trials. Variants of the continual reassessment method (CRM) are forms of model-based dose-finding design.

The 3 + 3 design enrolls patients in groups of three. If none of the three patients experiences toxicity, the dose is increased one level for the next group of three. If two or three of the three patients experience toxicity, then the next lower dose is the MTD, providing that at least six patients have been treated at that dose. If one of the three experiences toxicity, then three more patients are added at the same dose level. If two or more of the six patients at that dose experience toxicity, then again the next lower dose with at least six patients treated is the MTD.⁴⁰ This algorithm-based design is crudely adaptive and is likely to assign low doses and to select an ineffective MTD. Moreover, the decision of the next dose depends on only the result of the current dose and ignores the information accumulating from all other doses administered in the trial. In other words, dose assignments are myopic and not based on sufficient statistics.⁴¹

The CRM and its extensions^{42–44} use Bayesian updating, which assumes a particular model of the relationship between dose and toxicity (such as the logistic function). The CRM assigns each patient to the dose that has the probability of toxicity closest to some predetermined target value. This is the Bayesian posterior probability calculated from the data available up to that point (and so is based on sufficient statistics). Variations of the CRM include the escalation with overdose control (EWOC) design⁴⁵ and the Bayesian model averaging continual reassessment method (BMA-CRM).⁴⁶

The CRM more effectively finds the MTD than does the 3 + 3 design. Although the CRM-type of design has been the preferred design for phase I trials at MD Anderson Cancer Center, it is being improved in a number of ways. One of these uses the fundamental principle that ignoring information is wrong. (A catch, of course, is that taking information into account is work, and it can require modeling.) There is some information that accrues about efficacy in a phase I trial. This information is limited, especially regarding the dose–efficacy relationship. However, at a minimum, in proceeding to phase II with a particular dose (usually the MTD), one should use the efficacy information from those patients in phase I who were assigned to that dose. This notion leads to using a phase I/II design that addresses safety and efficacy simultaneously, or one that focuses on efficacy after an initial focus on toxicity. Such an approach is efficient from the perspective of both time and patient resources.

In terms of trial conduct in which both 3 + 3 and CRM designs are suboptimal is the need to pause the accrual while waiting for toxicity information. Such pauses are inefficient and cause logistical problems. Trials should be paused or stopped if there are safety concerns, not because the design cannot get out of its own way. When obtaining information about toxicity (or efficacy), there is seldom a magical dose that the next patient must receive. All doses are potentially informative. Rather than stopping, one should use a design that models dose response (toxicity and efficacy) by the look-ahead principle or the TITE-CRM, which is able to assign a next dose even though patients previously treated are not yet fully evaluable.^{47, 48} Other designs for when the toxic effects of a new drug are not expected to be observable soon after the dose is administered, but only after a delay, include the expectation-maximization CRM⁴⁹ and the data augmentation CRM.⁵⁰ Model-based dose-finding designs have also been developed for trials that evaluate drugs in combination.^{51–55}

Additional limitations of a phase I design, in which both 3 + 3 and CRM designs are constrained, are the assumption that toxicity is dichotomous and the exclusion of efficacy from consideration. A better approach—again because of using all available information—would be to account for both the severity of toxicity and the efficacy in a phase I/II design.^{56–62}

As more biologics are evaluated in clinical trials, dose-finding trials shift from determining the MTD (based on the use of highly toxic chemotherapies) to determining the optimal biological dose (OBD). Biologics are expected to have low toxicity within the range of therapeutic doses, and the optimal dose is generally defined as the lowest safe dose of the targeted agent that has the highest rate of efficacy. Several approaches have been proposed for determining the OBD in phase I dose-finding trials.^{52, 62–64} Readers may refer to Braun⁶⁵ for a comprehensive review of adaptive designs for phase I dose-finding trials.

Adaptive phase II trials

In many diseases, the standard phase II dose-finding design allocates a fixed number of patients to each of a number of doses in a grid. Such questions are of less interest in cancer chemotherapy trials because of the goal of administering as much of the drug as the patient can tolerate. However, with increased use of biological agents, dose finding for efficacy is becoming more important in cancer research.

After seeing the results of a dose-finding trial, investigators usually wish they had assigned patients in some other manner. Perhaps the dose–response curve was shifted more to the left or right than anticipated. If so, then the assignment of a bulk of the patients on one end or the other was wasted. Or perhaps the slope of the dose–response curve is greater than anticipated and the response of patients assigned to the flat regions of the curve would have been more informative if the doses assigned had been in the region where the slope is apparently greatest. Or perhaps, the results for the early patients made it clear that the dose–response curve was flat over the entire range and therefore the trial could have stopped earlier. Or perhaps, the results of the trial show that the standard deviation of the outcome of interest is greater or less than anticipated and so the trial should have been larger or could have been smaller.

Sequential designs for phase II studies have been developed to evaluate the efficacy of new treatments within a prespecified range of doses. This dose-ranging stage continues until a decision is made that the drug is not sufficiently effective to pursue future development or that the optimal dose for the confirmatory phase III trial is sufficiently well known. Early single-arm designs used two stages to reach a predetermined efficacy rate while controlling the type I and type II error rates.^{66, 67} Bayesian adaptive trial design for a binary outcome measure have been proposed with efficacy and/or futility-stopping rules.⁶⁸ The design of Berry et al.⁶⁹ also proceeds sequentially, analyzing the data as they accumulate (see also additional approaches^{70, 71}) as well as applying predictive probability for utility early stopping in phase II design.⁷² Further discussion of group sequential designs can be found in the work of Jennison and Turnbull.⁷³

The example trial of Berry et al.⁶⁹ involves a biological neuroprotective agent for stroke. However, the same principles of trial design apply in cancer research. Each patient entering the trial is assigned the dose (1 of 16, including a placebo) that maximizes the information about the dose–response relationship, given the results observed so far. This dose could be in the region of the greatest apparent slope, or it could be the placebo or a high dose. However, future patients are not assigned to doses in any region where accumulating evidence suggests that the dose–response curve is flat.

In the dose-ranging stage, neither the number of patients assigned to any particular dose nor the total number of patients assigned in this stage are fixed in advance. The dose-ranging sample size will be large when the data suggest that the drug has moderate benefit, when the dose–response curve is gently sloping, or when the standard deviation of the responses is moderately large. It will tend to be small if the drug has substantial benefit, if the drug has no benefit, if the dose–response curve rises over a narrow range of doses, or if the standard deviation of the responses turns out to be small. (In addition, and somewhat nonintuitively, the dose-ranging stage will be small if the standard deviation of the responses is very large. The reason is that a sufficiently large standard deviation means that a very large sample size would be required to demonstrate a beneficial drug effect. The required sample size may be so large that it would be impossible to study the drug and so the trial stops in the dose-ranging phase before it consumes substantial resources.)

In the stroke trial considered by Berry et al.,⁶⁹ the ultimate endpoint is an improvement in the stroke scale from baseline to 13 weeks. If the accrual rate is large, then the benefit of adaptive assignment can be limited by delays in obtaining the endpoint information. (Note: a “sweet spot” optimizing the accrual rate and the time of endpoint evaluation can be found.⁷⁴) To minimize the effects of delayed information, each patient's stroke scale is assessed weekly between baseline and week 13. Within-patient measurements are correlated, with correlations greater if they are closer together in time. We incorporate a longitudinal model into the analysis of the trial and carry out Bayesian predictions of the ultimate endpoint based on the current patient-specific information, and we update the probability distributions of the treatment effect

accordingly.

A design with adaptive dosing is more effective than the standard design at identifying the right dose. In addition, it usually identifies the right dose with a smaller sample size than when using fixed-dose assignments. Another advantage is that many more doses can be considered in an adaptive design. (Even though some doses will be little used and some may never be used, these cannot be predicted in advance.) An adaptive design therefore has some ability to distinguish responses at adjacent doses and to estimate the nuances of the dose–response curve.

The circumstances of the stroke trial are similar to those in many other types of trials. Finding the right dose is a ubiquitous problem in pharmaceutical development, and it is seldom done well or efficiently. The adaptive nature of the stroke trial would be less advantageous if we had not exploited early endpoints. Cancer, too, is characterized by the availability of information about a patient's performance (local control of the disease, biomarkers, etc.) before reaching the primary endpoint. Furthermore, Bayesian adaptive design can be applied to screen efficacious combination therapies in phase II trials by formulating the selection procedure as a Bayesian hypothesis testing problem and using the current values of the posterior probabilities to adaptively allocate patients to treatment combinations.⁷⁵ Finally, the possibility of moving seamlessly from phase I to phase II or from phase II to phase III, contingent upon promising results, exists for many types of drugs. That issue leads naturally to the subject of the next section.

Seamless phase I/II and phase II/III designs

The convention of discretizing drug development into phases is unfortunate. We proceed from one phase to the next when we think we know something: the MTD from phase I, or that a drug's impact on a phase II endpoint will translate into a benefit in phase III, and at the phase II dose. In the Bayesian approach, one never takes a quantity to be perfectly known. Instead, the Bayesian perspective is to carry along uncertainty with whatever knowledge is available. Phases of drug development are arbitrary labels that describe a process that is, or should be, continuous.

One of the consequences of partitioning drug development into phases is that there are delays between phases. For example, there is a pause between phases II and III to set up one or more pivotal studies. As mentioned in the context of the stroke trial, its design allows for avoiding such a hiatus. At each time point, say weekly, the algorithm that guides the conduct of the trial carries out a decision analysis and recommends either (1) continue the dose-ranging stage of the trial, (2) stop the trial for lack of efficacy (inadequate slope of the dose–response curve or, more accurately, evidence of a positive dose–response that is insufficient to justify continuing the trial), or (3) shift into a confirmatory trial. This shift can be made seamlessly, with no break in the accrual. Indeed, it is even theoretically possible to implement such a shift in a double-blind trial without informing the investigators: they simply continue to randomize doses, but unbeknownst to them, the only two being assigned are the phase III dose and the placebo.

Many trial designs have encompassed both phases I and II.^{37, 57–61, 64, 76–80} Such designs allow for addressing toxicity and efficacy throughout the trial. Only “admissible” doses or combinations of doses are used, and doses are escalated as others become admissible. All the while, the designs allow for learning about the relationship between dose and efficacy as well as about dose and toxicity.

Trials designed to encompass both phases II and III use a seamless switch to phase III.^{81–85} The seamless aspect is as follows. Patients are accrued to a trial, which we can think of as phase II. If the accumulating data are sufficiently strong in suggesting that the drug/treatment has no effect on local control or survival, then the trial stops. If the data suggest that the drug may have an impact on local control and that this

impact translates into a survival benefit, then the trial will be expanded and the accrual rate will increase accordingly. During such an expansion, patients continue to accrue at the initial site so that there is no downtime in the local accrual while other centers prepare to join the trial. This is an efficient use of patient resources because data from the patients who enrolled early contribute to the eventual inferences about survival. These patients are the most informative of all those enrolled because their follow-up times are the longest.

The trial continues until stopping occurs because (1) continuing would be futile, judged by predictive probabilities, (2) the maximum sample size is reached, or (3) the predictive probability of eventually achieving statistical significance becomes sufficiently large. If the third event occurs, the accrual ceases and the pharmaceutical company prepares a marketing application.

For example, the sample size of a conventional phase III trial with the desired operating characteristics is 900. This is taken to be the maximum sample size in the seamless design as well. Actual accrual is very likely to be much less than this maximum sample size, particularly, when the experimental treatment is either very promising or not promising at all. On the other hand, incorporating the same number of interim analyses in a conventional design using a conventional type of stopping boundary allows for only a slight decrease in the average sample size. A Bayesian design occasionally leads to a relatively large trial (close to 900 patients). However, a pleasant aspect of the design is that the sample size is large precisely when a large trial is necessary. Conventional trials may well (and sometimes do!) come to their predetermined end with an ambiguous conclusion. In a Bayesian approach, one may choose to continue such a trial to resolve the ambiguity, and this option has substantial utility. (Carrying this argument to the maximum sample size, there may be times for which stopping at 900 is ill advised, but for logistical reasons we specified a maximum size.) Within a seamless adaptive design, one can use the data accumulating in the trial to re-estimate the sample size, which can result in reduced sample sizes.^{86–90}

A conventional drug-development strategy involves running a phase I trial to identify the MTD, then, following that by a phase II trial to address local control; digesting the results, and if the results are positive, starting to develop a phase III trial with survival as the primary endpoint. In comparison with such a strategy, a seamless approach can greatly reduce the sample size. In addition, a seamless design minimizes the pauses between phases, which greatly shorten the total drug-development time.

Adaptive randomization

The adaptive designs discussed so far are motivated by the desire to learn efficiently and as rapidly as possible. Another kind of adaptive design aims to assign patients to treatments as effectively as possible. Adaptive randomization encompasses two primary approaches: covariate-adjusted adaptive randomization and outcome-adaptive randomization. A covariate-adjusted adaptive randomization scheme may assign patients to a treatment arm on the basis of baseline measurements of particular characteristics that are associated with prognosis (prognostic markers). This balances the determinant factors among the treatment arms.^{91, 92} In contrast, an outcome-adaptive randomization scheme assigns patients to a treatment arm on the basis of the responses to treatment that are accumulating from patients already enrolled in the trial, which tends to assign more participants to treatments that are achieving better patient responses.^{93, 94} Outcome-adaptive randomization increases the likelihood that more patients will receive the more efficacious treatment. This strategy benefits the individuals participating in the trial, which strengthens the “individual ethics” of the trial.⁹⁵ Equal randomization, on the other hand, maximizes the statistical power, which emphasizes the “group” or “collective ethics” of the trial, with the goal of identifying effective treatments from the trial and then applying that information to benefit future patients. In addition to making clinical trials more attractive to patients and thereby increasing participation in clinical trials, outcome-

adaptive randomization strategies have the important side benefit of being efficient, and so they result in rapid learning.

The purpose of adaptive randomization is to shift the probability weight toward better performing arms as the trial proceeds and the results accumulate. Other allocation algorithms can be considered, for example, assigning doses in proportion to the powers of these probabilities. Many of these trials have more than two treatment arms. The arms may be distinct or closely related therapies. An example of the latter is a trial to determine the dose of an additional prophylactic agent that would inhibit acute graft-versus-host-disease (GVHD) in leukemia patients who received bone marrow transplants.⁹⁶ The trial evaluated five doses (including 0) of a drug (pentostatin) added to the standard prophylaxis regimen. The problem was that the drug might inhibit the successful engraftment of the transplant, which was necessary for survival. Such inhibition might be related to dose. A combination endpoint was used in the trial: survival at 100 days free of GVHD. The conflict between engraftment and freedom from GVHD meant that the dose–response curve might not be monotone. In particular, it might increase for small doses and then decrease. Doses were initially assigned in a graduated manner, slowly climbing the dose ladder. However, as doses became admissible, more patients were assigned to the doses that were performing well.

Consider a patient who qualifies for the trial. To decide which pentostatin dose to assign, one calculates the current (Bayesian) probabilities that each admissible dose is better than the placebo. This calculation uses all the information from the patients treated to date. Doses are allocated randomly, with weights proportional to these probabilities. Doses that are doing sufficiently poorly become inadmissible in the sense that their assignment weight becomes 0. When and if it is learned that the drug is effective, the trial is stopped. When and if it is learned that the drug is ineffective, then again the trial is stopped. Patients in the trial benefit from data collected in the trial. The explicit goal is to treat patients more effectively as well as to learn more efficiently. Each design's frequentist operating characteristics are evaluated using Monte Carlo simulation, with possible modification of the parameters of the assignment algorithm to achieve desired characteristics.

Outcome-adaptive randomization can be constructed under either a frequentist or a Bayesian framework. A frequentist approach has been used to derive the optimal randomization probability under various criteria,^{97, 98} and interim data available at the time of patient allocation have been used to estimate the response rates.⁹⁹ The “doubly adaptive biased coin” design^{100, 101} extends this approach by considering the proportion of patients assigned to each treatment and the current estimate of the desired allocation proportion to compute the randomization probability to achieve optimal design properties with less variability.

The most intuitive approach is standard Bayesian adaptive randomization, which assigns patients to treatment arm 1 with $\phi_1 = \text{Prob}(\theta_1 > \theta_2)$, where θ_i is the posterior probability of p_i for $i = 1, 2$ at the time of randomization. This approach has been extended by applying a power transformation, $\phi_1 = \text{Prob}(\theta_1 > \theta_2)^c / (\text{Prob}(\theta_1 > \theta_2)^c + \text{Prob}(\theta_1 < \theta_2)^c)$, and using $c = n/(2N)$, where n is the number of currently enrolled patients and N the maximum number of patients in the trial, to decrease the variability of the randomization probability.¹⁰² Thus, the randomization probability is approximately 0.5 at the start of the trial, and varies as more data accumulate, particularly if the data show a large difference in the response rates between the treatment arms. The randomization probability can be restricted to a range around 0.5 to decrease its variability. Other schemes use the posterior mean (or median) of the treatment effect to determine the randomization probability: $\phi_1 = \hat{\theta}_1 / (\hat{\theta}_1 + \hat{\theta}_2)$, where $\hat{\theta}_i$ is the posterior mean (or median) of θ_i for $i = 1, 2$.^{103, 104}

One can design a clinical trial to begin with an equal randomization scheme and then transition to an

adaptive randomization scheme after observing patient responses to the treatment. The adaptive randomization strategy can be combined with early stopping rules for futility and/or efficacy based on predictive probability. This format can result in a sensible drug-development process. (1) When the trial starts, equal randomization is applied as there is not much information on treatment efficacy. (2) After a reasonable amount of data are accumulated, one can switch to adaptive randomization so more patients can be assigned to the better-performing arms based on the available data. (3) The trial continues to accrue patients toward the maximum sample size, but allows for interim monitoring such that the trial can be stopped early when sufficient evidence has accrued that will allow for the inference of treatment efficacy. The flexible format of the trial illustrates the advantages of the Bayesian adaptive clinical trial design.¹⁰⁵

Using adaptive randomization to evaluate multiple treatments requires the trial statistician to carefully check for population drift to prevent biased comparisons of the various treatments. This is of concern when using an adaptive randomization scheme that tends to assign more patients to the better-performing treatments because the scheme may cause imbalance in the patient characteristics across the treatment arms.¹⁰⁶ The trial can be designed to partially correct for population drift by including a control arm and placing limits on the randomization probability to achieve a nonnegligible randomization probability for each treatment arm. A marked population drift can invalidate proper inference. This issue can be resolved using regression analysis, for example, to account for the imbalance in prognostic covariates among the treatment arms. Recommendations for monitoring adaptive trials are provided by Marchenko et al.¹⁰⁷

The advantages and disadvantages of incorporating outcome-adaptive randomization strategies in a clinical trial have prompted numerous discussions and may depend on the specific scenario under which the strategy is applied. Equal randomization has been preferred in a two-arm trial with a binary endpoint because it is easier to implement, and results in smaller sample sizes and fewer nonresponders.¹⁰⁶ A recent analysis of outcome-adaptive randomization questioned the ethics of using this strategy for two-arm trials.¹⁰⁸ Adaptive randomization strategies can increase the favorable response rate and achieve better statistical power when a large difference exists between the effects of the different treatments tested in a trial.¹⁰⁹ Adding an early stopping rule to the trial design will somewhat decrease this advantage. Compared to equal randomization strategies, adaptive randomization strategies may be advantageous in trials that evaluate a rare disease. Adaptive randomization is advantageous in trials that evaluate multiple treatments and which combine multiple stages of study, and particularly when one treatment is much more beneficial than the others.^{69, 104, 109}

Extraim analyses

A common circumstance is that a clinical trial ends without a clear conclusion. For example, a statistical significance level of 5% in the primary endpoint may be required for drug registration, and the p -value may turn out to be 6%. The regulatory agency then suggests that the trial was “underpowered” and that the company should carry out another trial. It would be much more efficient to simply increase the sample size in the present trial. The problem is that the possibility of such an extension increases the type I error rate. The principle is identical to that for interim analyses.

The solution is to build into the design the possibility of continuing the trial depending on the results, and suitably adjusting the significance levels. In contrast to the adjustments for interim analyses, the adjustments for “extra-im” (extraim) analyses are reversed, with much of the overall significance level “spent” at the originally planned sample size. For example, taking equal significance levels at each possible termination point is preferable to O’Brien-Fleming stopping boundaries because the latter are too

conservative for extraim analyses. Allowing for extending the trial increases the maximal sample size and also the average sample size. However, a modest increase in the average sample size (such as 20%) comes with a substantial increase in statistical power (such as 80% increasing to 95%). The reason for this beneficial tradeoff is that the trial is extended only when such an extension is worthwhile.

The “penalty” in the significance level can be either partially or fully offset by including futility analyses as part of the design. Namely the trial would be stopped for sufficiently negative results at preset interim time points. The reason such analyses offset the penalty for extraim analyses is that the null hypothesis is never rejected when the trial stops for futility. The increment in sample size depends on the available data at the time the decision is made to continue the accrual. It also depends on the number of possible extensions. In trials we have designed, we have based each extension on the predictive power. The usual definition of power assumes a particular value of the parameter of interest, say r . Predictive power considers all possible values of r . The data available at the time of the extraim analysis plays two roles. First, they count in the final results of the trial. Second, they are used to update the (Bayesian) probability distribution of r . Fix the total sample size n and calculate the power for detecting each possible value of r . Average this power with respect to the probability distribution of r to give the predictive power for sample size n . Extend the accrual by the minimum sample size that will achieve a total sample size having a prespecified predictive power. If there is no such value of n , then continuing the accrual may be unwise.

There is no need to stop a trial just because some of the endpoint information is unavailable. Early information (biomarkers and performance status) that is correlated with the endpoint of interest can be used to inform the prediction. Processes that can be completely and precisely described can be simulated. An advantage of simulations is that each iteration provides data from a fully accrued trial. Therefore, it is possible to check any characteristic of interest regarding the trial's design by calculating the proportion of the trials that have that characteristic. Characteristics of interest include the power, the actual sample size, and the probability of extending the accrual.

The Bayesian framework is ideally suited for incorporating information from outside the trial to make inference. For example, hierarchically commensurate priors and power priors can be applied to adaptively incorporate historical information into clinical trials.^{110, 111} Historical data on similar therapies or devices can be readily available in many settings. The efficient and appropriate use of such historical information to strengthen the inference for a new trial has been demonstrated in the development of medical devices.¹¹²

Process or trial? Evaluating many drugs simultaneously in platform trials with or without adaptive allocation

The greatest need for innovation in drug development is the process of effectively dealing with the enormous numbers of potential drugs that are available for development. The notion of developing drugs one at a time is changing. Companies that are able to screen many drugs simultaneously and effectively will survive and others will not.

The platform-based clinical trial design is an example of innovation in the process of developing new agents and therapies.^{113, 114} A platform is an operational and statistical framework that is specific to a particular disease or condition rather than being specific to a particular clinical protocol. Each new agent or therapy can be considered as a “module” that can be plugged in and out of the “platform” that targets a particular disease or condition. These new treatments can be simultaneously screened as they are developed as an alternative to conducting several separate phase II trials to evaluate multiple treatment arms. Bayesian modeling and randomization can be easily incorporated into the platform-based design. It

can be shown that the platform design is much more efficient than running multiple, separate trials. Once the appropriate dose of a new agent has been determined in a phase I trial, that new agent may be added to the platform. An agent may also be dropped from the platform if the data accumulating in the screening process demonstrate that the agent is not producing the desired results. An agent that is dropped from the platform can be returned to a phase I study to re-examine the optimal treatment dose or schedule of doses. If that phase I trial determines that an alternative dose or schedule of doses may be beneficial, then the agent previously dropped from the platform may re-enter the screening process.

The platform-based design brings important statistical challenges to the conduct of such screening trials. The Bayesian posterior distributions and predictive probabilities are computationally intensive to calculate; however, after the predictive probabilities are calculated, boundaries can be specified for the continuous monitoring of the platform-based designs. Sequential adaptive strategies must be properly implemented to monitor the futility of the many experimental agents while maintaining the predetermined type I error rate. The platform-based design bases its futility stopping rule on the posterior predictive probability of achieving a successful trial. The design uses a Bayesian model to account for the uncertainty emanating from interim estimations of the model parameters, and uses simulations to calibrate the design parameters. A Bayesian model is also used to account for the variability resulting from the treatment responses of future patients in the trial.

Much of the research on multiarm and/or multistage trial designs includes similar strategies for improving the efficiency of drug development.^{115–119} The platform-based design and the related master protocol, umbrella trials, and basket trials, with particular application to biomarker studies, are discussed by Berry.¹²⁰ The platform-based design has potential advantages that include decreasing the overall duration of the treatment screening process; substantially decreasing the number of patients allocated to the control arm; increasing the number of treatments that can be screened, thereby expanding the treatment options available to patients in the trial; decreasing the bias arising from the heterogeneity of separate trials; improving the control of inherent multiplicities; and better informing decisions about subsequent confirmatory trials.

Application of statistical innovation in clinical oncology trials

This section briefly describes two clinical oncology trials that employ statistical innovations: the “Biomarker-integrated approaches of targeted therapy of lung cancer elimination” (BATTLE) trial and the “Investigation of serial studies to predict your therapeutic response with imaging and molecular analysis” (I-SPY 2) trial.

The BATTLE trial^{121, 122} evaluated four targeted therapies in patients with stage IV recurrent non-small-cell lung cancer, matching each therapy with one of the four biomarker profiles evaluated (defined by expressions of genes, gene mutations, copy numbers, and proteins measured by immunohistochemistry). The outcome was the 8-week disease control rate. The trial incorporates outcome-adaptive randomization and a futility stopping rule under the probit hierarchical model. The stopping rule may exclude specific agents from randomization possibilities for a given patient when that patient's biomarker profile indicates that he/she will not benefit from that agent. The BATTLE-2 trial uses the results from the first trial to screen patients for 10–15 candidate biomarkers. It incorporates adaptive randomization in a two-stage design to evaluate four treatments for non-small-cell lung cancer. The trial is a process, involving training, test, and validation procedures to select the most appropriate biomarkers to use in the trial. The design uses group lasso and adaptive lasso methods to identify prognostic and predictive markers.^{123, 124}

The multicenter I-SPY 2 trial¹²⁵ employs adaptive randomization within each biomarker-based patient

group and uses a futility or efficacy stopping rule. The I-SPY 2 trial evaluates neoadjuvant treatments in breast cancer in addition to the administration of up to 12 experimental drugs.¹²⁶ This trial has randomized more than 700 patients, transferred two experimental agents to confirmatory studies, and successfully demonstrated that this adaptive trial design can reduce drug-development costs and improve the efficiency of screening new drugs.^{125–127}

Clinical trial software

Numerous software programs to use in planning and implementing clinical trials are available online as propriety products or as free offerings.¹²⁸ Many useful computer programs for the design, conduct, and analysis of innovative trials can be found at the MD Anderson software download site. (<https://biostatistics.mdanderson.org/SoftwareDownload/>). Software developed for the CRM¹²⁹ in a phase I dose-finding trial includes the CRM simulator, the BMA-CRM, and the TITE-CRM. The CRM simulator uses the prior means of toxicity to select the optimal dose level and permits the user to vary the parameters until achieving the desired output. The BMA-CRM⁴⁶ uses multiple sets of probabilities of the prior means for toxicity to select the optimal dose. Software developed for the TITE-CRM⁴⁸ has comparable application for determining the optimal dose of an agent when delayed toxicity is expected.

For a dose-finding cancer trial, software developed to determine dose EWOC^{45, 130} employs adaptive learning. This method has been shown to allocate fewer patients to subtherapeutic or severely toxic doses, treat more patients at doses near the MTD, and estimate that dose with lower average bias and mean squared error when compared to the CRM. Another method uses modified toxicity posterior intervals (mTPI) and Bayesian decision theory to determine the optimal dose of an oncology drug.¹³¹

Another method that minimizes the likelihood of assigning patients to subtherapeutic or overly toxic doses is the Bayesian optimal interval (BOIN) design.¹³² Used in phase I clinical trials, the R function (BOIN.r) computes the optimal probability interval to determine the MTD, optimizing the dose assignment for each patient who enrolls in the trial. After specifying the design parameters, the BOIN design uses an algorithm and can be implemented similarly to the traditional 3 + 3 design. The BOIN design is comparable to the CRM in selecting the MTD, but the BOIN has a much lower risk of assigning patients to subtherapeutic or overly toxic doses.

The predictive probability design⁷² can determine the cutoff values of the predictive probability and calculate the stopping boundary needed for continuous trial monitoring on the basis of the input of the type I and type II error rates. The BFDesigner¹³³ is useful for creating efficient stopping rules. Other computational tools that are helpful when using adaptive designs are the *parameter solver*, which calculates the distribution parameters of a random variable given either two quantiles or the mean and variance, and *predictive probabilities* for a two-arm trial with a binary endpoint, which calculates the posterior predictive probabilities of finding one treatment arm to be superior to the other or of stopping for futility.¹⁶ With more software available for the design and conduct of novel clinical trials, more rapid translation of statistical innovation from theory to practice can be achieved.

Chapter 21

Biomarker-based clinical trial design in the era of genomic medicine

Richard Simon, DSc ■ Martine Piccart-Gebhart, MD, PhD

Overview

The increasingly recognized molecular heterogeneity of human cancers together with the growing availability of powerful tools providing “molecular portraits” of this heterogeneity require the development of new paradigms for the development of a reliable basis for “personalized” medicine. We review new approaches to the design and analysis of clinical trials for the development of “targeted” therapeutics and diagnostics to inform their use.

Introduction: why we need new designs and analysis paradigms for biomarker-driven clinical trials

Randomized clinical trials have enabled the development of a reliable evidence-based medicine. They have generally evaluated a treatment relative to a control regimen for a broadly defined population of patients defined by primary site, histology, stage, and number of prior treatments. In recent years, sequencing of human tumor DNA has established that cancers of a primary site often represent a heterogeneous collection of diseases that differ with regard to the genomic aberrations that cause them and drive their invasion.¹ The tumors are often heterogeneous with regard to the genes and pathways that can be inhibited by molecularly targeted therapy. Broad eligibility clinical trials are severely underpowered for detecting benefit for the subset of patients whose tumors are most susceptible to the action of the new drug. In the broad eligibility clinical trials that are “positive” because the sample size has been increased to such an extent that even small average treatment effects are statistically significant, only a small proportion of the intent to treat population actually benefits from treatment resulting in toxicity for patients who do not benefit and a large societal economic cost for overtreatment of the population.

Today, we have powerful tools for characterizing the tumors biologically and using this characterization to prospectively structure the design and analysis of more informative clinical trials that result in larger treatment effects for a larger portion of the treated patients. In this chapter, we discuss these modern designs and analyses that should better respond to the needs of “personalized” oncology.

Phase II trials of molecularly targeted agents with companion diagnostics

Nowadays, most of the cancer drugs are being developed for defined molecular targets. In some cases, the targets are well understood, and there is a compelling biological basis and evidence from phase I clinical trials for restricting development to the subset of patients whose tumors are characterized by deregulation

of the drug target. For other drugs, there are multiple targets and more uncertainty about how to measure whether a drug target is driving tumor biology in an individual patient.²

The ideal approach in the former situation is the codevelopment of the drug and a companion diagnostic that measures the deregulation of the drug target in a robust way.

In the era of molecular oncology, not only must the phase II trial determine whether there is activity of the drug overall in a histologic type, but it also must determine whether the subsequent phase III trial should be restricted based on a candidate companion diagnostic. Freidlin et al.³ have described a design for use with a single binary candidate biomarker in a randomized phase II design. Their design enables one to determine whether the drug should be (1) developed in a phase III enrichment trial, (2) developed in an analysis stratified all comers' trial, (3) developed in an all comers' trial without measurement of the biomarker, or (4) dropped from further development. This design is shown in [Figure 1](#). The sample size is determined so that the treatment effect on progression-free survival (PFS) in the marker-positive subset has power 0.9 for detecting a doubling of median PFS at a one-sided significance level of 0.10. This will generally provide at least as many events for evaluating treatment effect in the marker-negative subset. If the treatment effect in the marker-positive subset is not significant, then the overall treatment effect is tested at a one-sided 0.05 significance level. If that treatment effect is not statistically significant, then the drug is not recommended for phase III development. If the overall treatment effect is significant, then a traditional phase III trial without measurement of the candidate biomarker is recommended. If the treatment effect in the marker-positive subset is significant, then one examines an 80% confidence interval for the hazard ratio of treatment effect in the marker-negative subset. If the upper confidence interval is below 1.3, then one concludes that the treatment is not active in the marker-negative patients and an enrichment phase III trial is recommended. If the lower confidence limit is above 1.5, then one concludes that the treatment works well in the marker-negative patients and a traditional phase III trial in which the biomarker is not even measured is recommended. Otherwise, a biomarker-stratified phase III trial is recommended.

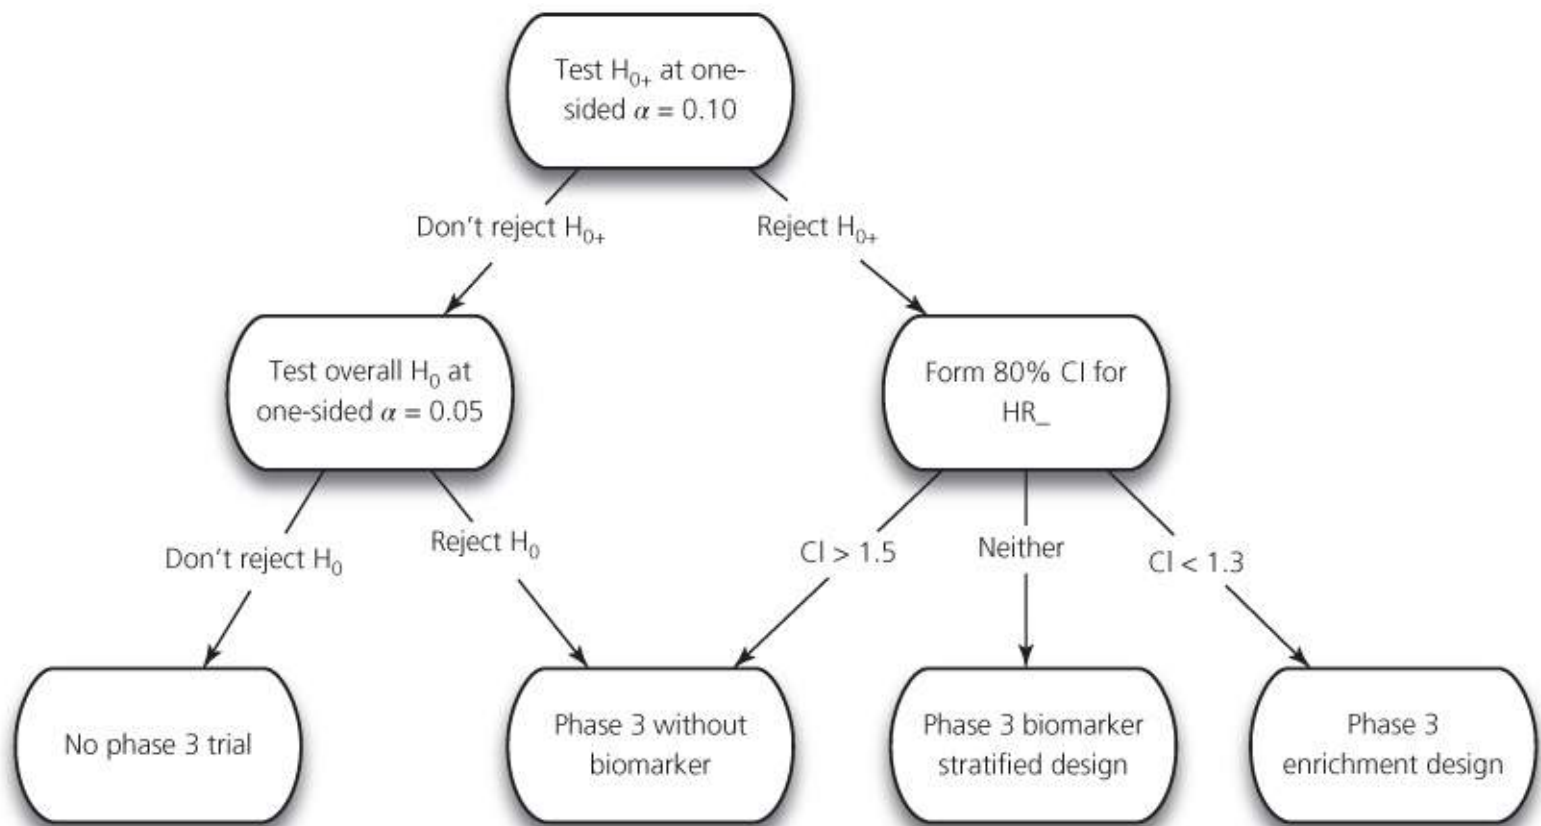

Figure 1 Analysis strategy for randomized phase II design to decide whether phase III trial should be restricted to biomarker-positive population, should include positives and negatives, whether biomarker should not even be measured or whether the conduct of a phase III trial is not supported by phase II results. Data from [3]. HR_+ is hazard ratio in biomarker-positive group. HR_- is hazard ratio for treatment in biomarker-negative group. H_{0+} is null hypothesis that $HR_+ = 1$. H_0 is null hypothesis that overall $HR = 1$.

Other phase II designs for evaluation of a treatment within marker subsets in single-arm phase II studies have been described by Puztai and Hess⁴ and Jones and Holmgren.⁵ These designs are focused primarily on ensuring that promising activity of the drug is not missed in cases where its activity is restricted to test-positive patients, and yet excessive numbers of patients are not required in cases where its activity is sufficiently broad that the marker is not needed.

There are more complicated phase II settings, where no natural cut-point of the biomarker is known in advance, or where there are multiple candidate biomarkers. The BATTLE I trial in NSCLC (nonsmall cell lung cancer) is an example of a phase II clinical trial using a response-adaptive randomization,⁶ which is discussed in another chapter of this book. Of note, some statisticians have raised doubts about the effectiveness of such adaptive randomization designs.⁷

Phase IIa basket and umbrella discovery trials

Large tumor sequencing studies such as the Cancer Genome Project in the United Kingdom and the Cancer Genome Atlas (TCGA) in the United States have identified recurrent genomic aberrations in a variety of primary tumor sites.¹ These data provide a scientific basis for treatment of individual patients based on the biological characterization of their tumors. There are, however, many challenges in moving tumor genomics to clinical oncology and the first one is the tremendous heterogeneity of the genomic landscapes of the tumors, implying the existence of multiple, rare genomic segments within a given tumor type.

Developing a single targeted drug in a single small genomic segment of one disease is a lengthy, inefficient, and costly exercise. Let us take the example of HER2 mutations that, contrary to HER2 gene amplification, occur at a low frequency of 1–2% in advanced breast cancer. There is preliminary evidence that these mutations are “actionable” using a potent irreversible tyrosine kinase inhibitor such as neratinib.⁸ Conducting a “confirmatory” phase II trial of around 40 patients would require the screening of 2000–4000 women with advanced breast cancer. Moreover, at the end of this exercise, the potential value of the new drug versus standard of care or in other tumor types harboring similar mutations would remain unknown. [Figure 2](#) highlights the challenges of a registration path of such a drug in a “small” genomic segment of the breast cancer (BC) population. This genomic aberration, therefore, would be best matched with its candidate drug in the context of an “umbrella” discovery trial, where a panel of genomic aberrations would be screened and investigated in the context of several breast cancer phase II arms. Alternatively, a basket trial could examine HER2 mutations across several tumor types and investigate the activity of the TKI (tyrosine kinase inhibitor) in each of them with “early stopping rules” in case of lack of antitumor activity. These increasingly popular forms of clinical trials are described later.

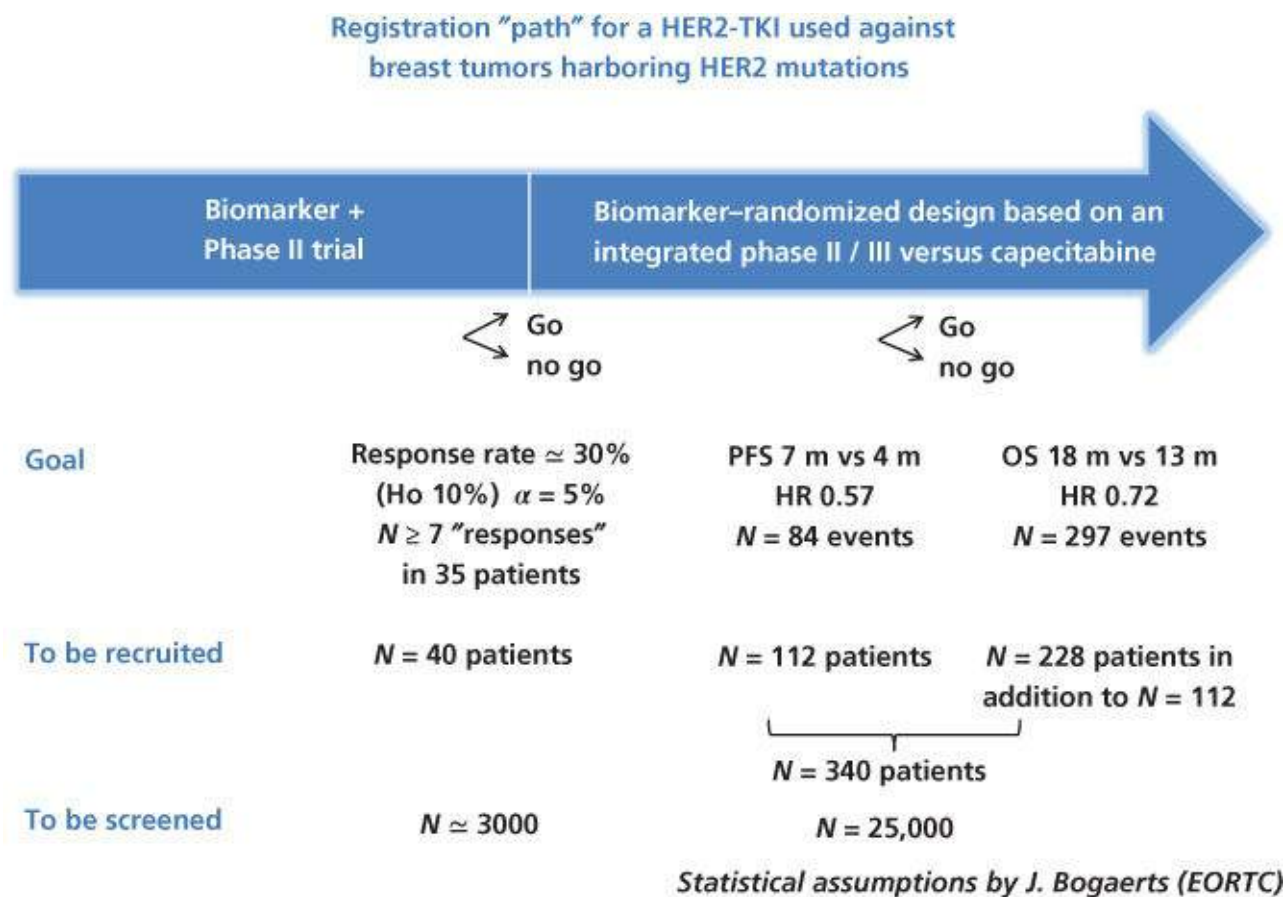

Figure 2 Schema for phase II and III clinical trials for developing a drug that inhibits a target, which is mutated in only 1–2% of cases. Although the number of patients required for the clinical trials are reasonable, the number screened is very large. It is more efficient to incorporate development of such a drug in an infrastructure of common national and international screening with regard to multiple targets and then triaging patients to clinical trials for which they are eligible.

“Basket” discovery trials include patients with advanced cancer of multiple primary sites that are resistant to standard treatment.⁹ A sequencing assay is used to evaluate the tumor DNA of a patient and it is determined whether an actionable aberration is present. “Actionable” means that a drug is available whose range of molecular targets overlap with the genomic alterations of the tumor in a way that suggest treatment may result in benefit for that patient. Various kinds of evidence may be used to determine whether a drug is a reasonable candidate for a given mutation. It will include biological understanding of

the targets of the drug and the role of those targets in the disease. It may involve using the COSMIC (Catalog of Somatic Mutations in Cancer) database to determine whether the gene is mutated frequently enough in that histologic type to be considered a “driver” mutation. It may involve using algorithms to determine whether mutations found in a gene are predicted to alter protein function. It may also involve using preclinical data about drug activity in cell lines, tumor grafts bearing that mutation in mice, or clinical data in a different tumor type. The rules of actionability should be prospectively defined. Defining levels of evidence for actionability of a drug and a genomic aberration may help trial organizers resolve difficult binary decisions of whether there is sufficient evidence to warrant considering a drug actionable.

The term “basket trial” is often reserved for clinical trials of a single drug with multiple histologic types of patients and multiple types of mutations of either a single gene or several genes. The trials with multiple drugs involved are often called “umbrella trials.” Both types of trials are early discovery trials and attempt to identify the genomic characterization of tumors for which there is evidence of substantial anticancer activity of a drug. These positive signals should be confirmed in later expanded phase II or II/III trials.

Some umbrella trials are randomized; outcome for patients who receive drugs based on actionability rules are compared to outcomes on a control drug or on drugs selected based on physicians' choice without genomic characterization. Both the MPACT (molecular profiling based assignment of cancer therapeutics) clinical trial being conducted by the National Cancer Institute and the Stand-Up-To-Cancer sponsored clinical trial in BRAF^{WT} melanoma use 2 : 1 randomization plans.¹⁰ The randomized umbrella designs address two distinct questions.¹⁰ One is testing the null hypothesis that the policy of trying to match the drug to the genomics of the tumor is no more effective than a treatment strategy that does not use any tumor characterization beyond that used for standard of care. Although most traditional randomized clinical trials evaluate a single drug or regimen, the null hypothesis here relates to a matching policy for a given set of drugs and biomarkers available for the study. This makes it particularly important to obtain a broad enough menu of potent inhibitors of the selected targets. The matching policy is also determined by the type of genomic characterization performed and by the “rules” for matching drug to tumor. If matching is done by a tumor board and is not rule based or if the rules change frequently, the pragmatic value of the clinical trial will be limited. It may also be difficult for regulatory bodies to approve investigational drugs for use as decided by a tumor board rather than in a more rule-based manner. The use of a randomized control group facilitates the use of PFS as endpoint. The proof-of-principle embodied by the null hypothesis may be more meaningful, however, in a trial of a single histologic category than in cases where a wide range of primary sites of disease are included.

A second objective of randomized umbrella studies is the screening of individual drugs used in specific genomic and histologic contexts. For some primary sites, a gene such as “NRAS” may be mutated sufficiently frequently for the study to provide an adequate phase II evaluation of the drug for that new indication. In many cases, however, the numbers will not be adequate for a proper phase II evaluation. Nevertheless, the trial may serve to screen for drug-mutation matches for which there is a substantial degree of activity, larger than is usually tested for in traditional phase II trials. These leads should be confirmed in an expanded cohort of a follow-up trial.⁸ In this discovery mode, assessment of activity of a drug against tumors with a given gene mutated must take into account the possibility that the cell type in which the mutation occurs or the histology of the tumor may modulate activity of the drug against the alteration. This was the case for BRAF inhibitors in colorectal cancer.¹¹

New statistical designs specifically for basket or umbrella trials have not yet been introduced. Many such trials incorporate a traditional two-stage design for drug-mutation strata that will have sufficient patients

to be separately analyzed. A traditional two-stage design for distinguishing a response rate of 10% from one of 35% with 85% power and 10% type I error requires only five first stage patients and has a 60% chance of terminating at the first stage if the true response probability is only 10%.¹² Such designs can be computed online at <http://brb.nci.nih.gov>.

LeBlanc et al.¹³ previously introduced a design for multiple histology phase II trials that can be used in some basket or umbrella clinical trials. It combines statistical significance tests of drug activity within histology strata with a combined analysis that borrows information from all the patients in the study. Sequential futility analyses are conducted once each strata or the overall group reaches a specified minimum amount. Thall et al.¹⁴ developed a hierarchical Bayesian method for evaluating treatment effects in discrete strata of a phase II trial while accounting for the relatedness of the strata. This approach has been critiqued by Freidlin and Korn¹⁵ who concluded that “there appears to be insufficient information in the outcome data to determine whether borrowing across subgroups is appropriate.”

Phase III designs with a single binary biomarker

Targeted (enrichment) designs

Designs in which eligibility is restricted to those patients considered most likely to benefit from the experimental drug are called “targeted designs” or “enrichment designs” and are illustrated in [Figure 3a](#). With an enrichment design, the analytically validated diagnostic test is used to restrict eligibility for a randomized clinical trial comparing a regimen containing a new drug to a control regimen. This approach has now been used for pivotal trials of many drugs whose molecular targets were well understood in the context of the disease. Prominent examples include trastuzumab,¹⁶ vemurafenib,¹⁷ and crizotinib.¹⁸

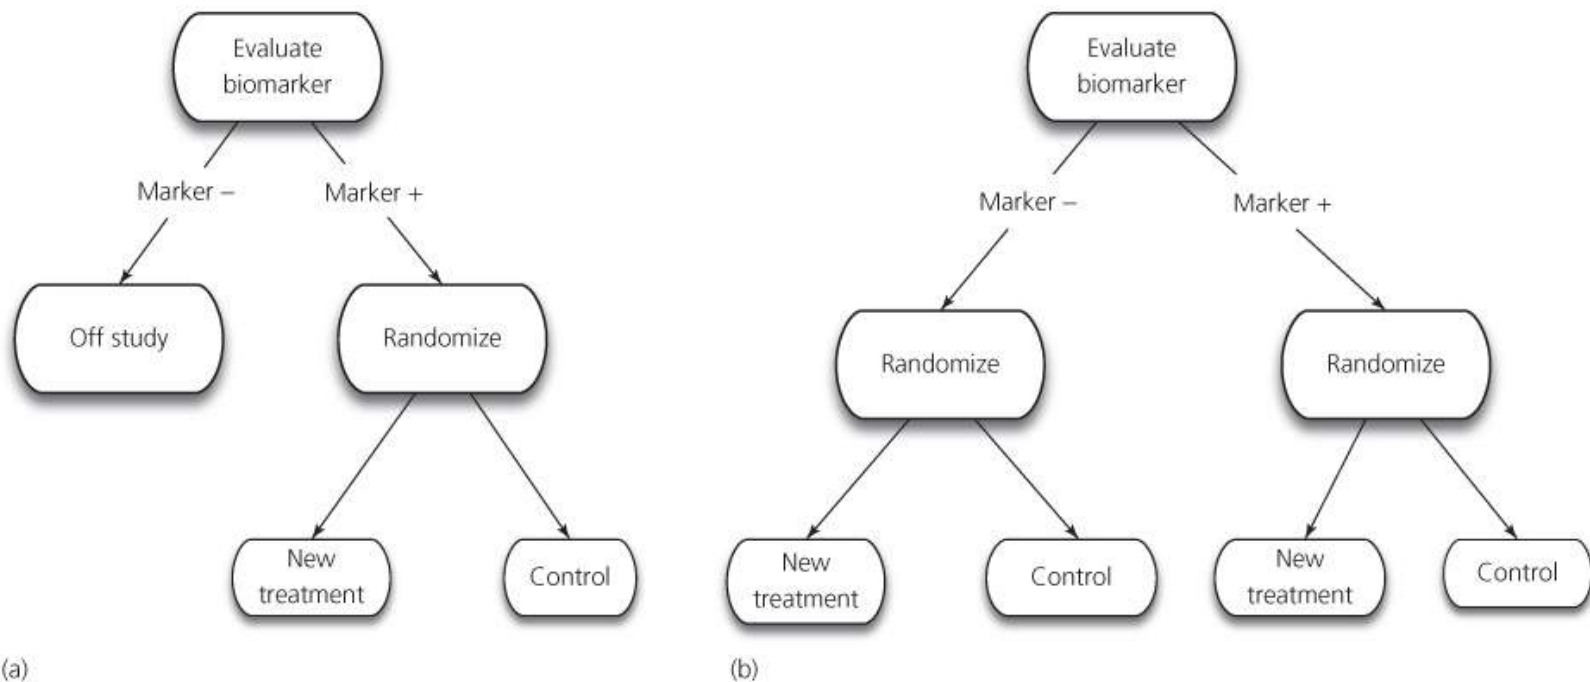

Figure 3 (a) The targeted enrichment design is used for evaluating a new treatment in the population of patients who are identified using a predictive biomarker as best candidates for benefit from the new treatment. It is primarily for settings where there is a compelling basis for believing that “marker-negative” patients will not benefit from the new treatment and an analytically validated test is available. (b) The “all comers’ design” or “marker stratification design” is used for evaluating the effectiveness of a new treatment versus a control in a population prospectively characterized by a binary predictive marker. A detailed prospective analysis plan should describe the primary comparison of treatment to control, in the marker-positive, marker-negative, and overall populations. With a focused analysis plan that limits the study-wide type I error to the traditional 5% level, claims of treatment effectiveness in marker-positive patients need not be restricted to cases where the treatment is effective overall or there is a significant interaction.

The enrichment design was very effective for the development of trastuzumab, even though the test was imperfect and has subsequently been improved. Simon and Maitournam^{19, 20} developed general formulas for comparing the enrichment design to the standard design with regard to the number of randomized and screened patients. They found the enrichment design very efficient and have made the methods of sample size planning for the design of enrichment trials available online at <http://brb.nci.nih.gov>. The web-based programs are available for binary and survival/disease-free survival endpoints. The enrichment design is appropriate for contexts where there is a strong biological basis for believing that test-negative patients will not benefit from the new drug.

All comers' (stratification) designs

When a predictive biomarker has been developed but there is not compelling biological or phase II data that test-negative patients do not benefit from the new treatment, it is often best to include both classifier positive and classifier negative in the phase III clinical trials comparing the new treatment to the control regimen. This is shown in Figure 3b. The biomarker is measured in all patients at entry to the trial, and then all patients are randomized to the test treatment or the control regimen. In this case, it is essential that an analysis plan be predefined in the protocol for how the predictive classifier will be used in the analysis. The analysis plan will generally define the testing strategy for evaluating the new treatment in the test-positive patients, the test-negative patients, and overall.²¹ The testing strategy must preserve the overall type I error of the trial. The overall type I error is the probability that a claim for a statistically

significant difference is made from any of the comparisons when in fact the treatments are equivalent both overall and within the biomarker-specific subsets. Controlling the overall type I error often requires that a threshold of significance <0.05 is used for interpreting the individual significance tests. The clinical trial should also be sized to provide adequate statistical power for these tests. It is not sufficient to just stratify, that is, balance, the randomization with regard to the classifier without specifying a complete analysis plan. The main value of “stratifying” (i.e., balancing) the randomization is that it assures that only patients with adequate test results will enter the trial. Prestratification of the randomization is not necessary for the validity of inferences to be made about treatment effects within the test-positive or test-negative subsets.²² If an analytically validated test is not available at the start of the trial but will be available by the time of analysis, then it may be preferable not to prestratify the randomization process.

Several primary analysis plans have been described and a web-based tool for sample size planning for some of these analysis plans is available at <http://brb.nci.nih.gov>. If one has moderate strength evidence that the treatment, if effective at all, is likely to be more effective in the test-positive cases, one might first compare treatment versus control in test-positive patients using a threshold of significance of 5%. Only if the treatment versus control comparison is significant at the 5% level in test-positive patients, the new treatment will be compared to the control among test-negative patients, again using a threshold of statistical significance of 5%. This sequential approach controls the overall type I error at 5%.²³ In the situation where one has limited confidence in the predictive marker, it can be effectively used for a “fallback” analysis. Outcomes for the new treatment group is first compared to those for the control group overall. If that difference is not significant at a reduced significance level such as 0.03, then the new treatment is compared to the control group just for test-positive patients. The latter comparison uses a threshold of significance of 0.02, or whatever portion of the traditional 0.05 not used by the initial test.²³ In situations where one has an intermediate level of confidence in the candidate biomarker, one can use the MAST analysis plan.²⁴ At the final analysis, one first tests the null hypothesis of no treatment effect for the marker-positive patients. The threshold of significance for this test is prespecified as some value α_+ less than the total type I error 0.05 of the design. For example, α_+ may be 0.04. If that null hypothesis is rejected, then the null hypothesis for the marker-negative patients is tested using a significance threshold of 0.05. If the null hypothesis for the marker-positive patients is not rejected, then the null hypothesis for the pooled overall population is tested using a significance threshold of $0.05 - \alpha_+$, 0.01 in this example.

Other “real-world” experience with stratification and enrichment designs are described by Freidlin et al.²⁵ and Mandrekari and Sargent.²⁶ Adaptive forms of the enrichment design in which one starts with “all comers” and adaptively restricts the eligibility are described by Wang et al.,²⁷ Rosenblum and VanDerLaan,²⁸ and Simon and Simon.²⁹

Prospective–retrospective designs

In some cases, a completed randomized clinical trial with archived tumor specimens can be used to evaluate treatment effect in a subset determined by a new candidate biomarker. For example, the hypothesis that the effectiveness of anti-EGFR antibodies in colorectal cancer would be limited to patients whose tumors did not contain K-RAS mutations was evaluated in randomized clinical trials that had been planned before this hypothesis was suggested by other investigators. Simon et al.³⁰ described a prospective–retrospective approach to using archived tumor specimens for a focused re-analysis of a randomized phase III trial with regard to a predictive biomarker. The approach requires that archived specimens be available on most patients, and that an analysis plan focused on a single marker be developed before performing the blinded assays. The finding must also be evaluated in two such

prospective–retrospective trials in order to be considered type I evidence. It is not necessary that the randomization should have used the marker as a stratification variable. This is not relevant to the validity of the analysis of treatment effect in marker-positive patients.²² Simon²² has also pointed out that there is no critical minimum proportion of the tumors archived necessary for the retrospective–prospective approach. The key factor is that there should be no bias between treatment groups with regard to availability of archived specimens. Lack of such bias can be assured if patient and physician agreement for tissue archival is established before randomization.

Run-in designs

Predictive biomarkers are usually thought of as biological measurements that are obtained from the tumor or the patient before the start of treatment. Hong and Simon³¹ developed a run-in design that permits a pharmacodynamic, immunologic, or intermediate response endpoint measured after a short run-in period on the new treatment or the control to be used as the predictive biomarker. After measuring the biomarker during the run-in period, either all patients are randomized between continuing the new treatment or switching to control or just the “marker-positive” patients, those showing substantial change in the measurement from the pretreatment baseline measurement are randomized. The biomarker is not used as an endpoint for comparing the treatments and randomization is not performed until after the marker is measured. The marker is used for stratifying the patients for separate analysis as in the all comers' stratified design or for excluding the marker-negative patients as in the enrichment design. The run-in period should be short because one does not want the survival or disease-free survival of the patients subsequently randomized to the control group to be extended during the run-in period on the test drug. The run-in designs offer substantial opportunity for increasing the efficiency of clinical trials in situations where pre-treatment-predictive biomarkers cannot be identified.

Phase II/III enrichment designs with multiple biomarkers

[Figure 4](#) shows the structure of a new lung-MAP biomarker-driven clinical trial prototype being used for drug development in patients with refractory advanced squamous cell carcinoma of the lung. The design was developed as a collaboration of FDA (Food and Drug Administration), pharmaceutical industry, US National Clinical Trials Network, NCI (National Cancer Institute), and Foundation Medicine under the coordination of Friends of Cancer Research. Plans call for enrolling up to 5000 patients through more than 200 medical centers during the next 5 years in randomized phase II/III studies of novel agents after participants have been screened for genomic alterations of their tumors using the FoundationOne DNA sequencing test, which analyzes 182 genes. On the basis of the results of the screening, patients will be channeled to one of five randomized phase II/III trials. Each of the five randomized trials will have a phase II stage and will progress to the phase III stage if results are promising. The primary endpoint is PFS. These trials are all potentially pivotal phase III enrichment clinical trials with companion diagnostics for different patient subsets. As the evaluations of these drugs are completed, an additional five to seven agents will be tested.

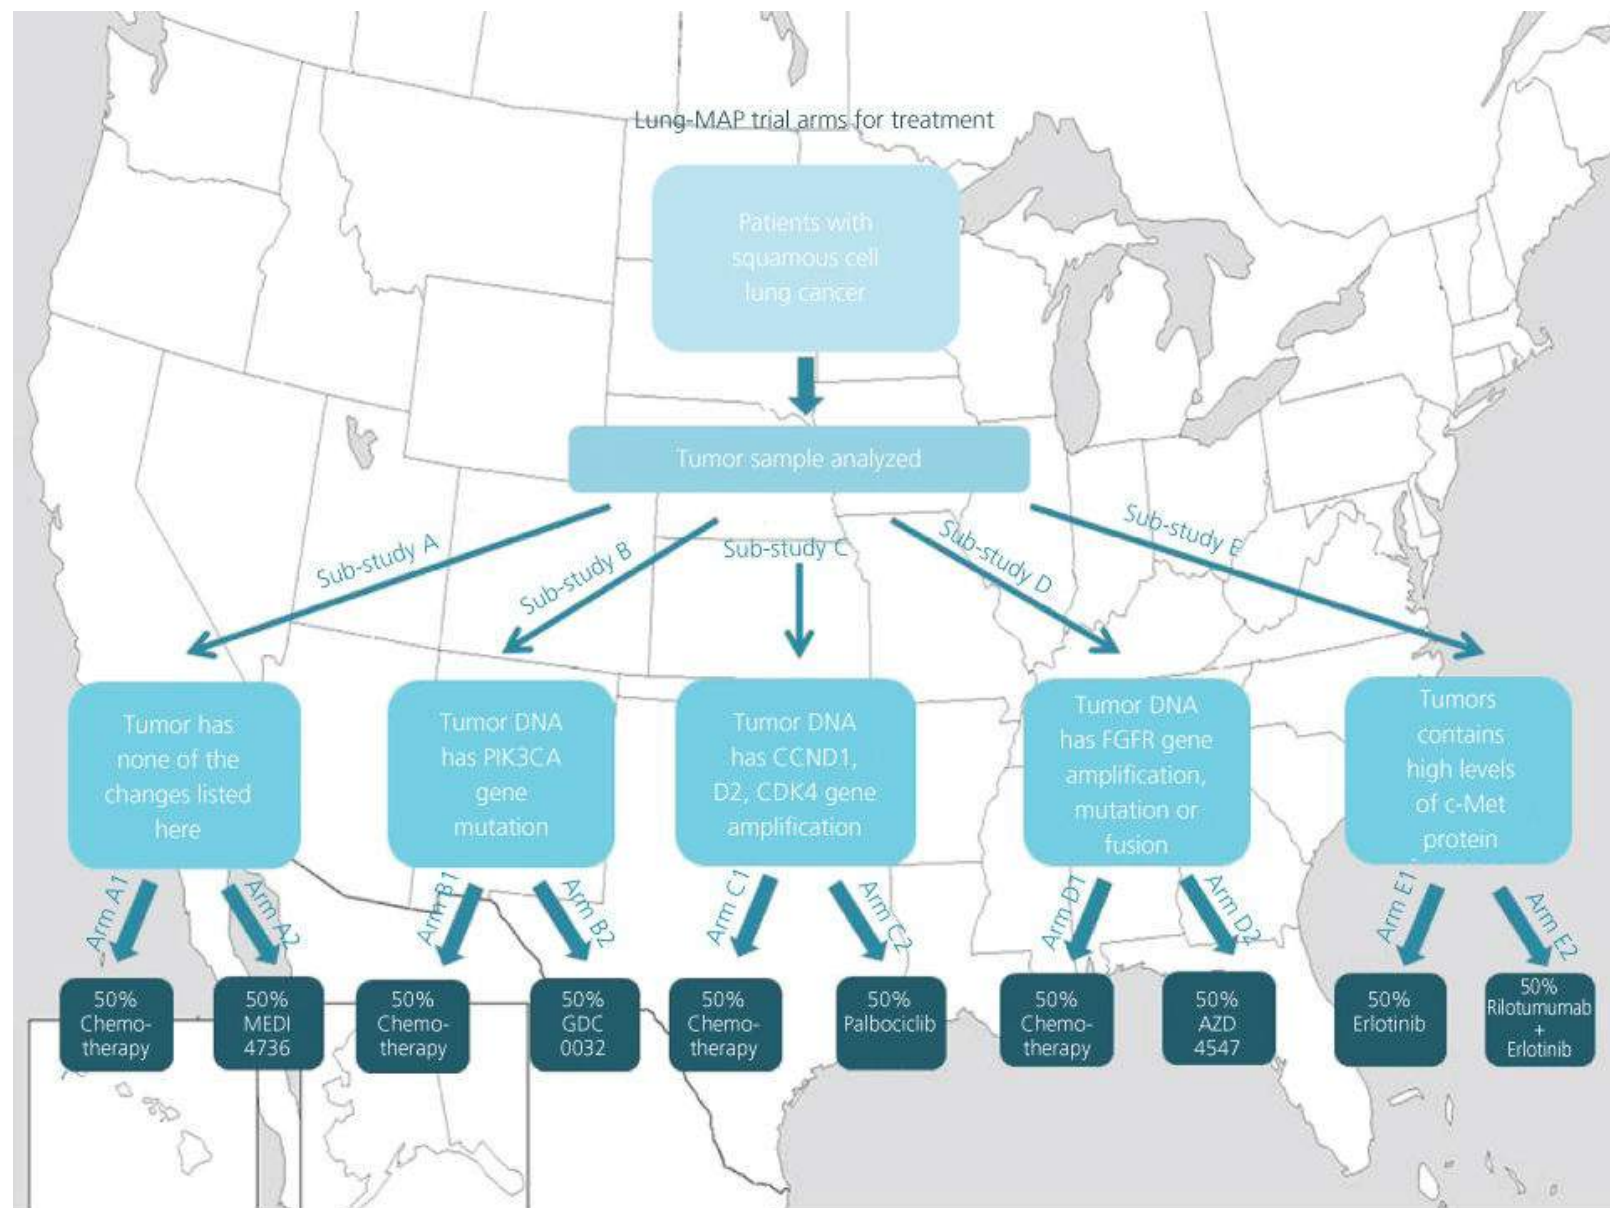

Figure 4 Lung-MAP clinical trial master design. Patients with squamous cell carcinoma of the lung are screened for genomic mutations in their tumors. Depending on the genomic alterations found, patients are enrolled on one of six randomized clinical trials. Each component trial compares the same control treatment to a treatment specially designed for patients with a class of genomic alterations. Each component clinical trial is a randomized phase II/III clinical trial, which may serve as a pivotal trial for approval of the test drug for the selected patient population. Source: National Cancer Institute, <http://www.lung-map.org>.

The new models of collaboration required by clinical trials of the “genomic era” and the challenges ahead

We are still at the start of a “learning curve” in classifying cancers molecularly in a therapeutically relevant manner. It is likely that we will soon be moving from simple classifications relying on aberrations at the DNA level toward more complex classifications also incorporating critical information generated by RNA sequencing and (phospho)protein platforms. It can also be foreseen that “pathway-directed” treatment strategies will replace single-target-directed strategies, as aiming at the latter is likely to fail in view of the plasticity of the cancer cell. Moving “genomics” to “therapeutics” implies dealing with uncertainty and statisticians will continue to play a critical role in this regard.

At the same time, it is clear that achieving the benefits of “personalized” oncology requires paradigm changes in academic clinical investigation, with the setup of large collaborative teams, in industry drug development, with less walls between drug development paths when it comes to combination strategies, and in regulatory evaluation, with more adaptive licensing routes for new compounds or innovative drug combinations.

Conclusion

In oncology, treatment of broad populations with regimens that do not benefit most patients is less economically sustainable with expensive molecularly targeted therapeutics currently in development and less likely to be successful. The established molecular heterogeneity of human diseases requires the development of new design and analysis paradigms for using randomized clinical trials to provide a reliable basis predictive medicine.

Chapter 22

Clinical informatics

Edward P. Ambinder, MD

Overview

Informatics is the integration of information technology into health care. For oncology, the need to understand informatics is critical because of the need to keep up with the rapidly changing basic, translational and clinical cancer research findings, therapeutic interventions using panomic data required for precision medicine, latest practice guidelines, shifting reimbursement practices, and the dominating and at times frustrating electronic health record (EHR) that is the repository of our health data and window into the health care system. All of this must take place in a value-enhanced practice environment that constantly measures our quality of care in a well-coordinated system for our engaged patients who are digitally connected to multiple practices, their hospital, their smartphones and medical devices, their personal health record and multiple EHRs. Oncologists will soon have a well-defined “Oncology Digital Health Information Technology System” that will redefine cancer research by capturing meaningful and actionable patient data in every cancer patient. They will continue to participate in the mobile computing revolution that is just beginning to have a transformative effect on all of medicine where computers will do our work, apps work with other apps and EHRs to educate us and our patients and use real electronically shareable and reusable medical data. Today, the majority of patients have their cancer care documented in EHRs. As rapid learning systems (RLSs) such as ASCO's CancerLinQ capture all this data and use Big Data analytic tools for capturing and comparing similar cancer patients as to the best treatments and outcomes, we will have real precision medicine. The evolving “Internet of Things” where medical devices and health care platforms will give us the unprecedented ability to measure in real time the health and wellness of our cancer patients undergoing chemotherapy treatments on a 24-h basis will provide huge monetary savings for the health system, improved quality of care, and innovative medical research as cancer care develops into a RLS.

Introduction

Oncologists and their patients are facing disruptive changes in health care practice, research, governmental oversight, business practices, communication, and reimbursement—changes brought on by the individual growth and merging of the fields of information technology with medical technology, medical practice, biology, and physics. We now practice in large hospital systems or accountable care organizations rather than in small group practice silos; deal with changing reimbursement methods as we transition from fee-for-service to bundling payments and defined encounters of care; document our patient care using electronic media rather than paper; and see the doctor–patient relationship become more patient-centric. We are increasingly communicating electronically with all health care stakeholders, including our patients.

This dramatic increase in the quantity, quality, and ease of finding information—brought about by the use of computers and the effortlessness of connecting everyone and everything—all of which has been brought

about by the Internet, has changed our lives forever. However, we remain frustrated with our electronic devices needed to communicate with our health care system because they still require typing or dictation for data entry, and the data entered are not easily understood by the computer or able to be shared, reused, or reported easily because of the absence of seamless data interoperability where data entered into one device could be understood, used, and reused effectively in another device.

Clayton Christensen presciently warned us about the disruptive effects of this transformation in 1997,¹ and he warned us specifically about its effects on health care in 2008.² Indeed, for the first time, this new, disruptive digital world of medicine is increasingly defined by information becoming electronically mobile, cheap, available to all, and consumer-oriented to such an extent that almost all recent information technology advances in hardware and software begin with the consumer rather than business. Oncologists and their patients must begin to understand this transformative event that will directly address our current frustrations.

An oncology digital health information technology system

Common data elements and value sets

Common data elements define the data to be collected in the medical record by specifically identifying the label of each data field and the appropriate value set to choose for data entry. When possible, the value set choice should reference a standard code system such as a clinical vocabulary used to describe the clinical encounter (e.g., SNOMED-CT), the laboratory data (e.g., LOINC), the terms describing basic and clinical research activities [e.g., cancer Biomedical Informatics Grid (caBIG)], and the elements and codes that define specific disease classifications used for billing and registry reporting purposes (e.g., ICD-9 and ICD-10 codes).

Data types

Computers capture electronic *structured* and *unstructured* data. Data can be structured using data elements and value sets that are machine readable, reusable, shareable, actionable, multiuser-able, and multipurposeful. Unstructured or narrative data are entered by typing or dictation and adds context making it is understood by humans but not by computers unless sophisticated natural language processing tools are used or the data can be tagged by metadata that renders them searchable. Searchable or machine-readable data would permit the EHR (electronic health record) to provide clinical decision support (CDS), user education, and secondary reporting purposes. In reality, both types of data are important in capturing the complete patient's health record.

Software functionalities and documentation

Software functionalities refer to the capabilities that a software program should provide. For all EHRs, ePrescription software is necessary, whereas for medical oncology, EHRs chemotherapy administration is required. [Table 1](#) lists EHR functional elements defined by ASCO's EHR workgroup and [Table 2](#) lists oncology-specific documentation required in an oncology EHR.

Table 1 EHR functional elements defined by ASCO's Electronic Health Record Workgroup

EHR functional element	How it is used in the practice
View patient information	Review patient's symptoms or chief complaints, medication list, test results, and other clinical documentation
Gather data	Build electronic patient charts that are searchable. Build patient charts from customizable templates
Compile data	Pull together patient or practice population, histories, and graph it or map it for analysis. Report generation
Query patient or practice data to generate standard and/or custom reports	Assist in evaluating, diagnosing, and reviewing acute or chronic diseases and treatment regimens and provide appropriate clinical alerts and warnings based on established guidelines. Interoperability with other systems
Clinical decision support	Interact with internal practice management and other internal information systems (e.g., laboratory information system—LIS); interface with external hospital, lab, imaging, pharmacies, and payers
Search capabilities	Query the database for reports on clinical issues and costs
Patient management	Manage the individual patient's acute and chronic diseases and conditions
Practice marketing	Provide information regarding types of services you perform most often. Provide analysis on your patients' clinical conditions, referral base, and patient population
Standardization	Standardize disease management goals and treatment regimens for patient groups within your practice
Billing and coding	Provide internal checks and balances with ICD and CPT codes to details of the patient encounter; integrate E&M coding and HCPCS codes. Order entry, order labs, imaging, referrals, and other nonmedications
Chemotherapy ordering	Initiate chemotherapy orders, associated ancillary therapies, and dose modifications with proper authorization and confirmation
e-Prescribing	Authorize and manage prescription refills. Access formulary information. Route new prescriptions online to pharmacy
Communication	Communicate online with patients, colleagues, payers, hospitals, and pharmacies
Provide built-in compliance and regulatory guidance	Compliance
Clinical trials	Conduct research, registry, and clinical trial activities
Patient interaction	Incorporate information originating from the patient, including data from a personal health record (PHR) and medical and patient devices
Quality measurement	Use data to participate in quality measurement programs

Table 2 Oncology-specific documentation required in an oncology EHR

Provide menu-driven site/histology/pathology findings
Manage patient response to treatment on flow sheets
Document intent and goals of adjuvant/curative versus palliative therapy
Document patient performance status per standardized guidelines
Maintain list of co-morbid conditions and major toxicities expected to complicate chemotherapy
Plan and manage chemotherapy/biotherapy regimens
Manage and automate body surface area (BSA), starting doses, and dose adjustments
Manage chemotherapy delivery—IV and oral, number of cycles, duration
Document drug administration process
Track duration of treatment and number of planned cycles
Schedule and document radiation therapy and/or maintain results
Assess pain and supportive care needs
Manage patients on clinical trials
Clinical Oncology Treatment Plan and Summary and Survivorship Report

Internet

The Internet serves as the communication and messaging component of the digital health care system. The development of the Internet can be separated into four stages. At its inception, the Internet was used for “searching” for information and “communicating” with text, files and pictures, and any media. Users were mostly academicians and business people. E-mail and bulletin boards were popular. Next, we were able to “do” things using web sites. Consumers discovered the Internet and commerce exploded. Then, we were able to “socialize” and “collaborate” using social media sites like Facebook. Apps exploded as mobile computing dominated the Internet. Now, we are entering the Internet of “Things,” where any medical device can inexpensively communicate over the Internet with other devices and computers.

Computer interoperability and data exchange

Computer interoperability and data exchange or the sharing of data requires that the data created in one EHR be sent to another EHR with full understanding and context so that it will be placed in the appropriate data field of the receiving program. ASCO and the National Cancer Institute's caBIG and Community Cancer Center Program created the Clinical Oncology Requirements for the EHR (CORE) that delineated the core common data elements, functionalities, and interoperability standards for oncology that helped to define the original oncology EHR certification criteria used by the Certification Commission for Healthcare Information Technology (CCHIT).³ Seamless interoperability standards have foundational importance by defining and transmitting medical information in a way that will make our data entry, computerized workflows, and result reporting dramatically simplified and efficient.

Most of the data elements that we use in medicine have been defined, standardized, and harmonized into code sets and SNOMED-CT, a clinical vocabulary. Meaningful Use Stage 1 brought some interoperability to public health reporting. Meaningful use stage 2 brought additional interoperability to well-defined content, vocabulary, and transport standards for transitions of care. Our leading Standards Developing Organization (SDO), Health Level Seven International (HL7®) has defined and standardized the use of

clinically useful summary documents known as consolidated clinical document architecture (C-CDA) documents.^{4, 5}

ASCO's Data Standards and Interoperability Task Force, which I chair, has developed two oncology-specific interoperable technology standards. We have taken two ASCO Treatment Plan and Summary paper templates developed for adjuvant breast cancer and adjuvant colorectal cancer⁶⁻⁸ and transformed them into implementation guides (IGs). The IGs can be used to create an interoperable document that can be electronically exchanged between any computer system that adheres to the HL7 C-CDA standard.⁹ CDAs define content and transport of a document that can be large. This document standard [entitled Clinical Oncology Treatment Plan and Summary (COTPS)] summarizes cancer data from almost all medical reports that are created by physicians, hospitals, laboratories, imaging centers, pharmacies, and patients during the cancer journey and gives review and guidance to the patient and their providers involved with their care. We plan on creating similar C-CDA documents for other common cancers, patient-reported outcomes, and cancer survivorship plans.

At the HIMSS Interoperability Showcase for 2014, ASCO's COTPS was used to demonstrate how the use of common data elements, standardized reports, adherence to interoperability standards, and use of innovative data entry tools can make provider workflows more efficient and our notes and reports sharable, actionable, and multipurposeful. There, 10 vendors used these standards for exchanging data in real time. Novel data entry tools including voice-recognition transcription to text to data to structured data, a care plan manager, medical devices in the patient's home demonstrating data capture and alerting capabilities, patient education, patient-reported outcomes and questionnaires, and actionable reports for quality, research, population health, and big data analytic registries were shown. A health information exchange captured and displayed the compilation of clinical reports in real time and made them available to all vendor systems while recording the cancer journey of a woman given adjuvant treatment for her breast cancer. The care plan manager was able to electronically create the ASCO COTPS for the patient, caregivers, and all providers.

HL7 is closer to approving a new, nimble, and simpler interoperability and data exchange standard called Fast Healthcare Interoperability Resources (FHIR).¹⁰ FHIR can represent granular or discrete data elements and documents. Part of the enthusiasm surrounding FHIR is due to the elegant simplicity of the technology. It combines the best features of HL7 V2, HL7 V3, and CDA, while leveraging the latest web service technologies. The major technology change embodied in FHIR is a fundamental move away from a document-centric approach to a data-level access approach using application programming interfaces (APIs). The ability of this interface to exchange data with any software including the EHR using a public API can foster an ecosystem of interoperability among health IT systems. Specifically, FHIR features a modular concept called *Resources* that can be extended and adapted as a step forward from today's document-based exchange architecture using a very basic set of structured data like a medication list or lab result. FHIR provides for a plug-and-play platform working within and between systems that is conceptually similar to the Apple app system. FHIR would also allow developers to create new and innovative apps by using the public APIs and following a well-defined set of rules. Most vendors would likely embrace a public API offering a unified approach to share data with any application. Systems can easily read the extensions using the same framework as other resources, and when FHIR and the SMART platform are combined, we have a nimble interoperable standard that can capture the functionalities of Apple's App model. Recently, many EHR vendors and health care organizations have formed the Argonaut Project to accelerate query/response interoperability under the auspices of ANSI-certified HL7 standards development organization processes for sharing electronic health care information, a most promising change from groups that have in the past encouraged being proprietary.¹¹

For the oncologist, we will have true interoperability and data exchange whereby small nimble apps will be able to accept data from another app or an enterprise-wide EHR, use that data effectively, send it to another app and eventually return it to the originating application source with updated data that can be understood and incorporated into the originating program's database. Efficient data entry tools, educational links for the oncologist or for their patients (think CDS), wellness data incorporation and useful personal health records (PHRs) creation, important current and meaningful alerts, and automated secondary uses of data can be reported such as quality measures, state registry data, and rapid learning systems (RLSs). Enterprise-wide EHRs that takes years for updates and do very little in educating the user can rely on these nimble apps from trusted sources to enhance their products. Centers for Medicare and Medicaid Services (CMS) has made interoperability a major goal for the country in its recent report "Connecting Health and Care for the Nation."¹²

Electronic health record database and repository

The EHR is a systematic database that collects longitudinal, attributable, secure, nonmodifiable digital health information and data about an individual patient or population. It should be capable of being shared across all health care settings, providers, and with the patient. It should represent data that accurately captures and presents the latest health status of the patient and their clinical encounters. It does a superb job in documenting EHR-defined clinical activities and administrative requirements, but today it is unacceptable in providing efficient data entry, educational and safety features, effective provider workflows, helpful CDS, seamless interoperability across all EHRs, plug-and-play modular designs and automated registry, and other secondary reporting needs. This is because the initial EHR creators modeled it after a paper chart that was passive and a nonparticipant in health care. It lacked an understanding of the clinical workflow or a provider's or the health care system's needs. Today, government financial incentives for purchasing EHRs and meeting meaningful use that require some interoperability, quality improvement, CDS, and registry reporting have persuaded the majority of oncologists to adopt them. Unfortunately, they are frustrated because these meaningful use functionalities are poorly designed into today's EHRs. EHR data must not only document our clinical activities with relevance, succinctness, and context that paper systems may have more easily captured in the past, but it also must be used for secondary purposes such as clinical and population research, quality measurements, registry reporting, reimbursement documentation, and RLS analytics to name a few that current EHRs do not effectively address. We spend less face-to-face interaction time with our cancer patients, more time with the computer screen using menus, interfaces, and alerts,¹³ and our workdays are averaging 48 min longer due to EHR use.¹⁴

EHRs must become more adept in data entry providing voice to text to data functionality (dictate and have the computer use natural language and machine reading skills to place the dictated material into corresponding data fields). Also, by opening up their software, EHR vendors could unleash a creative army of developers that could help their users and improve the product.

The Medical Informatics Committee of the American College of Physicians has recently explored EHR documentation issues and written an excellent position paper with cogent recommendations for changes that are listed in [Table 3](#). Yet, computers will remain our individual link to our health care system for the foreseeable future. We must find more efficient ways to capture and reuse data and have computers do more of our work.

Table 3 American College of Physicians proposed basic documentation for electronic health records

Primary purpose of clinical documentation should be to support patient care and improve clinical outcomes through enhanced communication
Physicians should define standards for documentation, and information exchange should be facilitated by standards set by individual specialties
EHRs should facilitate seamless patient care that improves outcomes and support data analysis that enables value-based care
Collecting structured data should only be done when useful for care or important for quality improvement
Prior authorizations should not require unique data and format requirements
Patient engagement and care quality will be enhanced when patients are able to access their progress notes as well as the rest of their record
Research is needed to improve the processes involved in documenting care and facilitating technological advancements that allow better, more accurate record of observations
EHR development should be optimized for longitudinal team-based care
Cognitive processes during documentation should be supported in EHR design
When reusing data, embedded tags should be included to identify the original source
Checkboxes to indicate something that has already been documented should be eliminated
Patient-generated data should be incorporated into their medical record and the source identity maintained

Source: Data from Ref. 15.

Personal health records

Patients will continue to take a more responsive role in health care as they pay a larger share of its cost, make known their values and wishes, and help make key decisions. With the unlimited educational resources of the Internet, our patients have access to the same medical literature and textbooks that we have. With meaningful use requirements for providing electronic patient reports to the patient, with the CMS proposing that patients have access to their laboratory test results, with e-mailing between patients and oncologists becoming commonplace (and reimbursable with some payers), and with most medical reports becoming available in digitized form, patients will be in control of their medical record. A pilot project that makes almost the entire medical record electronically available to patients has been successfully implemented at the MD Anderson Cancer Center; the majority of patients are more than satisfied, and most doctors, many of whom were skeptical initially, have become converted proponents of “open access” care.¹⁶ The highly successful OpenNotes project is an example of how eager patients are receiving more of their medical information.¹⁷

Knowledge and education

Oncology knowledge bases

After aggregating a cancer patient's actionable health data into our EHR using our data gathering and entry tools, we need to have our EHR assist us with CDS tools to search our available knowledge bases today

and prepare for contributing to a RLS for oncology with our EHRs to hopefully provide us with a “technology to aggregate individual patient data across populations that share common characteristics defining a health state in order to generate knowledge and learning” into improving patient outcomes, quality, and health care value utilizing practice guidelines or algorithms as so eloquently discussed by Yu.¹⁸ Our knowledge bases in oncology consist of clinical trials data, systems biology data, patient-sourced data (health and wellness), and health systems data on operational processes and patient outcomes.

Clinical trials data come from being published in peer-reviewed journals or systematic reviews of the medical literature and being vetted and weighed for quality and knowledge gaps by experts gathered by a professional society and published as a clinical practice guideline.

Systems biology data in oncology help us characterize the molecular, cell growth regulatory and immunologic changes found in different cancers as they progress, permitting us to understand their causation, classification, and therapies. As computational biology and their analytical tools begin to deal with the terabytes of panomic data from an individual patient whose genome, transcriptome, proteome, and metabolome could be routinely assessed in the near future, nimble resources such as The Cancer Genome Atlas¹⁹ and the Global Alliance for Genomics and Health²⁰ will support providers and researchers in their quest for providing personalized medicine and improved patient outcomes. These knowledge bases working together will permit a more rapid drug evaluation and approval process for targeted drugs by identifying exceptional cancer responses associated with specific panomic aberrations.

Finally, the Digital Health Information Technology System will use our EHR clinical data, patient-reported data, laboratory information systems and data repositories, administrative claim data, cancer registries, wellness, activity and nutritional data, and postmarketing surveillance data to capture health care systems data that reflect the real-world patient population experience with our therapies.

Clinical decision support systems (CDSS)

CDSS (clinical decision support systems) are user-chosen or situational awareness invoking application tools that have access to knowledge bases or practice guidelines that are used by EHRs to educate and/or alert their users about patient-specific clinical decision making and health management at the point of service. Musen et al. have described the following three types of CDSS²¹:

- Information management (direct link to a textbook section or Internet site or a tool such as an Infobutton that is a context-sensitive link embedded within an EHR, which allows easy retrieval and subsequent electronic reuse of the relevant information residing in the EHR or at an Internet link)²²
- Situational awareness (alerts or patient dashboards)
- Patient specific logic-based guidance on diagnostic and therapeutic choices such as could be derived from Knowledge bases or a RLS like CancerLinQ.¹⁸

Rapid learning systems

As cancer patients increasingly have their medical records digitized, it becomes obvious that there is a treasure trove of clinical data in these records that have the potential to benefit society by opening up what happens to the 97% of cancer patients who do not go on clinical trials. By learning about the comparative benefits or harm of our new treatments and procedures in nonclinical trial patients after these therapies have been granted regulatory approval, we can apply findings and improve treatments on a continuous, ongoing basis. The National Cancer Policy Forum of the Institute of Medicine workshop

entitled “A Foundation for Evidence-Driven Practice: A Rapid Learning System for Cancer Care” examined the elements of a RLS for cancer.²³ It recommended that the elements of such a system include registries and databases, emerging information technology, tools for patient-centered and patient-driven CDS and patient engagement, ways of accommodating culture change, clinical practice guidelines, point-of-care needs in clinical oncology, and federal policy issues and implications. ASCO and others have begun to define a RLS for cancer called CancerLinQ.^{24, 25} It will use these tools to develop a more thorough understanding of cancer biology, defining a cancer based on a molecularly driven diagnosis; it will also incorporate a therapeutic development system that uses oncology EHR registries to produce smarter and faster clinical trials. Because of its more seamless integration of clinical and translational research, it has the potential to ensure that every cancer patient's experience can inform research and improve care.

RLS will require computational tools for data compilation and analysis from pooled massive databases combining machine learning, data visualization, statistics, and programming. For our cancer patients, this *Big Data* operation could incorporate all clinical data, genomic data, wellness and health data derived from medical devices and medical payment data obtained from Medicare and the private payers. ASCO's CancerLinQ hopes to obtain all EHR and clinical knowledge base data for all cancer patients residing in the United States from our offices, cancer centers, and hospitals. An oncologist could enter all the clinical information on his patient and ask CancerLinQ to electronically match the patient to the closest group of patients with similar clinical characteristics and reveal the treatments that produced the best outcomes for these similar patients. In addition, it could generate knowledge for improving quality and cost effectiveness of care by creating an informatics infrastructure for practice-based research networks to collect practice-based evidence using CDSS functionality built into our EHRs to link machine-readable oncology knowledge bases and guidelines repositories as originally described by Sim et al.²⁶

The mobile computing revolution

Today, general-purpose Windows and Mac OS X computers are the devices most commonly used for EHRs, but they carry the burden of 30 years of rapid, unplanned change. Many physicians and patients are frustrated with a lot of the existing EHR software choices that rely on the existing PC and Mac paradigm that uses windows, icons, menus, and pointers for human-computer interaction.

With the introduction of the iPhone by Apple in 2007, Apple introduced a natural human-like interface that could sense touch, touch force, voice, vision, hearing, location, body position, height, and direction. It could communicate over Wi-Fi, Bluetooth, cellular, and NFC (near field communication). It has become the most easily learned and most efficient mobile operating system available. Most EHR vendors today are providing access to their programs via iPhones, iPads, and Android devices, and others are calling for an Apple-like app platform for EHRs.²⁷

Government and medical leadership consensus on a mobile HIT evolution

For the first time, our thought leaders in health information technology (HIT), governmental groups overseeing health information and EHR technology, Congress, our President and his expert panels, our medical leaders and specialty organizations, medical standards organizations, informatic experts, the health care industry and even many, vendors/developers agree that the technologic infrastructure, and recent advances in hardware, software, and services can provide a new relationship between physicians and their computers where computers serve us as an efficient, up to date, personalized, customizable, secure, shareable, and knowledgeable assistant. Halamka popularized the term “electronic medicine”²⁸ to

urge EHRs to adopt these mobile computing advances in 2011, and I have taken the liberty to include additional items that have been developed over the past 4 years that will help oncologists participate in a true Oncology Digital Health Information Technology System.

Cloud computing

Cloud computing refers to storing patient data in centralized servers connected to the Internet rather than in our offices and provides the ability to scale up complex software that can be updated frequently and simultaneously with all software users at different sites thus removing the need of our offices to deal with database administration, server hosting, and data security at great financial savings. By being Internet connected, EHRs can more easily share data with patients and other physicians, send reports to external registries and have sophisticated tools to assist with learning the software initially and later on with updates.

Apps

Apps are versatile, small programs that use web-based APIs, that have extensions which can work with data passed on from another app or an EHR program. Apps could provide new functionalities for the EHR or could collect data from the EHR and send it to registries or RLSs that could analyze this new data and provide CDS for the EHR program. APIs are simply a collection of functions that a programmer can call to use another programs services and data. APIs contain tiny, atomistic chunks of data that must use consistent units and terminology that are handled much more efficiently. Natural language processing is being used to extract these tiny chunks of data from our narrative dictations and create structured machine-readable content that can be used more effectively by the computer for any purpose. It is an ideal method for permitting a medical specialty society to provide specialty-specific updated tools for EHRs that find it hard to keep their software up to date with the needs of the medical specialist.

Modular software and application programming interfaces (APIs)

The SMART (substitutable medical apps and reusable technology) platform designed by Mandl and Kohane²⁷ is an ideal platform to bring Apple's App model system into the EHR ecosystem. Mandl recently pointed out how this platform could work in an emergency situation to permit the Center for Disease Control and Prevention (CDC) to create an App that could work with any cooperating EHR and reshape ER triage workflows to emphasize travel history and recommend rapidly updated assessment and isolation guidelines for handling patients who present to an ER with fever and recent travel to an Ebola-affected region.²⁹ The App could be immediately used by all EHRs, updated easily, and specific data about all patients quarantined by a hospital could be sent back to the CDC for monitoring and reporting purposes on a national level. He points out that this hypothetical app could be rapidly written once and run nearly everywhere.

Engaged, digitally connected digitized patients, medical devices, and the Internet of Things

Over this time period, our health system has been transformed so that patients instead of being passive participants in the health care system are now very engaged as they have access to the same medical literature that we have on the Internet and their complete medical record permitting joint decision making with their providers leading to better outcomes and fewer malpractice suits. Using digital educational tools now available on web sites or in Apps, patient have a better understanding of their diseases, treatments, upcoming procedures, suitable clinical trials, informed consent, and can provide their values,

wishes, and misconceptions directly to shared EHRs in some institutions.

As we enter the Internet of Things stage with inexpensive, accurate, intelligent medical devices, disease prevention and early medical interventions along with the increasing interest in the wellness of the patient will lead to the rapid uptake of these medical devices and wearable computing garments that connect wirelessly with our smartphones, facilitating reimbursable telemedicine consults with our patients with chronic illnesses at home and early detection of adverse events from our therapies or their diseases. Using digital devices to measure vital signs and digital EKGs, stethoscopes, cameras, ophthalmoscopes, otoscopes, and ultrasound devices attached to our smartphone, the physical exam can be completed remotely.³⁰ Monitoring and analyzing this digital data will require Big Data tools that are rapidly being developed to transform medicine as it is currently practiced. Also, certain regulatory and compliance issues arise when using medical devices such as security, auditability, and the need for provenance that are currently being addressed.

Precision medicine

Precision medicine is the prevention and treatment strategies that take individual variability into account using large-scale biologic databases (such as the human genome sequence), powerful methods for characterizing patients (such as proteomics, metabolomics, genomics, diverse cellular assays, and even mobile health technology), and computational tools for analyzing large sets of data. Whole genome sequencing is reaching the \$1000 threshold and we are fast approaching the ability to sequence the “digital” patient's germ line DNA, RNA, microbiome, epigenome along with their environment, anatomical, and clinical features.³¹ The breadth of this digital human data will permit President Obama to launch his Precision Medicine Initiative that supports a common medical data set, true interoperability of medical data that remains private and secure and a value- and quality-based payment system.^{32,33}

Apple-ization of medicine

Apple, through its unique ability to create, market, and integrate the best hardware, software, and computer services and its ability to work with other leading companies in many diverse fields, has caused a revolutionary transformation of many industries. Now with its latest mobile operating system, platform kits, mobile computing architecture and app models of software and their recent alliances with many of the largest health care industrial stakeholders, it has the ability to do the same for health care. Apple's HealthKit that synchronizes health and wellness data, PHRs and medical device data, is a platform that resides on the iPhone that interfaces with cooperating medical devices. The iPhone gathers information on vital signs, body position, activity, behavior, nutrition, pulmonary function, and sleep using its accelerometer, microphone, gyroscope, and GPS (global positioning system) sensors and links to other medical devices to gain insight into a patient's gait, motor impairment, fitness, speech, nutrition, memory, asthma inhaler use, and biomedical analytics such as glucose and oxygen. Data are safe, secure, and HIPPA compliant and is presented to the patient in a pleasant, graphic manner. It is a two-way medical communication platform that patients control. Data can be electronically sent to any cooperating EHR, analytics warehouse repository, or provider group and cannot be sold, misused, or seen by Apple.

Apple's medical ResearchKit platform is an open-source software tool that will empower consumers and patients to decide if they want to participate in a medical study and how their data are to be shared with researchers. It is designed to give medical researchers a new way to gather information on patients residing anywhere in the world by using their iPhones and Apple Watch. The ResearchKit platform is designed to work hand in hand with Apple's HealthKit software. Patients can digitally sign up for a trial, sign consent forms, communicate directly with the research center, have up to date information on the

study, and have their results and pooled results. Innovative research apps are able to monitor the physical, mental, and behavioral effects of disease along with monitoring adverse events to treatments. A Stanford cardiac study signed up over 10,000 patients in 3 days compared with their expectation of getting 50 patients per institution over 1 year!

For oncologists, these innovative developments will permit our patients to wear devices that can be used to measure and send data over the Internet to their smartphones that will have health platform software for HIPAA compliant storage, analytic and graphical representation of the captured data that can then be sent to an individual's providers, hospitals or medical alert capture stations all chosen by the patient.

Mobile computing, actionable, and shareable data provided by seamless interoperability standards and an oncologic RLS will continue to provide us with the tools to efficiently and effectively produce a health care system that “just works” for all stakeholders.

Part 4

Carcinogenesis

Chapter 23

Chemical carcinogenesis

Lorne J. Hofseth, PhD ■ Ainsley Weston, PhD ■ Curtis C. Harris, MD

Overview

Human exposure to chemical carcinogens can result in cancer. What dictates this outcome is relatively predictable but highly variable. Factors governing the outcome include type of exposure, amount of exposure, time of exposure, and genetic makeup of the host (i.e., humans). The latter is comprised of variations in single nucleotides within genes (e.g., single nucleotide polymorphisms in deoxyribonucleic acid–repair genes), as well as the metabolomic, proteomic, microbiomic, transcriptomic, and epigenomic background of the individual. It is becoming increasingly clear that these endpoints can be modified by chemical carcinogens and that inflammatory load influences outcome. To this end, the past decade has seen an explosion of extremely sensitive and highly accurate technology. Linking this technology to the rapid development of bioinformatics has enabled us to begin merging the totality of lifetime exposure (exposome) with the totality of metabolomic, proteomic, microbiomic, transcriptomic, epigenomic, and other “omic” profiles. We feel optimistic that the next decade will bring the development of tools to identify an individual's weighted risk signature as a biomarker for cancer risk and develop a personalized and precise approach to cancer chemoprevention and treatment.

Human chemical carcinogenesis is a multistage process that results from carcinogen exposure; usually in the form of complex chemical mixtures, and often encountered in the environment or through our lifestyle and diet ([Tables 1](#) and [2](#)). A prominent example is tobacco smoke, which can cause cancers at multiple sites with the highest risk being that of lung cancer. Although most chemical carcinogens do not react directly with intracellular components, they are activated to carcinogenic and mutagenic electrophiles by metabolic processes evolutionarily designed to clear the body of toxins and to modify endogenous compounds. Electrophilic chemical species are naturally attracted to nucleophiles like deoxyribonucleic acid (DNA) and protein; and genetic damage results through covalent bonding to DNA. Once internalized, carcinogens are subject to competing processes of metabolic activation and detoxification, although some chemical species can act directly. There is considerable variation among the human population in these competing metabolic processes, as well as the capacity for repair of DNA damage and cellular growth control. This is the basis for inter-individual variation in cancer risk and is a reflection of gene–environment interactions, which embodies the concept that heritable traits modify the effects of chemical carcinogen exposure.^{55, 56} Such variations in constitutive metabolism, DNA repair, and cellular growth control contribute to the relative susceptibility of individual members of the population to chemical exposures. For example, only 10% of tobacco smokers develop lung cancer, albeit that tobacco use accounts for other fatal conditions, including cardiovascular disease, emphysema, and chronic obstructive pulmonary disorder (COPD). Within the conceptual framework of multistage carcinogenesis, the primary genetic change that results from a chemical–DNA interaction is termed *tumor initiation*.^{13, 14, 57} Thus, initiated cells are irreversibly altered and are at a greater risk of malignant conversion than are normal cells. The epigenetic effects of tumor promoters facilitate the clonal expansion of the initiated cells.^{58, 59} Selective, clonal growth advantage causes a focus of pre-neoplastic cells to form. These cells are more

vulnerable to tumorigenesis because they now present a larger, more rapidly proliferating, target population for the further action of chemical carcinogens, oncogenic viruses, and other cofactors. Additional genetic and epigenetic changes continue to accumulate.^{58, 59} The activation of oncogenes, and the inactivation of tumor suppressor and DNA-repair genes, leads to genomic instability or the *mutator phenotype* and an acceleration in the genetic changes taking place.^{29, 60, 61} This scenario is followed by malignant conversion, tumor progression, and metastasis. The underlying molecular mechanisms that govern chemical carcinogenesis are becoming increasingly understood, and the insights generated are assisting in the development of better methods to investigate human cancer risk and susceptibility. The results of such studies are intended to mold strategies for prevention and intervention. Moreover, insights into the normal operations of so-called *gatekeeper* genes,⁶² like the tumor suppressor *TP53*, have provided an opportunity to develop new, targeted, therapeutic approaches.

Table 1 Selected examples of human chemical carcinogenesis

Organ system (specific pathology)	Chemical carcinogen	Co-carcinogen
Lung (small and nonsmall cell)	Tobacco smoke	Asbestos
	Metals: As, Be, Cd, Cr, Ni	—
	BCME	—
	Diesel exhaust	—
Pleural mesothelium	Asbestos	Tobacco smoke
Oral cavity	Smokeless tobacco	—
	Betel quid	Slaked lime [Ca(OH) ₂]
Esophagus	Tobacco smoke	Alcohol
Nasal sinuses	Snuff	Powdered glass
	Isopropyl alcohol	—
Skin (scrotum)	Cutting oil	—
	Coal soot ^a	—
Liver (angiosarcoma)	Aflatoxin B1	HBV, HCB
	Vinyl chloride	Alcohol
Bladder	Aromatic amines (e.g., 4-ABP and benzidine)	—
	Aromatic amines from tobacco smoke ^b	—
ALL	Benzene	—
Lymphatic and hematopoietic malignancies	Ethylene oxide	—

4-ABP, 4-aminobiphenyl; ALL, acute lymphoblastic leukemia; BCME, bischloromethyl ether; HBV, hepatitis B virus; HCV, hepatitis C virus.

^a Early report of occupational chemical carcinogenesis from 225 years ago.

^b Strong circumstantial evidence.¹

A comprehensive treatise on the evaluation of the carcinogenic risk of chemicals to humans can be found in the ongoing International Agency for Research on Cancer monograph program initiated in 1971.

Table 2 Some landmark discoveries in chemical carcinogenesis

Year	Event/discovery/finding	References
3000 BC	First written description of cancer (breast) in the Edwin Smith Papyrus	2
1500 BC	Egyptians treat tumors with chemicals (arsenic)	2
1620	Thomas Venner warns about immoderate use of tobacco	3, 4
1742	Hermann Boerhaave and Jean Astruc link inflammation to cancer	3, 5, 6
1775	Percival Pott describes association between soot exposure and scrotal cancer in chimney sweeps	7
1863	Rudolf Virchow: cancers tend to occur at sites of chronic inflammation	8
1879	Harting and Hesse: lung cancer is an occupational disease of miners	9
1909	First chemotherapy drug (an arsenobenzene analog, compound 606, or salvarsan) treats syphilis	10
1910	Viruses found to cause cancer	11
1932	Female hormones (estrogen) cause breast cancer in mice	12
1941	Two-stage initiation and promotion of cancers by chemical carcinogens proposed	13, 14
1950	Tobacco exposure linked to lung cancer	15, 16
1956	Nitrosamines cause cancer	17
1956	Evidence that enzymes can be activated by chemical carcinogens	18
1962, 1963	Evidence that chemical carcinogens can methylate DNA and proteins	19, 20
1964–1968	Aflatoxin B1, a fungal toxin, is carcinogenic in rats, binds to DNA and is carcinogenic in humans	21–23
1968	DNA-repair defects linked to cancer	24
1971	“Two-hit” theory of cancer causation in the Rb gene, and tumor suppressor gene discovery	25
1971	Epigenetic mechanisms for carcinogenesis proposed	26
1973	Ames assay identified to test mutagenicity of chemical carcinogens	27
1974	Evidence that chemical carcinogens are activated to form DNA adducts in human tissues	28
1974	Mutator phenotype concept identified	29
1976	Inter-individual variation in the binding of chemical carcinogens to DNA and gene–environment interactions	30
1973	Oncogene discovery	31, 32
1977	Cancer stem cells identified	33

1979	p53, the most frequently altered gene in human cancer, discovered	34, 35
1981	First quantitative estimation of the contribution of the environment and genetics to carcinogenesis	36
1982	Formal structure/model of molecular epidemiology introduced	37
1983	Single nucleotide polymorphisms can guide carcinogenesis	38
1988	Chemical carcinogens cause site-specific mutagenesis	39
1990	Sequential mutations in colon cancer introduced	40
1991	p53 identified as a tumor suppressor gene	41
1991	Identification of selective mutations in p53 (mutational hotspots) associated with specific environmental and chemical carcinogens	42, 43
2001	Draft sequence of the human genome	44, 45
2002	MicroRNA alterations in cancer	46
2002	Gene expression signatures predict prognosis	47
2005	Concept of the exposome (the entirety of exposure to which an individual is subjected, from conception to death) is introduced	48
2006	Genetic landscape of two human cancer types defined (colon and breast)	49
2006	MicroRNA signatures predict prognosis and survival	50
2006	FDA approves HPV vaccine [human papillomavirus quadrivalent (types 6, 11, 16, 18) vaccine, recombinant]	51
2011	National Research Council (United States) committee on A Framework for Developing a New Taxonomy of Disease introduces precision medicine	52
2012	Victor Velculescu: detection of chromosomal alterations in the circulation of cancer patients	53
2012	Use of integrative personal omics profile to distinguish between healthy and diseased states at an individual level	54

Multistage carcinogenesis

Carcinogenesis can be divided conceptually into four steps: tumor initiation, tumor promotion, malignant conversion, and tumor progression ([Figure 1](#), Box 1). The distinction between initiation and promotion was recognized through studies involving both viruses and chemical carcinogens.^{13, 14, 57} This distinction was formally defined in a murine skin carcinogenesis model in which mice were treated topically with a single dose of a polycyclic aromatic hydrocarbon (PAH) (i.e., initiator), followed by repeated topical doses of croton oil (i.e., promoter),¹³ and this model has been expanded to a range of other rodent tissues, including bladder, colon, esophagus, liver, lung, mammary gland, stomach, and trachea.⁵⁹ During the last 65 years, the sequence of events comprising chemical carcinogenesis has been systematically dissected and the paradigm increasingly refined, and both similarities and differences between rodent and human carcinogenesis have been identified.⁶³ Carcinogenesis requires the malignant conversion of benign hyperplastic cells to a malignant state, and invasion and metastasis are manifestations of further genetic

and epigenetic changes.⁶⁴ The study of this process in humans is necessarily indirect and uses information from lifestyle or occupational exposures to chemical carcinogens. Measures of age-dependent cancer incidence have shown, however, that the rate of tumor development is proportional to the sixth power of time, suggesting that at least four to six independent steps are necessary.⁶⁵ Partial scheduling of specific genetic events in this process has been possible for some cancers. Examples of sequential genetic and epigenetic changes that occur with the highest probability are those found in the development of lung cancer⁶⁶ and colon cancer.⁶⁷ Recent advances in sequencing technology have allowed us to identify the genomic landscape of many tumors. In common solid tumors such as those derived from the colon, breast, brain, or pancreas, an average of 33–66 genes display subtle somatic mutations that can alter their protein products.⁶⁸ Certain tumor types display many more or many fewer mutations than average. Melanomas and lung tumors, for example, contain approximately 200 nonsynonymous mutations per tumor; a reflection of the involvement of potent mutagens [ultraviolet (UV) light and cigarette smoke, respectively] in the pathogenesis of these tumor types.⁶⁸

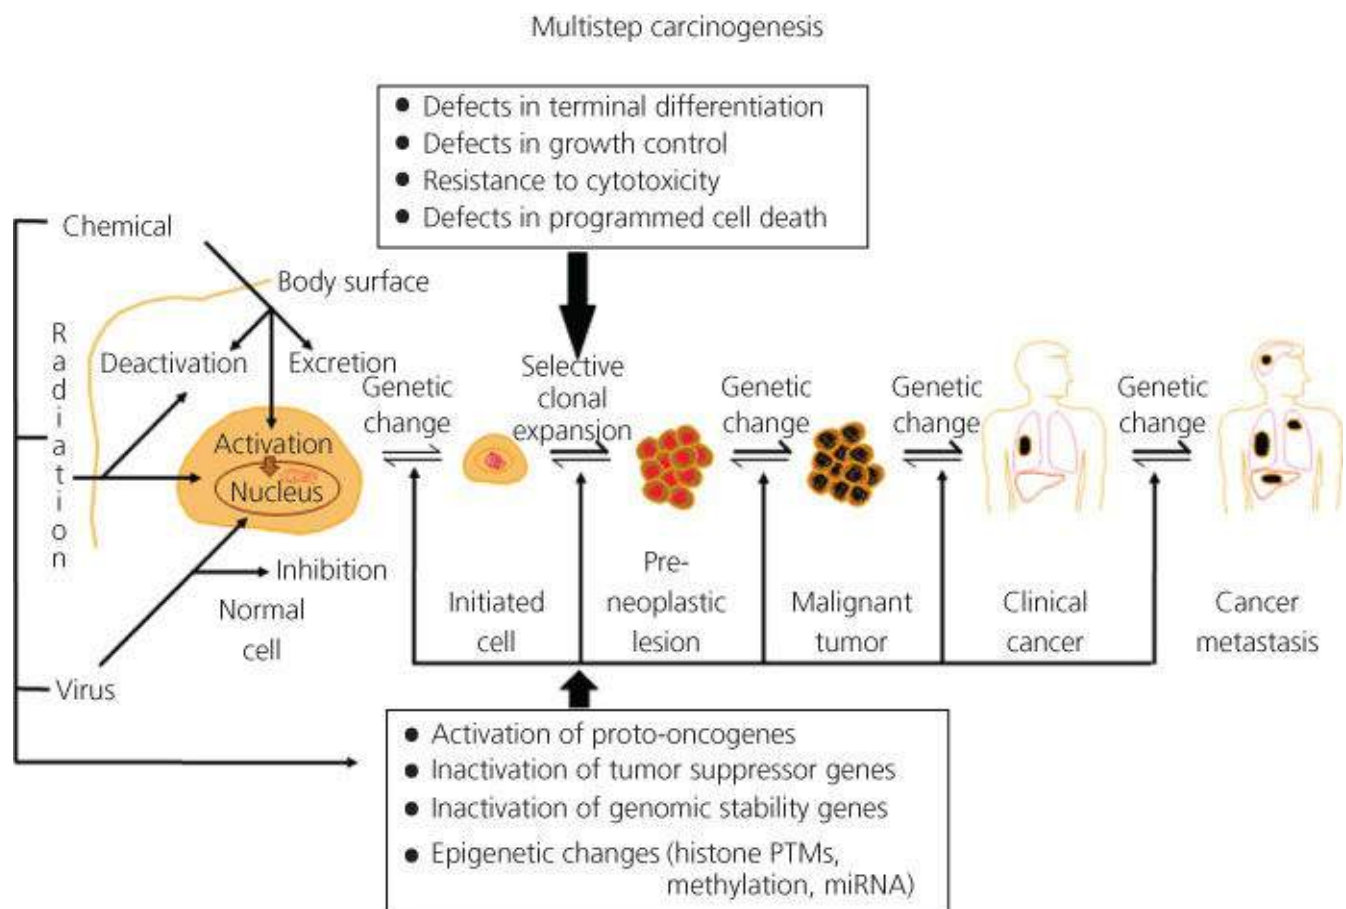

Figure 1 Multistep chemical carcinogenesis can be conceptually divided into four stages: tumor initiation, tumor promotion, malignant conversion, and tumor progression. The activation of proto-oncogenes and the inactivation of tumor suppressor genes are mutational events that result from covalent damage to DNA caused by chemical exposures. The accumulation of mutations, and not necessarily the order in which they occur, constitutes multistage carcinogenesis. During these stages, progressive epigenetic changes are also occurring due to chemical exposure.

Tumor initiation

Earlier concepts of tumor initiation indicated that the initial changes in chemical carcinogenesis are irreversible genetic damage. However, recent data from molecular studies of pre-neoplastic human lung and colon tissues implicate epigenetic changes as an early event in carcinogenesis. DNA methylation of

promoter regions of genes can transcriptionally silence tumor suppressor genes.⁶⁹ In a broad sense, then, chemical carcinogens can be divided into genotoxic [e.g., benzo(a)pyrene or B(a)P; generally considered to act at the initiation stage] and nongenotoxic agents [e.g., 3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) or 12-*O*-tetradecanoylphorbol-13-acetate (TPA); generally considered to act in the promotion stages]. These nongenotoxic or epigenetic agents ([Figure 1](#)) neither do not induce mutations nor do they induce direct DNA damage in the target organ. They modulate cell growth and death and exhibit dose-response relationships between exposure and tumor formation. Although the exact mechanism(s) of action of these agents on neoplastic cell formation are yet to be determined, changes in gene expression and cell growth parameters appear to be critical, and nongenotoxic compounds exhibit temporal and threshold characteristics frequently requiring chronic treatment for carcinogenicity.

Overall, most human cancers are caused by two to eight sequential alterations that develop over the course of 20–30 years.⁶⁸ For mutations to accumulate, they must arise in cells that proliferate and survive the lifetime of the organism. A chemical carcinogen causes a genetic error by modifying the molecular structure of DNA that can lead to a mutation during DNA synthesis. Most often, this is brought about by forming an adduct between the chemical carcinogen or one of its functional groups and a nucleotide in DNA (the process by which this occurs for the major classes of chemical carcinogens is discussed in detail in “Carcinogen Metabolism”). In general, a positive correlation is found between the amount of carcinogen–DNA adducts that can be detected in animal models and the number of tumors that develop.⁷⁰⁷¹ Thus, tumors rarely develop in tissues that do not form carcinogen–DNA adducts. Carcinogen–DNA adduct formation is central to theories of chemical carcinogenesis, and it may be a necessary, but not a sufficient, prerequisite for tumor initiation (the concept of so-called *nongenotoxic carcinogens* is also explored in “Carcinogen Metabolism”). DNA adduct formation that causes either the activation of a proto-oncogene or the inactivation of a tumor suppressor gene can be categorized as a tumor-initiating event (see Sections titled “Tumor progression” and “Oncogenes and tumor suppressor genes”).

Tumor promotion

Tumor promotion comprises the selective clonal expansion of initiated cells. Because the accumulation rate of mutations is proportional to the rate of cell division, or at least the rate at which stem cells are replaced, clonal expansion of initiated cells, produces a larger population of cells that are at risk of further genetic changes and malignant conversion.^{64, 68} Tumor promoters are generally nongenotoxic, are not carcinogenic alone, and often (but not always) are able to mediate their biologic effects without metabolic activation. These agents are characterized by their ability to reduce the latency period for tumor formation after exposure of a tissue to a tumor initiator, or to increase the number of tumors formed in that tissue. In addition, they induce tumor formation in conjunction with a dose of an initiator that is too low to be carcinogenic alone. Croton oil (isolated from *Croton tiglium* seeds) is used widely as a tumor promoter in murine skin carcinogenesis, and the mechanism of action for its most potent constituent, TPA, which occurs via protein kinase C activation, is arguably the best understood among tumor promoters.⁷² Chemicals or agents capable of both tumor initiation and promotion are known as complete carcinogens [e.g., B(a)P and 4-aminobiphenyl]. Identification of new tumor promoters in animal models has accelerated with the sophisticated development of model systems designed to assay for tumor promotion. Furthermore, ligand-binding properties can be determined in recombinant protein kinase C isozymes that are expressed in cell culture.⁷³ Chemicals, complex mixtures of chemicals, or other agents that have been shown to have tumor-promoting properties include dioxin, TPA, TCDD, benzoyl peroxide, macrocyclic lactones, bromomethylbenzanthracene, anthralin, phenol, saccharin, tryptophan, dichlorodiphenyltrichloroethane (DDT), phenobarbital, cigarette-smoke condensate, polychlorinated

biphenyls (PCBs), teleocidins, cyclamates, estrogens and other hormones, bile acids, UV light, wounding, abrasion, and other chronic irritation (i.e., saline lavage).⁷⁴

Malignant conversion

Malignant conversion is the transformation of a pre-neoplastic cell into one that expresses the malignant phenotype. This process requires further genetic changes. The total dose of a tumor promoter is less significant than frequently repeated administrations, and if the tumor promoter is discontinued before malignant conversion has occurred, premalignant or benign lesions may regress. Tumor promotion contributes to the process of carcinogenesis by the expansion of a population of initiated cells, with a growth advantage, that will then be at risk for malignant conversion. Conversion of a fraction of these cells to malignancy will be accelerated in proportion to the rate of cell division and the quantity of dividing cells in the benign tumor or pre-neoplastic lesion. In part, these further genetic changes may result from infidelity of DNA synthesis.⁷⁵ The relatively low probability of malignant conversion can be increased substantially by the exposure of pre-neoplastic cells to DNA damaging agents,⁷⁶ and this process may be mediated through the activation of proto-oncogenes and inactivation of tumor suppressor genes.

Box 1 Multistage carcinogenesis

Multistage carcinogenesis involves four stages:

1. *Tumor initiation*: The initial changes to normal cells that occur early in chemical carcinogenesis and involve irreversible genetic mutation(s) (genotoxic initiation) or epigenetic changes (nongenotoxic initiation) so that they are able to form tumors.
2. *Tumor promotion*: The selective clonal expansion of a population of initiated cells, causing additional genetic changes with a growth advantage that will then be at risk for malignant conversion. Tumor promoters are generally nongenotoxic, cannot drive tumorigenesis alone, and require repeat exposure over time.
3. *Malignant conversion*: The transformation of a preneoplastic cell into one that expresses a malignant phenotype. The probability of malignant conversion increases through additional genetic changes, continued exposure of preneoplastic cells to DNA damaging agents, and may be mediated through the activation of proto-oncogenes and inactivation of tumor suppressor genes.
4. *Tumor progression*: The expression of the malignant phenotype and the tendency of malignant cells to acquire more aggressive characteristics over time. A prominent characteristic of the malignant phenotype is the propensity for genomic instability and uncontrolled growth. During this process, further genetic and epigenetic changes can occur, again including the activation of proto-oncogenes and the functional loss of tumor suppressor genes.

Tumor progression

Tumor progression comprises the expression of the malignant phenotype and the tendency of malignant cells to acquire more aggressive characteristics over time. Also, metastasis may involve the ability of tumor cells to secrete proteases that allow invasion beyond the immediate primary tumor location. A prominent characteristic of the malignant phenotype is the propensity for genomic instability and

uncontrolled growth.⁷⁷ During this process, further genetic and epigenetic changes can occur, again including the activation of proto-oncogenes and the functional loss of tumor suppressor genes. Frequently, proto-oncogenes are activated by two major mechanisms: in the case of the *ras* gene family, point mutations are found in highly specific regions of the gene (i.e., the 12th, 13th, 59th, or 61st codons), and members of the *myc*, *raf*, *HER2*, and *jun* multigene families can be overexpressed, sometimes involving amplification of chromosomal segments containing these genes. Some genes are overexpressed if they are translocated and become juxtaposed to a powerful promoter, for example, the relationship of *bcl-2* and immunoglobulin heavy chain gene promoter regions in B-cell malignancies. Loss of function of tumor suppressor genes usually occurs in a bimodal fashion, and most frequently involves point mutations (caused by DNA adducts, errors in DNA replication, and errors in DNA repair) in one allele and loss of the second allele by a deletion (caused by a recombinational event, chromosomal nondisjunction, or hypermethylation). These phenomena confer to the cells a growth advantage as well as the capacity for regional invasion, and ultimately, distant metastatic spread. Despite evidence for an apparent scheduling of certain mutational events, it is the accumulation of these mutations, and not the order or the stage of tumorigenesis in which they occur, that appears to be the determining factor.⁶⁸ Recent evidence from microarray expression analysis of human cancers supports an alternative, and not mutually exclusive, mode of tumor progression. Gene expression profiles of a primary cancer and its metastases are similar, indicating the molecular progression of a primary cancer is generally retained in its metastases.⁷⁸

Over the last decade, sequencing efforts have identified genomic landscapes of common forms of human cancer. Vogelstein and colleagues recently defined these landscapes as consisting of a small number of “mountains” (genes altered in a high percentage of tumors) and a much larger number of “hills” (genes altered infrequently).⁶⁸ Approximately 140 genes that when altered by intragenic mutations can drive tumorigenesis. A typical tumor contains two to eight of these “driver gene” mutations that control cell fate, cell survival, and genomic maintenance. Other “passenger mutations” confer no selective growth advantage. Overall, the identification of specific genes and their function in primary cancers and metastases have clinical implications in molecular diagnosis of primary cancers and targeted therapeutic strategies for personalized medicine.

Epigenetics and chemical carcinogenesis

Epigenetics describes a change in gene activity without a change in the DNA sequence.⁷⁹ Well-described mechanisms involved in epigenetics include DNA methylation and histone modification; each of which alters how genes are expressed without altering the underlying DNA sequence. Another mechanism (described in detail later) also falling under the definition of “epigenetic” is the effects of microRNA (miRNA; [Figure 2](#), Box 2) on carcinogenesis. Both nongenotoxic and genotoxic chemical carcinogens impact these epigenetic processes. At the cellular level, exposure to environmental factors may leave an epigenomic signature that can be exploited in discovering new biomarkers for risk assessment and cancer prevention.^{80, 81}

Figure 2 Epigenetic impact of chemical carcinogens. Chemical carcinogens can affect the activity of the different enzymes involved in epigenomics. Ac: acetyl; Me: methyl; DNMT: DNA methyltransferase; HAT: histone acetyltransferase; HDAC: histone deacetylase; HMT: histone methyltransferase.

Box 2 Epigenetics

Epigenetics describes a change in gene activity without a change in the DNA sequence. It involves changes in *DNA methylation* [hypomethylation/hypermethylation caused by carcinogens modifying methylation enzymes (e.g., DNMTs)], *histone tail modification* [acetylation, methylation, citrullination, ubiquitination, sumoylation, and phosphorylation caused by carcinogens modifying enzymes involved in such changes (e.g., HDACs)], and *small noncoding RNA's* (e.g., miRNAs caused by genetic abnormalities, modulation of biogenesis machinery, and/or epigenetic mechanisms).

DNA methylation is catalyzed by a family of DNA methyltransferases (DNMTs). In somatic mammalian cells, DNA methylation occurs at cytosine residues of CpG dinucleotides; in embryonic stem cells, DNA methylation occurs at both CpG and non-CpG sequences. DNMT expression, and therefore indirect control of DNA methylation, is controlled by DNMT3L, lymphoid-specific helicase, miRNAs, and piwi-interacting RNAs.⁸² It is becoming increasingly clear that many chemical carcinogens are involved in DNA methylation. For example, the tobacco-specific carcinogen, 4-(methylnitrosoamino)-1-(3-pyridyl)-1-butanone (NNK), induces DNMT accumulation and tumor suppressor gene hypermethylation in mice and lung cancer patients.⁸³ As well, B(a)P and many others not only genotoxic, but also

nongenotoxic chemical carcinogens have been shown to induce aberrant methylation patterns.^{82, 84} Several mechanisms may explain aberrant methylation patterns due to chemical carcinogens. As an example, cigarette smoke may alter DNA methylation by (1) inducing DNA damage, stimulating recruitment of DNMT1; (2) the ability of nicotine to down-regulate DNMT1 mRNA and protein expression; (3) modulating expression and activity of DNA-binding factors, such as Sp1; and (4) inducing hypoxia, which increases HIF1 α , leading to the up-regulation of methionine adenosyltransferase 2A⁸⁵ ([Figure 2](#)).

Chromatin is the complex of DNA wrapped around histone octamers, consisting of four different histones, H2A, H2B, H3, and H4. Gene expression changes with histone post-transcriptional modification (e.g., acetylation, phosphorylation, and methylation) in the *N*-terminal tail region. Enzymes that regulate histone modification include histone deacetylases (HDACs), histone acetyltransferases (HATs), and histone methyltransferases (HMTs). Chemical carcinogens can alter the activity of such enzymes. For example, challenging cells with B(a)P induces early enrichment of the transcriptionally active chromatin markers histone H3 trimethylated at lysine 4 (H3K4Me3) and histone H3 acetylated at lysine 9 (H3K9Ac), and reduces association of DNMT1 with the long interspersed nuclear element-1 (L1) promoter. These changes are followed by proteasome-dependent decreases in cellular DNMT1 expression and sustained reduction of cytosine methylation within the L1 promoter CpG island.⁸⁶ Similarly, long-term exposure of immortalized bronchial epithelial cells (HBEC-3KT) to low doses of tobacco-related carcinogens leads to oncogenic transformation, increased HDAC expression, cell-cycle independent increased DNMT1 stability, and DNA hypermethylation.⁸⁷

miRNA's in chemical carcinogenesis

miRNA expression is regulated by a growing list of factors, including inflammatory cytokines, free radicals, and chemical carcinogens.^{88–91} The specific effects of chemical carcinogens on each miRNA *in vitro* and *in vivo* have been described in detail elsewhere, so the reader is guided to that source.⁹¹ For the purposes of this chapter, we will provide an overview of miRNAs, examples of key miRNAs affected by chemical carcinogens, and the mechanisms by which this occurs.

miRNAs are nonprotein coding small RNAs of about 22 base pairs and regulate mRNA stability and translation into proteins.⁹² miRNA genes are regulated by transcription factors including by the p53 tumor suppressor protein⁹³ and are involved in carcinogenesis including tumor invasion and metastasis.⁹⁴ miRNAs are produced by processing of a hairpin precursor by an enzyme called dicer, and the mature miRNA incorporates into a protein complex (the RNA-induced silencing complex—RISC), where it acts as a guide to find complementary target RNAs. Binding of RISC to the target RNA causes degradation of the target or blocks translation—in either case, preventing production of the encoded protein. The alteration of miRNA expression by chemical exposure or during inflammation potentially has enormous consequences, because of the large number of genes each miRNA regulates. Each organism encodes hundreds of miRNAs, and these affect many key biological processes, including cell proliferation, differentiation, survival, and metabolism. In the 15 or so years since miRNAs were discovered,^{95–97} it has become clear that post-transcriptional control of gene expression by miRNAs provides an important and widely used level of gene regulation. In humans, it is estimated that about 60% of all protein-coding genes are regulated by a miRNA.^{98, 99} Because miRNAs are highly specific, potent suppressors of gene expression; and aberrant regulation of miRNA expression is associated with cancer (and many other diseases), the potential value of these small RNAs as therapeutic agents is now widely recognized.^{100–104} Not surprisingly, miRNAs are also clinical biomarkers associated with diagnosis, prognosis, and therapeutic outcome of cancer.^{105, 106} Because miRNA levels change upon exposure to environmental and

endogenous chemicals, it is possible that miRNAs can be used for biomonitoring purposes. This is supported by the understanding that miRNAs are released from the target tissues into the blood stream; and therefore, their analysis is feasible via noninvasive sampling (e.g., urine and feces).^{107–109}

Oncogenic miRNAs (OncomiRs)

In 2002, the Croce group reported the first link between miRNA and the pathogenesis of cancer; specifically, miR-15a and miR-16-1 were observed to be downregulated in B-cell chronic lymphocytic leukemia (CLL) patients.⁴⁶ Since this seminal observation, many of the known miRNA genes were shown to reside in genomic regions that are commonly associated with cancer.¹¹⁰ To this end, miRNAs themselves are now known to act as tumor suppressors and oncogenes (oncomiRs); and environmental carcinogens alter miRNA expression by down-regulating suppressor miRNA and up-regulating oncomiRs.

OncomiRs are miRNA that have a causal role in driving cancer phenotypes. As discussed throughout this chapter, cancer represents the summation of extensive genetic and epigenetic abnormalities found in genes involved in diverse biological pathways. Even with this complexity, certain cancers can be dependent on a single, powerful oncogene, and abrogation of this oncogene can reverse the malignant phenotype. Targeting the Philadelphia chromosome with inhibitors of the BCR-ABL kinase domain in chronic myelogenous leukemia is a classic, successful example of this approach.^{111, 112} Herceptin and its success in treating Her2+ breast cancer is another example.^{113, 114} It is also known that single oncogenes can affect miRNA expression, exemplified by Myc, which can induce the oncomiR miRNA-17/92 cluster, and negatively regulate tumor suppressor miRNA's, such as let-7 and miRNA-29.^{115, 116} Thus, the potential to target oncomiRs is appealing due to their capacity to control many cancer pathways. One way is to identify the exogenous and/or endogenous (e.g., free radicals) chemicals leading to an increase in oncomiR expression or imbalance of oncomiRs. miR-21 is one key oncomiR, up-regulated in a number of human cancers.^{90, 117} It has been shown to be up-regulated by exposure to cancer-causing agents such as arsenite,¹¹⁸ reactive oxygen species (ROS),¹¹⁸ hydrogen peroxide,¹¹⁹ UV irradiation,¹²⁰ TPA,¹²¹ and nitric oxide from NOS2.¹²² In addition, absence of miRNA-21 results in suppressed skin tumorigenesis induced by 7,12-dimethylbenz[a]anthracene (DMBA)/TPA. miR-21 targets include multiple tumor suppressor genes, such as phosphatase and tensin homolog (PTEN) and tropomyosin α -1 (TPM1) as well as DNA mismatch repair genes, mutS homolog 2 (MSH2) and mutS homolog 6 (MSH6).¹¹⁷ Other oncomiRs, including miRNA's-17/92, -20, -106, -107, -141, -146, -155, -181, -200, -221/222, and -373, have all been shown to be a target of chemical carcinogens (e.g., BPDE, DMBA),^{92, 123} in that their expression is increased by these agents. This gives us initial insight into chemicals to target, as well as molecular oncomiR targets/signatures for protection against cancers associated with these chemicals.

Suppressor miRNAs

Many forms of cancer are associated with misregulation of miRNA expression and, indeed, miRNA expression profiles are now used as one way to classify tumors.^{105, 124–126} Often, tumor cells show a decrease in the level of certain miRNAs that function as tumor suppressors [for reviews, see refs ^{100, 127–130}]. Each tumor suppressor miRNA is thought to regulate the expression of a broad spectrum of genes that work in different cancer pathways. Although only a subset of the direct targets of each tumor suppressor miRNA is currently known, it is clear that the overall impact of losing a tumor suppressor miRNA is to promote one or more aspects of carcinogenesis. In several cases, experiments using animal models have demonstrated that loss of a particular tumor suppressor miRNA can drive tumorigenesis. In these cases, tumorigenesis is suppressed when the missing miRNAs are added back.^{129, 131–133} miRNA-34a, which is a

component of the p53 transcriptional network¹³⁴ and regulates cancer stem cell survival,^{135, 136} is a good example of this, and so far, arguably, appears to be the furthest in development for use in clinical trials.^{127, 136} miRNA-34a is down regulated in cancer and has been demonstrated to block the initiation and/or inhibit the growth of tumors in animal models of different kinds of cancer when levels are restored.^{137–142} Thus, miRNA replacement therapy appears quite promising for treating cancer. However, as is the case for other therapies based on small RNAs, delivery of the RNA to target sites is a critical barrier to implementation.^{130, 133, 143, 144} A variety of systems have been developed to overcome these challenges. Many methods make use of commercially synthesized molecules produced with novel chemical modifications designed to improve stability.^{144–146} In addition, synthetic RNAs are generally introduced as a duplex rather than as the mature single-stranded miRNA, a feature that not only promotes stability, but also triggers mammalian defense pathways that recognize double-stranded RNA. In many cases, the chemically modified RNA is conjugated to another molecule (e.g., cholesterol) or encapsulated into nanoparticles to overcome barriers to cellular uptake of the RNA.^{123, 141} Downsides here include the following: (1) the specificity and functionality of the modified molecule may be altered from that of the natural miRNA, resulting in decreased therapeutic potential; (2) adverse side effects can be induced, including stimulation of immune response, toxicity due to packaging components, and activation of the complement pathway; and (3) increased expense. Furthermore, delivery strategies involving expression of small RNA precursors via adenoviral- or lentiviral-based vectors are often used in animal models but are not deemed safe enough for therapies in humans. Thus, although researchers have met with some success in systemic delivery of therapeutic small RNAs, many challenges remain, including safety concerns, efficacy, and economic feasibility.

There are multiple examples of changes in (mostly decreases in) suppressor miRNA levels by chemical carcinogens. The full list has been reviewed recently, so the reader is referred to the reference.⁹¹ Highlights include suppression of the suppressor miRNA's let-7 family and miR-34b in lungs of cigarette smoke-exposed mice. Interestingly, the expression of the let-7 family was restored 1 week after smoking cessation. However, the recovery was incomplete for a limited array of miRNAs, including miRs-34b, -345, -421, -450b, -466, and -469. Thus, it appears that miRNAs mainly behave as biomarkers of effect and that exposure to high dose, lasting for an adequate period of time, is needed to trigger the cigarette-smoke-related carcinogenesis process associated with miRNA changes.¹⁴⁷

Mechanisms of chemical carcinogen-induced changes in miRNA expression

Changes in miRNA levels by environmental carcinogens appear to be reversible at low doses and short periods of exposure, but irreversible with higher doses and long periods of exposure; and that irreversible miRNA changes are predictive of the future appearance of cancer.^{91, 147} The mechanisms of how chemical carcinogens lead to an imbalance and changes in miRNA expression appear to involve genetic abnormalities, modulation of the biogenesis machinery, and/or epigenetic mechanisms^{92, 115, 116} (Box 2). Genetic abnormalities include chromosomal rearrangements, genomic amplifications, deletions, and mutations.⁹² This was demonstrated in the first studies identifying miRNA's in tumorigenesis. The miRNA-15/16-1 cluster was shown to be deleted in CLL, with subsequent reduced accumulation.⁴⁶ Germline mutation was also associated with reduced accumulation of this cluster.¹⁴⁸ The miRNA biogenesis machinery can be altered through multiple mechanism, each resulting in altered miRNA levels. For example, mutations can occur in key biogenesis enzymes (Dicer and Drosha) and/or their complexes,¹⁴⁹ resulting in aberrant miRNA production. Indeed, it has been shown that a series of

chemical carcinogens (e.g., PAHs, heterocyclic compounds, nitrosamines, morpholine, ethylnitrosourea, benzene derivatives, hydroxyl amines, and alkenes) interfere with miRNA maturation by binding Dicer.^{91, 149} Although the effects of environmental chemical carcinogens on the miRNA machinery have been described in detail recently,⁹¹ they can be summed up by three mechanisms. First, in response to DNA damage, the p53/miRNA interconnection can modify the expression of miRNA genes in the nucleus. Second, electrophilic metabolites of environmental carcinogens can bind to nucleophilic sites of miRNA precursors thus forming miRNA adducts that cannot access the catalytic pockets of Dicer in the cytoplasm. Third, metabolites of environmental carcinogens can bind to Dicer in the proximity of miRNA catalytic sites thus blocking maturation of miRNA precursors⁹¹ ([Figure 2](#)). It remains, however, unclear to why oncomiR's are upregulated, which will be an important mechanism to delineate for a better understanding of chemical carcinogenesis and chemoprevention. To this end, there are ongoing studies identifying specific small molecule inhibitors of oncomiR biogenesis.¹⁵⁰

Because miRNA expression is also altered by nongenotoxic carcinogens,⁹¹ there are additional mechanisms modulating expression outside of the DNA damage response pathway. Epigenetic mechanisms (e.g., hypermethylation of tumor suppressor miRNA), as well as direct effects on the transcriptional machinery and post-transcriptional modifiers, play a role. For example, hypermethylation of miRNA-124a in colon cancer results in the up-regulation of the oncogene, Cdk6 kinase and the phosphorylation of the tumor suppressor, pRb.¹⁵¹ CpG island hypermethylation of additional tumor suppressor miRNAs have been shown, and the list is growing.^{152–155} miRNA's have also been shown to target and alter the activity of DNMT and other enzymes involved in epigenetic modulation (HDACs and histone acetyl transferases)^{156–159} ([Figure 2](#)). Carcinogens, in turn, can play an integral part in this process. For example, nickel sulfide, which is a weak mutagen but strong carcinogen, can down-regulate miRNA-152 via promoter-DNA hypermethylation.¹⁵⁷ Similarly, ROS inhibit miR-199a and miR-125b expression through increasing the promoter methylation of the miR-199a and miR-125b genes by DNMT1.¹⁶⁰

As many miRNAs are transcribed by PolII and associated factors,^{92, 161, 162} it stands to reason that miRNA levels are altered by an impact of environmental carcinogens on PolII and other factors with resulting altered transcriptional regulation. miR-34a and miR-34b/c, for example, are direct, conserved p53 target genes that mediate induction of apoptosis, cell-cycle arrest, and senescence by p53.¹⁶³ When p53 is mutated (often by environmental carcinogens¹⁶⁴), its' transcriptional activity is compromised.¹⁶⁵ In a similar way, environmental carcinogens affect the activity of PolII.¹⁶⁶

Overall, it is clear that chemical carcinogens alter miRNA expression. As with many biological entities, these changes occur initially due to exposure as an adaptive response to the chemical insult. Such mechanisms that miRNA work include the activation of p53, cell-cycle arrest, and apoptotic induction (e.g., by the miR-34 suppressor miRNA family). Proto-oncogene mutation (“initiation”; e.g., k-ras) can induce expression of other suppressor miR's such as the let-7 family.¹⁶⁷ With long-term, extensive exposure, miRNA expression changes can become irreversible. This has been shown with the miR-34 and let-7 family members where their inactivation results in the suppression of p53 and activation of k-ras.^{91, 168} If miRNA replacement therapy becomes mainstream, this will be a powerful tool for changing and perhaps reversing the carcinogenic process induced by chemical carcinogens. Interestingly, recent studies have found that plant miRNAs consumed by mammals are detected in mammals (including humans), have activity in mammals, and have tumor-suppressive properties.^{169–171}

Gene–environment interactions and inter-individual variation

A cornerstone of human chemical carcinogenesis is the concept of gene–environment interactions ([Figure 3](#), Box 3).^{56, 172} Potential inter-individual susceptibility to chemical carcinogenesis may well be defined by genetic variations in the host elements of this compound system. Functional polymorphisms in human proteins that have, or may have, a role in chemical carcinogenesis include enzymes that metabolize (i.e., activate and detoxify) xenobiotic substances, enzymes that repair DNA damage, cell surface receptors that activate the phosphorylation cascade and cell-cycle control genes (i.e., oncogenes and tumor suppressor genes that are elements of the signal transduction cascade).

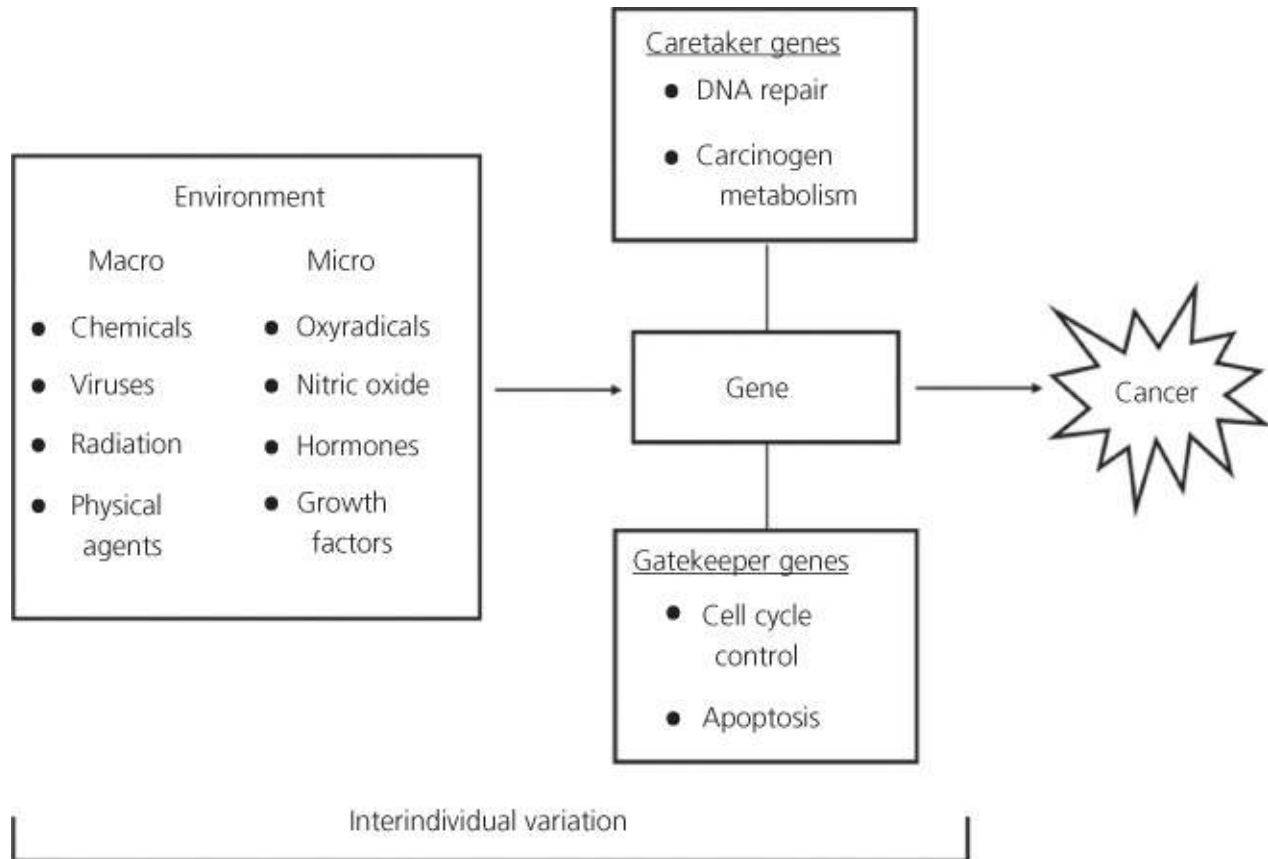

Figure 3 The concept of gene–environment interactions is multifaceted: (1) environmental chemicals are altered by the products of metabolic genes; (2) environmental chemicals disrupt the expression (induce or inhibit) of carcinogen metabolizing genes; and (3) environmental exposures cause changes (mutations) in cancer-related genes. The cancer-related genes have been classified as gatekeeper (e.g., APC) and caretaker (e.g., MSH1 and MLH1) genes. The interaction of these genes with external and internal environmental agents can lead to the derangement of regulatory pathways that maintain genetic stability and cellular proliferation.

Box 3 Gene–environment interactions

Genes identified that modify response to chemical carcinogens include those involved in carcinogen metabolism (e.g., p450's), DNA repair (e.g., NER), cell signaling, cell cycle, and hormonal regulation.

When chemicals or xenobiotics encounter biologic systems, they become altered by metabolic processes.

This is an initial facet of gene–environment interaction. The inter-individual variation in carcinogen metabolism and macromolecular adduct formation arising from such processes was recognized almost 40 years ago.³⁰ The cytochrome P450 (CYP) multigene family is largely responsible for the metabolic activation and detoxification of many different chemical carcinogens in the human environment.¹⁷³ CYP P450s are phase I enzymes that act by adding an atom of oxygen onto the substrate; they are induced by PAHs and chlorinated hydrocarbons.¹⁷³ Phase II enzymes act on oxidized substrates and also contribute to xenobiotic metabolism. Some phase II enzymes are methyltransferases, acetyltransferases, glutathione transferases, uridine 5'-diphosphoglucuronosyl transferases, sulfotransferases, nicotinamide adenine dinucleotide (NAD)- and nicotinamide adenine dinucleotide phosphate (NADP)-dependent alcohol dehydrogenases, aldehyde, steroid dehydrogenases, quinone reductases, NADPH diaphorase, azo reductases, aldoketoreductases, transaminases, esterases, and hydrolases. The pathways of activation and detoxification are often competitive, providing yet further potential for individual differences in propensity for carcinogen metabolism to DNA damaging species. This scenario is further complicated by a second facet of gene–environment interaction that leads to enzyme induction or inhibition. In this case, environmental exposures alter gene expression, and genes responsible for carcinogen metabolism can be upregulated or repressed by certain chemical exposures.

A third facet of gene–environment interaction occurs when the chemical alters gene structure (environmentally predisposed abnormal DNA). Once a procarcinogen is metabolically activated to an ultimate carcinogenic form, it can bind covalently to cellular macromolecules, including DNA. This DNA damage can be repaired by several mechanisms.¹⁷⁴ Differences in rates and fidelity of DNA repair potentially influence the extent of carcinogen adduct formation (i.e., biologically effective dose) and, consequently, the total amount of genetic damage. The consequences of polymorphisms in genes controlling the cell cycle (serine/threonine kinases, transcription factors, cyclins, cyclin-dependent kinase inhibitors, and cell surface receptors) are much less clear. However, molecular epidemiologic evidence suggests that certain common variants of these types of genes have a role in susceptibility to chemical carcinogenesis.¹⁷⁵ The evaluation of polymorphisms as potential biomarkers of susceptibility in the human population is discussed in Weston and Harris.¹⁷⁶

Carcinogen metabolism

Inter-individual variation in cancer susceptibility, and, consequently, meaningful human cancer risk assessment, involve determination of inherited host factors as well as exposure assessment. Metabolic polymorphisms have historically been determined by the use of indicator drugs (e.g., caffeine, debrisoquine, dextromethorphan, dapsone, and isoniazid), however, these assays are being replaced by direct genetic assays. This approach has allowed the investigation of diverse host factors for which indicator drugs were not available, and it has been applied to a wide variety of cancers.^{177–181} Such studies have not only made a key impact in the area of pharmacogenomics,^{182, 183} but genetic indicators of propensity for carcinogen activation and detoxification, DNA-repair capacity, apoptosis, and cell-cycle control are all features of molecular epidemiologic studies that are complementary to adduct studies because of the implications for a biologically effective dose after exposure.

CYP P450 polymorphisms, involved in carcinogen activation, and glutathione-S transferases, uridine diphosphate (UDP) glucuronosyltransferases, sulfotransferases, and N-acyltransferases, involved in both carcinogen activation and detoxification, could explain variations in cancer susceptibility among the human population. Evidence that absent protection of a functionally intact *GSTM1* gene correlates with an increased risk of tobacco-related lung cancer.¹⁸⁴ Similarly, the absence of *GSTM1* and *GSTT1* genes

increases the risk of lung cancer because of radon exposure.¹⁸⁵ There is a substantial reduction in risk of lung adenocarcinoma associated with genetic polymorphism in CYP2A13, the most active CYP P450 for the metabolic activation of tobacco-specific carcinogen NNK.¹⁸⁶ The finding that XRCC1, GSTM1, and COMT polymorphisms was strongly associated with lung cancer risk in smoking women is supportive of an interaction of repair, tobacco smoke metabolism, and estrogen metabolism in this disease and continues the controversy of an increased risk of lung cancer in women.¹⁸⁷ Also, UDP glucuronosyltransferases (e.g., *UGT1A1*, *UGT1A9*, and *UGT2B7*) have been implicated in cancers of the head and neck. Persons inheriting reduced activity variants of *NAT1* and *NAT2* genes, resulting in the slow acetylator phenotype, are at a greater risk of aromatic amine-induced bladder cancer. This may include persons exposed through tobacco smoke inhalation.^{188, 189} Over the past 25 years, there have been advances in the understanding of carcinogen metabolism, inter-individual variations, and cancer risk. A good review of the existing literature can be found elsewhere.¹⁹⁰

PAHs, for example, B(a)P, were the first carcinogens to be chemically isolated.¹⁹¹ They are composed of variable numbers of fused benzene rings that form from incomplete combustion of fossil fuels and vegetable matter, they are common environmental contaminants. PAHs are chemically inert, and require metabolism to exert their biologic effects.¹⁹¹ This multistep process involves the following: initial epoxidation (CYP P450), hydration of the epoxide (epoxide hydrolase), and subsequent epoxidation across the olefinic bond.^{173, 192} The result is the ultimate carcinogenic metabolite; in the case of B(a)P it is r7, t8-dihydroxy-c9, 10 epoxy-7,8,9,10-tetrahydroxybenzo[a]pyrene (B[a]P-7,8-diol 9,10-epoxide, BPDE).¹⁹³ The biology of CYP P450 (e.g., CYP1A1) metabolism has been elucidated providing a molecular basis for inducibility and inter-individual variation, and variations in CYP levels among humans have been documented.¹⁹⁴ The arene ring of BPDE opens spontaneously at the tenth position, revealing a carbonium ion that can form a covalent addition product (adduct) with cellular macromolecules, including DNA. Several DNA adducts can be formed, the most abundant being at the exocyclic amino group of deoxyguanosine ([7R]-N 2-[10-7 β ,8a,9a-trihydroxy-7,8,9,10-tetrahydro-benz[a]pyrene}yl]-deoxyguanosine; BPdG). One electron oxidation has been suggested as an alternative pathway of PAH activation, here a radical cation forms at the meso position (L-region). The resulting DNA adducts at the C8 of guanine (B(a)P-6-C8Gua and BP-6-C8dGua), the N7 of guanine and adenine (B(a)P-6-N7Gua and BP-6-N7Ade) likely undergo spontaneous depurination. Firm evidence for the exfoliation of these adducts in urine has been provided.¹⁹⁵

Aromatic amines are found in cigarette smoke, diesel exhaust, industrial environments, and certain cooked foods. The compound, 4-aminobiphenyl, is thought to be responsible for bladder cancer among tobacco smokers and rubber industry workers.¹⁹⁶ In addition, nitrated PAHs are environmental contaminants that are related to aromatic amines by nitroreduction. Aromatic amines can be converted to an aromatic amide that is catalyzed by an acetyl coenzyme A-dependent acetylation.¹⁹⁷ The acetylation phenotype varies among the population. Persons with the rapid acetylator phenotype are at a higher risk of colon cancer (especially in smokers),¹⁹⁸ whereas, those who are slow acetylators are at risk of bladder cancer.¹⁹⁸ This latter association may result from the fact that activation of aromatic amines by *N*-oxidation is a competing pathway for aromatic amine metabolism. The *N*-hydroxylation products when protonated (e.g., in the urinary bladder) are reactive and can cause DNA damage.

An initial activation step for both aromatic amines and amides is *N*-oxidation by CYP1A2. The reactions of *N*-hydroxyarylamines with DNA appear to be acid catalyzed, but they can be further activated by either an acetyl coenzyme A-dependent *O*-acetylase or a 3'-phosphoadenosine-5'phosphosulfate-dependent *O*-sulfotransferase. The *N*-arylhydroxamic acids arise from the acetylation of *N*-hydroxyarylamines or *N*-

hydroxylation of aromatic amides; they are not electrophilic and require further activation. The predominant pathway here occurs through acetyltransferase-catalyzed rearrangement to a reactive *N*-acetoxyarylamine. Sulfotransferase catalysis forms *N*-sulfonyloxy arylamides. This complex pathway results in two major adduct types, amides (acetylated) and amines (nonacetylated).

Heterocyclic amines form in food cooking from pyrolysis (>150 °C) of amino acids, creatinine, and glucose. They have been recognized as food mutagens, shown to form DNA adducts and cause liver tumors in primates.¹⁹⁹ These compounds are activated by CYP1A2 and their metabolites form DNA adducts in humans. The *N*-hydroxy metabolites of heterocyclic amines like 2-amino-3-methyl-imidazo-[4,5-f]quinoline (IQ) can react directly with DNA. Enzymic *O*-esterification of *N*-hydroxy metabolites plays a key role in activating food mutagens, and because the *N*-hydroxy metabolites are good substrates for transacetylases, these chemicals may be implicated in colorectal cancer.

Aflatoxins (B1, B2, G1, and G2), metabolites of *Aspergillus flavus*, contaminate cereals, grain, and nuts. A positive correlation exists between dietary aflatoxin exposure and the incidence of liver cancer in developing countries, where grain spoilage is high. Aflatoxins B1 and G1 have an olefinic double bond at the 8,9-position that can be oxidized by several CYP P450.^{173, 192} This implies that the olefinic 8,9-bond is the activation site. Further support for this mechanism comes from studies of DNA adducts and the prevalence of TP53 mutations in liver cancer. In people with liver cancer from parts of China and Africa, where food spoilage caused by molds is high, G : C to T : A transversions in codon 249 are frequent.^{42, 43, 200} This phenomenon is consistent with metabolic activation of aflatoxin B1 and the formation of depurinating carcinogen–deoxyguanosine adducts.

Carcinogenic *N*-nitrosamines are ubiquitous environmental contaminants and can be found in food, alcoholic beverages, cosmetics, cutting oils, hydraulic fluid, rubber, and tobacco.²⁰¹ Tobacco-specific *N*-nitrosamines (TSNs), for example, NNK, are not formed by pyrolysis, which accounts for the highly carcinogenic nature of snuff and chewing tobacco.²⁰² TSNs are not symmetric so both small alkyl adducts and large bulky adducts can be formed; for example, NNK metabolism gives rise to either a positively charged pyridyl-oxobutyl ion or a positively charged methyl ion, both of which are able to alkylate DNA.^{70, 203} Endogenous nitrosamines form when an amine reacts with nitrate alone or nitrite in the presence of acid. Thus, nitrite (used to cure meats) and L-cysteine, in the presence of acetaldehyde (from alcohol), form *N*-nitrosothiazolidine-4-carboxylic acid. *N*-Nitrosodimethylamine undergoes α -hydroxylation, catalyzed primarily by the alcohol inducible CYP2E1, to form an unstable α -hydroxynitrosamine. The breakdown products are formaldehyde and methyl diazohydroxide. Methyl diazohydroxide and related compounds are powerful alkylating agents that can add a small functional group at multiple sites in DNA.

Nongenotoxic carcinogens may function at the level of the microenvironment by dysregulation of hormones and growth factors, or indirectly inducing DNA damage and mutations through the action of free radicals. These chemicals are none or poorly reactive and are resistant to activation through metabolism. They are also characterized by their persistence in biological systems and consequently tend to accumulate in the food chain. However, they can stimulate oxyradical formation by at least three mechanisms: organochlorine species interact with the Ah receptor, which can lead to CYP P450 induction and associated oxyradical formation; interaction with other receptors, like interferon (IFN)- γ , can stimulate elements of the primary immune response and again generate oxyradicals; and agents like asbestos can promote oxyradical formation through interaction with ferrous metal. The resulting oxyradicals can then damage DNA. Some of the so-called “nongenotoxic” carcinogens might more appropriately be considered to be “oxyradical triggers.” Indeed, chronic inflammatory states, which

involve oxyradical formation, can also be cancer risk factors.^{204–208}

DNA damage and repair

Another facet of inter-individual variation in risk for cancer from chemical carcinogens is inter-individual differences in the ability to repair damage from chemical carcinogens. DNA damage initiates a complex network of signaling cascades.²⁰⁹ The chemical structure of DNA can be altered by a carcinogen in several ways: the formation of large bulky aromatic adducts, small alkyl adducts, oxidation, dimerization, and deamination. In addition, double- and single-strand breaks can occur. Chemical carcinogens can cause epigenetic changes, such as altering the DNA methylation status that leads to the silencing of specific gene expression.⁶⁹ A complex pattern of carcinogen–DNA adducts likely results from a variety of environmental exposures, because of the mixture of different chemical carcinogens present.

Many DNA-repair genes have been described recently, and a growing number of polymorphisms have been identified for which molecular epidemiologic studies have provided evidence that genetic variation in these attributes can be a human cancer risk factor; as well as be used to tailor cancer chemotherapy.^{210, 211} Typically, these types of molecular epidemiological studies initially focus on high-exposure groups such as workers, patients taking therapeutic drugs, and tobacco smokers. Several polymorphisms in DNA-repair genes have now been implicated in tobacco-related neoplasms.²¹² An interesting theory developed recently is a so-called, “hide-then-hit” hypothesis. This describes the importance of DNA-repair variants in escaping checkpoint surveillance. Only cells with subtle defects in repair capacity arising from low-penetrance variants of DNA-repair genes would have the opportunity to grow and to accumulate the genetic changes needed for cancer formation, without triggering cell-cycle checkpoint surveillance.²¹³

BPDE reacts with the exocyclic (N2) amino group of deoxyguanosine and resides within the minor groove of the double helix, it is typical of PAHs. This adduct, BPdG, is probably the most common, persistent adduct of B(a)P in mammalian systems, but others are possible. Adducts like BPdG are thought to induce ras gene mutations, which are common in tobacco-related lung cancers.^{214, 215} Aromatic amine adducts are more complex, because they have both acetylated and nonacetylated metabolic intermediates, and they form covalent bonds at the C8, N2, and sometimes O6 positions of deoxyguanosine as well as deoxyadenosine. The major adducts, however, are C8-deoxyguanosine adducts, which reside predominantly in the major groove of the DNA double helix.²¹⁶

Aflatoxin B1 and G1 activation through hydroxylation of the olefinic 8,9-position results in adduct formation at the N7 position of deoxyguanosine. These are relatively unstable with a half-life of approximately 50 h at neutral pH; depurination products have been detected in urine.²¹⁷ The aflatoxin B1-N7-deoxyguanosine adduct also can undergo ring opening to yield two pyrimidine adducts; alternately, aflatoxin B1-8,9-dihydrodiol could result, restoring the DNA molecular structure if hydrolysis of the original adduct occurs.²¹⁸

DNA alkylation can occur at many sites either following the metabolic activation of certain *N*-nitrosamines, or directly by the action of the *N*-alkyl ureas (*N*-methyl-*N*-nitrosourea) or the *N*-nitrosoguanidines. The protonated alkyl-functional groups that become available to form lesions in DNA generally attack the following nucleophilic centers: adenine (N1, N3, and N7), cytosine (N3), guanine (N2, O6, and N7), and thymine (O2, N3, and O4). Some of these lesions are known to be repaired (O6-methyldeoxyguanosine), while others are not (*N*7-methyldeoxyguanosine), which explains why O6-methyldeoxyguanosine is a promutagenic lesion and *N*7-methyldeoxyguanosine is not.^{219, 220}

Another potentially mutagenic cause of DNA damage is the deamination of DNA-methylated cytosine residues. 5-Methylcytosine comprises approximately 3% of deoxynucleotides. In this case, deamination at a CpG dinucleotide gives rise to a TpG mismatch. Repair of this lesion most often restores the CpG; however, repair may cause a mutation (TpA).²²¹ Deamination of cytosine also can generate a C to T transition if uracil glycosylation and G-T mismatch repair are inefficient.

Oxyradical damage can form thymine glycol or 8-hydroxydeoxyguanosine adducts. Exposure to organic peroxides (catechol, hydroquinone, and 4-nitroquinoline-*N*-oxide) leads to oxyradical damage; however, oxyradicals and hydrogen peroxide can be generated in lipid peroxidation and the catalytic cycling of some enzymes, as well as environmental sources (e.g., tobacco smoke).^{204, 222} Certain drugs and plasticizers can stimulate cells to produce peroxisomes, and oxyradical formation is mediated through protein kinase C when inflammatory cells are exposed to tumor promoters like phorbol esters.²²³ Oxyradicals can contribute to deamination through induction of NO synthase.²²⁴

Maintenance of genome integrity requires mitigation of DNA damage. Thus, diminished DNA repair capacity is associated with carcinogenesis, birth defects, premature aging, and foreshortened life span. DNA-repair enzymes act at DNA damage sites caused by chemical carcinogens, and six major mechanisms are known: direct DNA repair, nucleotide excision repair, base excision (BER) repair, nonhomologous end joining (double-strand break repair), mismatch repair, and homologous recombination (HR) (postreplication repair).^{225, 226}

In the presence of nonlethal DNA damage, cell-cycle progression is postponed for repair mechanisms. This highly coordinated process involves multiple genes. A DNA-damage recognition sensor triggers a signal transduction cascade and downstream factors direct G1 and G2 arrest in concert with the proteins operationally responsible for the repair process. Although there are at least six discrete repair mechanisms, within five of them, there are numerous multiprotein complexes comprising all the machinery necessary to accomplish the step-by-step repair function.

Generically, DNA repair requires damage recognition, damage removal or excision, resynthesis or patch synthesis, and ligation. Recent advances have led to the cloning of more than 130 human genes involved in five of these DNA-repair pathways. A list of these genes and their specific functions was published elsewhere.²²⁷ These genes are responsible for the fidelity of DNA repair, and when they are defective, the mutation rate increases. This is the mutator phenotype.^{29, 60, 61} Mutations in at least 30 DNA-repair associated genes have been linked to increased cancer susceptibility or premature aging ([Table 3](#)).²²⁷ Moreover, the role of common polymorphisms in some of these genes is associated with increased susceptibility in a gene–environment interaction scenario (this is discussed in Weston and Harris¹⁷⁶). Indeed, molecular epidemiologic evidence suggests that tobacco-smoking-related lung cancer is associated with a polymorphism in the nucleotide excision repair gene, XPC (ERCC2).²²⁸

Table 3 Examples of disease susceptibility and disease syndromes associated with mutations in DNA-repair genes

Gene	Function	Pathology or cancer
<i>Cancer susceptibility</i>		
MMRa		
<i>MLH1</i>	Damage recognition	HNPCC2b, glioma
<i>MLH2</i>	DNA binding	HNPCC1, ovarian cancer

<i>MSH3</i>	—	Endometrial cancer
<i>MSH6</i>	Sliding clamp	Endometrial cancer, HNPCC1
<i>PMS1</i>	Damage recognition	HNPCC3
<i>PMS2</i>	Repair initiation	HNPCC4, glioblastoma
NER		
<i>BRCA-1</i>	Directs <i>p53</i> transcription toward DNA-repair pathways	Breast cancer, ovarian cancer
<i>RB1</i>	Cell-cycle restriction	Retinoblastoma, breast cancer, and progression osteosarcoma
DSB		
<i>BRCA-2</i>	Regulation of RAD51	Breast cancer, pancreatic cancer
HR		
<i>RAD54</i>	Helicase	Colon cancer, breast cancer, NHL
Other		
<i>TP53</i> (DSB, NER, HR)	Cell-cycle control; exonuclease; apoptosis; DNA binding	Colon cancer, common somatic defect in human cancer in general; inherited in Li–Fraumeni syndrome and some breast cancers
<i>hOgg1</i> (Various)	Glycosylase	Cancer susceptibility
Xeroderma pigmentosum (XP)		
NER		
<i>XPD</i>	DNA helicase	Skin and neurologic, but later onset than XPA
<i>XPB</i>	DNA helicase	Skin lesions
<i>XPG</i>	Endonuclease	Acute sun sensitivity, mild symptoms; late skin cancer
<i>XPC</i> (and BER)	Exonuclease	Mental retardation; skin sensitivity; microcephaly
<i>DDB1</i> and <i>DDB2</i>	Binds specific DNA damage	XPE—mild skin sensitivity
<i>XPA</i>	Damage sensor	XPA—skin and neurologic problems: the most severe XP
<i>XPC</i>	Damage sensor	XPC—skin, tongue, and lip cancer
<i>XPE</i>	Damage sensor	XPE—neurologically normal
PRR		
<i>POLH</i>	Polymerase	XPV—Mild to severe skin sensitivity; neurologically normal
<i>Other syndromes</i>		
NER		

Cockaynes		
<i>CSB</i>	ATPase	Cutaneous, ocular, neurologic, and somatic abnormalities; short stature, progressive
		deafness, mental retardation, neurologic degeneration, early death; sometimes presents together with XPB
Juberg-Marsidi		
<i>ATR</i>	Putative helicase	Thalassemia/mental retardation
SB		
Nijmegen		
<i>NBS1</i>	Nibrin, cell-cycle regulation	Microencephaly; mental retardation; immunodeficiency; growth retardation; radiation sensitivity; predisposition to malignancy
Ataxia-telangiectasia		
<i>ATM</i>	Phosphorylation	Neurologic deficiencies, manifest by inability to coordinate muscle actions; skin and corneal telangiectases. Leukemia, lymphoma, and other malignancies (breast cancer?)
<i>MRE11</i> (Ataxia-like)	Exonuclease	DNA damage sensitivity; genomic instability; telomere shortening; aberrant meiosis; severe combined immunodeficiency
<i>PRKDC</i>	Ser/Thr kinase	SCID
Bloom's		
<i>BLM</i>	DNA helicase	High rate of spontaneous lymphatic and other malignancy; high rate SCE
Fanconi anemia		
<i>FANCA-G</i>	Protein control	Multiple congenital malformations; chromosome breaks; pancytopenia.
		Telomere shortening
Werner		
<i>WRN</i>	DNA helicase/exonuclease	Premature senility, short stature, exonuclease rapidly progressing cataracts, loss of connective tissue and muscle, premature arteriosclerosis, increase risk of malignancy
<i>RecQ4</i>	DNA helicase	Osteosarcoma; premature aging

Repair mechanisms: BER, base excision; DSB, double-strand break; HR, homologous recombination; MMR, mismatch; NER, nucleotide excision; PRR, postreplication; SB, strand break.

Diseases: HNPCC, hereditary nonpolyposis colon cancer; NHL, non-Hodgkin lymphoma.

Other abbreviations: SCE, sister chromatid exchange; SCID, severe combined immunodeficiency.

Direct DNA repair is affected by DNA alkyltransferases. These enzymes catalyze translocation of the alkyl moiety from an alkylated base (e.g., O6-methyldeoxyguanosine) to a cysteine residue at their active site in the absence of DNA strand scission. Thus, one molecule of the enzyme is capable of repairing one DNA alkyl lesion, in a suicide mechanism. The inactivation of this mechanism by promoter hypermethylation is associated with Kras G to A mutations in colon cancer.²²⁹

In DNA nucleotide excision repair, lesion recognition, preincision, incision, gap filling, and ligation are required, and the so-called excinuclease complex comprises 16 or more different proteins. Large distortions caused by bulky DNA adducts (e.g., BPDE-dG and 4ABP-dC) are recognized [xeroderma pigmentosum (XPA)] and removed by endonucleases (XPF, XPG, and FEN). A patch is then constructed (pol α and pol ϵ) and the free ends are ligated.

Base excision repair also removes a DNA segment containing an adduct; however, small adducts (e.g., 3-methyladenine) are generally the target so that there is overlap with direct repair. The adduct is removed by a glycosylase (hOgg1 and UDG), an apurinic endonuclease (APE1 or HAP1) degrades a few bases on the damaged strand, and a patch is synthesized (pol β) and ligated (DNA ligases: I, II, IIIa, III β , and IV).

DNA mismatches occasionally occur, because excision repair processes incorporate unmodified or conventional, but noncomplementary, Watson–Crick bases opposite each other in the DNA helix. Transition mispairs (G-T or A-C) are repaired by the mismatch repair process more efficiently than transversion mispairs (G-G, A-A, G-A, C-C, C-T, and T-T). The mechanism for correcting mispairings is similar to that for nucleotide excision repair and resynthesis described earlier, but it generally involves the excision of large pieces of the DNA containing mispairings. Because the mismatch recognition protein is required to bind simultaneously to the mismatch and an unmethylated adenine in a GATC recognition sequence, it removes the whole intervening DNA sequence. The parental template strand is then used by the polymerase to fill the gap.

Double-strand DNA breaks can occur from exposure to ionizing radiation and oxidation. Consequences of double-strand DNA breaks are the inhibition of replication and transcription, and loss of heterozygosity. Double-strand DNA break repair occurs through HR, where the joining of the free ends is mediated by a DNA-protein kinase in a process that also protects the ends from nucleolytic attack. The free ends of the DNA then undergo ligation by DNA ligase IV. Genes known to code for DNA-repair enzymes that participate in this process include XRCC4, XRCC5, XRCC6, XRCC7, HRAD51B, HRAD52, RPA, and ATM.

Postreplication repair is a damage-tolerance mechanism and it occurs in response to DNA replication on a damaged template. The DNA polymerase stops at the replication fork when DNA damage is detected on the parental strand. Alternately, the polymerase proceeds past the lesion, leaving a gap in the newly synthesized strand. The gap is filled in one of two ways: either by recombination of the homologous parent strand with the daughter strand in a process that is mediated by a helical nucleoprotein (RAD51); or when a single nucleotide gap remains, mammalian DNA polymerases insert an adenine residue. Consequently, this mechanism may lead to recombinational events as well as base-mispairing.

Persistent nonrepaired DNA damage blocks the replication machinery. Cells have evolved translesion synthesis (TLS) DNA polymerases to bypass these blocks.²³⁰ Most of these TLS polymerases belong to the recently discovered Y family, have much lower stringency than replicative polymerases, and thus are error prone. An increased mutation frequency is an evolutionary trade-off for cellular survival.

Mutator phenotype

Cancer cells contain substantial numbers of genetic abnormalities when compared to normal cells. These abnormalities range from gross changes such as nondiploid number of chromosomes, that is, aneuploidy, and translocations or rearrangements of chromosomes, to much smaller changes in the DNA sequence including deletions, insertions, and single nucleotide substitutions. Therefore, carcinogenesis involves *errors* in (1) chromosomal segregation, (2) repair of DNA damage induced by either endogenous free

radicals or environmental carcinogens, and (3) DNA replication. Loeb originally formulated the concept of the mutator phenotype in 1974^{29, 60} to account for the high numbers of mutations in cancer cells when compared to the rarity of mutations in normal cells. Recent advances in the molecular analysis of carcinogenesis in human cells and animal models have refined the mutator phenotype^{61, 231} concept that is also linked to the clonal selection theory proposed by Nowell (Figure 4).²³² Generally, the mutator phenotype hypothesis proposes that mutation rates in normal cells are insufficient to account for the large number of mutations found in cancer cells. Consequently, human tumors exhibit an elevated mutation rate that increases the likelihood of a tumor acquiring advantageous mutations. The hypothesis predicts that tumors are composed of cells harboring hundreds of thousands of mutations, as opposed to a small number of specific driver mutations, and that malignant cells within a tumor therefore constitute a highly heterogeneous population.²³¹

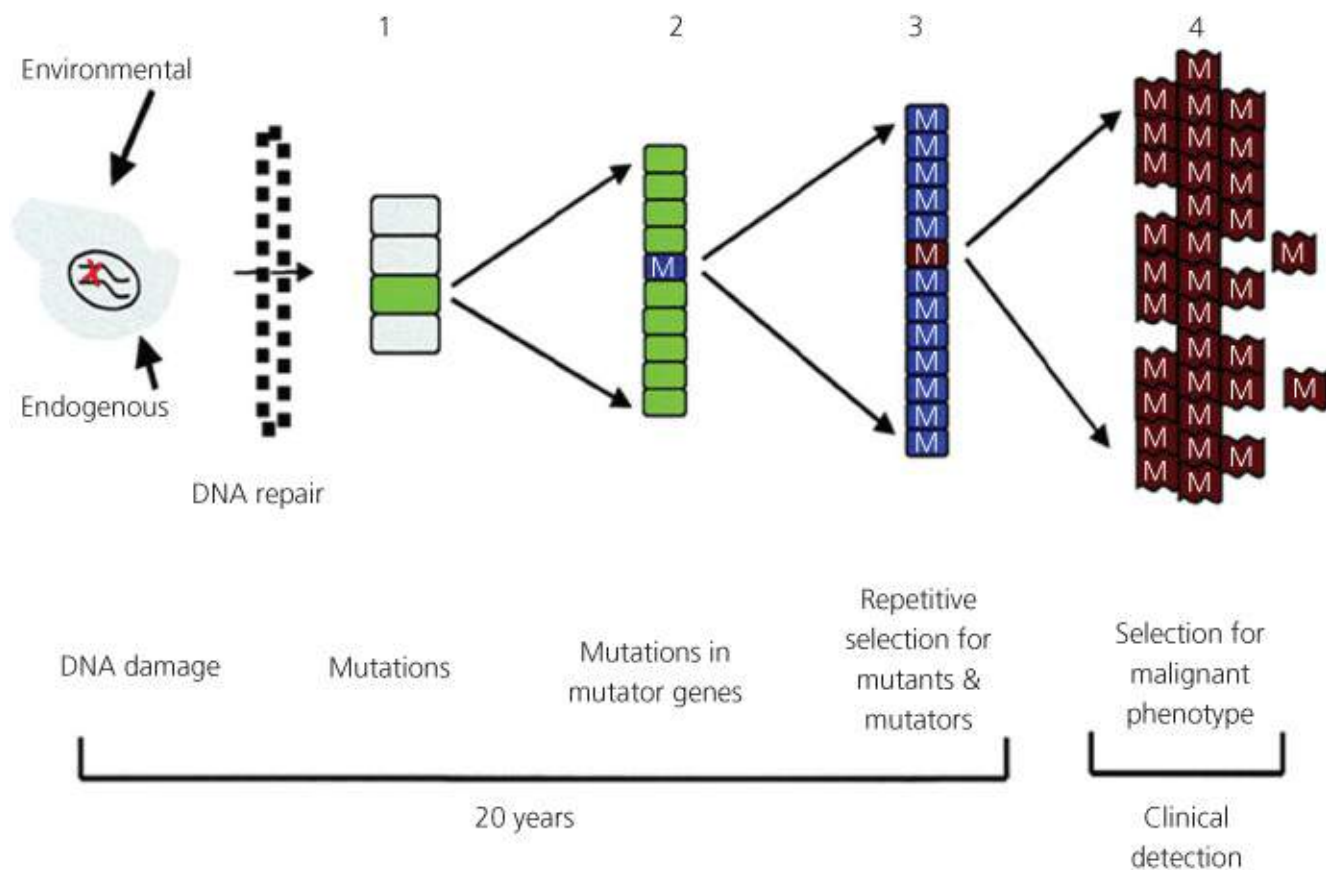

Figure 4 Mutation accumulation during tumor progression. (1) Random mutations result when DNA damage exceeds the cell's capacity for error-free DNA repair. (2) These random mutations can result in clonal expansion and mutations in mutator genes (M). (3) Repetitive rounds of selection for mutants yield coselection mutants in mutator genes. (4) From this population of mutant cancer cells, there is selection for cells that escape the host's regulatory mechanisms for the control of cell replication, invasion, and metastasis.

Racial, gender, and socioeconomic disparities in chemical carcinogenesis

Genetic polymorphisms may also partially explain the increased risk of cancer-associated chemical carcinogens amongst different genders, race, and ethnicity. One of the biggest controversies surrounding this issue is the risk of lung cancer in women smokers. The initial studies finding a higher risk of lung cancer in smoking women versus smoking men²³³ have been explained biologically in a number of ways.

Several sources of evidence, though inconsistent, suggest that estrogens may play a role in lung cancer. Variation in risk factors and tumor characteristics between men and women has been reported in studies showing that women are more likely to have adenocarcinomas of the lung, a higher risk in never smokers, higher levels of PAH–DNA adducts, higher levels of expression of the gene encoding CYP P450 (CYP) 1A1, more frequent G : C to T : A transversions in p53, and more frequent epidermal growth factor receptor (EGFR) mutations than men.¹⁸⁷ Inherited genetic polymorphisms affecting activating and detoxifying enzymes could also explain a different susceptibility between the sexes to tobacco carcinogens.²³⁴ In addition, several lifestyle and behavioral factors related to smoking habits or environmental and occupational exposures could account for some sex differences.²³⁵ However, in recent years, differences in the susceptibility to lung cancer among smoking men and women have been called into question.^{236, 237}

A consistent theme is that nonsmoking women are at increased risk for lung cancer compared to nonsmoking men^{237, 238}; and nonsmoking women are at increased risk for lung cancer due to environmental tobacco smoke (ETS) compared to nonsmoking women not exposed to ETS.^{239–244} This risk may be associated with polymorphisms. For example, in female populations, it appears that a common genetic polymorphism divides the population of never smokers into two groups of approximately equal size, one (homozygous carriers of the GSTM1 null allele) that has a statistically significant greater risk of lung cancer from ETS than the other (heterozygous or homozygous carriers of the wild-type GSTM1 allele).²⁴⁰ In a similar context, genetic variants at 13q31.3 alter the expression of the glypican-5 (GPC5) gene, and down-regulation of GPC5 might contribute to the development of lung cancer in never smokers.^{245, 246} Other genes that have been found in never smokers and associated with lung cancer risk are LEM domain-containing protein 3 (LEMD3), transmembrane Bax inhibitor containing motif (TMBIM), ataxin 7-like 2 (ATXN7L2), Src homology 2 domain containing E (SHE), inter- α -trypsin inhibitor heavy chain H2 (ITIH2), Nudix (nucleoside diphosphate linked moiety X)-type motif 5 (NUDT5), EGFR, and echinoderm microtubule-associated protein like 4–anaplastic lymphoma kinase (EML4–ALK) fusions.^{243, 247, 248} Similarly, α (1)ATD carriers are at a 70–100% increased risk of lung cancer.²⁴⁹ Finally, as is the case for p53, the mutational profile of k-ras seems to differ greatly according to smoking status: G to T transversions are more common in ever smokers, whereas G to A transitions are seen more frequently in never smokers. K-ras and EGFR mutations are generally mutually exclusive, underlining their ordered participation in an intracellular signaling pathway, and suggesting different oncogenic mechanisms in lung cancer as a function of smoking status: tobacco carcinogens seem to be directly responsible for k-ras mutations, whereas the cause of mutations in EGFR, found particularly in never smokers, is currently not clear.

For race, it appears that compared to Caucasians, African-Americans are diagnosed earlier, have more aggressive, and consequently, have lower survival rates from breast cancers.^{250, 251} Racial disparities also exist in colorectal cancer.²⁵² Although these differences can be explained by socioeconomic differences, screening behaviors, and other behavioral differences, biological influences can affect risk. For example, polymorphisms in nucleotide excision repair genes may modify the relationship between breast cancer and smoking in African-American women.²⁵³ As well, the chemical carcinogen detoxifying gene, GSTM1, has a polymorphism that plays a role in the development of lung cancer and modifies the risk for smoking-related lung cancer in African-Americans.²⁵⁴ Interesting recent findings highlighting gene–environment interactions indicated household income is associated with the p53 mutational frequency in patients who develop breast cancer (especially ER-negative). Furthermore, high-income patients may acquire fewer p53 mutations than other patients, suggesting that lifetime exposures associated with socio-economic status may impact breast cancer biology.^{255, 256}

Chronic inflammation and cancer

More than a century ago, the German pathologist, Virchow proposed that inflammation was associated with cancer.⁸ Infection and inflammation significantly contribute to more than 25% of cancer cases worldwide ([Table 4](#)).²⁰⁴ Free radicals, endogenous chemicals, are released during the inflammatory response. These ROS and reactive nitrogen species are generated as a physiological protective response to pathogenic microorganisms and toxic agents. During chronic inflammation (e.g., chronic viral hepatitis) and oxyradical overload conditions (e.g., hemochromatosis and inflammatory bowel diseases), these free radicals can induce genetic and epigenetic changes including somatic mutations in cancer-related genes and post-translational modifications in proteins involved in DNA repair, apoptosis, and arachidonic acid cascade ([Figure 5](#)).⁸ Epigenetic transcriptional silencing of cancer-related genes including p16, Runt-related transcription factor 3 (RUNX3), and MutL homolog 1 (MLH1), by DNA methylation of their promoter regions has been associated with chronic inflammation in ulcerative colitis and Barretts esophagus.^{257, 258} Inflammation-mediated genetic and epigenetic alterations can also drive cancer development in the neighboring epithelium upon stromal abrogation of transforming growth factor- β signaling.²⁵⁹ Finally, polymorphisms in genes involved in the production of [e.g., COX2, NOS's (NOS1, NOS2; but mostly NOS3)] or protection from (e.g., GpX, catalase, and MnSOD) free radicals also exist; can modify the effects of drugs; and increase or decrease cancer risk associated with exogenous chemical carcinogens.^{260–268}

Table 4 Chronic inflammation and infection can increase cancer risk

Disease	Tumor site	Risk
<i>Inherited</i>		
Hemochromatosis	Liver	219
Crohn's disease	Colon	3
Ulcerative colitis	Colon	6
<i>Acquired</i>		
<i>Viral</i>		
Hepatitis B	Liver	88
Hepatitis C	Liver	30
<i>Bacterial</i>		
<i>Helicobacter pylori</i>	Gastric	11
PID	Ovary	3
<i>Parasitic</i>		
<i>Schistosoma hematobium</i>	Urinary bladder	2–14
<i>Schistosoma japonicum</i>	Colon	2–6
Liver fluke	Liver	14
<i>Chemical/physical/metabolic</i>		
Acid reflux	Esophagus	50–100
Asbestos	Lung pleural	>10
Obesity	Multiple sites	1.3–6.5

“18% of human cancers, that is, 1.6 million per year, are related to infection.”—B. Stewart and P. Kleihues, World Cancer, Report, IARC Press, Lyon 2003, p. 57.

Rheumatoid arthritis is an example of a chronic inflammatory disease without a marked increased cancer risk, for example, joint sarcoma. Oncogenic human papilloma viruses are examples of cancer-prone chronic infections without inflammation.

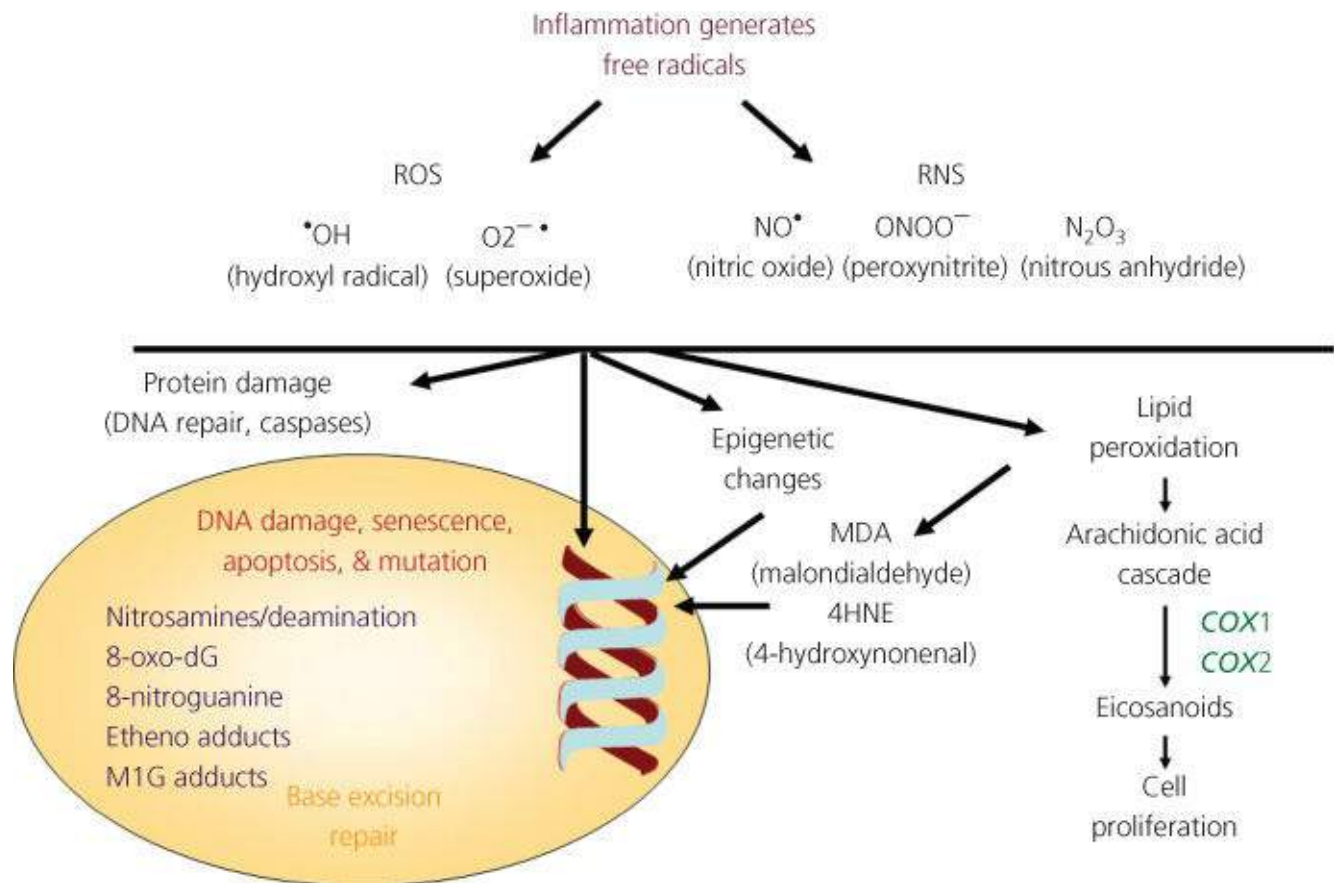

Figure 5 Several reactive oxygen species (ROS) and reactive nitrogen species (RNS) are generated during chronic inflammation. The reactive species can induce DNA damage, including point mutations in cancer-related genes, and modifications in essential cellular proteins that are involved in DNA repair, apoptosis, and cell cycle, either directly or indirectly through the activation of lipid peroxidation and generation of reactive aldehydes, for example, malondialdehyde (MDA) and 4-hydroxynonenal (4-HNE).

Oncogenes and tumor suppressor genes

Chronic exposures to carcinogens, accumulation of mutations, development of the mutator phenotype, and clonal selection during several decades result in cancer. Although the phenotypic traits of individual cancers are highly variable, commonly acquired capabilities include limitless replicative potential, self-sufficiency in growth signals, insensitivity to antigrowth signals, evading apoptosis, tissue invasion, sustained angiogenesis, and metastasis.⁶⁴ These phenotypic traits reflect a complex molecular circuitry of biochemical pathways and protein machines within cancer cells.²⁶⁹

The genes encoding the proteins within the cancer-associated molecular circuitry are of many functional classes and, historically, have been conceptually divided into oncogenes and tumor suppressor genes^{269, 270} (Box 4). Detailed descriptions of oncogenes and tumor suppressor genes are found in [Chapters 4–7](#). The *ras* oncogene and the *TP53* tumor suppressor gene will be used as examples of molecular targets of chemical carcinogens.

Box 4 Mutational hotspots in cancer genes

Oncogenes and suppressor genes are targets of chemical carcinogens. Many genes, including K-ras and p53, have specific sequences targeted by chemical carcinogens resulting in mutational

“hotspots.” These mutations cause a change in expression and activity of the RNA and protein they code for.

Activated *ras* genes predominate as the family of oncogenes that are induced by chemicals in laboratory animals. Members of the *ras* gene family code for proteins of molecular weight 21,000 (p21); these proteins are membrane bound, have GTPase activity, and form complexes with other proteins. The *ras* genes code for small G proteins (guanine nucleotide binding) that exert a powerful proliferative response through the signal transduction cascade. The first direct evidence of proto-oncogene activation by a chemical carcinogen was obtained from *in vitro* studies.²⁷¹ A wild-type recombinant clone of the human *Ha-ras* gene (pEC) was modified with BPDE. The treated plasmid was then used to transfect murine NIH-3T3 cells, with the result that the transformed cell foci contained the same point mutations (in either codon 12 or 61) known to exist in activated *ras* genes isolated from human tumors including the bladder (pEJ). In animal models of chemical carcinogenesis and surveys of different types of human tumors that arise from a variety of environmental exposures, *ras* mutations have been found.^{272–275} For example, tobacco smoke can mutate *K-ras* during the molecular pathogenesis of human lung adenocarcinoma.²⁷⁶ In rodents, PAHs (3-methylcholanthrene, DMBA, and B[a]P) have been used repeatedly to produce both benign tumors and malignant carcinomas. A large proportion of these premalignant and malignant lesions have mutations in either the 12th or the 61st codons. Similarly, treatment of rats with either DMBA or *N*-methyl-*N*-nitrosourea resulted in the development of mammary carcinomas containing *ras* codon 12 or 61 mutations. These types of mutations also have been observed in mouse skin after initiation with DMBA and tumor promotion with TPA. Mutations in *ras* have been found in mouse liver after treatment with vinyl carbamate, hydroxydehydroestragole, or *N*-hydroxy-2-acetylaminofluorene. The same point mutations have been found in murine thymic lymphomas after treatment with *N*-methyl-*N*-nitrosourea or γ -radiation, and in other rodent skin models after treatment with methyl methanesulfonate, α -propiolactone, dimethylcarbamyl chloride, or *N*-methyl-*N*9-nitro-*N*-nitrosoguanidine.

These data indicate that chemical carcinogens may produce site-specific mutations based, in part, on nucleoside selectivity of the ultimate carcinogen. Interestingly, noncovalent binding sites for (+)-anti-BPDE have recently been found on codons 12 and 13 of the *K-ras* gene.²⁷⁷ Persistence of a specific mutation, however, also depends on the amino acid substitution in that the function of the mutant protein is altered to confer on the cell a selective clonal growth advantage. The types of mutations that are found in chemically activated *ras* genes cause conformational changes that alter protein binding (GTPase activating protein) in such a way that the *ras*-MAP kinase pathway is permanently activated. Data support the hypothesis that *ras* activation is associated with malignant conversion as well as tumor initiation. Transfection of activated *ras* genes into benign papillomas that did not contain a constitutively activated *ras* gene caused malignant progression.^{275, 278} These and other results implicate *ras* mutations in chemical carcinogenesis. Similarly, malignant transformation occurred when immortalized human bronchial epithelial cells were transfected with an activated *ras* gene.^{279, 280} *Ki-ras* gene mutations are also one of many changes that can arise either early or late in the development of colorectal carcinoma.²⁸¹ These findings indicate that the accumulation of mutations, and not necessarily the order in which they occur, contributes to multistage carcinogenesis. Furthermore, the stage of carcinogenesis in which each mutation occurs is not necessarily fixed. In the model for human colorectal carcinoma, *ras* mutations most often occur during malignant conversion, but can be an early event (i.e., tumor initiation), but in the rodent skin models, *ras* mutations appear to be primarily a tumor initiating event. These differences may reflect the type of exposure, both in terms of chemical class and chronic versus acute exposure, or they may be a function of tissue type.

The *TP53* tumor suppressor gene is central in the response pathway to cellular stress.²⁸² For example, DNA damage caused by chemical carcinogens activates the p53 tumor suppressor protein by post-translational modification to transduce signals to “guard the genome”²⁸³ by engaging cell-cycle checkpoints and enhancing DNA repair, and as a fail-safe mechanism, to cause replicative senescence or apoptotic death.^{284, 285} Mutations in the *TP53* gene or inactivation of its encoded protein by viral oncoproteins generally lead to a loss of these cellular defense functions. Not surprisingly, *TP53* mutations are common in human cancer.^{286, 287}

Molecular analysis of *TP53* can give clues to the environmental etiology of cancer (Table 5). It is implicit from the preceding text (see section titled “DNA damage and repair”) that the covalent binding of activated carcinogens to DNA is not random. Therefore, the formation of a particular DNA lesion to some extent may be deduced from the resulting mutation. A dramatic example of this phenomenon is the previously mentioned *TP53* codon 249 mutation, which is detected in almost all aflatoxin-related hepatocellular carcinomas (HCC).^{41, 289, 290} The striking nature of this association could arise by two distinct mechanisms. First, the third base in codon 249 (AGG) may be unusually susceptible to activated aflatoxin B1 mutations. As discussed earlier, aflatoxin B1-8,9-oxide causes a promutagenic lesion by covalently binding to the N7 position of deoxyguanosine. Alternately, cells bearing the codon 249 lesion may have an important selective growth advantage. Evidence that a combination of these factors is responsible has been presented as well.²⁹¹ Another prominent example where circumstantial evidence points to specific molecular events is that of *TP53* mutations indicative of pyrimidine dimer formation in UV-light-related skin cancers.²⁹² In the case of tobacco smoking and lung cancer, G : C to T : A transversions indicate the formation of adducts from activated bulky carcinogens (e.g., PAHs).^{41, 293}

Table 5 Mutational spectra of *TP53* in human cancers.^a

Carcinogen exposure	Neoplasm	Mutation
Aflatoxin B1	Hepatocellular carcinoma	Codon 249 (AGG 6 AGT)
Sunlight	Skin carcinoma	Dipyrimidine mutations (CC 6 TT) on nontranscribed DNA strand
Tobacco smoke	Lung carcinoma	G:C 6 T:A mutations on nontranscribed DNA strand (frequently codons: 157, 248, and 273)
Tobacco and alcohol	Carcinoma of the head and neck	Increased frequency p53 mutations (especially codons 157 and 248)
Radon	Lung carcinoma	Codon 249 (AGG 6 ATG)
Vinyl chloride	Hepatic angiosarcoma	A:T 6 T:A transversions
Aristolochic acid	Urothelial carcinoma	A to T transversions

Precision medicine, molecular epidemiology, and prevention

Precision medicine is a concept developed by an *ad hoc* committee of the National Research Council in

2011.⁵² The four basic premises are as follows: (1) the *Information Commons* for cancer has to be populated with a variety of –omic, phenotypic, clinical, and epidemiological data; (2) these data are integrated into a *Knowledge Network* that examines the interconnectivity of each layer of data from the Information Commons; (3) the Knowledge Network is used to develop *Taxonomic Classifiers* with the goal of improving patient diagnosis, decisions on therapeutic strategies, and health outcomes; and, finally, the knowledge is used to *guide biomedical, prevention, and clinical research* in mechanistic and observational studies ([Figure 6](#)). Precision medicine builds on the –omics revolution in molecular biology, advances in bioinformatics, tumor metabolism, tumor immunology, and the gene–environment concept of molecular epidemiology.

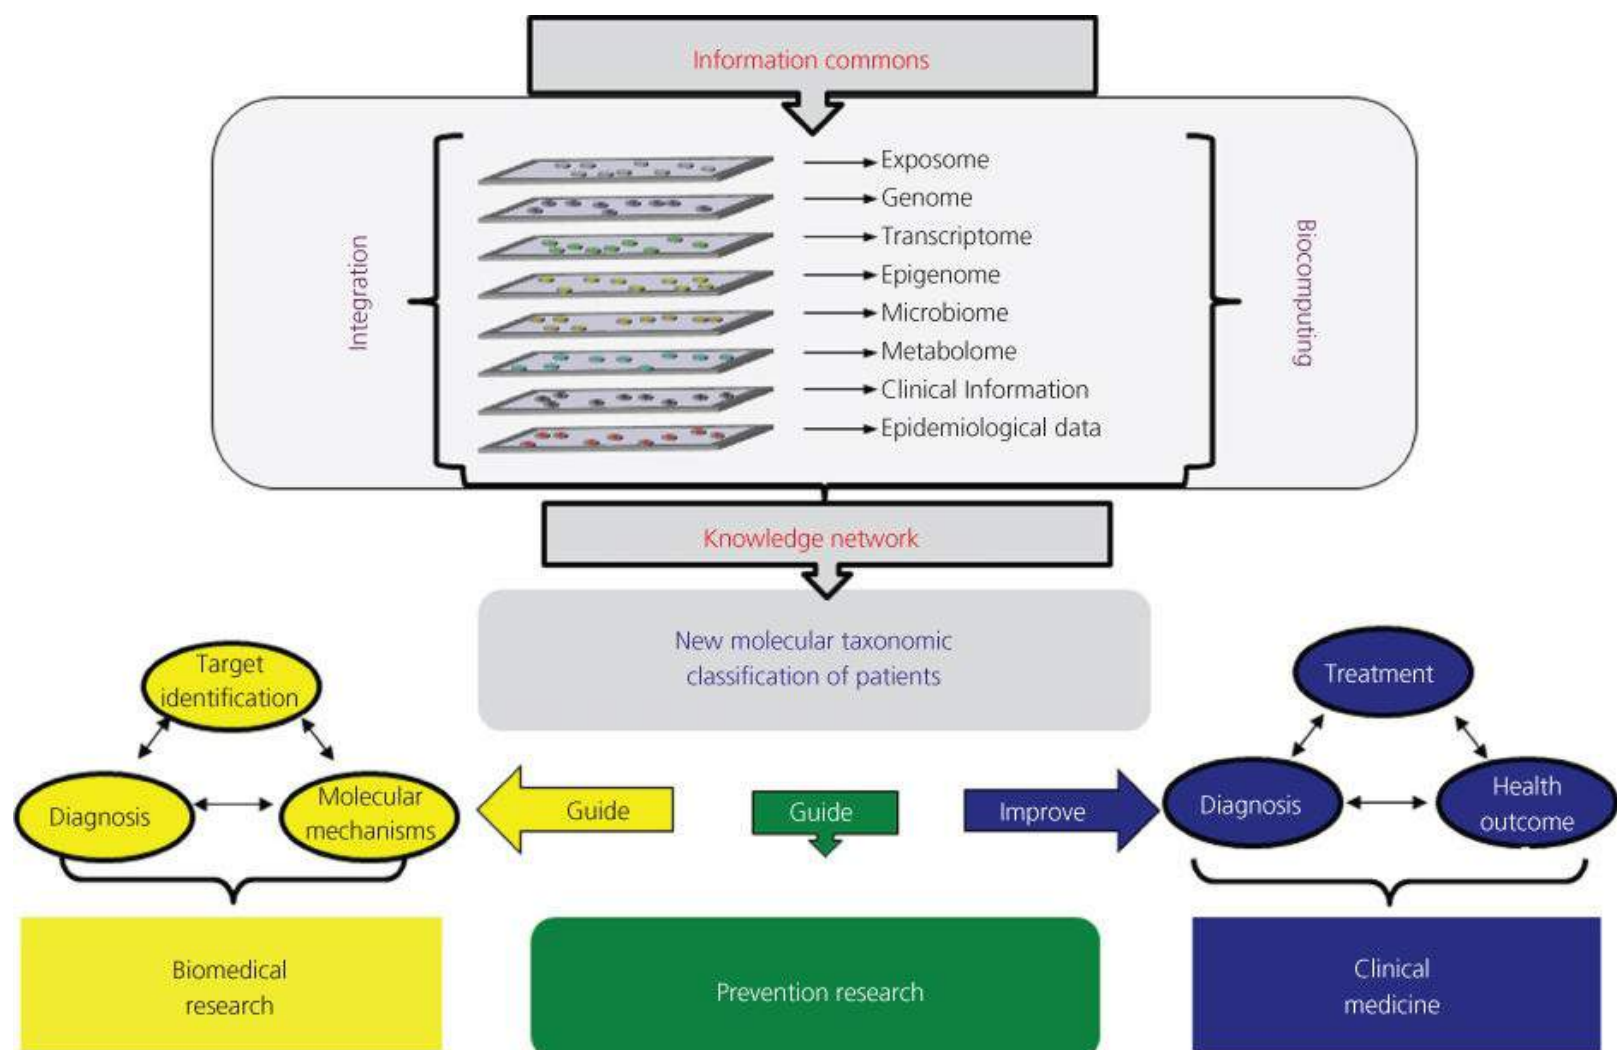

Figure 6 Precision medicine. In March 2011, at the request of the Director of the National Institutes of Health, an *ad hoc* committee of the National Research Council met to discuss the feasibility, need, scope, impact, and consequences of defining a “New Taxonomy” of human diseases based on molecular biology. The concept that developed, that of precision medicine, includes four basic premises.⁵² First, the information commons for each disease type has to be populated with a variety of -omic, phenotypic, clinical, and epidemiological data. Second, these data are integrated into a knowledge network that examines the interconnectivity of each layer of data from the information commons. Third, the knowledge network is used to develop new taxonomic classifiers with the goal of improving patient diagnosis, decisions on therapeutic strategies, and health outcomes. Finally, the knowledge is used to guide biomedical and clinical research in mechanistic and observational studies. If realized, the benefits of precision medicine can be leveraged for most, if not all, disease types including cancer.

One of the biggest challenges in molecular cancer epidemiology associated with exposure to chemical

carcinogens is to accurately measure exposure and then link this exposure to cancer risk. In this sense, so far, results have been disappointing. Traditionally, the paradigm, first defined by Perera and Weinstein in 1982,³⁷ has involved the assessment of exposure (what chemical and how much of that chemical; e.g., how much tobacco smoke or more specifically, B(a)P; BPDE; TSN), internal dose (how much of that chemical is in the body fluids, and tissues; e.g., amount of nicotine/cotinine), biological effective dose (the interaction of the chemical with biological entities; e.g., BPDE adducts), early biological response (e.g., TP53 mutation and k-ras mutation), altered structure/function (e.g., TP53 downstream functions and k-ras overexpression), and clinical disease (cancer). Intertwined with this paradigm are genetic factors and an individual's susceptibility (e.g., polymorphisms in metabolic enzymes such as p450's discussed earlier). A goal, then, of molecular cancer epidemiology is to identify biomarkers (of exposure, effect, and susceptibility) that accurately predict risk of disease. Unfortunately, to date, other than susceptibility markers [e.g., BRCA1/2 for breast cancer risk, APC (adenomatous polyposis coli) for familial colon cancer and more], few truly accurate biomarkers exist. Part of the reason is the money, man power, and time it takes to identify a biomarker, then follow that ahead in time (decades for the most part) to accurately assess cancer risk.

To this end, over the past decade, with new, highly sensitive, and sophisticated technology, this concept is evolving. The “omics” field, for example, has quickly advanced, with uses in the field of chemical carcinogen exposure and risk of cancer from that exposure. Using genetic information (genomics), biomarkers of susceptibility have been identified. In addition to such examples as BRCA1 or APC, polymorphisms in metabolic enzymes and DNA-repair pathways have been discussed. Genomics, tied in with other “omics” (adductomics, epigenomics, transcriptomics, proteomics, microbiomics, metabolomics, and cytokinomics) can be a powerful tool if properly linked to environmental chemical exposure. An evolving concept has been the “exposome”.^{48, 294} In general, the exposome comprises every exposure to which an individual is subjected, from conception to death. Three broad categories of exposure are categorized: (1) internal exposure (metabolism, endogenous circulating hormones, body morphology, physical activity, gut microbiota, inflammation, and aging); (2) specific external exposures (radiation, infections, chemical contaminants, diet, tobacco, alcohol, occupation, and medical interventions); and (3) more general exposures/social/economic influences (education, financial status, psychological stress, and climate). Although the concept has obvious uses in epidemiological studies to establish risk factors at a population level,²⁹⁴ linking numbers to and quantifying the exposome (exposomics) will be a necessary step to devise chemopreventive strategies ([Figures 6 and 7](#)).

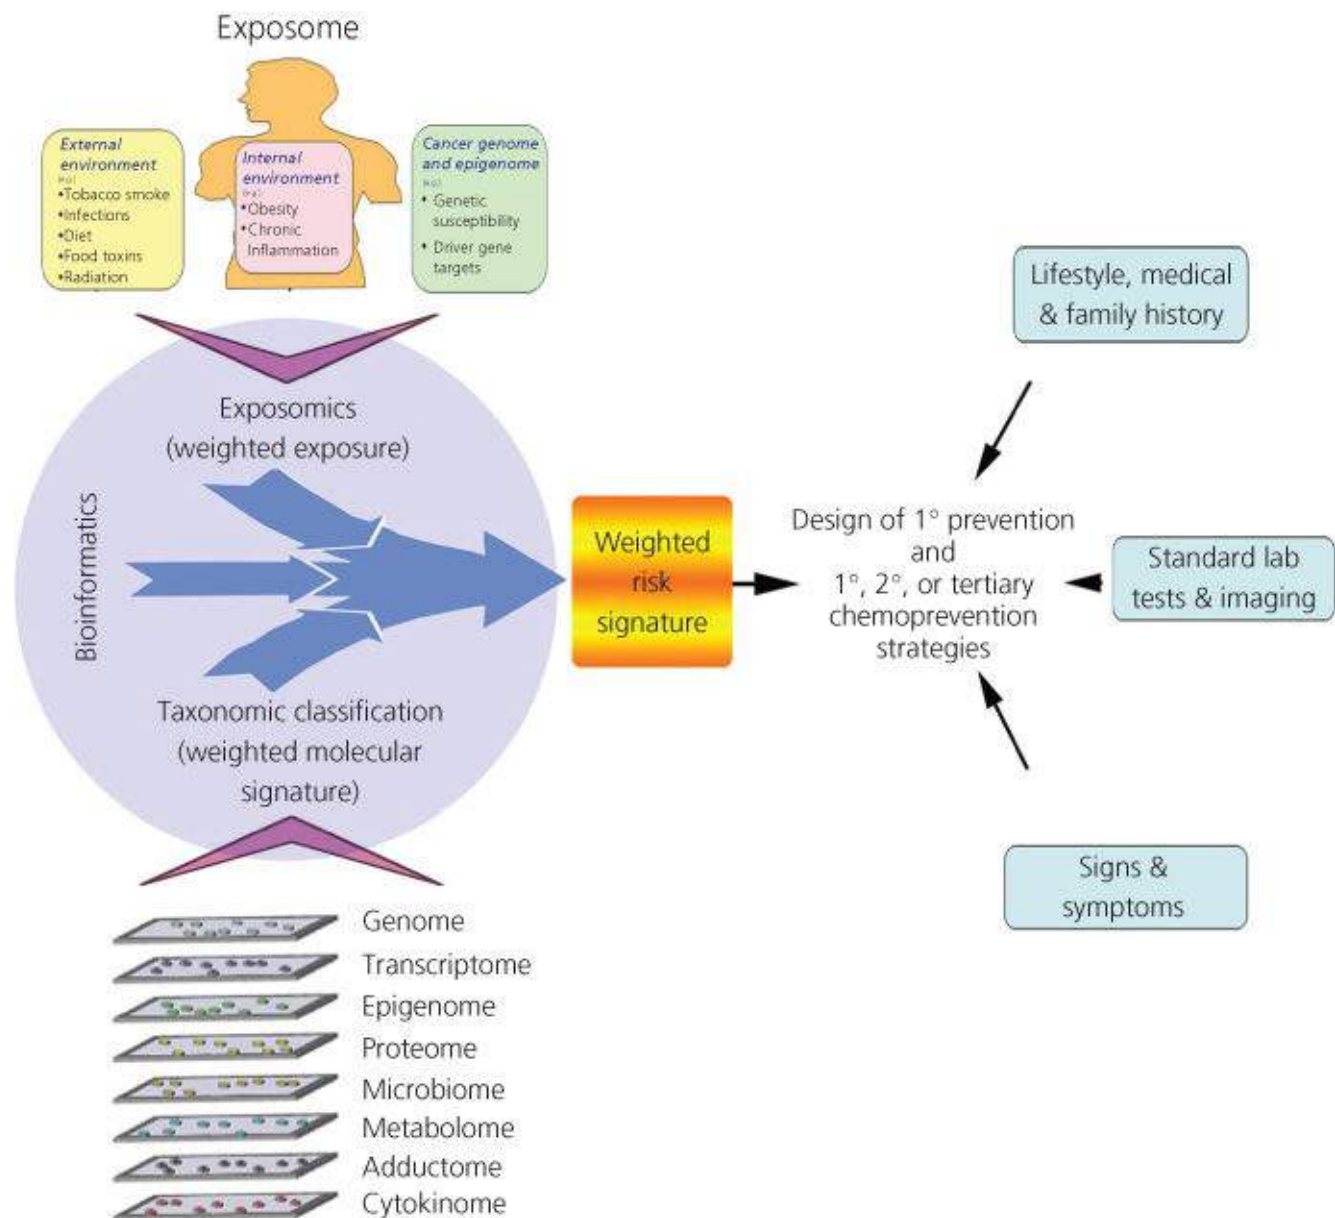

Figure 7 Connecting exposomics to toxonomics to generate a weighted risk signature for primary prevention and chemoprevention strategies. With the explosion of technology, extensive and massive data set generation over the past decade, we are in a position to use bioinformatics to merge the exposome with the various “omics” collected to generate a weighted and precise risk signature. Quantifying the internal, specific, and general external exposure of an individual or population (exposomics), then linking this to the molecular profile of an individual or population can generate a risk signature for an individual or population. Additional and continued consideration of signs/symptoms, standard lab tests, and family history will bring together a targeted primary and chemo-prevention strategy to reduce the risk of carcinogenesis in an individual or high-risk population of individuals.

Reconsideration of the dogma is necessary, because an extremely difficult task is to directly link a single genomic change to risk of specific types of cancer. Using genomics for somatic mutations, for example, as discussed earlier, we have identified specific k-ras and *TP53* mutational hotspots linked to specific carcinogens. The catalog of somatic mutations in cancer (COSMIC) indicates k-ras is the most frequently mutated isoform of ras isoforms and is present in 22% of all tumors analyzed compared to 8% for N-ras and 3% for H-ras and may prove to be an indicator of prognosis or a guide to treatment. The *TP53* tumor suppressor gene is mutated in most types of human cancers and it is the most commonly mutated gene yet known (e.g., mutations in *TP53* are found in approximately 50% of lung cancers).⁴¹ Unlike *ras* gene mutations that are found in highly specific regions (codons 12, 13, 59, and 61), *TP53* mutations occur

more widely. This is presumably because a positive growth advantage is conveyed only with specific ras mutations and the loss of *TP53* tumor suppressor function can occur with less specificity. However, for some malignancies, *TP53* mutations have provided clues to cancer etiology with a specific signature (hotspot) linked to specific carcinogenic exposure (Table 5).^{41–43, 55, 286, 295, 296} *TP53* is further distinguished from other genetic lesions in that several possible mutant phenotypes can exist. Mutations may simply lead to the absence of *TP53*, an inactive mutant protein may exist, or the mutant might convey a growth advantage. Several studies have investigated *TP53* expression, and even though its role in prognosis has not been clearly defined, it may provide a guide to treatment options. To this end, recent advances have led to the decoding the “cancer landscape,”⁶⁸ with the identification of driver genes, classified into signaling pathways that regulate cell fate, cell survival, and genome maintenance. Such an understanding of these driver mutations will allow for the synthesis of new drugs focusing in on these molecules/pathways within a specific cancer of a specific individual to allow for specific treatment options in personalized medicine.

With the advent of microarray and other RNA detection technology [e.g., quantitative real-time PCR (polymerase chain reaction)], transcriptomics has also evolved, and transcription signatures have been identified associated with specific cancer subtypes, as well as with specific chemical carcinogen exposure. For example, papillomavirus infection is associated with the deregulation of genes involved in cell cycle; most of them E2F genes and E2F-regulated genes.²⁹⁷ Genes up-regulated in samples from HCV (hepatitis C virus)-related Hepatocellular Carcinomas (HCC) have been shown to be classified in metabolic pathways, and the most represented are the aryl hydrocarbon receptor (AHR) signaling and protein ubiquitination pathways, which have been previously reported to be involved in cancer, and in particular in HCC progression. Genes up-regulated in samples from HCV-related non-HCC tissue have been shown to be classified in several pathways involved in inflammation and native/adaptive immunity and most of the overexpressed genes belonged to the antigen presentation pathway.²⁹⁸

Most studies to date investigating transcriptome changes in response to environmental exposures have relied on peripheral blood. Although details of these studies have been reviewed by Wild et al.,²⁹⁴ here are a few highlights. Using peripheral blood mononuclear cells, Thomas et al. showed low levels of benzene (at or below 0.1 ppm) were observed in association with altered expression of AML pathway genes and CYP2E1. This is an important finding, because it shows that benzene alters disease-relevant pathways (AML) and genes in a dose-dependent manner, with effects apparent at doses as low as 100 ppb in air.²⁹⁹ Another study showed leukemia-related chromosomal changes in hematopoietic progenitor cells from workers exposed to benzene.³⁰⁰ Others have found that telomere length was modestly, but significantly ($p = 0.03$) elevated in workers exposed to more than 31 ppm of benzene compared to controls.³⁰¹ Finally, polymorphisms in the CYP2E1 gene have been shown to be involved in benzene induction of micronuclei and may contribute to risk of cancer among exposed workers.³⁰²

Interestingly, many gene expression changes associated with smoking are involved in inflammatory and oxidative stress pathways. Recently, Tilley et al.³⁰³ identified a “chronic obstructive pulmonary disease-like” small airway epithelium transcriptome signature and found xenobiotic and oxidant-related categories contained the genes displaying the greatest magnitude of change in expression levels in healthy smokers. Beane et al. showed that although large airway epithelial expression of many smoking-responsive genes is reversible upon smoking cessation, there are a number of smoking-responsive genes with persistently abnormal expression after smoking cessation. In this study, they also showed that pathways related to the metabolism of xenobiotics by CYP P450, retinol metabolism, and oxidoreductase activity were enriched among genes differentially expressed in smokers; whereas chemokine signaling pathways, cytokine–cytokine receptor interactions, and cell adhesion molecules were enriched among

genes differentially expressed in smokers with lung cancer.³⁰⁴ More recently, the same group showed SIRT1 activity is significantly up-regulated in cytologically normal bronchial airway epithelial cells from active smokers compared to nonsmokers.³⁰⁵ Pierrou et al.³⁰⁶ found significant changes in the expression of oxidant-related genes in the large airway epithelium of nonsmokers, healthy smokers, and COPD smokers, as did other studies^{307, 308} examining nonsmokers versus healthy smokers. Overall, transcriptomics has shown that it is possible to distinguish individual pathways associated with tobacco smoke, distinguish between individuals exposed and unexposed to tobacco smoke, and distinguish between current and past exposure to tobacco smoke. As reviewed by Wild et al.,²⁹⁴ transcriptomics has also been able to identify specific signatures associated with dioxin (cell growth/ proliferation, glucose metabolism, apoptosis, and DNA replication, repair), metal fumes (inflammation, oxidative stress, phosphate metabolism, cell proliferation, and apoptosis), and diesel exhaust (inflammation and oxidative stress). In human lung tissues, a gene expression signature of 599 transcripts consistently segregated never from current smokers. Members of the CYP1 family, including CYP1A1, CYP1A2, and CYP1B1, were among the top genes up-regulated by smoking. The gene most strongly up-regulated by smoking was the aryl hydrocarbon receptor repressor (AHRR). Interestingly, six known genes were still significantly higher than never smokers after 10 years of smoking cessation (SERPIND1, AHRR, FASN, PI4K2A, ACSL5, and GANC).³⁰⁹ Together, studies done with transcriptomics have demonstrated specific signatures associated with specific exposures to chemical carcinogens, suggesting potential mechanisms promoting cancer and identification of biomarkers associated with cancer risk.

The epigenome describes the totality of epigenomic changes [epigenetic marks present along the DNA and associated structures (e.g., histones) in a particular cell type]. We have already described some of the epigenetic events (mainly DNA methylation, histone modifications, and RNA-mediated gene silencing) associated with specific chemical carcinogen exposure. To this end, there have been a few studies to date attempting to link specific exposures of humans to epigenomic change. Overall, the impact of chemical carcinogens on the epigenome in human populations are limited to tobacco smoking (MTHFR and CDKN2A hypermethylation; GPR15, MSH3, NISCH, CYP1A1; RPS6KA3, ARAF, and especially AHRR hypomethylation), benzene (alu, long interspersed nucleotide elements, PTEN, ERCC3, p15, p16 hypermethylation; STAT3, MAGE-1 hypomethylation), cadmium (long interspersed nucleotide elements hypomethylation), air pollution (long interspersed nucleotide elements, tissue factor, F3, ICAM-1, and TLR-2 hypomethylation, and alu, IFN- γ , and IL-6 hypermethylation), smokey coal emissions (p16 hypermethylation), workplace exposures (iNOS hypermethylation; SAT α , NBL2 hypomethylation; mgmt hypermethylation), and arsenic (alu, long interspersed nucleotide elements, RHBDF1, p16, p53 hypermethylation).^{310–345} It should be pointed out that AHRR hypomethylation has been found as a common biomarker of smoking in multiple recent studies.^{313, 316–321, 323, 346} Also, importantly, recent studies suggest epigenetics is proving useful to the identification of both current and past smoking history. Past exposures can be detected and possibly even quantified based on the epigenetic footprints they leave on specific genes. Zhang et al.³⁴⁷ found that coagulation factor II (thrombin) receptor-like (F2RL3) methylation intensity showed a strong association with smoking status, which persisted after controlling for potential confounding factors. Clear inverse dose-response relationships with F2RL3 methylation intensity were seen for both current intensity and lifetime pack-years of smoking. Among former smokers, F2RL3 methylation intensity increased gradually from levels close to those of current smokers for recent quitters to levels close to never smokers for long-term (>20 years) quitters. A recent study from the EPIC and NOWAC studies found 8 and 897 CpG sites differentially methylated in former and current smokers, while compared to never smokers, respectively. The eight candidate markers of former smoking showed a gradual reversion of their methylation levels from those typical of current smokers to those of never smokers. Further analyses using cumulative (over varying time windows) smoking intensities, highlighted

three classes of biomarkers: short- and long-term biomarkers (measuring the effect of smoking in the past 10, and in the past 10–30 years, respectively), and lifelong biomarkers detected more than 30 years after quitting smoking.³⁴⁸ Such studies show a promising ability, through epigenetics, to detect short-term to lifelong biomarkers of tobacco smoke exposure and, more generally, to potentially identify time-varying biomarkers of exposure.

Histone marks (post-translational modifications) in humans have also recently been assessed in association with chemical carcinogen exposure. Smoking is associated with a decrease in HDAC2 protein expression by 54% and activity by 47%, and concomitant enhancement of phosphorylation of Akt1 and HDAC2; workplace exposure to nickel is associated with an increase in H3K4me3 and decrease in H3K9me2; exposure to benzene is associated with reduced histone H4 and H3 acetylation and H3K4 methylation, and increased H3K9 methylation in the Topo II α promoter; and, finally, exposure to arsenic is associated with an increased H3K4me2 and changes in global H3K9ac and H3K9me2 levels.^{349–352}

In human populations, miRNA changes have been associated with exposure to cigarette smoke (40 upregulated in smokers, including miR-21, -16, -17, -29a, -221, and -223; repression of miR-15a, -199b, -125b, -218, -487, and -4423), workplace exposure (miR-21 and -222 increased in electric furnace steel plant workers post-exposure vs pre-exposure), benzene (up-regulation of miR-34a, -205, -10b, let-7d, miR-185 and -423-5p-2; down-regulation of miR-133a, -543, hsa-miR-130a, -27b, -223, -142-5p, and -320b), air pollution (up-regulation of miR-132, -143, -145, -199a*, -199b-5p, -222, -223, -25, -424, and -582-5p), and arsenic (up-regulation of miR-190, -29a, -9, and -181b; down-regulation of miR-200b).^{349, 353–361} Interestingly, miRNA levels have been shown to be reversed back to baseline after cessation of smoking.³⁵⁵ Overall, it is becoming increasingly clear that epigenomics is providing useful and specific biomarkers of chemical carcinogen exposure, and that these changes can be detected in humans. In addition, the observation that some changes are reversible, and some changes are not reversible allow careful monitoring of both present and past exposures and their consequences on clinical outcome.

The impact of environmental carcinogens associated with inflammatory load/cytokinomic, proteomics, metabolics, and microbiomics are still emerging. Moore et al. reviewed the use of “omic” technologies to study arsenic exposure in human populations.³⁶² The reader is referred to this reference for full details. In brief, though, genomic profiling has revealed long-term arsenic exposure may increase the risk of chromosome alteration prevalence in exposed bladder tissue and that chromosome 17p loss was unique to arsenic-exposed bladder cancer cases independent of p53 inactivation or aberrant protein expression. Additionally, in either human tissues or peripheral cells, arsenic has been shown in many studies to change gene expression (often involved in cell-cycle regulation, apoptosis, and DNA damage response), epigenetic events (e.g., heavily methylated promoter regions of p53 and p16), proteomic profiles (e.g., decreased levels of human b-defensin-1 and ADAM28), and metabolomic profiles.³⁶² In a few examples, an association with HCV and cirrhotic livers, it was recently found that there was a significant up-regulation of IL-1 α , IL-1 β , IL-2R, IL-6, IL-8, CXCL1, CXCL9, CXCL10, CXCL12, MIF, and β -NGF in serum compared to healthy controls.³⁶³

Although the concept of personalized medicine has been around for decades (and it can be argued, for centuries as medicine is given largely based on personal symptoms), we have only recently reached a tipping point with technology that has allowed us to be more precise with personalized medicine (precision medicine).⁵² In the broadest sense, precision medicine is the molding of medical treatment to individual patient characteristics and moves beyond the current approach of stratifying patients into treatment groups based on phenotypic biomarkers. Now, with sensitive instrumentation and a capacity to gather large amounts of data regarding chemical carcinogens, we are poised to begin packaging,

integrating, and quantifying large data sets for precise measurement of chemical carcinogen exposure. We have already discussed the exposome, which is a key first step toward this goal. Putting this exposure into numbers remains a challenge, but meeting this challenge will bring real and precise numbers that can be linked to a quantified taxonomic profile, which is a compilation of the massive data sets acquired through the different “omic” endpoints.⁵² In this context, then, a precise risk signature might be realized for precision medicine and chemopreventive purposes (Box 5 and [Figure 7](#)).

Box 5 The exposome

The exposome comprises every exposure to which an individual is subjected, from conception to death. It takes into consideration the following: (1) internal exposure (metabolism, endogenous circulating hormones, body morphology, physical activity, gut microbiota, inflammation, and aging); (2) specific external exposures (radiation, infections, chemical contaminants, diet, tobacco, alcohol, occupation, and medical interventions); and (3) more general exposures/social/economic influences (education, financial status, psychological stress, and climate). Linking the exposome to metabolomic, proteomic, microbiomic, transcriptomic, and epigenomic profiles will allow us to identify an individual's risk signature as a biomarker for cancer risk and develop a precision medicine approach to cancer chemoprevention and treatment.

Chapter 24

Endocrine and genetic bases of hormone-related cancers

Leslie Bernstein, PhD ■ Xia Pu, PhD ■ Jian Gu, PhD

Overview

Neoplasia of hormone-responsive tissues currently accounts for more than 30% of all newly diagnosed male cancers and almost 40% of all newly diagnosed female cancers in the United States. Given that endogenous hormones apparently affect the risk of these cancers and their overall frequency, concern exists about the effects on cancer risk if the same or closely related hormones are administered for therapeutic purposes (e.g., as contraceptives, as menopausal hormone therapy, or for the prevention of miscarriage). Depending on the timing of hormone use and the tissue-specific effects, some of these compounds will reduce risk while others increase risk of “hormone-dependent” cancers. This chapter focuses on breast, endometrial, and ovarian cancers among women and prostate cancer among men and provides a review of the epidemiologic and endocrinologic evidence for the role of hormones in cancer development. It also reviews the current status of the relationship between exogenous hormones and risk of cancers of the breast, endometrium, and ovary. In addition, it summarizes our current knowledge of genetic susceptibility to breast, endometrial, ovarian, and prostate cancers. Other less common cancers (e.g., cervical cancer, clear cell vaginal adenocarcinoma, thyroid cancer, testicular cancer, and osteosarcoma) may have a hormonal basis as well, but are not reviewed in this chapter.

Substantial and convincing bodies of experimental, clinical, and epidemiologic evidence indicate that hormones play a major role in the etiology of several human cancers. The concept that hormones can increase the incidence of neoplasia was first proposed by Bittner,¹ on the basis of experimental studies of estrogens and mammary cancer in mice. This theory has been refined into epidemiologic hypotheses related to cancers of the breast, endometrium, prostate, ovary, thyroid, bone, and testis.^{2,3} The underlying mechanism proposed for these cancers is that neoplasia is the consequence of prolonged hormonal stimulation of the target organ, the normal growth and function of which is controlled by one or more steroid or polypeptide hormones. Evidence is mounting to show that the amount of hormone to which a tissue is effectively exposed is under strong genetic control.⁴ Therefore, although external factors such as physical activity or exogenous hormone use may modify hormone profiles, the current evidence supports a multigenic model of cancer susceptibility.^{5,6}

The major carcinogenic consequence of this hormonal exposure at the end organ is cellular proliferation, although direct carcinogenesis resulting from metabolic activation and direct DNA (deoxyribonucleic acid) binding is another potential mechanism. The emergence of a malignant phenotype depends on a series of somatic mutations that occur during cell division, but the entire sequence of genes involved in progression from normal cell to a particular malignant phenotype is not known ([Figure 1](#)). Candidate genes include those in the endocrine and growth factor pathways,^{4,7,8} as well as DNA repair genes, tumor suppressor genes, and oncogenes.^{9,10} Germline mutations have been described in two such tumor suppressor genes, *BRCA1* and *BRCA2*, which are associated with susceptibility to breast and ovarian cancer.^{11–14} Germline mutations in *TP53* are also associated in certain kindreds with an increased risk of

breast cancer.¹⁵ However, mutations in these genes do not appear to be involved in the majority of sporadic breast cancer. Recent genome-wide association studies (GWAS) have identified many common, low-penetrance susceptibility loci for sporadic cancers.¹⁶

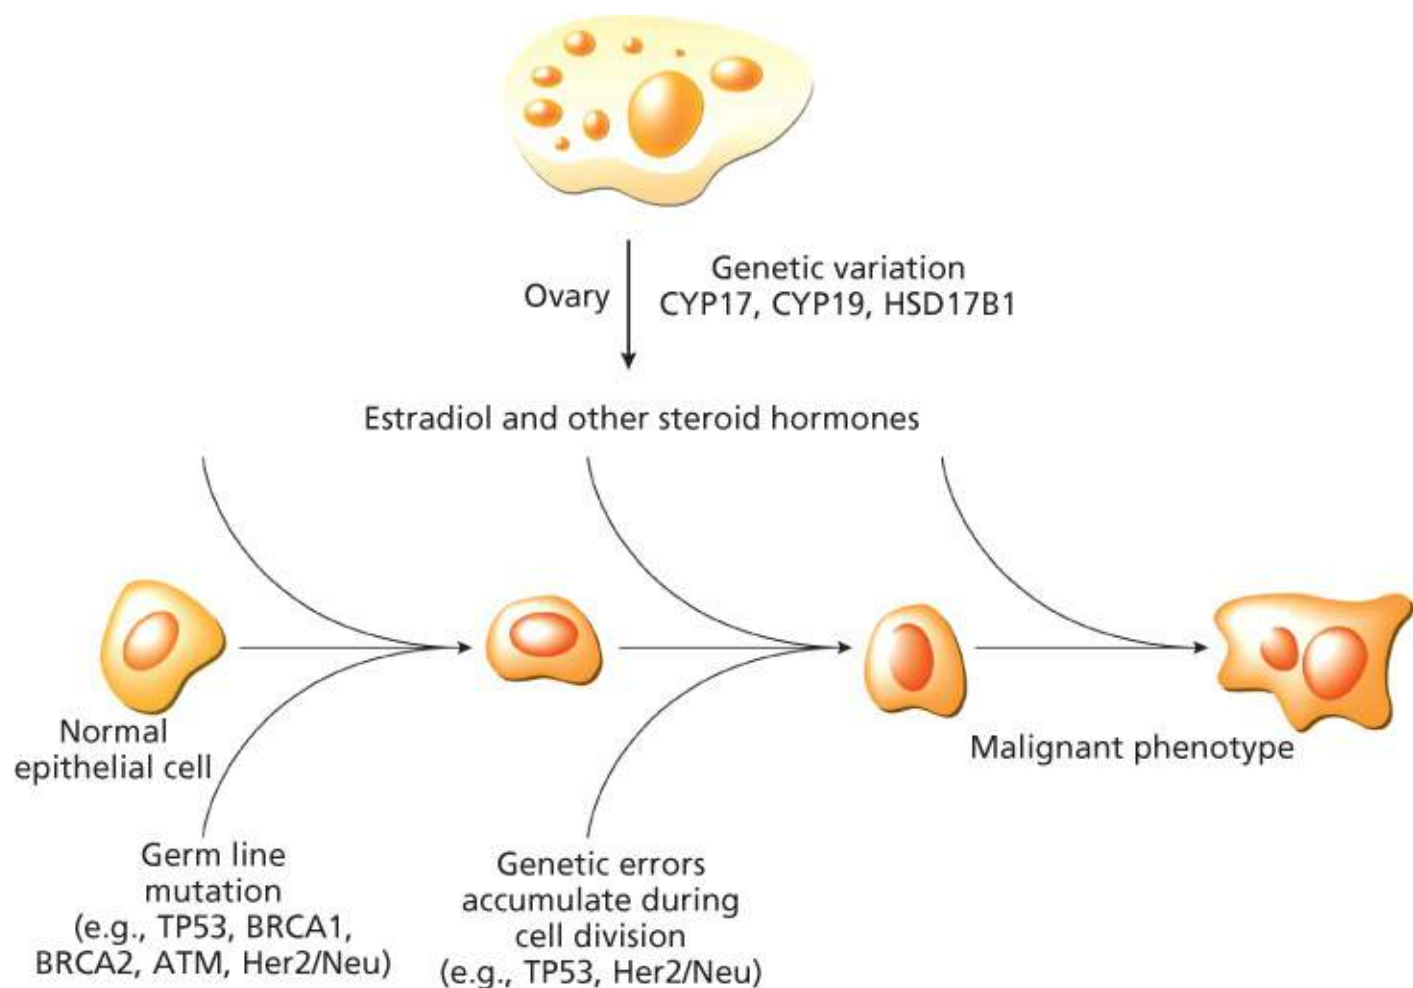

Figure 1 Estradiol and other steroid hormones (e.g., progesterone) drive breast cell proliferation, which facilitates the accumulation of random DNA copying errors in critical genes on the pathway to a malignant phenotype. Germ line mutations in relevant tumor suppressor genes accelerate the transformation to the malignant phenotype.

Neoplasia of hormone-responsive tissues currently accounts for more than 30% of all newly diagnosed male cancers and almost 40% of all newly diagnosed female cancers in the United States. Given that endogenous hormones apparently affect the risk of these cancers and their overall frequency, concern exists about the effects on cancer risk if the same or closely related hormones are administered for therapeutic purposes (e.g., as contraceptives, as menopausal hormone therapy, or for the prevention of miscarriage).¹⁷ This chapter focuses on breast, endometrial, and ovarian cancers among women and prostate cancer among men and provides a review of the epidemiologic and endocrinologic evidence for the role of hormones in cancer development. It also reviews the current status of the relationship between exogenous hormones and risk of cancers of the breast, endometrium, and ovary. Other less common cancers (e.g., cervical cancer, clear cell vaginal adenocarcinoma, thyroid cancer, testicular cancer, and osteosarcoma) appear to have a hormonal basis as well, but are not reviewed here.

Breast cancer

Breast cancer is the most common cancer in women; it is expected that 232,670 new cases of invasive breast cancer and 62,570 new cases of breast carcinoma *in situ* will be diagnosed in the United States in

2014 and that 40,430 United States women will die of breast cancer.¹⁸ A perceptible decline in breast cancer mortality has occurred since 1990,¹⁹ resulting from greater use of mammographic screening, hormonal therapy, and therapy that targets *HER2/neu*.^{20, 21} Available evidence regarding the hormonal etiology of breast cancer is most consistent with the hypothesis that estrogen is the primary stimulant for breast cell proliferation.^{2, 3} The simultaneous presence of progesterone further increases the rate of proliferation.²² This latter conclusion is based largely on the fact that breast mitotic activity peaks during the luteal phase of the menstrual cycle²³ and it is consistent with the increasing number of publications demonstrating that added progestins substantially augment the increased risk of breast cancer from estrogen therapy (ERT).^{24–28}

The most consistently documented, hormonally related risk factors for breast cancer are early age at menarche, late age at menopause, late age at first full-term pregnancy, and excess weight ([Table 1](#)). The age-incidence curve for breast cancer emphasizes the importance of ovulation in determining risk.¹⁷ Cases first occur during early adulthood, and the rate of increase in incidence then rises sharply with age until the time of menopause, when it slows dramatically. The rate of increase in the postmenopausal period is approximately one-sixth the rate of increase in the premenopausal period. This age-incidence curve appears, then, to be shaped in a major way by the effects of ovarian activity. Therefore, it is critical to understand the determinants, both genetic and environmental, of the onset, regularity, and cessation of ovulation in order to continue to develop effective prevention modalities for breast cancer.

Table 1 A summary of established hormonal risk and protective factors for breast cancer

Risk factors (increased exposure to estrogen and/or progesterone)
Early menarche
Late menopause
Obesity (postmenopausal women)
Hormone replacement therapy
Protective factors (reduced exposure to estrogen and/or progesterone)
Lactation
Early age at full-term pregnancy
Physical activity (exercise)

Reproductive factors

Early age at menarche is an established risk factor for breast cancer.³ In general, risk decreases approximately 5–6% for each year that menarche is delayed, and this relationship may be further modified by the age at onset of regular ovulatory menstrual cycles. In a study of young women, Henderson et al.²⁹ reported that women with menarche at age 12 years or younger who experienced rapid onset of regular cycles had nearly a fourfold greater breast cancer risk than women with later menarche who experienced a long duration of irregular cycles. This is further supported by results from a study that showed that circulating estrogen and progesterone levels in daughters of women with breast cancer were higher than those of age-matched daughters of women without breast cancer.³⁰

Although menarche and the onset of ovulation are to some extent genetically determined,³¹ it is also

critical to establish behaviors that may alter the number of ovulatory menstrual cycles a woman experiences during her reproductive years. Strenuous physical activity may delay menarche.³² For example, in one study, the mean age at menarche of ballet dancers was 15.4 years compared to 12.5 years for control subjects. Moderate physical activity during adolescence can lead to anovulatory menstrual cycles. Girls who regularly engaged in moderate levels of physical activity (averaging at least 600 kcal of energy expended per week during a 9-month school year) were nearly three times more likely to have anovulatory menstrual cycles than were girls who were less physically active.³³ Bernstein et al.³⁴ have reported that lifetime patterns of leisure-time exercise activity significantly impact the breast cancer risk in young women (<40 years of age), older, postmenopausal women (55–64 years of age),³⁵ and African-American and Asian-American women.^{36, 37} Evidence continues to accumulate in support of a protective effect of physical activity on breast cancer risk with risk reductions observed in both case-control and cohort studies, although studies may vary according to the subgroups of women who benefit the most.^{38–40}

Later occurrence of menopause and extended exposure to ovulatory cycles at the end of menstrual life also increase breast cancer risk. The risk of women whose natural menopause occurs before age 45 years is one-half that of women whose menopause occurs after age 55 years.⁴¹ Artificial menopause, induced by bilateral oophorectomy or by pelvic irradiation, also markedly reduces breast cancer risk; this reduction is greater than that associated with natural menopause before age 50 years.^{41–43} Following natural menopause, estrogen exposure declines gradually due to the continuing, but declining function of the ovaries and the continuing, persistent ovarian production of a small amount of testosterone.

The relationship between weight and breast cancer risk depends on menopausal status. Among postmenopausal women, a 10-kg increment in body weight results in about an 80% increase in breast cancer risk.⁴⁴ One explanation for this effect is that heavier postmenopausal women have higher circulating estrogen levels because of the conversion of an adrenal androgen, androstenedione, to estrone by aromatase present in body fat. In premenopausal women, the relationship between weight and risk is less clearly established, but if anything, the situation is the reverse of that in postmenopausal women; here, high weight is associated with reduced risk.⁴⁵ This may result from a reduction in the frequency of ovulatory menstrual cycles associated with high body weight.

Assuming ovarian activity affects breast cancer risk, case-control and cohort studies of breast cancer should find higher levels of circulating estradiol among breast cancer patients than among healthy women. Bernstein et al.⁴⁶ described the results of two concurrent case-control studies of premenopausal women in the United States (Los Angeles) and China (Shanghai). Overall, breast cancer patients had 14% higher serum estradiol concentrations, with a case-to-control excess of 17% in Chinese women and 11% in white American women, respectively. Los Angeles control women had 21% greater estradiol concentrations than did Shanghai control women, and adjustment for body weight only accounted for 25% of this difference. The results from a pooled analysis of nine prospective studies of endogenous hormones and postmenopausal breast cancer risk provide strong evidence that high estradiol concentrations are predictive of breast cancer risk, with women in the highest quintile of estradiol exposure having a twofold greater breast cancer risk than those in the lowest exposure quintile.⁴⁷

Age at first birth

Having a first full-term pregnancy at a young age (i.e., before age 20 years) lowers a woman's breast cancer risk by about 50% relative to nulliparous women. Full-term pregnancies at later ages provide smaller increments of protection.⁴⁸ Women who have a late first full-term pregnancy (i.e., in their thirties) have greater breast cancer risk than nulliparous women have. This paradoxical cross-over effect of a late

first full-term pregnancy has been repeatedly confirmed by epidemiologic studies.

The immediate effect of a full-term pregnancy on breast cancer risk is a short-term increase. Among women who have given birth within the past 3 years, breast cancer risk is nearly three times higher than that of women of the same age, parity, and age at first birth whose most recent birth occurred at least 10 years earlier.⁴⁹ On the basis of these results, it appears that a first pregnancy confers two contradictory effects on breast cancer risk: a short-term increase in risk, followed in the long term by a substantial reduction in risk.⁴⁹

This apparent paradox has a physiologic explanation based on patterns of estrogen as well as prolactin secretion and metabolism during pregnancy. During the first trimester, the level of bioavailable estradiol rapidly rises, an effect that is more apparent during the first than in subsequent pregnancies.⁵⁰ Thus, in terms of estrogen exposure to the breast, the net effect during this early part of pregnancy is an increased risk that is equivalent to the exposure from several ovulatory cycles over a relatively short period of time.⁵¹ At a molecular level, it is likely that the hormonal changes during pregnancy induce irreversible differentiation and apoptosis in some cells that have already accumulated one or more of the relevant somatic mutations necessary for breast cancer development. In the long run, however, this negative effect of early pregnancy on breast cancer risk can be overridden by two beneficial hormonal consequences of completing the pregnancy. It has been reported that prolactin levels are substantially lower in parous compared to nulliparous women.^{52–54} Prolactin, a polypeptide hormone, regulates lactation and appears to enhance estrogen effects on breast tissue. In addition, parous women have been reported to have lower levels of bioavailable estradiol than nulliparous women.⁵¹

Evidence is fairly convincing that lactation reduces the breast cancer risk of premenopausal women,^{55–57} but is less consistent for postmenopausal women.^{56, 58} In two publications, Enger et al.^{55, 58} showed substantial breast cancer risk reductions, of 35% for premenopausal and 30% for postmenopausal parous women in the United States who breast fed for more than 15 months (relative to similar women who never lactated). In the United States, rates of breast feeding have varied over time; some studies may have not observed lower breast cancer risk among women who have breast fed due to the small proportion of women with a sufficient duration of lactation. Among premenopausal and postmenopausal women in Shanghai, where breast feeding often extends to more than 1 year per child, a strong dose–response effect of decreasing breast cancer risk with increasing breast feeding duration was observed.⁵⁹ The time when supplementary feedings are introduced to the infant as well as the frequency and duration of each breast feeding episode may also contribute to the inconsistent findings. Lactation may reduce breast cancer risk by reducing the total number of ovulatory menstrual cycles a woman experiences because breast feeding results in a substantial delay in reestablishing ovulation following a completed pregnancy.

Diet

Much attention has focused on dietary differences between countries, particularly fat consumption patterns, to explain both the international pattern of breast cancer occurrence and changes in rates of breast cancer following migration to high-risk from low-risk countries.⁶⁰ International breast cancer mortality and incidence rates correlate highly with per capita consumption of fat in the diet (correlation coefficient, $r = 0.93$ and $r = 0.84$, respectively).⁶⁰ As implied previously, nutrition may influence breast cancer occurrence by modifying age at menarche and body weight, but the correlation of fat consumption with international breast cancer mortality remains highly significant, even after statistical adjustment for these factors.

Although it has been theorized that fat intake in the diet may be an important contributor to breast cancer

risk, many case-control studies of fat consumption and breast cancer find only small differences between cases and controls. Similarly, most of the cohort studies that have used food-frequency questionnaires to study the relationship with total fat, saturated fat, or vegetable fat have found little or no difference in breast cancer risk over a wide range of fat intake. In a meta-analysis of studies of total fat intake and breast cancer risk, the extent of increase in risk comparing women in the highest intake category with those in the lowest intake category was 14% for case-control studies (summary odds ratio (OR) = 1.14; 95% confidence interval (CI) = 0.99–1.32) and 11% for cohort studies (OR = 1.11; 95% CI = 0.99–1.25).⁶¹ The Women's Health Initiative randomized trial of more than 48,000 women tested the hypothesis that reducing intake of total fat to 20% of energy and increasing consumption of vegetables and fruit to at least five servings daily and grains to at least six servings daily would lower cancer, and particularly breast cancer, risk.⁶² During 8.1 years average follow-up after randomization, the RR (relative risk) was lower in women who adhered to the diet compared to the nondietary intervention group, although the results were not quite statistically significant (RR = 0.91; 95% CI = 0.83–1.01), but were suggestive of an impact of diet on breast cancer risk.

High-fiber diets may protect against breast cancer, perhaps because fiber reduces the intestinal reabsorption of estrogens excreted via the biliary system.⁶³ Assessment of fiber intake in epidemiologic studies has been problematic because of a paucity of data on the fiber content of individual foods and disagreement about the most appropriate methods of biochemical analysis to determine the different types of fiber. Case-control, but not cohort, studies have shown a consistent inverse association between dietary fiber intake and breast cancer risk.⁶⁴

Several investigations have been undertaken to demonstrate a reduction in serum estrogen levels following dietary interventions that reduce fat or increase fiber intake.^{65, 66} A meta-analysis of these studies demonstrated a 7.4% average reduction in estradiol levels of premenopausal women and a 23% reduction in estradiol in postmenopausal women following trials of reduced dietary fat intake.⁶⁶ This analysis could not distinguish between a direct dietary effect on hormone levels and an indirect effect that was due to disruption of ovulatory cycles in premenopausal women; nevertheless, whatever the mechanism, such a reduction in estradiol levels is potentially very important.

Exogenous hormones

Hormone therapy and oral contraceptives are the exogenous counterparts to endogenous hormonal exposures experienced by women and therefore are of concern as potential contributors to breast cancer risk.

Oral contraceptives

The relationship between oral contraceptive use and breast cancer risk has been the topic of many review articles. A combined analysis of 54 studies that included more than 150,000 women has provided many important answers about the risk of breast cancer among users of combination oral contraceptives (COCs), which combine an estrogen and a progestin in a single pill.⁶⁷ This analysis indicates a modest increased risk of breast cancer among current (RR = 1.24) and recent (RR = 1.16) COC users. Age at first COC use modifies the association with recent use. For recent users, the risks are highest for those who began COC use before the age of 20 years. However, total duration of COCs use was not associated with increased risk of breast cancer, once recency of use was taken into account.

The pooled analysis compiled studies that mainly focused on younger women as most of these studies were conducted at a time when oral contraceptive users had not achieved their perimenopausal and

postmenopausal years.⁶⁷ The Women's Contraceptive and Reproductive Experiences (Women's CARE) Study, a population-based case-control study conducted in five geographic regions of the United States,⁶⁸ involved more than 4500 newly diagnosed breast cancer patients and more than 4500 control subjects, all of whom were 35–64 years of age. This study was specifically designed to assess the impact of oral contraceptives among women who no longer used oral contraceptives. Relatively few participants in the Women's CARE Study were current oral contraceptive users; many women had stopped use at least 20 years earlier. No significant associations were observed between duration of use, estrogen dose of the formulation, age at first use, interval since last use, or use in relation to timing of pregnancy and breast cancer risk. Further, results for younger women (35–44 years) were similar to those for older women (45–64 years) who were more likely to have used earlier formulations, but were less likely to have recently used oral contraceptives.

The International Agency for Research on Cancer completed a review of all of the existing literature on COCs and breast cancer risk concluding that breast cancer risk is increased in current or recent oral contraceptive users, particularly among women under age 35 years whose first oral contraceptive use was before age 20 years.⁶⁹ The increase in risk disappeared as age at current or recent use increased and, following cessation of oral contraceptive use, any increase in risk disappeared within 10 years.

Hormone therapy

Hormone therapy has evolved over time. Originally designed to reduce the symptoms of menopause, hormone therapy gained popularity because of its efficacy in reducing the risk of osteoporosis and its purported benefits in reducing the risk of heart disease. Initially formulated as ERT, the number of women using hormone therapy increased through the mid-1970s, until concerns were raised about the carcinogenic potential of ERT on the endometrium. In the 1980s, cyclic estrogen–progestin regimens became widely recommended and prescribed to eliminate the increase in endometrial cancer associated with estrogen-alone therapy. Initially, these were prescribed as sequential regimens with estrogen given during the first 15–20 days of a 28-day cycle followed by 5–10 days when both estrogen and progestin were given. More recently, continuous combined regimens have gained favor because they reduce menstrual-like bleeding episodes and because of their ease of administration.

Most studies that have included sufficiently large numbers of women who have used ERT for extended periods of time (e.g., for more than 10 years) indicate a modest increase in breast cancer risk among exposed women, with risk increasing approximately 3% per year of use.⁷⁰ Among studies conducted in the United States, where the use of conjugated equine estrogens is the norm, it was estimated that breast cancer risk increased about 2.2% per year of use of a standard dose regimen (0.625 mg/day).

The Collaborative Group on Hormonal Factors in Breast Cancer pooled data from 51 epidemiologic studies and more than 160,000 women to assess the impact of hormone therapy on breast cancer risk.⁵⁵ Where information was available regarding type of hormone preparation used, 80% of women in these studies had used mostly estrogen-only therapy and 12% of women had used combination hormone therapy. This study showed that hormone therapy (primarily ERT) increased breast cancer risk with RRs of 1.09, 1.15, and 1.14 comparing ever users to never-users in cohort studies, population-based case-control studies, and hospital-based case-control studies, respectively. Risk was substantially elevated among women who had used hormone therapy for at least 15 years (RR = 1.58). Risk increased by 2.3% ($p = 0.0002$) for each year of use among women who had used hormone therapy within 5 years of diagnosis or an equivalent reference date ([Figure 2](#)). However, women who stopped hormone therapy use 5 or more years earlier had only a modest, nonsignificant increase in risk, regardless of duration of use.

Figure 2 (a,b) Relative risk of breast cancer by duration and time since last use of hormone therapy according to extent of tumor spread relative to never-users, stratified by study, age at diagnosis, time since menopause, body mass index, parity, and the age of a woman when her first child was born. “Last use within 5 years before diagnosis” includes current users. *Floated standard errors (FTEs) and floated confidence intervals (FCIs) calculated from floated variance for each category.

Consistent with these estimates are the results from the Million Women Study, conducted in the United Kingdom, which recruited a cohort of women aged 50–64 years who had undergone routine mammography.⁶¹ In this study, incidence of breast cancer was significantly greater among current users of ERT than among women who had never used hormones (RR = 1.30; 95% CI = 1.22–1.38). Risk increased with increasing duration of use among these current users, with 5–9 years of use associated with a RR of 1.32 and 10 or more years of use associated with a RR of 1.37.

The Women's Health Initiative randomized trial compared an estrogen-alone regimen to placebo among women 50–79 years of age who had previously had a hysterectomy and assessed the impact of a combined estrogen plus progestin regimen versus placebo among similarly aged women who had an intact uterus. The estrogen-alone regimen consisted of 0.625 mg/day of conjugated equine estrogen,⁷¹ and the combined regimen consisted of 0.625 mg/day of conjugated equine estrogen and 2.5 mg/day of medroxyprogesterone acetate.²⁷ The results for the ERT study were somewhat surprising in that, after an average follow-up of 7.1 years, the RR of breast cancer was not elevated (RR = 0.80; 95% CI = 0.62–1.04).⁷² In the trial, the reduction in risk was greater and was statistically significant for ductal cancers although even in a trial this large, numbers were too small to demonstrate a difference in risk by tumor histology. In comparison to ductal tumors, risk appeared elevated for lobular cancers and the comparison of ductal to lobular cancer was of borderline statistical significance ($p = 0.054$). A similar, nonstatistically significant difference was observed by stage with risk reduced for localized cancers but not for regional cancers ($p = 0.09$).

For combined hormone therapy (CHT), the Women's Health Initiative assessed only the continuous combined regimen. Three population-based observational studies, published in 1999 and 2000, showed that CHT conferred a greater risk of breast cancer than did an estrogen-alone regimen.^{24, 25, 73} For example, Ross et al.²⁵ found that the increment in risk for each 5 years of use was nearly four times greater for CHT users than for ERT users. Results from the Women's Health Initiative trial arm comparing a continuous CHT to placebo provided a risk estimate that was similar to those from these prior studies (RR = 1.24; 95% CI = 1.01–1.54).²⁷

Lee et al.⁷⁴ conducted a meta-analysis of the results of studies that have evaluated the impact of CHT on breast cancer risk, separating results for use of sequential (cyclic) combined regimens from those for use of continuous combined regimens and including results from the Collaborative Group on Hormonal Factors in Breast Cancer⁵⁵ and the Women's Health Initiative.²⁷ Overall, users of a combined regimen had substantially elevated risk that increased 7.6% per year of use.⁷⁴ Not all studies provided data on progestin schedule. Those that did showed a small difference in risk between sequential and continuous combined regimens (increase in breast cancer risk per year of use of 8.9% and 10.3%, respectively). Notably, results from Scandinavian studies showed that continuous regimens had a greater impact on risk than sequential regimens. This difference was not as apparent among studies from the United States or the Million Women's Study. In the United States, the total dose of progestin is comparable in continuous combined compared to sequential regimens, whereas in Scandinavia, continuous combined regimens provide a substantially higher dose of progestin. Thus, evidence is quite strong that the progestin component of combined regimens adds substantially to any increase in breast cancer risk conferred by estrogen alone and that differences in results between the United States and Scandinavia are likely due to differences in the progestin dose administered.

Recently, the Women's Health Initiative investigators published an update on health risks and benefits of CHT, examining risk following cessation of hormone therapy.⁷⁵ Risk for invasive breast cancer remained elevated after an average 2.4-years follow-up after use was stopped among women who had been randomized to the estrogen plus progestin arm of the trial evaluating combined therapy (RR = 1.27; 95% CI = 0.91–1.78), although the CI did not exclude 1.0.⁷⁵

CHT preferentially increases the risk of lobular and ductal-lobular breast cancers, particularly those judged to have more than a 50% lobular component.⁷⁶ Among older women, ages 55–74 years, current users of combined therapy were at 2.7-fold greater risk of lobular carcinoma and 3.3-fold greater risk of ductal-lobular carcinoma compared to women who had no use of combined therapy.

Declining use of combined therapy has had a marked impact on breast cancer incidence rates in the United States and Germany.^{77–79} It is important to note that rates of breast cancer in the United States began to decline before publication of the Women's Health Initiative result for combined therapy in 2002.²⁶ An evaluation of data from the Surveillance, Epidemiology, and End Results (SEER) registries for 1975–2003 shows a decline in invasive breast cancer from 1999 onward in all age groups of women 45 years or older, with a sharp decrease in incidence in 2002 and 2003, particularly of estrogen receptor- (ER) positive tumors, in women 59–69 years of age.⁷⁸ Data from a mammography registry in San Francisco indicate that hormone therapy prescribing peaked in 1999, then began to decline, which was amplified following publication of the Women's Health Initiative.⁸⁰ Robbins and Clarke⁸¹ confirmed this in their analysis of breast cancer incidence across 58 counties in California, clearly demonstrating that breast cancer rates declined between 2001 and 2004, with the rate of decline paralleling the reduction in prescriptions of combined therapy recorded by the California Health Interview Survey. Although some have suggested that part of this decline in breast cancer incidence among older women might be due to decreasing use of mammographic screening, rates of *in situ* breast cancer, which is diagnosed almost exclusively by mammography, have not decreased in parallel with the decrease in invasive breast cancer,⁷⁸ and the California Health Interview Survey has not indicated any significant change in the proportion of women reporting a screening mammogram within the prior 2 years.⁸¹

Endometrial cancer

Among the hormone-related cancers, etiologically the best understood is endometrial cancer. All the major demographic characteristics of the disease, as well as the major nondemographic risk factors, are explicable on the basis of cumulative exposure of the endometrium to that fraction of estrogen, which is unopposed by the modifying influences of progesterone.^{2, 3}

Mitotic activity in the endometrium

Key and Pike⁸² summarized the existing data on endometrial mitotic activity during normal menstrual cycles. Mitotic rates are low during days 1–4 of the cycle, then increase rapidly and remain stable thereafter until day 19, after which rates essentially drop to zero for the remainder of the cycle. There appears to be a lag period of about 4 days before the stimulatory effects of unopposed estrogen or the modifying influence of progesterone on endometrial mitotic activity are fully apparent.

The cellular basis for the antiestrogenic activity of progestogens on the endometrium is well understood.² Progestogens reduce the concentration of estradiol receptors and increase the activity of the 17- β -hydroxysteroid dehydrogenase type II enzyme, which converts estradiol to estrone,^{83, 84} a biologically less-potent estrogen because of its lower affinity for cellular ERs. Luteal phase progesterone causes endometrial cells to differentiate to a secretory state and progestogen withdrawal leads to cyclic sloughing of endometrial tissue.

On the basis of the concept that frequency of mitotic activity is the primary determinant of endometrial cancer risk and that such activity is controlled by cumulative exposure to unopposed estrogens, one can readily predict the most important risk factors for this disease ([Table 2](#)). Pregnancies and oral contraceptives, which expose the endometrium to constant high levels of both estrogen and progestogen, should protect against endometrial cancer development. ERT and obesity should increase the risk. All of these predicted effects have been repeatedly well documented in epidemiologic studies.²

Table 2 A summary of established hormonal risk and protective factors for endometrial cancer

Risk factors (increased exposure to “unopposed” estrogen)
Estrogen replacement therapy
Obesity
Sequential oral contraceptives
Late menopause
Protective factors (decreased exposure to “unopposed” estrogen)
Pregnancy
Combination oral contraceptives

Estrogen therapy

Hormone therapy in the form of unopposed ERT gained widespread popularity in the United States during the 1960s and 1970s.⁸⁵ Concomitantly, incidence rates of endometrial cancer in postmenopausal women also increased rapidly, especially in western US states, where use of ERT was particularly common.⁸⁶ By 1975, the results of epidemiologic case-control studies, demonstrating a strong overall association between ERT and risk of endometrial cancer, were being published.^{87, 88} Dozens of studies have now

documented a high relative increase in the risk of endometrial cancer following ERT. Risk is strongly related both to dose and to duration of use, but high relative increments in risk follow even moderate doses taken for intermediate length periods of time. Women who use ERT for 5 years or longer have approximately a 3.5-fold increase in risk compared to that of women who have never used such therapy (Figure 3a).¹⁷

Figure 3 Age-specific incidence rates for cancers of the endometrium in women using estrogen therapy (ERT) (a) and combination oral contraceptives (COCs) (b) for 5 years. Data are from the UK Birmingham Cancer Registry for the years 1968–1972. These data largely avoid problems arising from the high hysterectomy and oophorectomy rates in the United States, which artificially distort the age-incidence curves. Dots, actual incidence data; solid lines marked “normal,” mathematic models predicting these rates from the major known risk factors for these cancers.

Although use of estrogen clearly increases the incidence of aggressive endometrial cancer, the overall mortality from endometrial cancer among affected users somewhat paradoxically is much lower than among nonusers who develop endometrial cancer.⁸⁹ In fact, such women have little reduction in life span when compared to healthy women of the same age. The reasons for this are not completely known, but this phenomenon likely can be explained by the increased medical surveillance among estrogen users. Women who use ERT tend to be closely monitored because the drug frequently induces vaginal bleeding. Part of the favorable survival experience may also result from patients with estrogen-induced benign hyperplasia being misdiagnosed as having endometrial cancer. Although past users of ERT have a risk of endometrial cancer that is intermediate between that for current users of comparable duration and lifetime nonusers, risk in such women remains substantially elevated over baseline even after many years without treatment.⁹⁰

As noted above, the newer regimens of hormone therapy typically follow one of two patterns: sequential or combined estrogen and progestin. The sequential regimen attempts to reproduce the hormonal pattern of the normal menstrual cycle, albeit at lower levels of both estrogen and progestogen. One therefore might predict that this method of hormone therapy administration would only partially offset the increased risk of endometrial cancer that is associated with unopposed ERT. Pike et al.⁹¹ showed that if progestins are added for less than 10 days per month, the risk is only slightly reduced. However, regimens that include progestins for more than 10 days in a month, or where progestins are given continuously with estrogen, do not increase endometrial cancer risk.⁹¹

The Million Women Study conducted in Great Britain, which included 716,738 postmenopausal women without prior cancer or hysterectomy who were recruited between 1996 and 2001, also provides data on this issue.⁷⁴ Relative to women who had never used any hormonal therapy, endometrial cancer risk was substantially lower among women who had used continuous CHT as their most recent hormone therapy, with a RR of 0.71 (95% CI = 0.56–0.90). For women using cyclic CHT, however, risk did not differ from that of nonusers (RR = 1.05; 95% CI = 0.92–1.22). The number of cases among women taking estrogen-alone therapy was small, as, since the mid-to-late 1970s, this has rarely been given to women with an intact uterus. Among women on estrogen-alone therapy, the RR of endometrial cancer was substantially lower than prior studies had observed (RR = 1.45; 95% CI = 1.02–2.06). As expected, based on the fact that obesity increases endometrial cancer risk through an estrogen pathway causing endometrial proliferation,^{82, 92} the reduction in risk on CHT was greatest among obese women and the increase in risk for estrogen-alone therapy was greatest among nonobese women.

The authors of the Million Women Study also provided an extensive assessment of published studies, including their own, on the impact of CHT on endometrial cancer risk.⁷⁴ Overall, they calculated a summary estimate that the RR for continuous CHT across all studies was 0.88 (95% CI = 0.75–1.03) compared to never-users. This estimate, however, was based on relatively few cases—with only 265 cases identified across six studies, including the Women's Health Initiative.⁹³ The estimated RR of endometrial cancer associated with use of cyclic CHT was 1.14 (95% CI = 1.01–1.28),⁷⁴ based on a total of 456 cases, from six studies, four of which overlap with the studies of continuous CHT. Overall, it appears that regimens in which estrogen and progestin are taken daily together (continuous CHT) provide a slight protection against endometrial cancer relative to the risk among women who had never used any hormonal regimen, whereas cyclic use of progestins results in a risk of endometrial cancer that is slightly higher than that of women who had never used hormone therapy.

Tamoxifen, an antiestrogen to the breast, acts as an estrogen agonist in the endometrium, and the risk of endometrial cancer is elevated by tamoxifen in a manner analogous to that of ERT.⁹⁴ Furthermore, the increase in risk is greater among women who previously used ERT and among those with high body mass.⁹⁴ The molecular basis of this agonist effect on the endometrium as opposed to the antagonist activity of tamoxifen on the breast, however, is not totally understood.

Body weight

Unlike breast cancer where high body weight is associated with lower risk among young women and higher risk among older women, high body weight leads to increased risk of endometrial cancer at all ages. Studies of postmenopausal women show at least a doubling of risk of endometrial cancer between thin and heavy women.^{95, 96} Adipose tissue is rich in an aromatase enzyme system that converts androstenedione to estrone. In turn, estrone can be converted directly to estradiol. In addition, protein binding of estrogens in blood is lower in obese women, so the amount of bioavailable estradiol in obese

postmenopausal women is higher than would be expected from the peripheral conversion of androstenedione to estrone alone.

The explanation for the substantially increased risk of endometrial cancer with obesity in premenopausal women is less obvious.⁹⁶ Although obesity does appear to be associated with slightly increased levels of bioavailable estradiol in premenopausal women, this alone appears to be insufficient to account for such a profound effect. The more likely explanation is that obesity in premenopausal women is associated with amenorrhea and subnormal luteal phase progesterone levels, thus resulting in prolonged exposure of the endometrium to unopposed estrogen.⁹⁷

Among postmenopausal women, obesity has become a more important factor in determining endometrial cancer risk subsequent to the declining use of CHT following publication of the Women's Health Initiative results. Results from the American Cancer Society Cancer Prevention Study II Nutrition Cohort show that the risk of endometrial cancer associated with obesity is strongly influenced by whether a woman has used CHT.⁹⁸ Increasing body size, measured by body mass index (kg/m^2), is associated with increasing endometrial cancer risk among postmenopausal women with no prior history of hormone therapy use but has no impact on endometrial cancer risk among women who have used CHT.⁹⁸

Oral contraceptives

The role of estrogens as the principal cause of endometrial cancer is further supported by the markedly increased risk after a relatively short duration of use of sequential oral contraceptives, which deliver an unopposed estrogen during most of the monthly cycle.^{96, 99} These potent effects can be mitigated by the simultaneous administration of progestogens. A series of case-control and cohort studies has consistently demonstrated that combined oral contraceptives, which deliver estrogen and progestogen simultaneously during each day of use, decrease the risk of endometrial cancer by 11.7% per year of use ([Figure 3b](#)).¹⁷ Use of unopposed ERT for at least 3 years following discontinuation of oral contraceptive use may counter the reduction in risk observed for oral contraceptive use.¹⁰⁰

Parity

The other major, established risk factor for endometrial cancer, low parity, also is readily explained by the unopposed estrogen hypothesis.⁹⁵ The highest risk of endometrial cancer occurs in nulliparous women, and an incremental decrease in risk occurs with each increment in parity. Nulliparous women have a risk of endometrial cancer that is three to five times that of women with parity of greater than three. This effect is expected as no endometrial mitotic activity occurs during pregnancy because of the persistently high progesterone levels.

Ovarian cancer

Existing epidemiological data on hormonal exposures across the four major histopathological subtypes of epithelial ovarian cancer (serous, endometrioid, clear cell, and mucinous) suggest that risk factors are consistent across all subtypes except perhaps mucinous tumors. Traditionally, the cell of origin of epithelial ovarian cancer (herein referred to as ovarian cancer) has been described as the single layer of cells lining the surface of the ovary; because these cells replicate during or after each ovulation any respite from ovulation would be protective against ovarian cancer.¹⁰¹ This hypothesis, called “incessant ovulation,” is supported by epidemiologic data, which consistently demonstrate that the risk of developing ovarian cancer decreases with increasing parity^{102–104} and with COC use ([Table 3](#)),^{104–109}

both of which induce anovulation. However, emerging evidence that serous tumors of the fallopian tube and peritoneum share the same epidemiology as serous ovarian cancers has brought into question the notion that it is the actual act of ovulation and subsequent wound healing that underlies the epidemiology of the disease; instead, it may be the hormonal milieu induced as a result of parity and oral contraceptive use.¹¹⁰ Further, clear evidence of an association between menopausal hormone therapy exists, suggesting that the hormonal milieu rather than ovulation itself influences risk of ovarian cancer.

Table 3 A summary of established hormonal risk and protective factors for ovarian cancer

Risk factors (increased number of ovulations)
Late menopause
Protective factors (decreased number of ovulations)
Pregnancy
Oral contraceptives

As with breast and endometrial cancer, the age-incidence curve for ovarian cancer emphasizes the importance of menopause in determining risk. The age-incidence curve of ovarian cancer can be brought into line with the familiar linear log–log plot of other nonhormone-dependent epithelial tumors, if ovarian age is considered as starting at menarche, but increasing at a reduced rate (approximately 30% of normal) during periods of anovulation, including the postmenopausal years.¹⁷

Parity

Parity has been consistently identified as a protective factor against ovarian cancer.^{102–104} After a woman's first birth, ovarian cancer risk is reduced approximately 40% with a 10% reduction associated with subsequent births.^{103–105, 111–113} Although part of the greater reduction in risk with a first birth may be an artifact of including infertile women who are at increased risk of ovarian cancer¹¹⁴ in the nulliparous reference group, this does not fully explain the greater reduction in risk seen with a first birth. An older age (35 years or older) at birth may be more protective than a birth at a young age (under 25 years),^{104, 105, 115} but this result has not been observed in all studies and requires further follow-up.^{103, 112}

Oral contraceptives

Epidemiologic studies have consistently demonstrated that oral contraceptive use decreases the risk of ovarian cancer, in a duration-dependent manner analogous to the protective effect observed for endometrial cancer.^{104–109} A collaborative, pooled analysis of 45 epidemiological studies showed that any use of oral contraceptives is associated with a 27% reduction in ovarian cancer risk (95% CI = 0.70–0.76), with risk reduced 20% with each 5 years of use.¹⁰⁹ This analysis also showed an attenuation in risk reduction over time; women whose use ended less than 10 years previously had a 29% reduction in risk per 5 years of use, whereas women who last used oral contraceptives 20–29 years previously had only a 15% reduction per 5 years of use. Nevertheless, the reductions in risk persisted for decades. In this study, substantial statistically significant heterogeneity was observed across histopathological subtypes with no statistically significant risk reduction for mucinous tumors.

It has been hypothesized that the blocking of ovulation is the mechanism through which both parity and oral contraceptives protect against ovarian cancer; however, an alternate explanation may be the high levels of progesterone achieved through oral contraceptive use and pregnancy. The average daily

exposure to progesterone during the normal menstrual cycle is approximately 3.5 ng/mL compared to 9.2 ng/mL for women taking oral contraceptives.^{116, 117} Likewise, pregnancy is associated with high progesterone levels. A study of female macaque monkeys showed that progestins used in oral contraceptives induce apoptosis in the ovarian epithelium, which can protect against ovarian cancer.¹¹⁸ Also, *in vitro* evidence that estrogen can increase ovarian tumor cell growth exists and this effect can be blocked by progesterone.^{119, 120}

Hormone therapy

The epidemiologic evidence regarding hormone therapy and ovarian cancer risk has become much clearer in recent years. A detailed meta-analysis of the published literature through 2007 from population-based case-control studies^{105, 121–127} and cohort studies^{128–132} showed that use of menopausal ERT increases ovarian cancer risk by 22% for each 5 years of use ($p < 0.0001$). These results are consistent in all but one of the publications, which showed no association.¹²¹ Across the 13 publications showing an association, the dose–response relationship is clear.

The results with regard to menopausal estrogen–progestin therapy, while not as consistent, still provide a clear picture. The meta-analysis of population-based case-control studies,^{105, 121, 123–126, 129} cohort studies^{130–132} and the Women's Health Initiative⁹³ show a 10% increase in ovarian cancer risk per 5 years of CHT use ($p = 0.001$). The difference in risk between estrogen-only therapy and CHT use is statistically significant ($p = 0.004$), suggesting that the addition of a progestin to ERT ameliorates the effect of the estrogen. These analyses provide further support for a protective effect of progestins on ovarian cancer risk.

It is not clear whether the effect of CHT differs depending on whether the sequential or continuous combined regimen is prescribed. Four studies shed some light on this question. The Million Women Study¹³¹ did not find a difference in ever-use risk estimates; however, no duration of use information was provided. The National Institutes of Health American Association for Retired Persons cohort study reports higher risk associated with sequential combined therapy than with continuous combined therapy, but both regimens were associated with increased risk.¹³⁰ A case-control study report from the United States shows a reduced risk of ovarian cancer associated with both types of combined therapy regimens,¹²⁶ whereas a case-control study from Sweden found that sequential combined therapy increased risk, but continuous combined therapy did not.¹²⁵ The higher dose of progestin delivered in the continuous combined versus sequential formulation in Sweden may explain the lack of association with this regimen in the Swedish study.²⁸ Further follow-up is needed in this area.

Given these findings for menopausal hormone therapy, the interpretation of the observations that parity and oral contraceptive use reduce risk can be viewed in a new light, specifically that the mechanism of action of these two protective factors may act by increasing exposure to progestins. This is more consistent with emerging views that the single layer of cells on the surface of the ovary may not be where ovarian cancer originates.

Prostate cancer

Prostate cancer is the most frequently diagnosed cancer in American men, with an estimated 233,000 cases expected in 2014.¹⁸ It is also the second leading cause of cancer deaths in males, exceeded only by lung cancer, with approximately 29,480 deaths from prostate cancer occurring annually.¹⁸ The prostate is an androgen-regulated organ with androgens considered as the major stimulus for cell division in

prostatic epithelium.^{7, 133} Thus, androgens are strong candidates as major contributors to prostatic carcinogenesis. Until recently, only indirect evidence supported a causal role for androgens in prostate cancer development. Results from the Prostate Cancer Prevention Trial (PCPT) using an agent that reduces androgen action in the prostate provided the first direct evidence in support of an important androgen role in this process.¹³⁴ Assessing the role of androgens in prostate cancer development has been difficult in part because of a lack of easily measurable hormonal events in men as exist in women (e.g., menarche, menopause, reproductive experiences). Furthermore, use of exogenous androgens in men is relatively uncommon.

The epidemiology of prostate cancer is dominated by three observations: (1) the profound international and racial–ethnic variation in incidence and mortality, historically reported to be as much as 80-fold between the extremes of high-risk (African-Americans) and low-risk (native Japanese and Chinese) populations¹³⁵; (2) the occurrence of occult, subclinical prostate cancer at a relatively comparable prevalence across populations¹³⁶; and (3) the strong relationship between prostate cancer incidence and aging.⁷ Prostate cancer is extremely rare before age 50 years, but it is still the most common cancer of American men, in large part because the rate of increase in prostate cancer incidence with aging is greater than for any other cancer.

Some of the indirect evidence for a role of androgens in prostate cancer development has come from comparisons of hormonal profiles of healthy men from racial–ethnic groups at high, intermediate, and low risk of prostate cancer. Although studies have not shown differences in testosterone levels between whites and African-Americans,^{12, 137, 138} recent evidence suggests African-Americans have higher estradiol levels than whites and Latinos.¹³⁹ Asian men, while showing no evidence of low circulating testosterone levels relative to whites and African-Americans at any age, have substantially reduced levels of androstenediol glucuronide.^{140, 141} This hormone reflects 5 α -reductase activity (5 α -reductase is the prostatic enzyme that bioactivates testosterone to dihydrotestosterone, the most biologically potent human androgen). Based on these results and the presumptive role of androgens in prostate cell proliferation, Ross et al.¹⁴⁰ proposed that a 5 α -reductase inhibitor might be an effective chemopreventive agent for prostate cancer.

Several additional indirect lines of evidence point to a role of androgens in prostate cancer pathogenesis. Androgens are required for prostate cancer development or progression in most animal models of prostatic adenocarcinoma.¹⁴² Prostate cancer has never been reported to occur in eunuchs or in men with genetically determined decreased 5 α -reductase activity, groups with very low androgen activity and highly underdeveloped prostates.⁷ Prostate cancers, at least early in their course, are almost uniformly androgen dependent, and androgen ablation therapy has been the mainstay for treating early metastatic prostate cancer for many decades.

The role of circulating androgens and prostate cancer risk has been investigated by several studies, yielding inconsistent results. A large pooled analysis of 18 prospective studies from the Endogenous Hormones and Prostate Cancer Collaborative Group found no association between the risk of prostate cancer and circulating levels of testosterone, dihydrotestosterone, dehydroepiandrosterone sulfate, androstenedione, androstenediol glucuronide, or estradiol.¹⁴³ Circulating sex hormone–binding globulin was associated with a decreased risk of prostate cancer, with a RR reduction of 14% when comparing men in the highest quintile of exposure to those in the lowest quintile. Sex hormone–binding globulin regulates circulating levels of free testosterone and estradiol and may also play a role in steroid signaling.¹⁴⁴ Although the majority of circulating androgens do not appear to influence prostate cancer risk, an important consideration of these studies is whether a single hormone measurement can accurately

reflect the average hormone profile of an individual.

The most convincing evidence for a role of androgens in prostate cancer development comes from the PCPT.¹³⁴ In the PCPT, 18,882 healthy men aged 55 years or older, with normal range prostate-specific antigen (PSAs), were randomized to receive 5 mg daily of finasteride, a 5 α -reductase inhibitor, or placebo. After 7 years, all men were designated for an end-of-trial prostate biopsy. Prostate cancer incidence in the treatment arm was reduced approximately 25%. However, paradoxically, there was a statistically significant 25% increase in high-grade prostate cancer incidence in the therapeutic arm. These disparate findings have created substantial controversy regarding the role of 5 α -reductase inhibitors in prostate cancer prevention in healthy men, as well as substantial disagreement regarding the underlying cause of these curious results. It has been argued, for example, that this finding represents an artifact of disruptive morphological changes induced by finasteride in the prostate, or that the increased risk of high-grade prostate cancer is the result of detection bias due to finasteride-induced reduction in prostate volume.¹⁴⁵ On the other hand, others have argued that these results are more foreboding with a clear biological basis; for example, Ross et al.¹⁴⁶ consider that high-grade prostate cancer precursor cells, possibly with androgen receptor alterations (amplification, gene mutations) thrive in an androgen-depleted environment, that prostate cancer cells with somatic mutations of the 5 α -reductase type II gene respond differently to an inhibitor than those without such changes, and that finasteride, by virtue of increased intraprostatic levels of testosterone, selectively stimulates prostate cancer precursor lesions. Understanding the true nature of these results will have enormous public health implications.

Genetic determinants

Familial risk

A family history of breast cancer is associated with an increased risk of the disease.⁴ This is particularly apparent when the family history includes a woman who was affected at an early age or had bilateral disease. Whereas a two to threefold increase in the risk of the disease has been observed in first-degree relatives of women with breast cancer overall, a ninefold increase in risk has been found in the first-degree relatives of premenopausal women with bilateral breast cancer. Very high risks (i.e., fivefold or greater) also have been found in women with more than one first-degree relative with breast cancer.

Similarly, population-based case-control studies have described a two to threefold increased risk of ovarian cancer in first-degree relatives of ovarian cancer patients.^{147, 148} Heritability estimates for both breast and ovarian cancer are approximately 25% as estimated by a classic twin study.¹⁴⁹ The impact of family history on endometrial cancer risk is still controversial.^{150–155} Also, unlike breast and ovarian cancer, heritability estimates from twin studies do not suggest a strong genetic component for endometrial cancer.¹⁴⁹

Prostate cancer is also a highly familial disease. Men with a first-degree relative with prostate cancer have approximately a two to threefold increase in risk compared to men with no such history and this increase is observed across different racial–ethnic groups.¹⁵⁶ As with breast cancer, risk is elevated further when multiple first-degree relatives are affected or when affected relatives are diagnosed at relatively young ages.¹⁵⁷ The heritability of prostate cancer as estimated by twin studies is approximately 42%, the highest among all sporadic cancers.¹⁴⁹

Genes and variants

Extraordinary success has been achieved in the past two decades to identify genetic susceptibility alleles for cancers. Genetic susceptibility alleles can be broadly categorized into high-, moderate-, and low-penetrance alleles.⁵ The high-penetrance alleles typically confer a RR of ≥ 10 and a lifetime risk of $>50\%$; the moderate penetrance alleles exhibit a RR of 2–9 (mostly 5 and lower) and a lifetime risk of 20–50%; and the low-penetrance alleles have a RR of <2 (mostly between 1 and 1.5) and a lifetime risk of 10–19%. The deleterious mutations of high- and moderate-penetrance genes are rare (generally 1% and lower), whereas the low-penetrance alleles are common (mostly $>5\%$) in the general population. High-penetrance alleles, such as *BRCA1* and *BRCA2* for breast cancer, were identified from family-based linkage analysis and positional cloning.^{11, 12} The lifetime cancer risks in germline *BRCA1*-mutation carriers are 60–80% for breast cancer and 30–40% for ovarian cancer. For germline *BRCA2*-mutation carriers, the corresponding estimates are 40–50% and 10–15%, respectively.¹⁵⁸ A few additional high-penetrance alleles for breast cancer have been identified from familial cancer syndromes, including *TP53* mutations in Li–Fraumeni syndrome,¹⁵ *STK11/LKB1* mutations in Peutz–Jeghers syndrome,¹⁵⁹ and *PTEN* mutations in *PTEN* hamartoma tumor syndrome.¹⁶⁰ The lifetime risk of endometrial cancer in hereditary nonpolyposis colorectal cancer (HNPCC or Lynch syndrome) patients reaches 40–60%, and mutations in mismatch repair genes (e.g., *MLH1*, *MSH2*, and *MSH6*) are responsible for Lynch syndrome and considered high-penetrance alleles for endometrial cancer.^{161, 162} For prostate cancer, despite two decades of effort, no consistent high-penetrance allele has yet been identified.⁶

Moderate-penetrance alleles for breast and ovarian cancers are mostly in DNA repair genes, most notably those involved in the Fanconi anemia (FA)–*BRCA* pathway.^{163, 164} These alleles were discovered by linkage analysis of DNA repair deficiency syndromes, resequencing of candidate genes, and most recently, whole exome sequencing. FA is a rare, recessive chromosome instability syndrome characterized by aplastic anemia in childhood, bone-marrow failure, and cellular sensitivity to DNA crosslinking agents.¹⁶⁵ To date, 15 genes have been identified as mutated in FA patients. The products of these genes interact with well-known DNA damage-response proteins, including *BRCA1*, *ATM*, and *NBS1*, and are involved in multiple cellular DNA repair pathways, particularly homologous recombination (HR) in repairing double-stranded breaks.^{165, 166} Biallelic mutations of FA genes result in FA syndrome; however, monoallelic carriers of several FA genes exhibit increased risks of breast and ovarian cancer. *BRCA2* (*FANCD1*) is one of the FA genes. Interestingly, in addition to predisposing to breast and ovarian cancer, *BRCA2* is also a moderate-penetrance gene for prostate cancer: men with germline *BRCA2* mutations have a nearly fivefold higher risk of prostate cancer than men without *BRCA2* mutations.^{167, 168} Two other FA genes, *FANCI/BRIP1* (a *BRCA1*-interacting protein) and *FANCD2/PALB2* (a *BRCA2*-interacting protein), were also demonstrated as moderate-penetrance alleles for both breast and ovarian cancers.^{164, 166, 169–171} Besides FA genes, a number of other DNA repair and cell cycle control genes have been established as moderate-penetrance alleles for breast and ovarian cancer.¹⁷¹ For example, a truncating variant (1100delC) in *CHEK2*, a cell cycle checkpoint kinase, results in an approximately twofold increase in women's breast cancer risk and a 10-fold increase in men's risk¹⁷²; *ATM* mutations that cause ataxia telangiectasia in biallelic carriers are breast cancer susceptibility alleles in monoallelic carriers, with an estimated RR of 2.4¹⁷³; deleterious mutations in *RAD51C* and *RAD51D*, two HR genes, are moderate-penetrance alleles for ovarian cancer but not breast cancer.^{174, 175} For endometrial cancer, germline mutations in the proof-reading domains of DNA polymerase delta (*POLD1*) gene confer a high risk.¹⁷⁶ For prostate cancer, a missense mutation Gly84Glu in *HOXB13*, a homeobox transcription factor involved in normal prostate development and a key determinant in response to androgens, was identified from sequencing of >200 genes of familial prostate cancers,¹⁷⁷ and a recent meta-analysis of 24,213 cases and 73,631 controls revealed that this mutation conferred a fourfold

increased risk of prostate cancer (OR: 4.07; 95% CI = 3.05–5.45).¹⁷⁸

All the high- and moderate-penetrance alleles together account for 20–25% of the familial risk of breast cancer.¹⁷⁹ A larger portion of the familial risk of common cancers is believed to be accounted for by common (minor allele frequency of >5% in general population), low-penetrance alleles. Association studies involving direct comparison of allele frequencies between unrelated cases and controls are the most powerful approach to identify low-penetrance alleles. Early cancer association studies starting from the mid-1990s applied a candidate gene approach, that is, selecting potential functional variants, mostly single nucleotide polymorphisms (SNPs), in genes relevant to the biology and etiology of a specific cancer. The candidate genes often encode proteins involved in hormone biosynthesis, DNA repair, cell cycle control, cell growth, apoptosis, and other critical cellular functions whose aberrations lead to carcinogenesis. However, despite the fact that hundreds of SNPs were initially reported as potential cancer susceptibility loci by candidate gene association studies, very few were convincingly replicated in larger validation studies.¹⁸⁰ The only convincing low-penetrance allele for breast cancer identified from candidate gene association studies was a functional SNP (Asp302His) in the caspase-8 (*CASP8*) gene: the minor allele (His allele, frequency: 13%) confers a protective effect in a per-allele dose-dependent manner (per allele OR = 0.88; 95% CI = 0.84–0.92). This result was based on an analysis of 16,423 breast cancer cases and 17,109 controls.¹⁸¹ No convincing susceptibility SNPs for ovarian, endometrial, or prostate cancers have emerged from candidate gene association studies.

The advent of GWAS in 2005 has ushered in a new era of genetic association studies.¹⁸² Leveraging high-throughput genotyping platforms that can type hundreds of thousands to millions of SNPs simultaneously, GWAS allows for an agnostic approach where no prior knowledge of gene function or SNP position is required. GWAS reveal associations between specific alleles and disease risk via a set of marker SNPs that “tag” all known common variants in the genome. As of December 2014, more than 250 publications on GWAS of cancer risks have identified hundreds of common, low-penetrance susceptibility SNPs for ~35 cancer types.¹⁶ To date, the greatest number of susceptibility SNPs have been identified for breast cancer and for prostate cancer: over 70 breast cancer susceptibility SNPs in 28 chromosome regions and approximately 80 prostate cancer susceptibility SNPs in 47 chromosome regions identified in different racial–ethnic groups. In contrast, 20 susceptibility SNPs in nine chromosome regions have been identified for ovarian cancer, whereas only one locus at chromosome 17q12 was identified for endometrial cancer.¹⁶ The difference in the number of GWAS-identified SNPs for different cancers can be attributed to different sample sizes (breast cancer and prostate cancer are more common and their GWAS have larger sample sizes than those of ovarian and endometrial cancer) and different genetic heritability (endometrial cancer has much lower heritability than the other three cancers). Almost all of these SNPs confer a modest risk with allelic ORs of less than 1.5. Most of these SNPs are cancer site-specific; however, there are several regions that show pleiotropic effects on multiple cancers and other traits, for instance, the *TERT-CLPTM1L* locus at 5p15.33 harbors common and distinct susceptibility SNPs for at least 10 cancers, including breast, ovarian, and prostate cancer.^{183–185} Further, the 8q24 region encompassing the *MYC* oncogene is associated with at least seven malignancies including breast, ovarian, and prostate cancer.¹⁸⁶ The vast majority of these SNPs lie in intergenic or intronic regions and some are found within complete “gene deserts,” therefore, the causal variants and culprit genes in most susceptibility regions are unknown. Nevertheless, the emerging fine mapping of the identified regions and functional studies of candidate genes have already provided significant biological insights into the etiology of specific cancers.

For breast cancer, *FGFR2* at 10q26, a tyrosine kinase receptor that is overexpressed in 5–10% of breast tumors, is the most strongly associated gene. At least three likely causal SNPs in the second intron of

FGFR2, which can interact with the promoter of *FGFR2*, have been identified and there was evidence of allele-specific transcription factor binding for these causal SNPs.^{187, 188} Another strong susceptibility locus for breast cancer is *CCND1* at 11q13. A fine-mapping study identified three independent association SNPs for ER-positive breast cancer.¹⁸⁹ All three SNPs map to either transcriptional enhancers or silencers, which were demonstrated by chromatin conformation studies to interact with each other and with their target gene *CCND1*.¹⁸⁹ With regard to hormone-related biology in breast cancer etiology, two breast cancer susceptibility SNPs are near genes related to the ER pathway. The SNP rs3757318 at 6q25.1 lies ~200 kb upstream of ER α gene *ESR1*,¹⁹⁰ and the nearest gene to SNP rs2823093 at 21q21 is *NRIP1/RIP140*, which interacts with ER α , represses the ER signaling and inhibits its mitogenic effects.¹⁹¹ Whether these two genes are the culprit genes in these two regions warrants further investigation. Other suspected susceptibility genes for breast cancer include growth factors, oncogenes, tumor suppressors, and those involved in DNA repair, cell cycle regulation, mammary gland development, telomere maintenance, apoptosis, and tumor aggressiveness.⁵ Together, the currently identified common, low-penetrance alleles explain about 14% of the familial risk of breast cancer.¹⁹² It is estimated that more than 1000 additional breast cancer susceptibility SNPs can be identified by current GWAS platforms with larger sample sizes; however, their individual effects are very small with ORs predominantly in the range of 1.02–1.05. All these identified and yet-to-be-identified common, low-penetrance SNPs are estimated to contribute ~28% of the familial risk of breast cancer.¹⁹²

For ovarian cancer, GWAS has identified 20 susceptibility SNPs in nine chromosome regions: 2q31, 3q25, 8q21, 8q24, 9p22.2, 10p12, 17q12, 17q21, and 19p13 in white populations¹⁹³ and two independent loci in Han Chinese.¹⁹⁴ The likely culprit genes in these regions include two homeobox genes *HOXD1* and *HOXD3* (both at 2q31), a poly (ADP-ribose) polymerase (PARP) gene *TiPARP* (3q25), chromatin-modifying protein 4C (*CHMP4C*) at 8q21, oncogene *MYC* (8q24), a DNA-binding zinc-finger gene *BNC2* at 9p22.2, a homeodomain-containing transcription factor *HNF1B* at 17q12, and a BRCA1-interacting gene *BABAM1/MERIT40* at 19p13. Together, these SNPs only explain about 5% of the familial risk of ovarian cancer.

For endometrial cancer, only one locus, *HNF1B* at 17q12, has been identified to date by GWAS.^{195, 196} SNPs at this locus are also associated with serous and clear cell ovarian cancer,^{193, 197} prostate cancer,^{198–200} and type II diabetes.¹⁹⁸ *HNF1B* encodes a member of the homeodomain-containing superfamily of transcription factors and acts as a transcription activator.²⁰¹ *HNF1B* expression is altered in numerous cancers and may play a role as a tumor suppressor or oncogene depending on the tissue context. A recent fine-mapping study refined the endometrial cancer association to a single signal in intron 1 of *HNF1B* and showed that the top SNPs are located within the extended *HNF1B* promoter that contains a negative regulatory element and are associated with *HNF1B* expression in endometrial tumors.²⁰²

Prostate cancer is one of the most heritable cancers and GWAS have yielded the largest number of susceptibility variants for prostate cancer compared to any other cancers. All the identified susceptibility SNPs together explain about 30% of the familial risk. Similar to breast cancer, the potential culprit genes in the 47 identified prostate susceptibility loci are involved in many cellular functions, such as DNA repair, cell cycle control, telomere maintenance, cell growth, cell adhesion, and AR signaling.⁶ Several regions stand out. The pleiotropic 8q24 locus is near the *MYC* oncogene and has the highest number of SNPs independently associated with prostate cancer.⁶ Functional studies have shown that SNPs in this region are located within transcription enhancers and can regulate *MYC* expression through long-range interaction with *MYC*.^{203, 204} Another pleiotropic region 5p15 has at least four independent loci in the promoter or intronic regions of *TERT* that are associated with prostate cancer as shown by a recent fine-

mapping study.²⁰⁵ Furthermore, gene expression analysis of normal prostate tissue showed that one of the loci was also associated with *TERT* expression, providing a potential mechanism for predisposing to disease.²⁰⁵ The 19q13 locus contains genes encoding proteins of the kallikreins (KLKs) family of serine proteases, among which PSA (encoded by *KLK3* gene) is the best known. A fine-mapping study identified a common missense coding SNP (rs17632542, Ile179Thr) in the *KLK3* gene that exhibits the most significant association with prostate cancer risk in this region.²⁰⁶ This SNP is also significantly associated with serum PSA level.²⁰⁷ As introduced earlier, a rare, missense mutation Gly84Glu in the *HOXB13* at 17q21 is a moderate-penetrance allele for prostate cancer. Interestingly, common SNPs in *HOXB13* are also associated with prostate cancer risk.²⁰⁸ A fine mapping of this locus identified a cluster of highly correlated common SNPs situated within or closely upstream of *HOXB13*. Furthermore, these common SNPs tag the rare, partially correlated Gly84Glu mutation. This is the first report that a modest GWAS association detected through common SNPs is driven by rare causal variants with higher RRs, providing evidence for the phenomenon of synthetic association contributing to cancer susceptibility.²⁰⁹ Finally, a SNP rs5919432 at the Xq12 locus is located 77 kb from AR gene, suggesting a role of AR variation in prostate cancer etiology.²¹⁰

Despite enormous progress in the identification of high-, moderate-, and low-penetrance alleles, 50% or more of the familial risk of any specific sporadic cancer remains unexplained. Large international collaboration is needed to uncover the remainder of cancer heritability, as an extremely large sample size (>100,000 cases) is needed to identify the remaining common, low-penetrance alleles with very small effect sizes. Whole exome sequencing and whole-genome sequencing are increasingly applied in cancer association studies. Again, large sample sizes are needed to identify rare, unknown high- and moderate-penetrance alleles. In addition, other forms of susceptibility variants, such as structural changes (e.g., copy number variations), and genetic interactions (gene–gene and gene–environment interactions) may explain some of the missing heritability.²¹¹

Conclusions

As our understanding of the relationship between epidemiologic risk factors and the circulating levels of the relevant hormones grows, avenues for primary prevention are becoming apparent. The control of obesity has obvious implications for both endometrial cancer and postmenopausal breast cancer. More information on the relationship between childhood diet and physical activity and the onset of puberty, in conjunction with the hormonal physiology of adolescence and young adulthood may provide increasing avenues for preventing breast, ovarian, and endometrial cancer in women. Chemoprevention trials have demonstrated that tamoxifen is effective in reducing breast cancer risk among high-risk women and that raloxifene, also a selective ER modulator, and anastrozole, an aromatase inhibitor, lower breast cancer risk among high-risk postmenopausal women. Hormonal chemoprevention of ovarian and endometrial cancer is already occurring in the population as a whole through the widespread use of COCs and of endometrial cancer with increasing use of CHT. A national trial to prevent prostate cancer through use of finasteride, a 5 α -reductase inhibitor, has been completed and provides convincing evidence for the role of androgens in the development of this disease. A growing knowledge of the mutations and polymorphisms in genes causing increased risk of these cancers should lead to better definition of individual susceptibility. It should then be possible to focus intervention strategies on the higher risk subgroups of the population.

Chapter 25

Ionizing radiation

David J. Grdina, PhD

Overview

Many experimental and epidemiologic studies have since confirmed the oncogenic effects of radiation. This chapter reviews briefly the effects of ionizing radiation on biological systems, adaptive and bystander effects, cellular and molecular mechanisms for radiation carcinogenesis, and pharmacologic countermeasures that can mitigate against these processes.

Development of radiation injury

The hazards of exposure to ionizing radiation were recognized shortly after Roentgen's discovery of the X-ray in 1895. Acute skin reactions were observed in many individuals working with early X-ray generators, and by 1902, the first radiation-induced cancer was reported arising in an ulcerated area of the skin. Within a few years, a large number of such skin cancers had been observed, and the first report of leukemia in five radiation workers appeared in 1911.¹ [Figure 1](#) describes the interaction of ionizing radiation with biologic tissues and the development of radiation injury. The ionizing event involves the ejection of an orbital electron from a molecule, producing a positively charged or “ionized” molecule. These molecules are highly unstable and rapidly undergo chemical change. This change results in the production of free radicals. The most common products of this process are the result of the decomposition of water giving rise to both superoxide anion (O_2^-) and hydrogen peroxide (H_2O_2) and the highly reactive hydroxyl radical, which has as a result a very short life span and can diffuse only on the average about 4 nm before reacting with other molecules.² Reactive oxygen species (ROS) production can be amplified by intermitochondrial communication that results in a subsequent magnification of the ROS damage signal.³ The process of “ROS-induced ROS release,” or RIRR is one potential mechanism for this. Under conditions of an excessive oxygen stress burden, the increase in ROS within the mitochondria reaches a threshold that triggers the opening of either the mitochondrial permeability transition (MPT) pore or the inner membrane anion channel (IMAC), which in turn leads to the simultaneous collapse of mitochondrial membrane potential and a transient increase in ROS generation by the electron transfer chain. Release of this ROS burst into the cytosol functions as a second messenger to activate RIRR in neighboring mitochondria.^{4, 5} Radiation can produce a transient generation of reactive oxygen or nitrogen within minutes accompanied by a reversible depolarization of mitochondrial membrane potential.³ Radiation damage in a single mitochondrion can be transmitted via a reversible Ca^{2+} -dependent MPT to adjacent mitochondria resulting in the amplification of ROS generation. ROS amplification and propagation resulting from such a cascade can then damage important biological targets such as DNA, the nuclear matrix, cytoplasmic transport mechanisms, and both mitochondrial and cellular membranes resulting in cell death. The ROS amplification process may also be interfered by endogenous antioxidants such as superoxide dismutases (SODs) or exogenously added antioxidants.

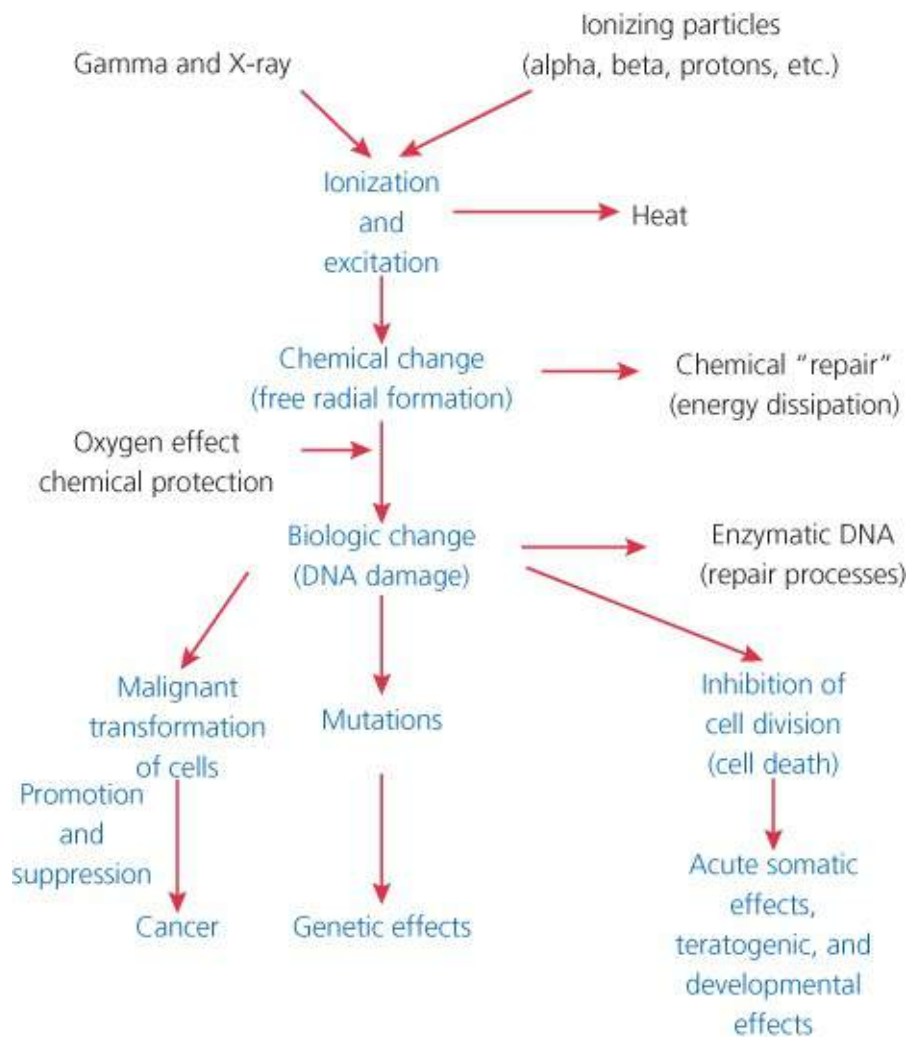

Figure 1 Development of radiation injury.

Principal cellular and tissue effects of radiation

Cell killing

Radiation can kill cells by apoptosis and interphase death.^{6–8} Cells undergoing apoptosis usually die in interphase within a few hours of irradiation. Apoptotic cell death can be induced by exposure to relatively low doses of radiation⁶ and be a significant cause of death in hematopoietic or lymphoid cells exposed to higher radiation doses.

Radiation-induced apoptosis is dependent upon both the functional activity of the p53 gene as well as p53-independent pathways⁹ all of which converge on the activation of proteases called caspases.¹⁰ It has been proposed that p53-dependent apoptosis may involve the transcriptional induction of redox-related genes with the formation of ROS, leading to cell death by oxidative stress.¹¹

The second mechanism for cell killing is radiation-induced reproductive failure. The inhibition of cellular proliferation is the mechanism by which radiation kills most mammalian cells. Symptoms of acute exposure to whole-body irradiation in human beings are usually observed only following doses of 100 cGy or greater.

Mutagenesis

Studies of the induction of single-gene mutations in human cells have been limited to several genetic loci.

Of particular note is the X-chromosomal gene for hypoxanthine-guanine phosphoribosyltransferase (HPRT).^{12, 13} The induction of mutations in human cells is a linear function of dose down to doses as low as 10 cGy, and perhaps as low as 1 cGy, and the dose-rate effect appears to be relatively small.^{14, 15} DNA structural analyses show that the majority of radiation-induced mutations in human cells result from large-scale genetic events involving loss of the entire active gene and often extending to other loci on the same chromosome.¹⁶

The major potential consequence of radiation-induced mutations in human populations is heritable genetic effects resulting from mutations induced in germinal cells. For high dose-rate exposure, the induced mutation rate per gamete generally falls in the range of 10^{-4} to 10^{-5} per cGy. The rates per locus are in the range of 10^{-7} to 10^{-8} per cGy. Protraction of exposure appears to decrease the mutation rate in rodent systems by a factor of 2 or greater. When all of the experimental data for the various genetic end points are considered, the genetic doubling dose (radiation dose necessary to double the spontaneous mutation rate) for low dose-rate exposure appears to be in the range of 100 cGy.

Chromosomal aberrations

Radiation can induce two types of chromosomal aberrations in mammalian cells. The first have been termed “unstable” aberrations in that they are usually lethal to dividing cells. They include such changes as dicentrics, ring chromosomes, large deletions, and fragments. The frequency of such aberrations correlates well with the cytotoxic effects of radiation.

The second type has been termed “stable” aberrations. These include changes such as small deletions, reciprocal translocations, and aneuploidy changes that do not preclude the cell from dividing and proliferating. Radiation-induced reciprocal translocations may be passed on through many generations of cell replication and emerge in clonal cell populations.^{17, 18}

Such deletions and translocations can result in gene mutations. Specific chromosomal abnormalities are associated with specific tumor types such as the chromosome 8:14 translocation in Burkitt lymphoma. The chromosomal change can result in the activation of a specific oncogene such as a chromosome 13q14 deletion in retinoblastoma (RB).

Radiation-induced genomic instability

Radiation exposure can induce a type of transmissible genetic instability in individual cells that is transmitted to their progeny, leading to a persistent enhancement in the rate at which genetic changes arise in the descendants of the irradiated cell after many generations of replication. This is a nontargeted effect of radiation. The end points include malignant transformation, specific gene mutations, and chromosomal aberrations.

Early evidence was derived from an examination of the kinetics of radiation-induced malignant transformation of cells *in vitro*.^{19, 20} Transformed foci did not arise from a single, radiation-damaged cell. Rather, radiation appeared to induce a type of instability in 20–30% of the irradiated cell population; this instability enhanced the probability of the occurrence of a second, neoplastic transforming event, which is rare occurring with the frequency of $\sim 10^{-6}$. This second event occurs with a constant frequency per cell per generation and has the characteristics of a mutagenic event.²¹

This phenomenon was subsequently demonstrated in a number of experiment systems for various genetic end points.^{22–25} In terms of mutagenesis, $\sim 10\%$ of clonal populations derived from single cells surviving

radiation exposure showed a significant elevation in the frequency of spontaneously arising mutations compared with clonal populations derived from nonirradiated cells.^{26, 27} This increased mutation rate persisted for ~30 to 50 generations postirradiation. An enhancement of both minisatellite²⁸ and microsatellite²⁹ instability has also been observed in the progeny of irradiated cells selected for mutations at the *thymidine kinase* locus.

Transmission of chromosomal instability has been shown to occur *in vivo*,^{30, 31} but susceptibility to radiation-induced chromosomal instability differed significantly among different strains of mice.^{32, 33} A persistent increase in the rate of cell death has been shown to occur in cell populations many generations after radiation exposure.^{34–36} Delayed reproductive failure has been linked to chromosomal instability³⁷ and malignant transformation,^{38, 39} and evidence presented to suggest that DNA is at least one of the critical targets in the initiation of this phenomenon.⁴⁰

A recent novel phenomenon has been identified and coined “the delayed radioprotective effect.” It is manifested by an enhanced resistance to ionizing radiation hours to days following exposure of cells to thiol-containing drugs such as *N*-acetylcysteine and captopril that have the ability to elevate intracellular antioxidant enzymes such as manganese superoxide dismutase (MnSOD).^{41, 42} The underlying mechanism of action responsible for this effect is the activation of the redox-sensitive nuclear transcription factor κ B (NF κ B) by thiol-reducing agents that subsequently results in the elevated transcription of MnSOD. The resulting 10- to 20-fold elevation of intracellular MnSOD facilitates the prevention and removal of radiation-induced oxidative damage and can enhance survival of cells by 10–30%.

Bystander effects in irradiated cell populations

It has long been thought that the cell nucleus is the target for the important biologic effects of radiation. However, recent evidence shows that targeted cytoplasmic radiation is significantly mutagenic. Damage signals may be transmitted from irradiated to nonirradiated cells in the population, leading to biologic effects in cells that received no radiation exposure,⁴³ for example, the “bystander” effect.

Following the exposure of monolayer cultures of cells to very low fluences of α particles, an enhanced frequency of sister chromatid exchanges (SCE) was observed in 20–40% of cells exposed to fluences by which only 1/1000 to 1/100 cells were traversed by an α particle.⁴⁴ This effect involves the secretion of cytokines or other factors by irradiated cells that leads to an upregulation of oxidative metabolism in bystander cells.^{45, 46} Examples of a bystander effect are presented in [Figure 2](#). Incubation with conditioned medium from irradiated cells has cytotoxic effects on nonirradiated cells, which may be related to the release of a factor(s) into the medium.⁴⁷ An enhanced frequency of specific gene mutations^{48, 49} as well as chromosomal aberrations^{50, 51} are observed to occur in bystander cells in populations exposed to very low fluences of α particles.

Figure 2 Bystander effect of radiation. The expression of p21^{Waf1} was determined in individual cells in monolayer cultures of human diploid fibroblasts by *in situ* immunofluorescence. In cultures exposed to 0.3 cGy (<1–2% of nuclei traversed by an α particle), enhanced expression occurred in many nonirradiated cells occurring in clusters (*center panel*). The effect was suppressed by incubation with lindane, an inhibitor of gap junction-mediated intercellular communication (*right panel*).

DNA damage in bystander cells appears to differ from that occurring in directly irradiated cells; whereas the mutations induced in directly irradiated cells were primarily partial and total gene deletions, >90% of those arising in bystander cells were point mutations.⁵² Suggesting that oxidative metabolism is upregulated in bystander cells.^{45, 46} Bystander effects indicate clearly that damage signals can be transmitted from irradiated to nonirradiated cells.

Adaptive responses

The original description of an adaptive response was made by investigators working with human lymphocytes in which they observed that following exposure to a very low dose of ionizing radiation in the range of 1–10 cGy cells acquired an enhanced resistance to a second but much larger dose of 2 Gy or more.⁵³ The expression of an adaptive response was linked to the requirement of *de novo* protein synthesis since inhibitors of protein synthesis such as cycloheximide were found to be inhibitory to this inductive effect.⁵⁴ Adaptive responses can be looked upon as the result of intercellular stress responses. The most studied such response has been identified as being mediated by MnSOD, an antioxidant enzyme localized in the mitochondria of cells, in both normal and malignant cells. As an example, it has been demonstrated that mouse skin JB6P+ epithelial cells exposed to 10 cGy exhibited an enhanced resistance to a subsequent dose of 2 Gy during which time a number of NF κ B-regulated genes including MnSOD, p65, phosphorylated extracellular signal-related kinase, cyclin B1, and 14-3-3Z were elevated.⁵⁵ The importance of elevated MnSOD synthesis in the adaptive response process has been observed in cells following exposure to not only a low dose of ionizing radiation⁵⁵ but also the cytokine TNF α ⁵⁶ and numerous reductive agents such as amifostine and *N*-acetylcysteine.^{42, 57} Treatment of cells with NF κ B inhibitors and/or antisense MnSOD oligomers or siRNA MnSOD completely inhibited the adaptive response induced by these agents.^{55, 56} Both the radiation and cytokine-induced adaptive responses are the result of oxidative damage-initiated processes in contrast to the thiol-induced reductive response in which NF κ B is activated following the reduction of cysteine residues on its p50 and p65 subunits,^{58, 59} a process that can be maintained in a persistent manner with chronic thiol exposure.⁶⁰

It is now recognized that there are multiple mediators of adaptive responses, each associated with either normal and/or neoplastic cells and different radiation protocols. Under conditions of multifractionated high-dose radiation exposures, each preceded by very low imaging doses, a survivin-mediated adaptive

response is expressed in tumor cells.⁶¹ Survivin, a member of the inhibitor of apoptosis protein (IAP) group, is primarily found in neoplastic cells and has been identified as an important factor in tumor cell resistance.^{62, 63} Its overexpression results in elevated tumor cell resistance to radiation- and chemotherapy-induced cell killing and reduced frequencies of apoptosis.^{64–66} A third adaptive response has been identified in normal cells where low-dose radiation exposure results in the induction of a metabolic shift from oxidative phosphorylation to aerobic glycolysis in cells and is mediated by the hypoxia-inducible factor HIF-1 α .⁶⁷

DNA damage

Track analysis studies of X-ray interactions in DNA have provided evidence for clustered damage, which results in complex DSB (double-strand break).⁶⁸ Certain types of DNA base damage such as 8-hydroxydeoxyguanosine and thymine glycols have significant potential biologic importance, but the available data suggest that such isolated base damage by itself probably plays a minor role in radiation mutagenesis. Clustered DNA damage may include abasic sites, oxidized purines, or oxidized pyrimidines.⁶⁹ The increased efficiency of DNA breaks induced by high-LET radiation appears to result primarily from their greater complexity.⁷⁰

Cells possess a complex set of signaling pathways for recognizing such DNA damage and initiating its repair. The ATM gene is a sensor of DNA damage, which activates by phosphorylation a variety of proteins involved in cell cycle control and DNA repair. Two mechanistically distinct pathways that function in complementary ways are involved in the repair of DSB: nonhomologous end joining (NHEJ), which requires little sequence homology between the DNA ends and is error prone, and homologous recombination (HR), which uses extensive homology and is generally error-free.⁷¹ NHEJ involves a complex of proteins, including Ku70, Ku80, the DNA-PK catalytic subunit DNA-PKcs, XRCC4, and ligase IV. The NBS1/MRE11/RAD50 complex⁷² is also involved in the nucleolytic processing stages of NHEJ; this complex also contributes to HR. HR also involves a complex of proteins, notably RAD51 and other factors in the RAD50 epistasis group.⁷³ Strong links have been established between recombinational repair and the breast cancer susceptibility proteins BRCA1 and BRCA2,^{74–76} as well as the Fanconi anemia family of proteins.⁷⁷ Un-repaired or mis-repaired DSB led primarily to large-scale genetic changes that are frequently manifested by chromosomal aberrations. However, no genetic alterations unique to radiation have been found in radiation-induced tumors.

General characteristics of radiation carcinogenesis

Ionizing radiation can induce cancer in most tissues of most species at all ages, including the fetus. It is carcinogenic to humans. It is, however, a relatively weak carcinogen and mutagen. The cancers induced by radiation are of the same histologic types as occur naturally, but the distribution of types may differ. There is a distinct latent period between exposure to radiation and the clinical appearance of a tumor.

Radiation carcinogenesis is a stochastic process; that is, the probability of the occurrence of the effect increases with dose with no threshold, but the severity of the effect is not influenced by dose. Radiation-induced cancer appears to be an all-or-none effect. The dose–response relationships for the induction of cancers in specific tissues of small animals vary with site, sex, and species.^{78–80} For low LET radiation, the frequency of induced cancers generally rises with dose in the range of 0–300 cGy. In some cases, tumor incidence levels off at higher doses and may even decline. This phenomenon is thought to reflect

cell killing. In the dose range up to 200–300 cGy, the dose–response curves for individual tumor types vary but generally assume a linear-quadratic to near-linear relationship. For high LET radiation, the rise in cancer incidence with dose is much steeper. The dose–response curves are approximately linear within the range of 0–20 cGy.^{78, 81}

The induction of carcinogenesis in experimental animals can be suppressed by treatment with certain agents that are known to inhibit radiation-induced transformation *in vitro*. An example of this includes amifostine, which is the only drug currently approved for clinical use as a radioprotector by the Food and Drug Administration.⁸² As described by Kaplan–Meier plots in [Figure 3](#), inoculation of B6CF1 hybrid mice with a single dose of 400 mg/kg of amifostine 30 min before whole-body irradiation with 2 Gy of low LET radiation significantly protected against carcinogenesis in both male and female animals. The reduction in cancer deaths due to lymphoreticular tumors by amifostine is reflected by a shift in the Kaplan–Meier survival curves for drug-treated irradiated animals to those describing the survival of nonirradiated control animals.^{83–85} Causes of death due to lymphoreticular tumors that included leukemias and lymphomas were determined by both gross and microscopic analysis of individual animals by veterinarian pathologists.⁸³ Likewise, certain protease inhibitors have also been shown to suppress the induction of cancer in several different tumor systems.⁸⁶ It is well known that the hormonal environment is important in certain radiation-induced rodent cancers, particularly ovarian and mammary tumors.

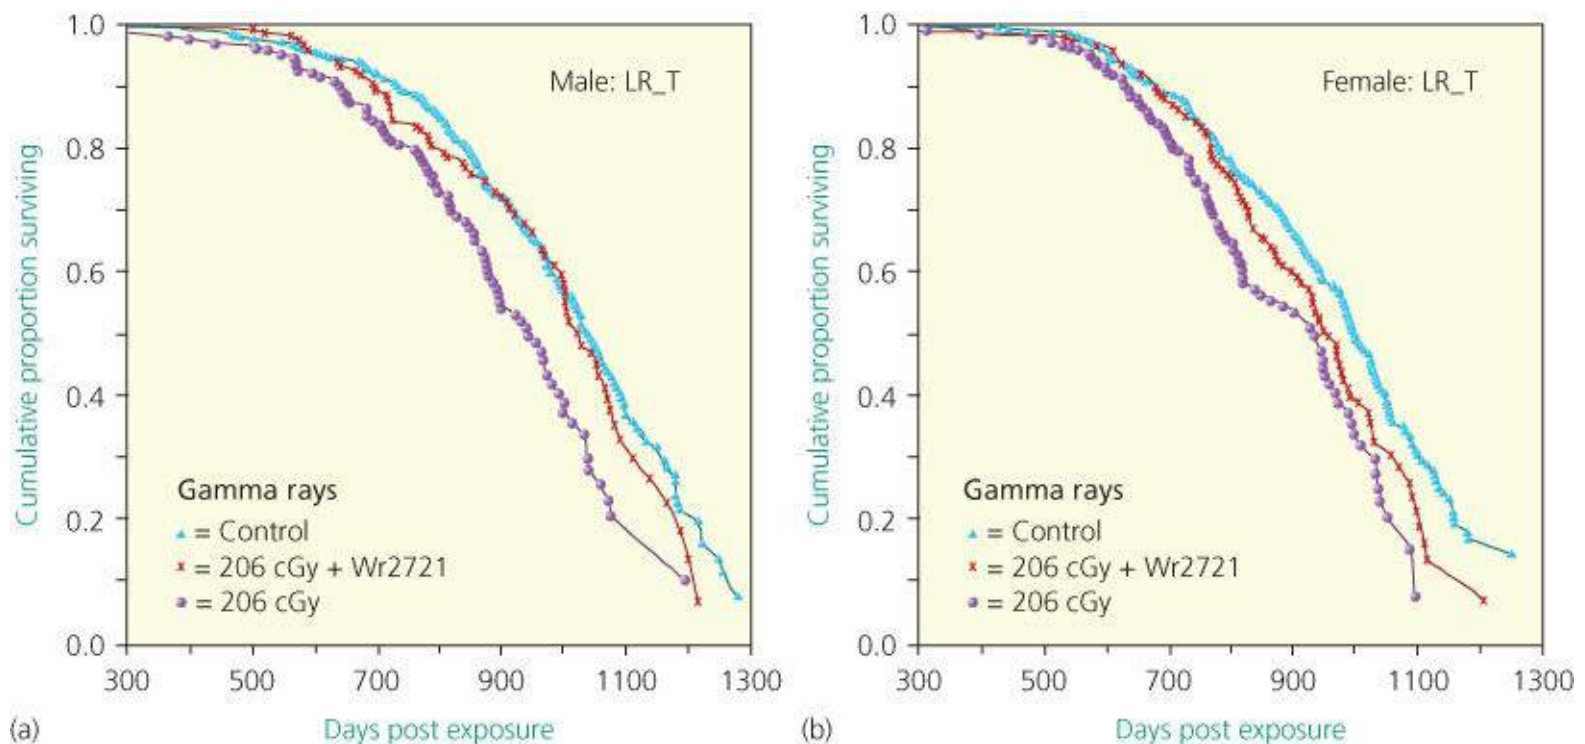

Figure 3 (a,b) Survival curves resulting from lymphoreticular cancers (LR-T), as determined by histopathological analysis of tissues taken from deceased animals that had been irradiated (206 cGy) either with or without amifostine. LR-T includes histiocytic leukemia and lymphoma, lymphocytic–lymphoblastic leukemia and lymphoma, myelogenous leukemia, undifferentiated leukemia and lymphoma, and mixed histiocytic leukemia and lymphoma.

Genetic susceptibility to radiation-induced cancer

There is little evidence to suggest that genetic factors are involved in most human cancers, but they do appear to play a role in some rare hereditary disorders that may serve as models for radiation–genetic interactions. For example, patients with hereditary RB whose somatic cells are heterozygous for the *RB*

gene are at markedly increased risk for the development of radiation-induced bone sarcomas,⁸⁷ whereas patients with the nevoid basal cell carcinoma syndrome are at high risk for the development of basal cell cancers in irradiated areas. Radiation has also been associated with an enhanced incidence of early onset breast cancer. Transgenic mice heterozygous for either the p53⁸⁸ or ATM⁸⁹ tumor suppressor genes show an increased sensitivity to radiation-induced cancer; ATM and p53 heterozygosity are associated, respectively, with the human cancer-prone disorders ataxia telangiectasia and the Li–Fraumeni syndrome.

Human epidemiologic studies

There is now a large body of data on radiation-induced cancer derived from epidemiologic studies in irradiated human populations. They are derived primarily from two sources: (1) the long-term follow-up of survivors of the nuclear bombings of Hiroshima and Nagasaki^{90, 91} and (2) populations exposed to medical X-rays.^{92, 93} The results of these studies have yielded significant dose–response data for the induction of cancer in at least five tissue sites. Unfortunately, the epidemiologic studies yielding useful dose–response data generally involve relatively high-dose exposures (>10 cGy). Thus, risk estimates in the low-dose range must be derived from an extrapolation from the high-dose data. The shape of the dose–response relationship becomes of critical importance in making such extrapolations.

The observed dose–response curves from the human epidemiologic studies appear to be either linear or linear-quadratic in form (i.e., a linear component at low doses with a quadratic component at higher doses); although a threshold (dose below which there is no effect) cannot be formally excluded at very low doses.^{94, 95} A linear curve implies a constant risk per centigray at all doses, whereas the linear-quadratic model implies a smaller risk per centigray in the low-dose range. The assumption of a linear model simplifies the extrapolation from high to low doses and the corresponding estimation of risks. A final parameter of importance in determining the hazards of a given dose of radiation is the choice of risk models. For many years, risks were estimated on the basis of an absolute risk model. This model assumed that a specific number of excess cancers was induced by a given radiation dose. Radiation-induced cancers occurred in addition to the natural incidence. Increased risk could be expressed as the number of excess cancer cases (or cancer deaths) per 10⁶ exposed people per year per centigray (the rate per year) or as the total number of excess cancers per 10⁶ exposed people per centigray (the total risk or lifetime yield of cancers to be expected from a given radiation dose). The absolute risk model generally assumes a linear dose–response relationship, although with certain corrections it can be applied to a linear-quadratic relationship. Because the radiation exposure in Hiroshima included a small fraction of neutrons, the doses in the atom bomb survivor studies are expressed in Sieverts (Sv) rather than gray, a term that takes into account the RBE (relative biological effectiveness) of neutrons.

An analysis of the recent data from the atom bomb survivors suggests that some types of radiation-induced cancer more likely follow a relative-risk model.⁹⁰ The relative-risk model implies that radiation increases the natural incidence of cancer at all ages by a dose-dependent factor. As the excess cancer risk is proportional to the natural incidence, radiation-induced cancers would occur primarily at the times when natural tumors arose, independent of the age at irradiation. Thus, the largest cohort of radiation-induced cancers would occur in older individuals. The relative-risk model appears to fit the epidemiologic data for several solid tumors, although it does not appear to be valid for leukemia or bone and lung cancers. Risk estimates derived from the studies involving medical exposures are similar to those of the atom bomb survivors;^{93, 96, 97} differences in the case of high-dose radiation therapy exposures can be ascribed to cell killing and the effect of dose fractionation.⁹² A significantly reduced effect with fractionation for high-dose exposure was observed for lung cancer.⁹⁸ This was not the case for breast

cancer, although a reduced effect was associated with low dose-rate protracted exposure.⁹⁷

Radiation-induced secondary tumors

Radiation alone used in conventional treatment regimens may not be a very potent inducer of secondary tumors. This prediction arises from the localized nature of the exposure during clinical radiotherapy, in which the dose to normal tissues is minimized, and from the fact that ionizing radiation tends to be cytotoxic rather than mutagenic. The high radiation doses employed may thus kill potentially transformed cells in the treatment field. Exceptions may be the treatment of Hodgkin disease in which lower radiation doses are delivered to a relatively large volume of tissue, and in the use of intensity-modulated radiation therapy (IMRT). IMRT involves the use of more fields with a larger normal tissue volume exposed to lower doses.⁹⁹ It has been estimated that IMRT is likely to almost double the incidence of second malignancies compared with conventional radiotherapy from about 1% to 1.75% for patients surviving 10 years.¹⁰⁰ The risk may be even higher for pediatric patients.

Low-dose exposures

Sufficient data are now available from the atomic bomb survivors to allow an analysis of those survivors who received <0.5 Sv; these data are providing preliminary estimates of risk for doses as low as 5–10 cGy.⁹⁵ They indicate a statistically significant risk in this range consistent with a linear dose–response relationship, with an upper confidence limit on any possible threshold of 6 cGy.

A careful analysis of nearly all low-dose studies indicates no significant increase in the incidence of all cancers or of cancers at specific sites. Analyses of a large number of radiation workers from the United Kingdom¹⁰¹ and Canada¹⁰² indicate that the risk estimates for leukemia and all cancers were consistent with an extrapolation from the atom bomb survivor data, providing no evidence for an unexpected increase in sensitivity at low doses such as to suggest that the current radiation protection standards might be appreciably in error.

Acknowledgments

I acknowledge the support of research grant DE-FG02-05ER64086 from the US Department of Energy (DJG) and RO1 CA132998 from the National Cancer Institute (DJG).

Chapter 26

Ultraviolet radiation carcinogenesis

James E. Cleaver, PhD ■ Susana Ortiz-Urda, MD, PhD, MBA ■ Radhika Gulhar, BA ■ Sarah T. Arron, MD, PhD ■ Lionel Brookes, 3rd PhD ■ David L. Mitchell, PhD

Overview

Skin carcinogenesis from solar ultraviolet (UV) exposure is initiated by UV photoproducts formed in the DNA of precursor cells that give rise to squamous cell carcinomas, basal cell carcinomas, and melanomas. These photoproducts consist of dimers between adjacent pyrimidines that are repaired by nucleotide excision repair (NER). Two branches of NER differ in mechanisms of damage recognition: in global genome repair (GGR), damage is recognized in nontranscribed DNA by the DDB2 and XPC proteins; in transcription-coupled repair (TCR), damage is recognized by arrest of the transcribing RNA polymerase at damaged sites. The T = C photoproduct is the predominant mutagenic product which, if unrepaired, gives rise to C to T or CC to TT mutations through replication by the low-fidelity polymerase Pol H. TCR reduces the mutation frequency in regions of transcription, in comparison to the rest of the genome subject to GGR. Deficiencies in GGR in the human disease xeroderma pigmentosum cause earlier onset and increased rates of skin cancer, which often contain UV-type mutations in genes that are rarely mutated in the general population. Deficiencies in TCR in the human disease Cockayne syndrome are associated with photosensitivity, developmental, and neurological disorders, but no cancer has been reported.

Epidemiology of skin cancer

Skin cancer frequency and age of onset

NMSCs (nonmelanoma skin cancers) are the most common cancers that occur in the United States each year,^{1, 2} comprising 30–40% of all cancers and have been increasing steadily for a century.^{3, 4} Skin cancer risks are associated with geographical location, skin type, various photosensitizing, enhancing, and protective applications and vitamin D.^{4–10} There is also a possibility of greater risk when the exposure is received during childhood and adolescence.^{5, 11} NMSC is, therefore, one of the few human malignancies for which there is clear evidence for the initiating agent. The relationship of melanoma to sun exposure and the possible action spectrum are less clear,^{12, 13} but may be related to acute burns rather than accumulated dose.^{5, 14}

The importance of DNA as a target for ultraviolet radiation (UVR) is highlighted by the autosomal recessive disease XP (xeroderma pigmentosum). In this disease, a failure of DNA repair causes a large increase in NMSC and melanoma.^{12, 13} Median age for first diagnosis of NMSC in the general US population occurs after 60 years of age; in XP patients, carcinogenesis is accelerated and median age at first diagnosis is within the first decade ([Figure 1](#)).^{12, 13} Melanoma is also increased in XP patients, but the acceleration is less. Consequently, in XP patients, the onset of NMSC precedes melanoma, whereas in non-XP patients, melanomas generally occur earlier than NMSC.¹³

Figure 1 Diagnosis of first cancer by age and type in XP patients compared with the US general population. (a) Proportion of NMSC patients diagnosed at selected ages. (b) Proportion of melanoma patients diagnosed at selected ages. Individuals with both NMSC and melanoma were used in both panels. Ages shown are at the midpoint of each decade. XP: blue bars; general population: red bars. Colored arrows designate median ages of diagnosis for each population. The age span of Cockayne syndrome patients is also shown (orange): solid bar ends at mean age at death (12.25 years), with dashed line extending to maximum reported ages. XP and general population data redrawn from.²⁷ Cockayne data drawn from.²⁹

Sunlight spectrum and wavelengths responsible for skin cancer

UVR is divided into three wavelength ranges: UVA, UVB, and UVC. UVA (320–400 nm) is

photocarcinogenic and involved in photoaging, but it is weakly absorbed in DNA and protein and may involve reactive oxygen species, which secondarily cause damage to DNA.^{15–18} Recent evidence, however, suggests that UVA may also induce DNA damage directly in human cells.¹⁹ UVB (290–320 nm) overlaps the upper end of the DNA and protein absorption spectra and is the range mainly responsible for skin cancer through direct photochemical damage to DNA. UVC (240–290 nm) is not present in ambient sunlight but is readily produced by low-pressure mercury sterilizing lamps (254 nm). UVC coincides with the peak of DNA absorption (260 nm) and is extensively used in experimental studies. Absorption of UVR by stratospheric ozone greatly attenuates these wavelengths, so that negligible radiation shorter than 300 nm reaches the earth's surface. Hence, although UVA and UVB light constitute a minute portion of the emitted solar wavelengths (10^{-9}), they are primarily responsible for the sun's pathological effects.

Sunlight-induced photoproducts in DNA

The absorption spectrum of DNA correlates well with photoproduct formation, lethality, and mutation.^{20–24} The absorbed energy produces molecular changes, which involve single bases, interactions between adjacent and nonadjacent bases, and between DNA and proteins. The relative proportion of DNA photoproducts varies across the UV (ultraviolet) spectrum.

Dimerizations between adjacent pyrimidines are the most prevalent DNA photoproducts. Two major photoproducts are the cyclobutane pyrimidine dimer (CPD) and, at about 25% the frequency, the [6-4] pyrimidine dimer ([6-4]PD). [6-4]PDs cause a 47° helical bend in DNA, compared with 7° for CPDs. The [6-4]PD can further undergo a UVB-dependent conversion to its valence photoisomer, the Dewar pyrimidinone.²⁵

The distribution of photoproducts in chromatin depends on base sequence, secondary DNA structure, and DNA–protein interactions.^{24, 26, 27} Because cytosine more efficiently absorbs longer wavelengths of UVR than thymine, CPDs containing this base are formed more readily after UVB irradiation.²⁸ Cytosine CPDs and [6-4]PDs, which are preferentially induced at thymine–cytosine dipyrimidines, may play a major role in UVB (solar) mutagenesis.²⁹ Cytosine methylation increases the formation of CPDs by UVB, but not UVC, by 1.7-fold.³⁰ Methylation at PyrCG sequences in the p53 gene enhances formation of CPDs and [6-4]PDs at sites that are hotspots for mutations.^{31, 32} Other less common lesions include purine–purine and purine–pyrimidine photoadducts, photohydrates, and photooxidations.³³ The total yield of these photoproducts is only 3–4% of the yield of CPDs, but a minor biological role as premutagenic lesions at specific sites cannot be excluded.

Genetic factors in skin carcinogenesis

Recognition of UV photoproducts in DNA

The repair of UV photoproducts in DNA [nucleotide excision repair (NER)] involves sequential steps of photoproduct recognition, assembly of the excision complex, displacement of the excised fragment, and polymerization of the replacement patch.³⁴ The importance of NER arose from the discovery that cells from patients suffering from XP were deficient in NER.^{35, 36} Two major pathways of NER are known ([Figure 2](#)): transcription-coupled repair (TCR) and global genome repair (GGR), which differ in their mechanisms of damage recognition.^{34, 37–39} TCR removes damage more rapidly from the transcribed strands of transcriptionally active genes, whereas GGR acts more slowly on nontranscribed regions.^{40, 41} The half-life of [6-4]PDs is 2–6 h, whereas for CPDs, it is 12–24 h, and much longer in rodent cells.^{42, 43}

Figure 2 Biochemical steps for nucleotide excision repair of CPDs and [6-4]PDs by global genome repair or transcription-coupled repair. Initial recognition of damage by GGR involves the DDB2 and XPC gene products; initial recognition by TCR involves RNA polymerase II arrest and disengagement of the transcription complex from damage by CSA, CSB, and UVSSA. Subsequent steps involve XPA and RPA that bind to photoproducts and download the helicases XPB and XPD for local unwinding. Excision occurs when UV-specific endonucleases (XPF/ERCC1 and XPG) make incisions on the 5' and 3' sides. Excision and subsequent polymerization releases a 29 base oligonucleotide containing the CPD and activates the cryptic XPG endonuclease for the final cut.

GGR involves initial binding by the DDB1/DDB2(XPE) complex,^{44, 45} followed by recruitment of XPC/HR23B/centrin via ubiquitylation by the E3 ligase activity of DDB1/DDB2.^{46–49} The XPC protein binds to the undamaged strand opposite a PD, inserting a peptide chain within the helix to displace the dimer to an extra-helical position.^{50, 51}

TCR is initiated by the arrest of RNA polymerase II at a damaged base, after which specific TCR factors CSA, CSB, UVSSA, and XABP, a binding partner of XPA, facilitate removal or degradation of arrested RNA polymerase II to permit access of NER proteins to damaged sites.^{52, 53} TCR is closely involved with the chromatin remodeling function of CSB that is a member of the SWI2/SNF2 chromatin remodeling protein family.^{54, 55} RNA polymerase II elongation is associated with cycles of ubiquitylation and deubiquitylation of histone H2B (H2Bub); arrest by UV damage tips the balance toward deubiquitylation and acetylation of histone H3.⁵⁶ Transcription is restored along with H2Bub after excision of the arresting photoproducts.⁵⁶

The mechanism of nucleotide excision repair

Subsequent to damage recognition, the open helix is stabilized by XPA/RPA, which binds with a higher affinity for the [6-4]PDs than CPDs and interacts with the unwinding activity of the 10 component transcription factor TFIIH, and the 3'–5' (XPB) and 5'–3' (XPD) nucleases.^{57, 58} The opened helix is cleaved first by the ERCC1/XPF nuclease presenting a 3'OH terminus for chain elongation by the DNA Pol D, proliferating cell nuclear antigen, and single-strand binding protein.^{59, 60} XPG is a cryptic nuclease that cuts 3' to the lesion after the ERCC1/XPF nuclease has cut 5' to the CPD and polymerization.⁶⁰ A 27–29nt oligonucleotide containing the photoproduct is subsequently released and the patch is sealed by ligase I.⁶¹

Mutagenicity of UV photoproducts and low-fidelity DNA polymerases

Most photoproducts act as blocks to the replicative class B polymerases, Pol A, D, and E, but can be bypassed by damage-specific class Y DNA polymerases.^{62–64} The class Y polymerases, Pol H, I, and K, have low fidelity due to expanded active sites, which allow the polymerases to read-through noninformative sequence information.⁶⁵ Pol H has the greatest capacity to replicate a large variety of DNA lesions,⁶⁶ and preferentially inserts adenine in the nascent strand opposite the lesion (called the "A rule").⁶⁷ Hence, Pol H replicates a thymine-containing CPD faithfully.^{68–71} Pol I preferentially inserts guanines and is capable of replicating C-containing photoproducts.^{72, 73} Pol H or I, therefore, can insert bases opposite dipyrimidine photoproducts, but the 3' complementary base can be mismatched by an erroneous insertion or the distortion caused by the photoproduct. Pol K or Pol Z can complete the replicative bypass by extension from the mismatched 3' terminus.^{74–76} The absence of Pol H results in increased mutagenesis in the XPV group,^{77, 78} but the absence of Pol Z has the converse effect of reducing mutation rates.⁷⁹

The replication by-pass mechanism has two important implications for UV mutagenicity. First, mutations will most often occur where cytosine is a component of the photoproduct as insertion of adenine opposite thymine is a correct and nonmutagenic event. Hence, CPDs that form between two thymine bases are not mutagenic. Second, the larger distortion of [6-4]PDs is more likely to be lethal than mutagenic.

Diseases of DNA repair

Xeroderma pigmentosum

XP is a rare autosomal recessive disease that occurs at a frequency of about 1 : 250,000 in the United States.¹² Affected patients (homozygotes) have sun sensitivity resulting in progressive degenerative changes of sun-exposed portions of the skin and eyes, often leading to neoplasia. Some XP patients also

have progressive neurologic degeneration. Obligate heterozygotes (parents) are asymptomatic. The median age of onset of symptoms is 1–2 years of age and the median age of first diagnosis of NMSC is 9 years of age (Figure 1).^{12, 13} The skin rapidly takes on the appearance of that seen in individuals with many years of sun exposure. Pigmentation is patchy, and skin shows atrophy and telangiectasia with development of NMSC and melanoma. The frequency of NMSC is about 2000 times that seen in the general population <20 years of age, with an approximate 30-year reduction in lifespan. Some patients develop myelodysplasia and leukemia in later life.

Among patients who are deficient in NER, there are eight complementation groups that correspond to components of NER, XPA through G and the exceedingly rare ERCC1.⁸⁰ An additional group, the XP variant, has mutations in the low-fidelity polymerase Pol H (Table 1). UV-damaged plasmids passaged through XP cells show increased mutagenesis due to defective repair of CPDs and nondimer photoproducts.⁸¹ Carcinogenesis from UV damage in XP patients arises, therefore, from the loss of either NER capacity or Pol H; both lead to an increase in the amount of persistent genetic damage (mutations, gene rearrangements, deletions, and genomic instability).

Table 1 Genes involved in repair of UV damage in humans.^d

Group (gene)	Chromosome location	Central nervous system and developmental disorders	Relative DNA repair (%) ^a
<i>Xeroderma pigmentosum</i>			
A	9q34.1	Yes	2–5
B ^b	2q21	Yes	3–7
C	3q25	No	5–20
D ^b	19q13.2	Yes	25–50
E	11p11-12	No	50
F	16q13.1	No	18
G	13q32.3	Yes	<2
V (pol H)	6p21	No	100
ERCC1 ^c	19q13.32	Yes	15
<i>Cockayne syndrome</i>			
A (ERCC8)	5q12.1	Yes	100 ^a
B (ERCC6)	10q11.23	Yes	100 ^a
UVSSA	4p16.3	No	100 ^a

^a Measurement of relative DNA repair represent mainly global genome repair. Cockayne syndrome is defective in transcription-coupled repair and has normal levels of global genome repair.

^b Patients also exhibit symptoms commonly associated with Cockayne syndrome: dwarfism, cutaneous features, and mental retardation. Group B is designated ERCC3 and Group D is designated ERCC2, F is designated ERCC4, and G is designated ERCC5. Some patients also have symptoms of trichothiodystrophy.

^c ERCC1 is rare and causes a neonatal fatal disorder, cerebro-oculo-facio-skeletal syndrome.

^d Further details can be found in the web sites <http://www.photobiology.info/> and http://www.cgal.icnet.uk/DNA_Repair_Genes.html.

Cockayne syndrome

CS (Cockayne syndrome) is an autosomal recessive disease characterized by photosensitivity, cachectic dwarfism, retinal abnormalities, microcephaly, deafness, neural defects, and retardation of growth and development after birth.^{82, 83} A major symptom is cerebellar degeneration and Purkinje cell loss causing difficulties in walking and balance.⁸⁴ Solar carcinogenesis is not seen in patients with CS, setting this disease apart from XP, even though their lifespan encompasses ages at which skin cancers are seen in XP ([Figure 1](#)).⁸² Mutations in either of two genes, *CSA* and *CSB*, are associated with CS.^{83, 85} Similar symptoms occur in XP groups B, D, and G.⁸⁶ The CS proteins facilitate removal of RNA polymerase II from damaged sites permitting access for the NER machinery ([Figure 2](#)). An additional gene product UVSSA also contributes to TCR, but mutations in the *UVSSA* gene only give rise to mild photosensitivity.^{87, 88}

CSA and *CSB* proteins also contribute to the redox balance of cells by interaction with oxidative phosphorylation in the mitochondria and mitophagy.⁸⁹ Conceivably, their mitochondrial role may be more important in the developmental and neurological pathology of CS than their nuclear TCR function.⁹⁰

Trichothiodystrophy

TTD (trichothiodystrophy) is a rare autosomal recessive disorder characterized by sulfur-deficient brittle hair that splits longitudinally into small fibers and ichthyosis. The levels of cysteine/cystine in hair proteins are 15–50% of those in normal individuals. Patients show physical and mental retardation of varying severity and often have an unusual facial appearance, with protruding ears and a receding chin. Mental abilities range from low normal to severe retardation.⁹¹ Several categories of the disease can be recognized on the basis of UV sensitivity and DNA repair deficiencies.^{92, 93} The most severe cases with repair deficiencies have mutations in *XPB* and *XPD*.⁹² Several other TTD genes are known that are not involved in DNA repair.

Mutations in *XPD* that give rise to XP symptoms correspond to mis-sense mutations in the DNA helicase motifs, whereas those that give rise to TTD are mis-sense mutations in the RNA helicase motifs and the C-terminal end of the protein.⁹⁴ Some TTD cases do not have mutations in *XPB* or *XPD* and are due to mutations in a small 8-kDa component of TFIIH that appears to regulate the overall level of the transcription factor.⁹⁵

Carcinogenesis

Mutations and skin cancer types

Loeb was the first to recognize the high frequency of mutations in cancer cells and invoked the concept of a mutator phenotype.⁹⁶ In triple-negative breast cancer, for example, the mutation frequency is 13.3 times that of the normal rate of 0.6 mutations per cell division.⁹⁷ NMSC and melanoma have among the highest mutation frequencies, most of which are C to T or CC to TT transitions resulting from sun exposure.^{98, 99} The frequency of mutations in normal and cancer genomes is reduced in transcribed regions, compared with the rest of the genome, and shows the strand bias of TCR.^{97, 98, 100} Patients with reduced TCR, that is, CS patients, should therefore have higher frequencies of mutations in transcribed regions of the genome and hence more cancers. But they do not, unlike Cs-a or Cs-b mice that do develop skin cancer from carcinogen exposure.¹⁰¹ Mutant cells in CS must, therefore, be prevented or delayed from progressing to

cancers.

Nonmelanoma skin cancer

SCCs and BCCs both have UV-type mutations in genes that drive development of these tumors. Actinic keratoses, precursors to SCCs, share many mutational spectrum and global gene expression profiles.^{102–104} The initiating molecular changes in SCC are UV-type mutations in p53 that result in expanding clones in the sun-exposed areas of the skin that are initially confined within the proliferating units.¹⁰⁵ In normal skin, 50% of SCCs have p53 mutations; in XP patients, the frequency is 90%.^{106–110} Loss of p53 function causes genomic instability during DNA replication when subjected to further UV irradiation.^{111–113} Many of these are likely passenger mutations that do not confer a growth advantage; mutated p53 being the more potent driver of SCC.

SCC mutations have been identified in Notch, *KNSTRN*, a kinetochore gene, *EGF*, *RAS*, *NFkb*, *JNK2*, and *MMP9*.^{114–118} Activating mutations in *H-RAS* and *N-RAS* oncogenes at codon 61 have been associated with solar UV exposure even though they involve transversions at a TT site.^{119–122}

BCCs and BCNS involve the Sonic Hedgehog pathway in which a transmembrane receptor, Patched (PTC), and the membrane protein, Smoothened (SMO), regulate signal transduction by the extracellular protein Hedgehog (HH) that binds to PTC.¹²³ In the general population, most UV-type BCC mutations are in the *PTC* gene or less frequently *SMO*, and rarely *HH*.^{109, 124–126} In XP patients, however, a significant number of mutations occur in *SMO* and *HH*.^{127, 128}

Melanoma

Melanomas involve a series of mutations, deletions, and amplifications (copy number changes) along the MAP kinase pathway, a phosphorylation cascade that regulates cell proliferations and differentiation.^{129–135} ([Figure 3](#)). A common mutation occurs in *BRAF* (V600E), but this sequence change is not a UV type.^{137, 136} In contrast, 10 of 11 mutations in *BRAF* from XP melanomas were UV type and different from V600E.¹³⁶ Mutations of UV type have been identified in the promoter region of hTERT resulting in gene activation.^{138, 139} In addition to point mutations, melanomas have a significant frequency of translocations involving protein kinases.¹⁴⁰ Nevi and melanomas in XP patients are generally lentiginous and have a high incidence (53–61%) of UV-type inactivating mutations in *PTEN*.¹³⁶ These frequencies are much higher than those in *BRAF*, *NRAS*, and *KIT*, unlike the general population where *PTEN* mutations are lower.

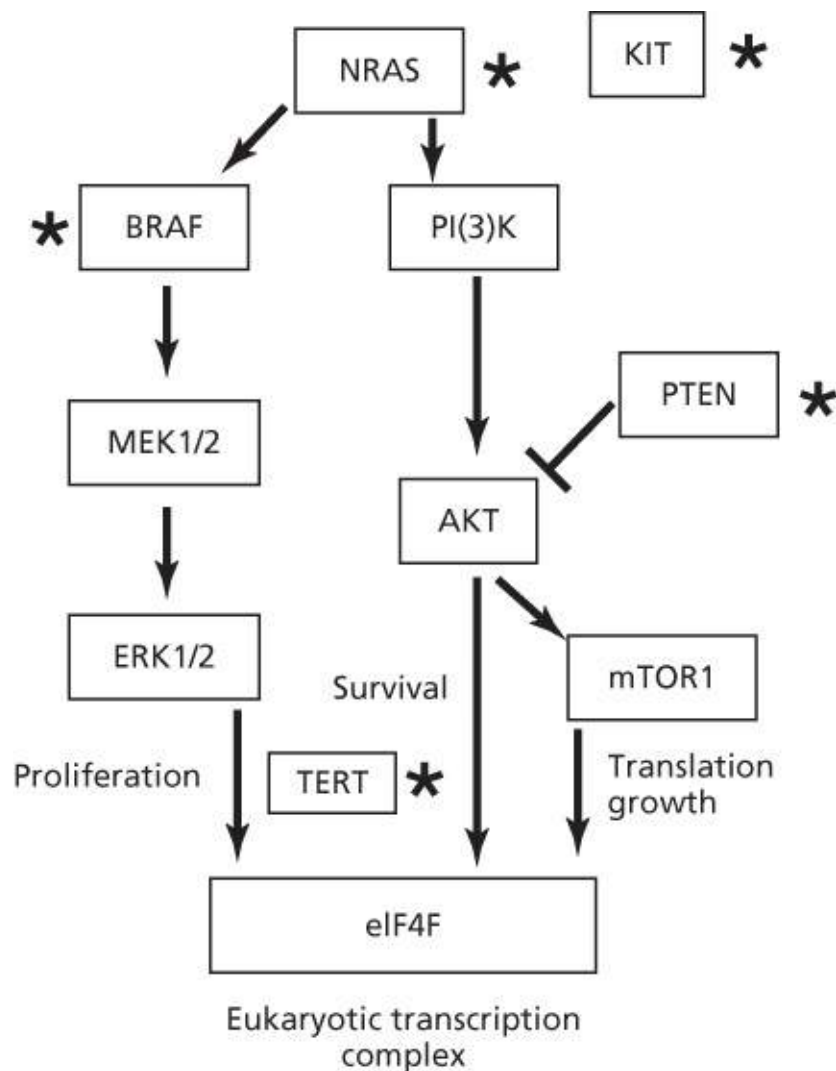

Figure 3 Pathways involved in melanoma. Proteins mutated by UV light in XP patients or the general population are designated by a star. Mutations in TERT are UV type but have yet to be reported in XP patients. Note the common *BRAF* melanoma mutation V600E is not induced by UV as it does not occur at a dipyrimidine site, but other mutations are formed by UV light in *BRAF*.¹³⁶ The most common mutated gene in XP patients is *PTEN*, in contrast to the MAPK pathway in the general population.¹³⁶

Summary

Skin tumors in man account for about 30% of all new cancers reported annually.^{141, 1} Epidemiological and laboratory studies provide evidence for a direct causal role of sunlight exposure in the induction of most forms of skin cancer,^{142, 5} and the high rate of skin carcinogenesis is a direct result of the high dose rate from the UV light component. Nonmelanoma skin cancers (NMSCs, basal cell, and squamous cell carcinomas) and melanomas are found on sun-exposed parts of the body (e.g., the face and trunk in men, face and legs in women), and their incidence is correlated with cumulative or acute sunlight exposure. Tumor incidence and mortality increases with occupational exposure, such as in ranchers fishermen and even flight crew members.^{6, 143–145} There

is also an increased risk of melanoma for people using tanning parlors,^{145, 146} PUVA or UVA therapy,¹⁴⁷ or sildenafil (Viagra).¹⁴⁸ The use of sunscreens can also contribute to melanoma if their use results in persons staying in the sun for increased times.¹⁴⁹ Melanomas are additionally found on protected sites, so other factors contribute to the incidence as well as sun exposure.^{12, 150, 151}

Human skin can be classified into types I–IV, ranging from individuals who always burn and never tan, to those who tan but never burn; skin cancer susceptibility varies accordingly.¹⁵² The most dramatic examples of variations in human susceptibility to sunburn and skin cancer are the human genetic disorders: XP, CS, TTD, basal cell nevus syndrome (BCNS), the porphyrias, albinism, and phenylketonuria.¹² XP, CS, and TTD involve genes with major roles in repair of UV damage to DNA. Other disorders associated with acquired sun sensitivity include polymorphous light eruption, actinic reticuloid and prurigo, solar urticaria, lupus erythematosus, and Darier's disease as well as medication and immunological status. Sunlight exposure can have an immunosuppressive effect leading to loss of antigen-presenting Langerhans cells and the appearance of dyskeratotic keratinocytes (apoptotic sunburn cells) in the upper epidermis. The erythematous response is also associated with vasodilation caused by a release of prostaglandins.¹⁵³ Immunosuppression in organ transplant and HIV patients also increases skin cancer incidence.¹⁵⁴

Chapter 27

Inflammation and cancer

Jelena Todoric, MD, PhD ■ Atsushi Umemura, MD, PhD ■ Koji Taniguchi, MD, PhD ■ Michael Karin, PhD

Overview

Epidemiological studies and experimental evidence have provided strong support to the long standing notion that chronic inflammation stimulates the development and progression of malignant neoplasms. It is now clear that pre-existing inflammation caused by persistent viral and microbial infections, autoimmune diseases, environmental irritants, and even obesity promote tumor development and may account for up to 20% of all cancer deaths. Inflammation also appears subsequent to cancer development and such “tumor-elicited inflammation” plays a key role in the malignant progression and metastatic dissemination of most cancers. Although some common anti-inflammatory drugs, such as aspirin, substantially reduce cancer risk, there is still an unmet need for the clinical development of new therapeutics that target cancer-associated inflammation.

Chronic inflammation and cancer

A potential link between inflammation and cancer was first proposed by the German pathologist, Rudolf Virchow, in the nineteenth century. Virchow supposedly detected immune cell infiltrates in solid tumors, leading him to suggest that inflammation could be a cause of tumorigenesis. Although largely forgotten for more than a century, the interest in the link between inflammation and cancer was rekindled by epidemiological studies suggesting that underlying chronic inflammation is associated with nearly 20% of cancer deaths. More recently, solid evidence has accumulated pointing to inflammation as a critical hallmark of cancer, and some of the key underlying molecular mechanisms were elucidated.¹ Furthermore, it has become clear that an inflammatory microenvironment is an important component of most cancers, including some hematopoietic malignancies, even in tumors where a direct causal relationship is yet to be established.² Notably, only 10% of all cancers are linked to germ line mutations, whereas the vast majority (90%) are caused by acquired somatic mutations, many of which may be caused by environmental factors that are often associated with chronic inflammation. However, in most cases, chronic inflammation caused by persistent infections ([Table 1](#)) and autoimmune disease acts as a tumor promoter.³ One of the most notable examples is inflammatory bowel disease (IBD), such as ulcerative colitis, which greatly increases the risk of colorectal cancer (CRC).³ Similarly, persistent *Helicobacter pylori* infection causes chronic gastritis and can lead to gastric cancer. Infections with hepatitis B virus (HBV) or hepatitis C virus (HCV) give rise to hepatitis (chronic liver inflammation), eventually culminating in liver cancer (hepatocellular carcinoma or HCC). About 85% of the current HCC cases, one of the leading causes of cancer death worldwide, are derived from chronic liver damage caused by either HBV or HCV infections.

Table 1 Major cancer sites and types associated with infectious agents

Infectious agent	Cancer site and type
<i>Helicobacter pylori</i>	Gastric cancer
Hepatitis B viurs (HBV), hepatitis C virus (HCV)	Liver cancer
<i>Human papillomavirus (HPV)</i>	Cervical cancer; anogenital cancer; oropharynx cancer
Epstein–Barr virus (EBV)	Nasopharynx cancer
<i>Schistosoma haematobium</i>	Bladder cancer
Human immunodeficiency virus (HIV)	Non-Hodgkin lymphoma; Kaposi sarcoma; cervical cancer

As of 2008, around 16% of cancer cases worldwide are attributed to infectious agents. The most important players are *Helicobacter pylori*, HBV and HCV, and HPV.

In the past generation, obesity has become a major public health problem in most developed countries, increasing the risk of various diseases, including cancer. Obesity induces low-grade, sustained inflammation that influences many organ systems and is currently one of the most common risk factors for almost all types of cancer. Inversely, long-term use of anti-inflammatory drugs, such as aspirin or selective cyclooxygenase-2 (COX-2) inhibitors, results in a substantial reduction in the risk of cancer development. These results further underscore the importance of inflammation as one of the major causes of cancer and a driver of malignant progression and metastatic dissemination.

It is important to note that only in some types of cancer is chronic inflammation present before malignant transformation or tumor initiation, but in the majority of cancers, oncogenic and neoplastic changes induce a localized inflammatory microenvironment that further enhances tumor development and progression. Understanding the links between inflammation and cancer is essential for the development of better preventative and therapeutic strategies.

Inflammatory cells, the microenvironment, and cancer

Macrophages

Macrophages are the most abundant immune cells in the tumor microenviroment. Tumor-associated macrophages (TAMs) aquire protumorigenic properties in both primary and metastatic sites⁴ and play several supportive roles in cancer development and progression. The tumor-promoting functions of TAMs affect cancer cell proliferation and survival, angiogenesis, cancer cell invasion, motility, intravasation and extravasation, as well as suppression of cytotoxic T-cell responses.^{5, 6} During tumor initiation/early promotion, TAMs secrete cytokines and growth factors that stimulate the proliferation and survival of initiated epithelial cells bearing oncogenic mutations.⁷ It is not clear whether, at this early stage of tumor development, macrophages can eliminate abberant cells before they undergo polarization to acquire tumor-promoting properties. Two major subsets of macrophages were described: classically activated (M1) and alternatively activated (M2).⁸ M1 macrophages express and secrete a variety of proinflammatory cytokines, chemokines, and effector molecules, including IL-12, IL-23, tumor necerosis factor (TNF), and iNOS, whereas M2 macrophages release anti-inflammatory mediators, such as IL-10, TGF- β , and arginase-1. During early tumor progression, several factors cause a phenotypic switch in

TAM polarization to the M2 phenotype, thereby providing an immunosuppressive microenvironment that is permissive for tumor growth. Exposure of macrophages to IL-4 produced by CD4⁺ T cells and/or cancer cells,^{5,9} growth factors such as colony-stimulating factor-1 (CSF1),¹⁰ GM-CSF,¹¹ and TGF- β secreted by cancer cells induces the tumor-promoting M2 phenotype, but the actual origin of TAMs is still a matter of debate. Most TAMs may be derived from Ly6C⁺ circulating monocytes,^{12–14} but the classical view of the bone marrow (BM) as the major site of monocyte production has been challenged by recent studies suggesting that extramedullary hematopoiesis sustains a reservoir of tumor-infiltrating monocytes.¹⁵ However, lineage tracing experiments demonstrated that the splenic contribution is minor and that the BM is still the major source of monocytes that give rise to TAMs, at least in some tumor models.¹⁶ In addition to its ability to support TAM proliferation and activation, CSF1 is the major lineage regulator and a chemotactic factor for macrophages.¹⁷ Blood vessels that provide oxygenation and nutrition dramatically increase in most tumors during malignant conversion, a process often referred to as the “angiogenic switch.” TAMs that express TIE2 regulate this process mostly via production of vascular endothelial growth factor (VEGF).¹⁸ TIE2⁺ macrophages also promote cancer cell migration and intravasation into the circulation.¹⁹ Furthermore, immunosuppression in the tumor bed is partially mediated by macrophages that contribute to the inhibition of cytotoxic CD8⁺ cells, which are discussed further in the following sections ([Table 1](#)).

T and B lymphocytes

Many tumors express antigens that can be recognized by T lymphocytes, and analysis of the tumor microenvironment in a variety of solid tumors has revealed the presence of T-cell infiltrates. However, despite an active immune response in a subset of patients, including infiltration with cytotoxic CD8⁺ T cells, tumors that progress are obviously not rejected. This indicates the existence of immunosuppressive mechanisms that counteract anticancer immunity. One such mechanism depends on accumulation of CD4⁺Foxp3⁺ regulatory T cells (Treg) that play a pivotal role in maintenance of immunological self-tolerance.²¹ Furthermore, Treg can also produce cytokines, such as RANK ligand (RANKL) that promote tumor progression, as first demonstrated in breast cancer.²² The CD8⁺ T-cell response in tumors involves the participation of stress-associated or damage-associated molecular patterns (DAMP), through which tissue injury or cancer cell death can promote immunity. Production of type I interferon by CD8 α ⁺ dendritic cells (DCs) also favors the activation of anticancer immunity.²³ DCs and macrophages express Major histocompatibility complex (MHC) class I molecules that present antigens to cytotoxic CD8⁺ T cells. However, macrophages that express membrane-bound or soluble forms of histocompatibility leukocyte antigen (HLA) molecules can directly inhibit activation of natural killer (NK) cells and other T-cell subsets.²⁴ In addition, HLA-G and HLA-E can inhibit NK-cell secretion of Interferon IFN- γ , an important mediator of CD8⁺ T-cell activation.²⁵ Activation of the inhibitory receptors programmed cell death protein 1 (PD-1) and cytotoxic T lymphocyte antigen 4 (CTLA-4) by ligands that are expressed on either cancer cells or immune cells controls the intensity of immune response and inhibits T-cell receptor (TCR) and B-cell receptor (BCR) signaling.²⁶ TAMs have been shown to upregulate PD-1 ligand expression in response to hypoxia inducible factor 1 α (HIF-1 α) in hypoxic tumor regions, leading to T-cell suppression.²⁷ Furthermore, TAMs secrete a variety of cytokines and chemokines that can directly suppress T-cell activation and recruit immunosuppressive Treg cells. Th17 cells are T cells that produce the inflammatory cytokines IL-17A and IL-17F. These cells are recruited into early colon cancers and play an important role in accelerating tumor progression.²⁸ B lymphocytes are also present in the tumor microenvironment. In mouse models of skin cancer or squamous cell carcinoma, B cells promote tumor

progression by activating cells and other myeloid cells.^{29, 30} In prostate cancer, newly recruited B cells promote the development of aggressive castration-resistant tumors by producing the proinflammatory cytokine lymphotoxin.³¹ Tumor-infiltrating B cells can also respond to the high local concentration of TGF- β present within certain tumors and assume an immunosuppressive phenotype that prevents the activation of cytotoxic T cells.

Cancer-associated fibroblasts (CAFs)

CAFs are fibroblastic cells that reside within the tumor microenvironment. CAFs promote tumorigenesis by stimulating cancer cell proliferation, enhancing angiogenesis, and modifying the architecture of the extracellular matrix (ECM).^{32–37} In normal tissues, fibroblasts prevent initiation of neoplastic growth through negative regulation of epithelial proliferation by TGF- β -mediated signaling. In contrast, CAFs show proinflammatory and tumor-promoting properties³⁸ and produce a wide variety of chemokines and cytokines including osteopontin (OPN), CXCL1, CXCL2, IL-6, IL1- β , CCL-5, stromal-derived factor (SDF-1 α), and TNF.^{39, 40} In early stages of the tumorigenic process, fibroblasts “sense” changes in tissue architecture that result from increased proliferation of neighboring epithelial cells. This results in activation of proinflammatory signaling in fibroblasts.^{41–43} Furthermore, the proinflammatory properties of CAFs are enhanced by mediators secreted by resident immune cells.⁴⁰ For example, B cells produce antibodies that are deposited in the tumor bed owing to small amounts of blood seeping out of leaky blood vessels and can induce secretion of IL-1 by resident immune cells. This in turn drives fibroblasts into a proinflammatory phenotype.^{44, 45} CAFs can also be affected by tumor hypoxia, which upregulates their ability to produce TGF- β and certain chemokines.⁴⁶ The major mechanism of tumor promotion by CAFs involves secretion of cytokines and chemokines that recruit immune cells into the tumor microenvironment and alter their function. For example, CAF-secreted CCL2 recruits macrophages to the tumor, whereas CAF-derived immunosuppressive cytokine TGF- β inhibits the function of NK and CD8⁺ T cells⁴⁷ while inducing differentiation of Treg cells.⁴⁸ CAF-derived CXCL13 mediates recruitment of B cells into androgen-deprived prostate cancer, leading to development of castration resistance.⁴⁶

Pro- and anti-inflammatory cytokines in cancer

Cytokines are small proteins produced and released by many types of cells, especially immune cells, and function as mediators of cell–cell communication via specific membrane receptors.⁷ Cytokines are usually induced in response to inflammation and provide an important link between inflammation and cancer through cancer-intrinsic (cancer cell proliferation, survival, and invasive properties) and cancer-extrinsic (tumor microenvironment) effects ([Figure 1](#)).⁴⁹ TNF and IL-6 are the best-studied protumorigenic cytokines linking inflammation to cancer and are overexpressed in most cancers ([Table 2](#)).⁵⁰ Several transcription factors, NF- κ B, signal transducer and activator of transcription 3 (STAT3), and AP-1, are the major downstream effectors of cytokine signaling and are activated in the majority of cancers, where they cooperate to regulate many cancer-related pathophysiological processes, including cell proliferation and survival, differentiation, immunity, metabolism, and metastatic behavior.⁵¹

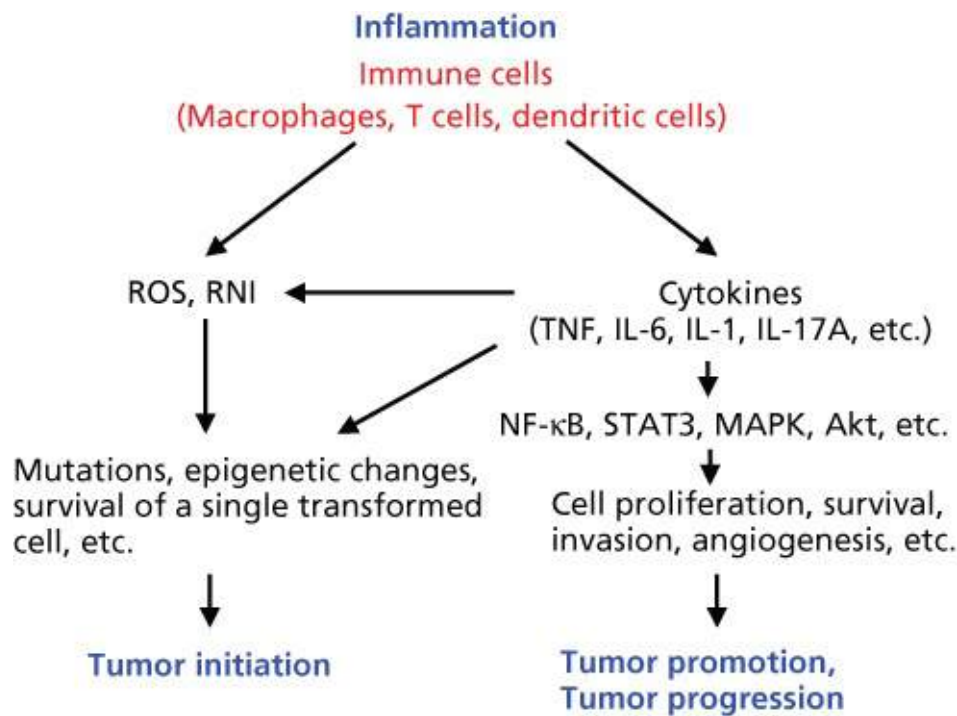

Figure 1 The role of inflammation in tumor initiation, promotion, and progression.

Table 2 Cytokines in inflammation and cancer

Cytokine	Functions in cancer and immune cells	Pathways
TNF	Proinflammatory, cell survival or death	NF-κB, MAPK
IL-6	Proinflammatory, cell proliferation and survival	JAK/STAT3, ERK, Akt
IL-11	Tissue-protective, cell proliferation and survival	JAK/STAT3, ERK, Akt
IL-1	Proinflammatory, activates immune cells	NF-κB, MAPK
IL-17A	Proinflammatory, increases inflammation	NF-κB, MAPK
IL-12	Proinflammatory, Th1 differentiation	JAK/STAT4
IL-23	Proinflammatory, Th17 differentiation	JAK/STAT3, STAT4
IL-10	Anti-inflammatory, inhibits NF-κB	JAK/STAT3
IL-22	Tissue-protective, cell proliferation and survival	JAK/STAT3
TGF-β	Anti-inflammatory, dual role in tumorigenesis	Smad, MAPK

Tumor necrosis factor

TNF is the founding member of a large cytokine family and major activator of inflammatory and immune responses to a variety of pathogens.^{52, 53} TNF is an important mediator of cachexia and several acute and chronic inflammatory diseases, such as sepsis, rheumatoid arthritis (RA), and IBD. TNF is mainly produced by macrophages, which are activated by pathogen-associated molecular patterns (PAMPs), such as lipopolysaccharide (LPS), via toll-like receptors (TLRs). TNF activates several signaling pathways by binding to TNF receptor (TNFR)1 and/or TNFR2. Activation of these pathways induces production of other inflammatory cytokines, such as IL-6 and IL-1 and, depending on cellular context, modulates cell survival and death. Elevated TNF expression promotes tumorigenesis and metastasis at multiple steps, including cellular transformation, survival, proliferation, invasion, and angiogenesis.^{52, 53} TNF-induced NF-κB activation enhances β-catenin activation, which leads to dedifferentiation of non-stem cells that

acquire tumor-initiating capacity in a mouse model of colorectal cancer.⁵⁴ Several TNF inhibitors are clinically available and are approved for the treatment of RA and IBD. Although high doses of TNF have been used in the treatment of sarcomas of the extremities, localized production of TNF is associated with tumor promotion.

The IL-6 family of cytokines

IL-6 is another proinflammatory cytokine that activates the acute phase response characterized by expression of C-reactive protein (CRP) and serum amyloid A (SAA).⁵⁵ IL-6 is also a mediator of cancer cachexia and is one of the best-characterized protumorigenic cytokines.^{56, 57} The IL-6 family also includes IL-11, IL-27, IL-31, leukemia inhibitory factor (LIF), oncostatin M (OSM), ciliary neurotrophic factor (CNTF), cardiotrophin-1 (CT-1), and cardiotrophin-like cytokine (CLC), all of which control cell proliferation, survival, migration, invasion, metastasis, angiogenesis, and inflammation. IL-6 family members activate the Janus kinase (JAK)-STAT3 pathway, the Src homology 2 (SH2)-containing protein tyrosine phosphatase-2 (SHP-2)-Ras-Raf-MEK-extracellular signal-regulated kinase (ERK) pathway, and the phosphoinositide 3-kinase (PI3K)-Akt-mammalian target of rapamycin (mTOR) pathway through engagement of their unique receptor(s) that associate with the common signaling subunit gp130. Among these effectors, STAT3 is considered an oncogene and a major downstream mediator of gp130 signaling in cancer.^{58, 59} IL-6 and IL-11 are produced by many different types of cells, including immune cells, fibroblasts, and epithelial cells, and IL-6, IL-11, and STAT3 are highly expressed in many solid tumors. A recent report described IL-11 as the dominant IL-6 family member during gastrointestinal (GI) tumorigenesis in mice.⁶⁰ IL-6 antagonists have been approved for the treatment of RA and related diseases but need to be further evaluated in cancer.

Interleukin 1

IL-1 is another major proinflammatory and protumorigenic cytokine produced by a variety of cell types.⁶¹ IL-1 induces fever and plays an important role in sepsis. There are two isoforms of IL-1: IL-1 α and IL-1 β , both of which activate NF- κ B, JNK, p38, and ERK via IL-1 receptor (IL-1R) and can induce expression of other cytokines. IL-1 α and IL-1 β have similar functions although they are only 26% similar at the protein level. Several IL-1 antagonists have been developed and are used for the treatment of auto-inflammatory conditions. These inhibitors also need to be tested for efficacy in cancer.

Interleukin 17A

IL-17A is a member of the IL-17 family and is mainly produced by IL-17-producing T-helper (Th17) cells, $\gamma\delta$ T cells, and innate lymphoid cells (ILCs).^{62, 63} IL-17A normally provides protection against extracellular bacteria and fungi and is associated with autoimmune diseases, such as psoriasis. IL-17A activates NF- κ B, JNK, p38, and ERK via IL-17 receptor A (IL-17RA) in many cell types and promotes tumorigenesis, metastasis, angiogenesis, and chemotherapy resistance.⁶⁴ IL-17A induces production of many proinflammatory cytokines, including TNF, IL-6, and IL-1 β , suggesting an important role of IL-17A in amplifying inflammation. IL-17A also signals within transformed enterocytes and promotes growth and progression of aberrant crypt foci in a mouse model of colorectal cancer.⁶⁴

IL-12 and IL-23

IL-12 and IL-23 are related heterodimeric proinflammatory cytokines that share a p40 subunit, whose receptors contain a common IL-12 receptor (IL-12R) β 1 subunit.⁶⁵ They are mainly produced by antigen-

presenting cells and are key players in the regulation of T-cell responses. IL-12 stimulates the development of Th1 cells (typically antitumorigenic) that produce IFN- γ , whereas IL-23 promotes the development of Th17 cells (often protumorigenic) together with IL-6 and TGF- β .

IL-10 and IL-22

IL-10, the founding member of the IL-10 family, is an anti-inflammatory cytokine that activates the JAK-STAT3 pathway via IL-10 receptor 1 (IL-10R1), which is mainly expressed in immune cells.⁶⁶ IL-10 exerts its anti-inflammatory activity in part through NF- κ B inhibition. IL-10 knockout mice spontaneously develop chronic colitis that resembles human IBD. In contrast, IL-22, another member of the IL-10 family of cytokines, is a proinflammatory cytokine that is produced by Th17- and IL-22-producing T-helper (Th22) cells and ILC. IL-22 also activates the JAK-STAT3 pathway via IL-22 receptor 1 (IL-22R1), which is exclusively expressed on epithelial cells and not on immune cells. IL-22 regulates innate responses related to host defense and autoimmune disease, promotes cell proliferation, survival, tissue regeneration, metastasis, and angiogenesis in a similar way to the IL-6 family of cytokines.⁶⁷

Transforming growth factor-beta

TGF- β is the prototypical member of the TGF- β superfamily of anti-inflammatory cytokines.⁶⁸ TGF- β activates the Smad pathway and non-Smad signaling via the JNK, p38 and ERK mitogen-activated protein kinases (MAPKs), through binding to heterodimeric type I and II TGF- β receptors (TGF-RI and -RII). TGF- β also inhibits cell proliferation and regulates Treg and Th17 differentiation. TGF- β plays a dual role in the progression of cancer⁶⁹; exerting suppressive effects in normal cells and early carcinomas, and promoting malignant progression, invasion, and metastasis in advanced tumors.

Inflammation and tumorigenesis

The tumorigenic process is composed of several steps: initiation, promotion, and metastasis. These progressive steps are accompanied by tumor angiogenesis, formation of new blood and lymph vessels that supply the growing tumor with essential nutrients and oxygen. These vessels also provide routes for metastatic dissemination. Through the release of inflammatory mediators, chronically activated TAM and CAF in the tumor microenvironment control malignant progression and tumor angiogenesis.

Tumor initiation

The initiation phase involves induction of oncogenic mutations that lead to oncogene activation and/or loss of tumor suppressors. These mutations change the behavior of normal cells to become malignant by providing them with growth and survival advantages over their neighbors. Mediators such as reactive oxygen species (ROS) and reactive nitrogen intermediates (RNI) produced by inflammatory cells can lead to DNA damage and acquisition of oncogenic mutations. These reactive intermediates also cause genomic instability and can accelerate cell proliferation, but their over-production leads to cell death. Another mechanism through which inflammation may enhance tumor initiation is the production of growth factors and cytokines that confer a stem-cell like phenotype upon tumor progenitors or stimulate stem cell expansion, thereby enlarging the cell pool that is targeted by environmental mutagens. However, this mechanism is more akin to early tumor promotion, which is discussed in the following sections.

In most cases, a single mutation is insufficient to cause cancer and at least 4–5 mutations are needed.^{70, 71} Thus, tumor initiation requires continuous exposure to ROS and RNI resulting in irreversible and

persistent DNA damage and accumulation of numerous mutations in dividing cells. Chronic inflammation also leads to epigenetic alterations, including DNA methylation and histone modification, that may further contribute to tumor initiation.

Tumor promotion

Tumor promotion is the process of tumor growth from a single initiated cell into a clonal population giving rise to a primary tumor. Tumor-promoting cytokines and growth factors produced by immune/inflammatory cells are central to this process. For instance, TNF and IL-6 activate AP-1, NF- κ B, and STAT3 to induce genes that stimulate cell proliferation and survival. Cytokines that stimulate angiogenesis provide the growing primary tumor with blood vessels that increase oxygen and nutrient availability, altogether resulting in net tumor growth.

Inflammation and angiogenesis

As mentioned earlier, the demand for blood supply increases during the course of tumor growth. Inflammatory cells are an important source of angiogenic cytokines, including VEGF. Tumor hypoxia can lead to activation of CAF and increased production of chemokines that recruit more inflammatory and immune cells into the hypoxic tumor.⁴⁶

Metastasis

The final stage in tumor progression is metastasis, which eventually causes over 90% of cancer deaths. Metastasis is a complex process that requires close collaboration among cancer cells, immune/inflammatory cells, and stromal elements. At first, cancer cells acquire mesenchymal characteristics through the loss of cell polarity and cell–cell adhesion, resulting in increased motility and ability to invade epithelial linings/basal membranes and enter efferent blood vessels or lymphatics.⁷² This process is called epithelial-mesenchymal transition (EMT) and it is characterized by loss of E-cadherin expression. Next, cancer cells intravasate into blood vessels and lymphatics. Inflammation promotes both EMT and intravasation through production of mediators that activate NF- κ B in cancer cells and increase vascular permeability, respectively. This is followed by the third step in which metastasis-initiating cells survive and travel throughout the circulation. It is estimated that only about 0.01% of cancer cells that enter the circulation will eventually survive and give rise to micrometastases.⁷³ Integrin-mediated attachment allows the extravasation of circulating cancer cells, and this process is governed by neutrophil-dependent upregulation of adhesion molecules.⁷⁴ Finally, single metastatic progenitors interact with immune, inflammatory, and stromal cells and start to proliferate.⁷⁵ Systemic inflammation enhances attachment of circulating cancer cells to target organs and stimulates neutrophil mobilization. Several proinflammatory cytokines present in the circulation of cancer patients upregulate expression of adhesion molecules on the endothelium or in target organs, thereby enhancing metastatic cell attachment.²

Inflammation-dependent cancers—examples and treatment

Colorectal cancer

IBD and colorectal cancer

IBD patients are at an elevated risk for CRC, which when present in such patients is referred to as colitis-associated cancer (CAC). Although IBD contributes to only 2–3% of all cases of CRC,^{76, 77} up to 20% of

IBD patients develop CAC within 30 years after disease onset. In mice, CAC-like disease can be induced by combining the chemical procarcinogen azoxymethane (AOM) with the mucosal irritant dextran sulfate sodium salt (DSS), which elicits colitis-like pathology.⁷⁸ Using this model, the IL-6/IL-11-STAT3 axis and NF- κ B were proven to be required for the proliferation and survival of premalignant intestinal epithelial cells and CAC development.^{7, 79}

Sporadic colorectal cancer and inflammation

Even sporadic CRC that does not develop as a consequence of apparent colonic inflammation exhibits extensive inflammatory infiltrates, referred to as “tumor-elicited inflammation,” with high levels of cytokine expression in the tumor microenvironment.⁷ Long-term intake of nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin, that inhibit the enzymatic activity of COX-2, reduces the relative risk of sporadic CRC and hereditary CRC, suggesting that inflammation also plays an important role in spontaneous CRC development.⁷⁶ The *Adenomatous polyposis coli* (*APC*) tumor suppressor gene, encoding a negative regulator of Wnt- β catenin signaling, is the most frequently mutated gene in sporadic CRC (60%), and germ line *APC* mutations cause familial adenomatous polyposis (FAP). Accordingly, *Apc^{min}* mutant mice and *Apc* intestinal epithelial-specific knockout mice provide good models for sporadic CRC and FAP.^{78, 80, 81} In these mouse models, colorectal adenomas, which develop upon loss of the normal *Apc* allele, exhibit defective expression of several epithelial barrier proteins, resulting in entry of microbial products into the tumors but not the adjacent tissue.²⁸ These microbial products activate macrophages associated with early adenomas to produce IL-23 and expand the population of IL-17 producing cells that drive tumor progression through activation of IL-17RA.⁶⁴

Gut microbiota and colorectal cancer

The GI tract is the largest reservoir of commensal bacteria in the human body.⁸² Commensal bacteria affect various physiological functions in the gut via host–microbe interactions, and dysbiosis of the microbiota can lead to or promote various GI diseases including IBD and CRC.⁸³ A correlation between gut microbiota composition and GI cancers has been investigated in experimental animal models and clinical and epidemiological studies. However, gut bacteria that trigger and promote CRC remain to be identified, although it is well known that *H. pylori* induces gastritis and gastric cancer.⁷⁶ Pathological microbes may promote intestinal tumorigenesis through chronic activation of inflammation, alteration of tumor microenvironment, induction of genotoxic responses, and metabolism. Alternatively, such pathological and tumor-promoting alterations could be caused by loss of protective or beneficial microbes.

Cancer prevention, therapy, and side effects

Conventional therapy for CRC includes surgery, chemotherapy, and radiation therapy. Given the growing body of evidence that inflammation triggers and promotes CAC and sporadic CRC, there is room for drugs that reduce inflammation in the prevention or treatment of CRC and other GI cancers. As mentioned earlier, NSAIDs and selective COX-2 inhibitors were proven effective for CRC prevention. Inhibitors of proinflammatory cytokines, such as neutralizing antibodies or decoy receptors to TNF, IL-6, IL-1, IL-17A, and IL-23 or inhibitors of cytokine signaling, including JAK, STAT3, IKK, and NF- κ B, might also be useful for the treatment of CAC and spontaneous CRC.⁷⁶ However, it is unlikely that such drugs would be effective as monotherapies, and thus, they should be tested in combination with chemo- or radiotherapy. Notably, JAK inhibitors were found effective for the treatment of IBD, but their side effects include mucositis, anemia, thrombocytopenia, liver dysfunction, and infection. Importantly, mucositis is the major

dose-limiting factor in cytotoxic chemotherapy, and therefore, caution should be exercised when drugs that inhibit the activity of cytokines, such as IL-6, IL-17A, and IL-23 that promote mucosal healing, are combined with chemotherapeutic agents. Some chemotherapeutics may be more amenable to such combinations, as recently shown for 5-FU in an *Apc* mutant mouse, where it was found to be much more effective in combination with an IL-17A neutralizing antibody.⁶⁴

Another approach to control GI inflammation is to use prebiotics or probiotics, with the aim of normalizing or skewing the host microbiome to influence cancer development.⁸³ Several dietary compounds were found to reduce inflammation and CRC risk, including carbohydrates, fiber, unsaturated n-3 fatty acids, vitamins, minerals, and phytochemicals (resveratrol and curcumin) although the underlying molecular mechanisms are unknown.⁷⁶

Pancreatic cancer

Inflammation and pancreatic ductal adenocarcinoma (PDAC)

Pancreatic ductal adenocarcinoma (PDAC) is an aggressive malignancy with an overall 5-year survival rate of <5%.⁸⁴ One of the major features of PDAC is remarkable desmoplasia that is composed of ECM, fibroblasts, vascular, and immune cells.⁸⁵ This cellular milieu is rich in inflammatory cytokines, growth factors and proteinases that stimulate the proliferation and survival of malignant cells.^{86, 87} Increased levels of proinflammatory cytokines including IL-6, IL-8, and TNF, as well as the anti-inflammatory cytokines IL-10 and TGF- β were found to correlate with cachexia and poor prognosis in PDAC patients.^{88–91} The progression of early PanIN lesions into PDAC in pancreatic *KRAS*-mutated mice has been shown to depend on activation of the STAT3 pathway by JAK tyrosine kinases in response to IL-6.⁹² In addition, IL-6 induces expression of VEGF in pancreatic cancer cells, thereby stimulating angiogenesis.⁹³ Although high-dose TNF was shown to have toxic effects on cancer cells, in the PDAC microenvironment, binding of TNF–TNFR2 results in upregulation of EGF receptor and its ligand TGF- α , leading to increased cancer cell proliferation.⁹⁴ IL-10 and TGF- β facilitate the shift from the Th1 immunophenotype, which has antitumor activity, to the Th2 immunophenotype, which has protumor activity.⁹⁵

Anti-inflammatory strategies for PDAC therapy

Major strategies to activate antitumor immune responses that were found to be effective in highly immunogenic cancers, such as cutaneous melanoma and bladder cancer, include adoptive transfer of cancer-reactive T cells and the use of immune checkpoint inhibitors.⁹⁶ For instance, blockade of the inhibitory receptors CTLA-4 and PD-1 with specific monoclonal antibodies or depletion of Treg cells with antibodies against CD25 can result in activation of anticancer immunity.^{97, 98} Such strategies, so far, have not been too effective against PDAC, perhaps due to the existence of additional, yet-to-be discovered, immunosuppressive mechanisms. IL-6 monoclonal antibodies, Siltuximab and Tocilizumab, that bind to the soluble form of the IL-6 receptor are currently under evaluation in ovarian cancer patients (clinicaltrials.gov) and should be tested in PDAC as well. Ruxolitinib is a selective JAK1/JAK2 inhibitor that was approved by the FDA in 2011 for the treatment of myelofibrosis. Ruxolitinib can block STAT3 activation by IL-6 and was found to significantly improve the survival rate of a subgroup of patients with recurrent or treatment-refractory PDAC ([clinicaltrial.gov](http://clinicaltrials.gov)). Testing whether IL-6 neutralizing antibodies or JAK inhibitors may also potentiate the activation of cytotoxic T cells targeting PDAC would be of interest.

Liver cancer

Etiology and pathogenesis

HCC is the fifth most common cancer worldwide and the third leading cause of cancer deaths. More than 90% of HCC develops in the context of chronic liver disease and persistent inflammation, with HBV or HCV infections being the main causes. Additional risk factors for HCC include fatty liver disease, aflatoxin, alcohol, and hereditary conditions such as hemochromatosis. HCC is characterized by phenotypic and molecular heterogeneity reflecting diverse pathological origin. Because of that, no clear evidence for oncogene addiction has been proved, even though hTERT, β -catenin, and p53 gene alterations are relatively common. As HCC develops in a liver with extensive inflammation and fibrosis, the role of inflammation in HCC development is particularly important.

Therapy

Early stage HCC may be eligible for surgical resection (total or partial hepatectomy), liver transplantation, or local ablation therapy. However, 70% of HCC cases recur at 5 years after these curative therapies. If the tumor is already at advanced stages at the time of diagnosis or recurs after curative treatment, systemic chemotherapy using molecular targeted drugs is considered besides chemoembolization. However, the 5-year survival rate for HCC has remained very low (<8%).

The protein kinase inhibitor sorafenib is currently the only approved systemic drug for advanced HCC and median survival was only 2.8 months longer for patients treated with sorafenib than control group (10.7 months vs 7.9 months, respectively). Although drugs that target signaling pathways involved in HCC-tumorigenesis have been the subject of many clinical trials after the approval of sorafenib, no other drug demonstrated clear survival benefits or positive results in first-line (brivanib, sunitinib, erlotinib, and linifanib) or second-line (brivanib, everolimus) HCC therapy. Currently, clinical trials testing the MET inhibitor tivantinib and Mitogen-activated protein kinase/ERK kinase (MEK) inhibitor refametinib in RAS(+) HCC patients are ongoing. However, these drugs may be beneficial only for a subset of HCC patients because RAS-mutated cases represent no more than 5% of HCC patients.⁹⁹

These failures may be due to the heterogeneous and complex molecular features of HCC, which remains a poorly understood malignancy. Liver toxicity was also seen frequently during clinical trials and is a main cause of their failure. Of note, coexistence of liver cirrhosis frequently limits treatment options for HCC patients. For instance, the rapalog everolimus did not extend overall survival compared to placebo and its use resulted in increased incidence of liver injury. Interestingly, either rapamycin treatment or hepatocyte-specific ablation of the raptor subunit of mTORC1, the molecular target for rapalogs, increased IL-6 production and activated the protumorigenic transcription factor STAT3 in a mouse model. Furthermore, loss of mTORC1 activity resulted in low-grade liver inflammation leading to enhancement of HCC development.¹⁰⁰

Obesity, inflammation, and putative therapeutic options

Recently, a certain portion of HCC patients in Western countries was found not to exhibit viral infections.¹⁰¹ Most of these patients are obese with manifestations of the metabolic syndrome and suffer from nonalcoholic steatohepatitis (NASH), a severe form of nonalcoholic fatty liver disease (NAFLD).¹⁰² Indeed, obesity increases male HCC risk by up to 4.5-fold.¹⁰³ Because the prevalence of obesity has been increasing rapidly worldwide, its association with liver tumorigenesis has attracted much attention. Importantly, obesity strongly enhances HCC development in mice, allowing mechanistic studies, which

revealed that obesity increases HCC risk by triggering low-grade liver inflammation associated with elevated expression of TNF and IL-6.¹⁰⁴ IL-6 signaling is also important to HCC development in nonobese settings, and HCC progenitor/stem cell expansion and malignant progression depend on autocrine IL-6 signaling.^{105, 106} In addition, obesity^{107, 108} and HBV/HCV infections¹⁰⁹ induce endoplasmic reticulum (ER) stress in hepatocytes and this may promote hepatosteatosis in humans.¹¹⁰ Furthermore, ER stress contributes to NASH-like disease development and progression to HCC in mice.¹¹¹ Interestingly, HCC development in this model can be attenuated through the relief of ER stress or inhibition of TNF signaling in hepatocytes. These findings suggest that NASH and its progression to HCC may be prevented or ameliorated by anti-TNF drugs and molecules termed “chemical chaperons” that are capable of relieving ER stress.

Chapter 28

RNA tumor viruses

Robert C. Gallo, MD ■ Marvin S. Reitz, PhD

Overview

Retroviruses are enveloped viruses that contain a diploid RNA genome and are defined by the presence of reverse transcriptase, a DNA polymerase that transcribes RNA into DNA, which is then inserted into the host cell chromosome. These processes often lead to the capture and/or alteration of genetic material and the transfer of information between cells, with neoplastic transformation of the infected cell being an occasional outcome of infection. Retroviruses are also associated with immunodeficiencies and with neurologic diseases, although infection is often asymptomatic. Retroviruses can also enter the germ line and be present as a part of the genetic complement of all members of a species. These viruses are called endogenous retroviruses. Although most retroviral malignancies occur as leukemia/lymphomas in nonhuman species, human T-cell leukemia virus type I (HTLV-I) causes adult T-cell leukemia/lymphoma in a minority of infected humans, as well as a neurologic disease and a variety of other pathologies. Human immunodeficiency virus type 1 (HIV-1), although not considered a tumor virus, is associated with an increased incidence of several types of tumors, especially those caused by viruses such as human papillomavirus and Epstein–Barr virus.

Retroviruses were discovered early in the twentieth century. Ellerman and Bang¹ showed the transmission of leukemia in chickens by a cell-free filtrate, and Rous² was similarly able to transmit sarcomas in chickens. These findings were extended to mammals by Bittner in the case of breast tumors in mice³ and by Gross for murine leukemias.⁴ Gross recognized the importance of inoculating newborn mice for development of leukemia, and in many respects, his work heralded the beginning of modern studies of retroviruses. Jarrett showed that a similar virus was responsible for leukemia in cats, which was the first demonstration of naturally transmitted leukemia in an outbred species.^{5, 6} Kawakami and Theilen and colleagues first showed that retroviruses could cause leukemia in primates, specifically in gibbon apes and new world monkeys.^{7–9}

Biologic assays for these viruses were in use from the 1950s, but a more fundamental understanding of their life cycle was considerably advanced in the early 1970s by the discovery that they contained reverse transcriptase (RT).^{10, 11} This provided a far simpler, quicker, and more sensitive assay for retroviruses. Another important finding in the 1970s was that some retroviruses [e.g., Rous sarcoma virus (RSV)] contained genes for cell transformation and tumorigenesis (oncogenes) that represented captured cellular genes (proto-oncogenes).¹² This led to the identification of many similar genes and to an appreciation of their roles in cell growth and neoplastic transformation.

Despite this work and the interest it engendered, it was widely believed during the 1970s that retroviruses did not play a role in human disease and were likely not even present in the human population. Several discoveries made it clear that this was not the case. Human T-cell leukemia virus type I (HTLV-I) was the first infectious human retrovirus identified; it was discovered and shown to be a unique virus by Gallo and his colleagues.^{13–16} HTLV-I was soon established as the etiologic agent of adult T-cell leukemia

(ATL), a type of leukemia endemic to various locales, including southern Japan and the Caribbean.^{17–21} This was quickly followed by the discovery of HTLV-II,²² a related virus that (although widespread) has not been compellingly associated with any disease. HTLV-I was shown to be able to neoplastically transform cord blood T cells.²³

Several years later, an epidemic of immunodeficiency and malignancies appeared within gay communities, especially in the United States. The first member of another group of human retroviruses was isolated from people with this disease, called acquired immunodeficiency syndrome (AIDS).²⁴ When it became possible to culture the virus on a large scale,²⁵ it was proven to be the etiologic agent of AIDS.^{26, 27} This virus, now called human immunodeficiency virus type 1 (HIV-1), has become established worldwide, and AIDS represents a current global medical and economic catastrophe. As with HTLV-I, a related virus, HIV-2, was discovered,²⁸ which also appears to be far less pathogenic than HIV-1.²⁹

Classification

The retroviridae are a large family of viruses that have been classified using a variety of criteria,³⁰ originally according to their biologic effects. The subfamilies included oncoviruses, which cause leukemias or other malignancies in their hosts; lentiviruses, or “slow” viruses, which cause slow degenerative diseases; and spumaviruses, or foamy viruses, which produce a “foamy” cytopathic effect in infected cultures. The subfamilies have been divided further based on their genomic structures ([Table 1](#)). They have been historically classified on the basis of the morphology of budding and mature virions in electron micrographs ([Table 2](#)). Retroviruses can also be classified as exogenous or endogenous depending upon whether they are transmitted by infection or genetically within the germ line of a species.

Table 1 Retrovirus groups

Oncornaviruses
<ul style="list-style-type: none">• Avian leukosis-sarcoma viruses (ALSV)• Avian reticuloendotheliosis virus• Mammalian leukemia and sarcoma viruses (mouse/cat type C viruses)
Mouse mammary tumor virus
<ul style="list-style-type: none">• Primate type D viruses (Mason–Pfizer monkey virus/simian AIDS virus)• Human T-cell leukemia virus/bovine leukemia virus/simian T-cell leukemia virus
Lentiviruses (including immunodeficiency viruses)
Spumaviruses

Table 2 Retrovirus morphology

<p>A-type particles</p> <ul style="list-style-type: none">• Intracellular core formation and budding• Intracisternal A-type particles (IAP) are products of endogenous proviruses• Noninfectious
<p>B-type particles (MMTV)</p> <ul style="list-style-type: none">• Core formation occurs in the cytoplasm• After budding at the plasma membrane, maturation to an eccentric core occurs• Prominent surface spikes
<p>C-type particles</p> <ul style="list-style-type: none">• Most oncornaviruses• Initially form electron-dense patches at the plasma membrane• Budding at plasma membrane• Maturation of core to yield centrally located cores• Spikes may or may not be prominent

Structure

Retrovirus particles are composed of a core structure or capsid, which encloses two copies of the single-stranded genomic RNA, surrounded by an envelope containing a lipid bilayer. The entire virion, or extracellular viral particle, is 100 nm in diameter. The genomic RNA is generally 8–9500 nucleotides long, and the simplest retroviruses contain three major genes (*gag*, *pol*, and *env*), all of which are

contained in the virion ([Figure 1](#)). The genomic RNA contains repeat regions at both ends, called the R region. The DNA (deoxyribonucleic acid) form of the genome integrated in the host cell genome contains the R region and other regulatory sequences in structures called the long terminal repeat (LTR) ([Figure 1](#)). Retroviruses often become replication-defective by loss of large regions of their genomes, which are sometimes replaced by oncogenes derived from the host cell. We now describe the genome and proteins of replication-competent retroviruses.

Figure 1 (a) Structure of typical retrovirus virion. (b) Structure of typical retroviral genome. All replication-competent retroviruses generate a full-length genomic ribonucleic acid (RNA) that encodes the gag and pol products and a singly spliced RNA that encodes the env product. Some retroviruses also generate smaller multiply spliced messages. *Abbreviations:* env, envelope; gag, core proteins; pol, polymerase; pro, protease.

Viral genome and gene products

Space precludes a detailed description of the retroviral genome structure and the viral proteins. Interested readers are referred to Teich et al.³⁰ for details. However, these are presented schematically in [Figures 2](#) and [3](#).

Figure 2 Long terminal repeat (LTR) structure. Replication-competent retroviruses contain identical LTRs at the 5' and 3' ends. The U3 portion of the 5' LTR contains all of the enhancer and promoter elements necessary for efficient initiation of transcription of either retroviral or cellular genes. *Abbreviations:* CA, capsid; FeLV, feline leukemia virus; IN, integrase; MA, matrix protein; MMTV, Maloney mammary tumor virus; MuLV, murine leukemia virus; NC, nuclear capsid; PR, protease; RT, reverse transcriptase.

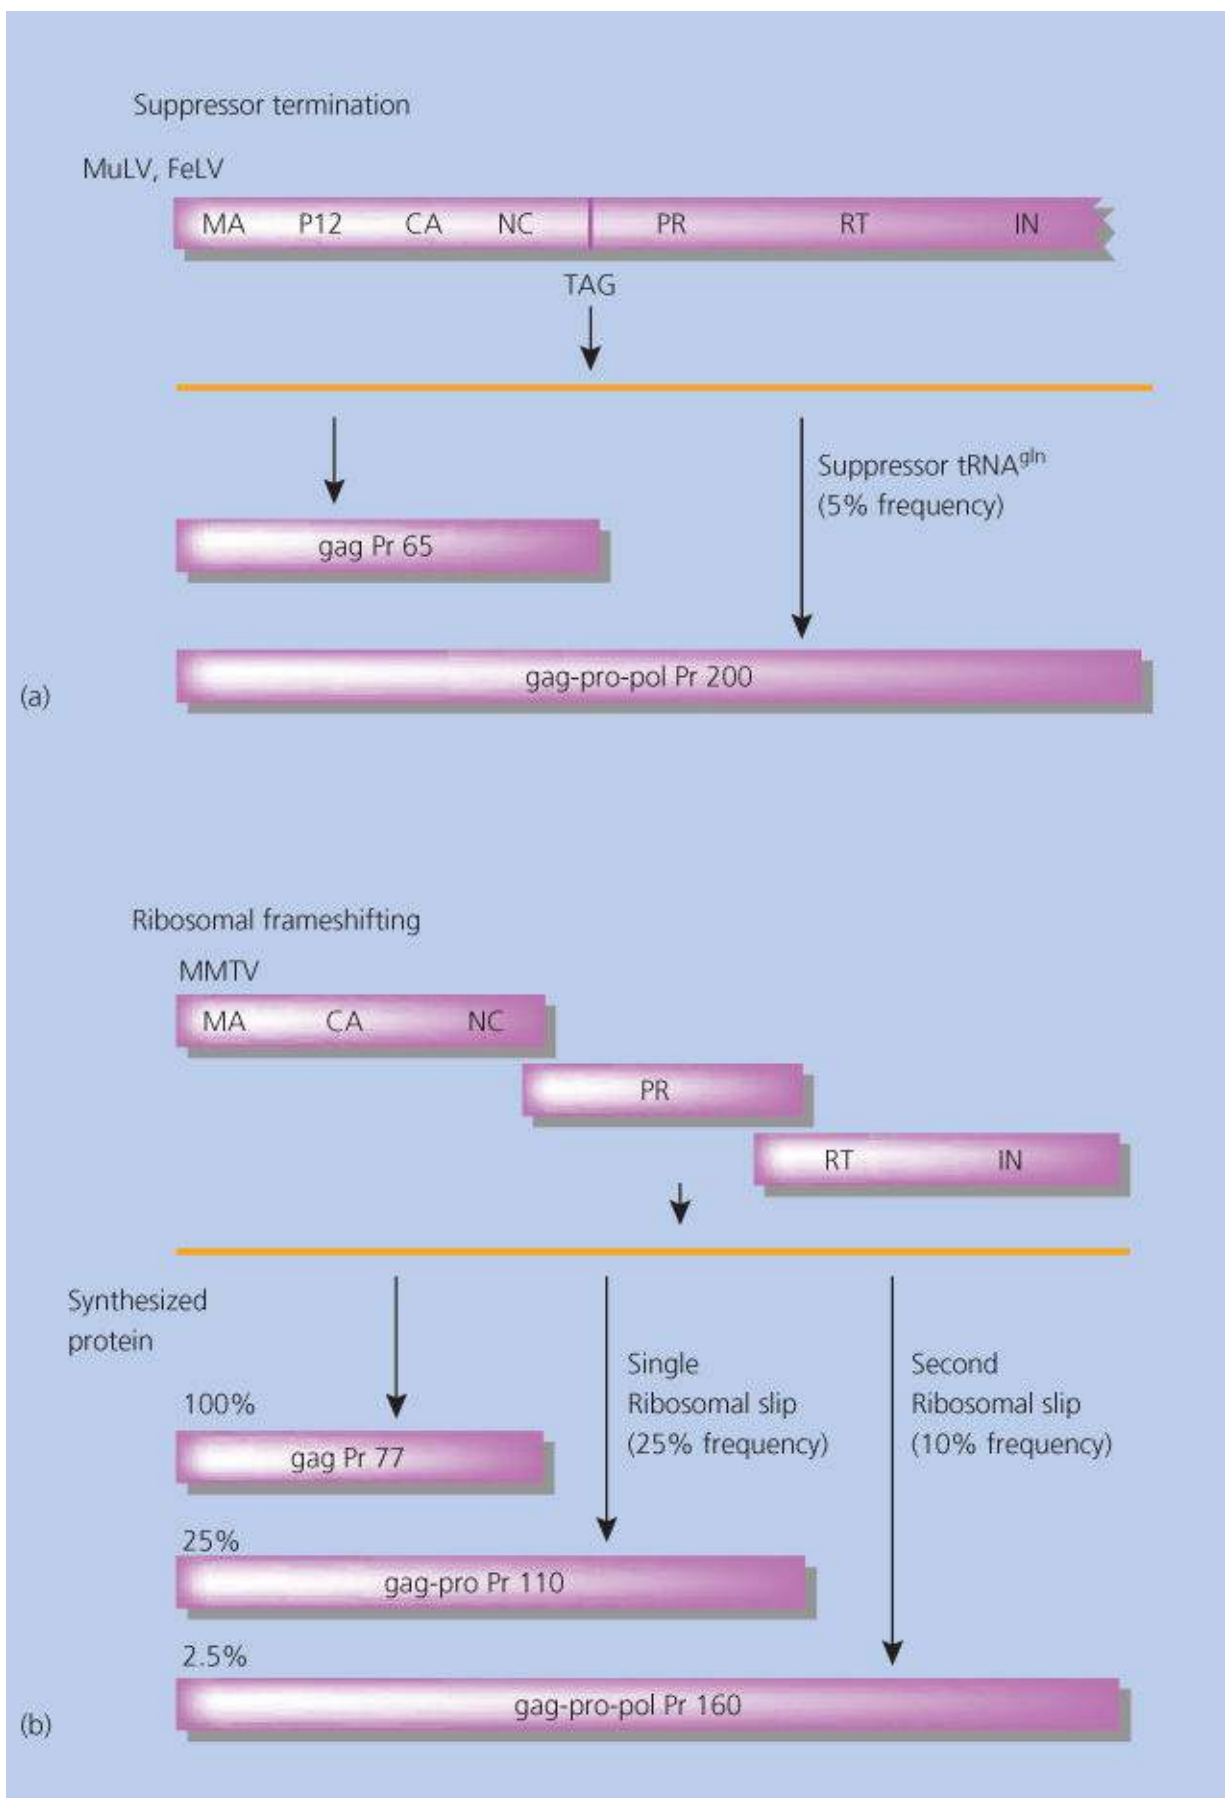

Figure 3 Alternative methods different retroviruses use to bypass the gag stop codon to generate the pro-pol products from the full-length genomic transcripts.

Genomic variation

The genomic structure described earlier is representative of the simplest retroviruses; other retroviruses, especially lentiviruses and members of the HTLV group (including the related bovine leukemia virus, BLV), contain extra genes and have a more complex genomic structure. HIV-1 encodes six regulatory proteins including a protein that activates viral RNA expression, a protein that regulates viral RNA splicing patterns, and proteins that interfere with host immune functions. The extra genes also result in a more complicated RNA splicing pattern, including multiple splicing for many of the regulatory genes. Similarly, HTLV-I encodes at least five additional proteins, including (like HIV) a protein that activates viral RNA expression and another that regulates viral RNA splicing patterns. Recently, evidence has been presented^{31–33} that a protein called HTLV-I bZIP protein (HBZ) is transcribed from the 3' LTR, translated from negative-strand viral RNA, and expressed in infected T cells and in uncultured ATL cells as a 31-kDa protein. The HBZ protein binds to cellular bZIP transcription factors including members of the CREB and Jun families^{34, 35} to repress Tax-mediated viral transcription and support ATL cell proliferation. At present, this appears to represent a novel genetic feature of HTLV-I. Murine mammary tumor virus (MMTV) and the spumaviruses also encode additional proteins, including those that activate viral RNA expression. Other retroviruses, especially those that are acutely transforming (such as the avian and mammalian sarcoma viruses), are generally replication-defective and have parts of their genomes deleted and replaced with captured cellular genes that confer transforming capability. These viruses require a replication-competent helper virus for transmission and replication.

Replication cycle

Space precludes a detailed description of the viral replication cycle. Details of the pertinent steps are covered in detail in Refs [^{36–39}]. Some of the steps are presented schematically in an abbreviated form in [Figures 4–6](#). A few important points with regard to the retroviral replication cycle should be noted. First, formation of the provirus, by the integration reaction, results in a stable genetic copy of the virus that cannot be removed from the infected cell. Infected cells can and do persist for the life of the host, and whenever the cell divides, the provirus is passed on to both daughter cells. Furthermore, when germ line cells are infected, they become part of the genome of subsequent offspring. Consequently, 5% or more of the human genome consists of proviruses from past retroviral infections. Integration, however, is not always accurate, and deletions and rearrangements can occur. Integrated proviruses can also occasionally become deleted or rearranged. Reflecting this, most endogenous proviruses are defective and not usually expressed, although expression of some does occur. It is likely, however, that this massive insertion of foreign DNA has had a profound impact on evolutionary processes. Second, after proviral formation, transcription and translation of viral gene products depend entirely on cellular factors. Thus, a retrovirus generally persists silently in quiescent cells. Activation of infected cells, such as occurs when cells of the immune system are stimulated by antigen or cells are activated by hormones, can activate viral expression, although this is modulated by the suite of transcriptional factor binding sites in the viral LTR. Also, complex retroviruses, such as HTLV and HIV, encode transcriptional activators that can profoundly affect the activity of the viral RNA polymerase promoter.^{40–45}

Figure 4 Life cycle of retrovirus. Following binding of the retrovirus to its specific cell membrane receptor, the viral and cellular membranes fuse, and the core virion is internalized into the cell. Reverse transcriptase-directed double-stranded retroviral genomic deoxyribonucleic acid (DNA) is then generated, followed by integrase-directed integration into host cell DNA. Retroviral transcripts using host transcriptional machinery then proceed, with the eventual formation of new retroviral virions that bud from the cell surface, allowing a new round of infection to occur.

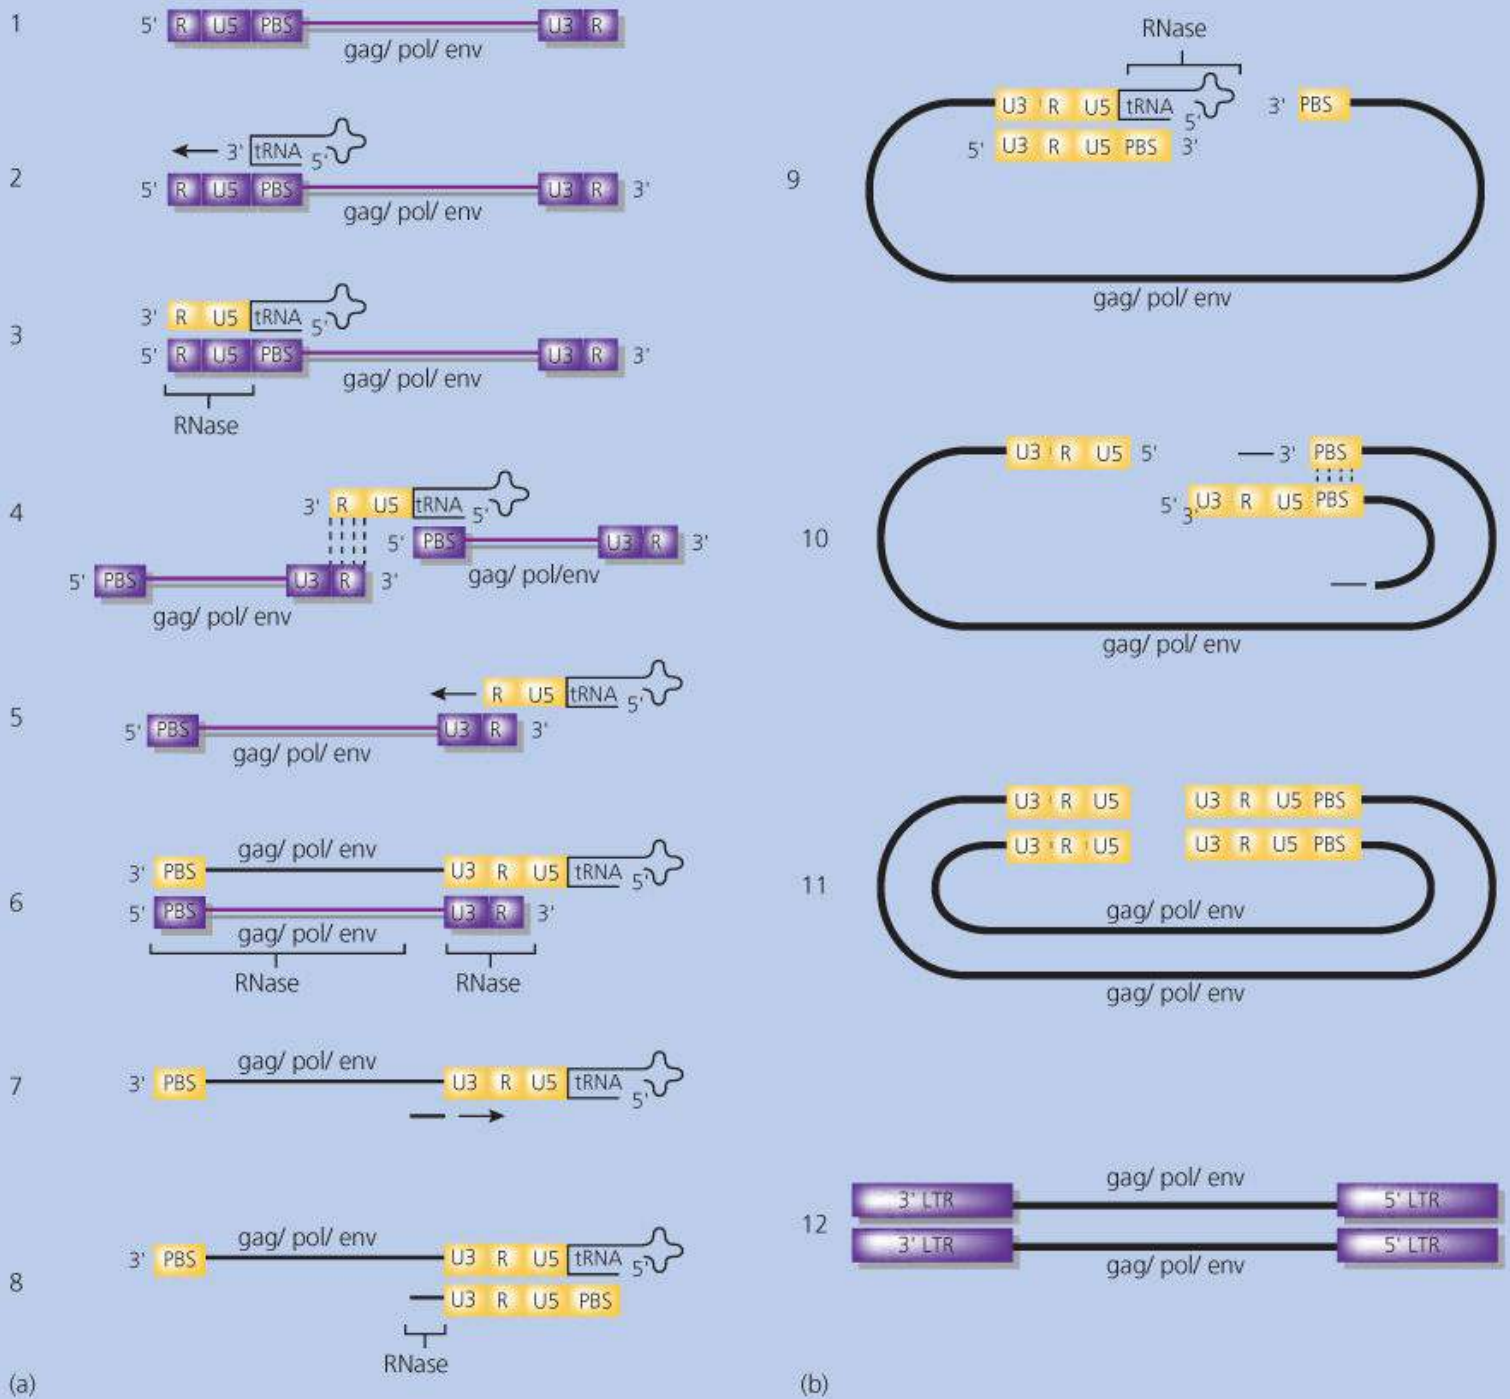

Figure 5 Reverse transcription. From a single-stranded ribonucleic acid genomic precursor (a), reverse transcriptase synthesizes a double-stranded deoxyribonucleic acid (DNA) provirus ready for integration into host cell DNA (b).

Figure 6 Integration. The newly reverse-transcribed double-stranded retroviral deoxyribonucleic acid (DNA) genome and a piece of chromosomal DNA are specifically cleaved by the retroviral integrase protein. This is accompanied by a deletion of two base pairs from the retroviral genome and a duplication of four to six base pairs from the host DNA. Following retroviral genomic insertion into the cleaved host DNA, the DNA is re-ligated.

Mechanisms of oncogenesis

Some retroviruses are acutely transforming; they are able to transform cells directly. Retroviral induction

of neoplasias *in vivo* in the infected host, however, involves a variety of mechanisms in addition to cell transformation by acutely transforming viruses. These are summarized in [Figure 7](#).

Figure 7 Four mechanisms of retrovirus-induced oncogenesis. (a) Oncogene capture. A mutated form of a cellular proto-oncogene (v-onc) is transferred (transduced) to a normal cell, thus inducing transformation (*c-oncogene). (b) Insertional activation. There is a significant increase in the rate of proto-oncogene expression secondary to LTR-directed transcriptional enhancement (*c-oncogene). (c) Growth stimulation plus two-step oncogenesis. A mutated env protein from the defective spleen focus-forming virus (SFFV) binds to the erythropoietin (EPO) receptor, causing an erythrocyte hyperplasia. This increases the target population susceptible to the actual transforming event, a retroviral insertional disruption of the Spi-I or TP53 gene. *Abbreviations:* FrMuLV, Friend murine leukemia virus. (d) Transactivation. The viral transactivating protein (tax in the case of human T-cell leukemia virus type I) causes expansion of the potential target population through transactivation of growth regulatory genes. An unknown second event then induces the actual transformation of a clone of these cells.

Oncogene capture

Acutely transforming viruses are usually generated when a cellular proto-oncogene is captured by insertion into the viral genome during viral replication. This process usually causes genetic changes in the proto-oncogene, resulting in an oncogene, or dominant transforming gene. The same process usually also results in a replication-defective virus that requires a helper virus for its replication. The helper virus provides viral proteins to form the virion in which the RNA of the defective virus is packaged. These mixed particles are called pseudotypes.

The first discovered oncogenic virus was RSV, which was shown to be a transmissible agent causing sarcomas in chickens.² RSV was the first acutely transforming virus of many shown to have acquired its oncogenicity by the capture of a cellular gene, in this case *src*.¹² This was perhaps made possible in part because RSV, unlike most acutely transforming viruses, is replication competent and does not require a helper virus, thus making it simpler to study. The *src* gene in RSV is inserted as a separate gene immediately 3' of the other viral genes.^{46, 47} The transforming potential could be assigned to the viral *src* gene (v-*src*) because transformation-defective RSV was shown to have mutations specifically in v-*src* and because it conferred transforming ability to recombinant viruses that contained it.^{48–50} These findings led to the recognition that normal cellular genes when modified and in the appropriate setting could cause malignant transformation.

Acutely transforming retroviruses produce tumors in susceptible hosts within days to weeks after infection. Because their transforming ability is so potent, a large fraction of infected cells become transformed; hence, the tumors that arise tend to be polyclonal. RSV infection of young chickens induces a variety of related tumor types, notably fibrosarcomas and histiocytic sarcomas. The younger the animal, the more sensitive it is to tumor formation. Tumor formation can occur within days in chicks younger than 1 month, the tumors progress rapidly, occur at many sites, and kill the animal. In the presence of an immune response, as in older chickens, the tumors tend to regress and disappear. Injection of v-*src* DNA into young birds can also induce tumors, further implicating v-*src* as causing the tumors.⁵¹ Tumor formation with DNA is less efficient, probably reflecting the inefficiency of functional DNA uptake compared with retroviral infection. RSV can also cause tumors in baby rodents, although inefficiently, and the tumors are restricted to the site of inoculation and tend to regress as the animal becomes older and presumably more immunocompetent. The lower tumorigenic potential probably reflects the reduced replication rate of RSV in rodent cells.^{52, 53}

A more typical acutely transforming oncogene-containing retrovirus is typified by Abelson murine leukemia virus (A-MuLV). Infection of a nude mouse with a replication-competent MuLV^{54, 55} resulted in

the replacement of most of the MuLV genes with a modified copy of the proto-oncogene *c-abl*,⁵⁶ a tyrosine kinase that is the target of the anticancer drug imatinib. Like most viral oncogenes and their cellular counterparts (summarized in [Table 3](#)), the *abl* portion of *v-abl* differs genetically from *c-abl*. The recombinant A-MuLV is unable to synthesize any of the viral genes and only codes for a fusion protein containing part of Gag and Abl (*v-Abl*). The presence of the amino-terminal portion of Gag on *v-Abl* causes it to be myristoylated and transported to the cell membrane, and this is critical for transformation by A-MuLV. The lack of functional viral genes means that A-MuLV is replication-defective and can infect and transform target cells only with the assistance of a helper virus. A-MuLV induces B-cell lymphomas in young mice, but adult animals are generally resistant to A-MuLV lymphomagenesis.⁵⁷

Table 3 Differences between v-onc and c-onc genes

Often only a portion of the cellular oncogene is present in v-onc
v-onc is derived from processed mRNA, which is devoid of introns and flanking sequences
Loss of cellular control elements (promoters/repressors as well as RNA destabilizers) for some oncogenes (<i>myc</i> and <i>mos</i>) elevated level of expression in itself may be transforming
Deletions/rearrangements may affect the structure of the protein itself: <ul style="list-style-type: none"> • Loss of C-terminal Tyr-containing region of <i>c-src</i> causes loss of phosphorylation-mediated control by host cell kinases • <i>v-erb B</i> differs from EGF receptor by deletion of the extracellular domain
v-onc genes are often fused to viral sequences important for transforming function: <ul style="list-style-type: none"> • <i>gag-abl</i> acquires a myristoylation signal for membrane localization important for transforming activity • <i>v-fms</i> is the CSF-1 receptor fused to the gag gene product, the latter providing a signal sequence for placement into the cell membrane

Several models have been put forth for how cellular sequences are acquired by retroviral genomes, summarized in [Figure 7](#). In one scenario ([Figure 7a](#)), a retrovirus integrates into the host cell genome just upstream from a proto-oncogene.⁵⁸ A subsequent deletion removes the 3' portion of the provirus and the 5' portion of the proto-oncogene, fusing the viral genome with cellular sequences and resulting in a reading frame for a fusion protein, generally including part of the *gag* gene. This gene is transcribed under regulation of the viral LTR, processed, and co-packaged into a pseudotype retroviral particle with the helper virus genome. When the pseudotype infects a target cell, RT mediates recombination between the 3' ends of the two viral RNAs, which places a 3' LTR on the end of the transduced cellular gene, allowing the resultant double-stranded DNA to be integrated into the host cell DNA. In a second model ([Figure 7b](#)), a replication-competent virus again integrates upstream from a proto-oncogene. On rare occasions, the termination signal in the 3' LTR is not recognized and transcription proceeds through the downstream gene. The large combined transcript then undergoes splicing or recombination that deletes the 3' portion of the viral region and the 5' portion of the cellular region and creates the open reading frame for the viral-proto-oncogene fusion, which is then pseudotyped for subsequent infection and generation of an integratable DNA. This requires either homologous regions between the viral and cellular genes to facilitate recombination or splice signals in the appropriate area for forming the fused open reading frame. Although examples of such homologies are found between the *pol* gene of the avian retrovirus MC29 and the chicken *c-myc* in the area of the fusion,^{58, 59} such homologies are not obvious in most

retroviruses, suggesting that the first scenario is probably more common.

Insertional mutagenesis

Most retroviruses that cause neoplasms in their hosts are not acutely transforming, contain the minimum complement of *gag*, *pol*, and *env* genes, and are replication competent. Because many of these viruses induce leukemias and are genetically somewhat related, they are collectively referred to as leukemia viruses. Representatives include avian, murine, feline, and gibbon ape leukemia viruses. The kinds of leukemias induced vary with the viral strain; thus, some strains of GaLV are associated with lymphocytic leukemia,^{7, 60} whereas another strain is associated with myeloid leukemia.⁶¹ Their lack of acutely transforming oncogenes means that they are not competent for direct transformation and do not transform target cells *in vitro*. The leukemias and other tumors that result from infection of the host are clonal in origin, as is evident from the insertion site of the provirus being identical in all of the neoplastic cells from a given tumor. This reflects the rarity of infection leading to malignant transformation and indicates that infection with the retrovirus preceded (and, by implication, resulted in) transformation. It also suggests that the specific insertion site is important and leads to the concept of insertional mutagenesis. In these kinds of viral neoplasias, the provirus is often found integrated in the vicinity of known cellular proto-oncogenes. The proximity of the viral LTR (or the insertion of the provirus into regulatory regions of the proto-oncogene) causes a dysregulation of its expression, leading in turn to dysregulated cell growth or differentiation. Alternatively, insertion may disrupt genes whose expression tends to prevent transformation. This mechanism of insertional mutagenesis obviously requires high levels of viral replication because integration occurs somewhat at random, and as a result, leukemia may only occur in a minority of infected animals, and latency phases (the time between infection and leukemia onset) can be quite lengthy.

Avian leukosis virus (ALV) is the prototypical simple leukemia virus. ALV is transmitted in birds both horizontally and vertically. Within several months, B-cell lymphoblasts begin to accumulate in the bursa of Fabricius.⁶² With involution of the bursa, many of the enlarged follicles regress, but some tumor nodules persist and grow, eventually giving rise to metastatic lymphomas. These tumors generally have a predominant provirus integrated near *c-myc*, a cellular proto-oncogene,^{63–65} and *c-myc* RNA expression in these tumors is significantly higher than in the normal cell counterparts. Transcription is often initiated from the 3' LTR,⁶⁶ resulting in a chimeric viral-cellular transcript, but continued expression of viral genes and viral replication is no longer needed.

Insertional mutagenesis also appears to play a critical role in MMTV and murine mammary tumors. As with ALV, MMTV can be transmitted either horizontally or vertically, and there is generally a predominant provirus in the mammary tumor cells, with similar implications. Integration was found to occur around but not within a 30-kbp sequence containing the *int-1* proto-oncogene.^{67–69} *Int-1* expression generally only occurs in the neural tube of mid-gestational embryos and in testicular postmeiotic cells, suggesting that inappropriate expression in cells in the breast contributes to tumorigenesis by MMTV. Transgenic mice in which an *int-1* transgene is regulated by the MMTV LTR develop mammary tumors, but this is also the case when any of several other genes (including *c-myc*) are substituted for *int-1*,^{70–73} suggesting that tumorigenesis simply depends on the delivery of a breast-specific promoter to dysregulate the expression of any of several proto-oncogenes.

Growth stimulation and two-step oncogenesis

The polycythemic strain of Friend murine leukemia virus (F-MuLV) represents another type of transforming replication-defective retroviruses. Unlike other viruses of these types, F-MuLV does not encode a cell-derived oncogene. An internal deletion of the *env* gene encompassing portions of the TM and SU proteins results in a nonfunctional Env, which can serve as a mimic of erythropoietin (Epo) and activate the growth of erythroid precursor cells through interaction with the Epo receptor.⁷⁴ This results in erythroleukemia and pronounced splenomegaly in infected mice,⁷⁵ which is more properly a hyperplasia than a transformation because the resultant erythrocytes do not form tumors in nude mice and are not immortalized. However, if erythrocytosis is maintained, after a long latent period, subsequent genetic alterations will occasionally transform one of the replicating cells, leading to a monoclonal erythroid leukemia. These events are summarized in [Figure 7c](#).

Transactivation

Insertional mutagenesis leading to the activation of expression of proto-oncogenes by the proximity of the viral LTR or the interruption of negative regulatory sequences by the integration event is referred to as *cis* activation. The genomes of some leukemia viruses are more complex than the simple leukemia viruses such as ALV and MuLV and contain extra genes that perform regulatory functions. The two prototypical examples are HTLV and BLV. These viruses (like the simple leukemia viruses) are replication competent, do not contain transduced proto-oncogenes in their genomes, and induce monoclonal hematopoietic malignancies only in the minority of infected hosts. However, they are like the acutely transforming viruses in that they transform cells in culture and do not appear to require a specific integration site for oncogenesis ([Figure 7d](#)). HTLV is the causative agent for ATL, a monoclonal T-cell lymphoma/leukemia with frequent cutaneous manifestations that is endemic to several areas including southern Japan and the Caribbean,^{17–19, 21, 76} and is also the cause of a neurologic disease resembling multiple sclerosis, called tropical spastic paraparesis or HTLV-associated myelopathy.⁷⁷

HTLV and BLV code for proteins, respectively, called Tax^{41–44} and p34 Tax,⁷⁸ which activate expression by binding to the viral LTR in cooperation with transcription factors. This type of activation by a protein product rather than a DNA regulatory region is called *trans* activation, and these viral proteins are called transactivators. HTLV-I codes for several other proteins as well, including Rex, a protein that regulates the complex splicing pattern of HTLV-I mRNAs.^{79, 80} Three proteins of unknown function are encoded by HTLV-I: p30(II), another transactivator that binds to CREB binding protein/p300 (CBP/p300),⁸¹ a transcriptional factor; p12(I), which activates the transcriptional factor NFAT and binds to the cytoplasmic domain of the IL-2 receptor^{82, 83}; and p13(II), which localizes to mitochondria and interacts with farnesyl pyrophosphate synthetase, an enzyme involved in activation of the proto-oncogene *ras*.^{84, 85} Much interest has focused on Tax as it is clearly critical to the viral replication cycle through transactivation of the viral LTR and as its transactivation extends to cellular genes, including those for the IL-2 receptor, lymphotoxin, and granulocyte–macrophage stimulating factor.^{86–90} The cross-transactivation of cellular genes leads to the idea that dysregulation of growth regulatory genes by Tax may play an important role in its pathogenesis.

A body of experimental evidence suggests that Tax could indeed play a role in leukemogenesis. The HTLV-I provirus in T cells transformed by HTLV-I infection or in leukemic ATL cells often has extensive deletions, but the Tax open reading frame is almost always preserved. Mice that are transgenic for Tax develop tumors, including lymphocytic leukemia, when the transgene is regulated by the viral LTR or a T-cell-specific promoter.^{91–94} The T-cell lymphomas, however, differ phenotypically from ATL cells.^{91, 92} Tax directly transforms a rat fibroblast cell line and transforms primary rat embryo cells in cooperation

with *ras in vitro*,^{95, 96} showing that Tax indeed has oncogenic properties. When Tax was inserted into the genome of a replication-competent but transformation-defective herpesvirus saimiri mutant, human hematopoietic cells infected *in vitro* by the chimeric virus were transformed and resembled ATL cells in morphology and cell surface phenotype,⁹⁷ suggesting that Tax is indeed important in ATL pathogenesis. It is likely that, as with F-MuLV leukemogenesis, subsequent steps are required for ATL to occur. The rarity of ATL as an outcome of HTLV-I infection indicates that a simple infection is not sufficient, and the lack of a common set of integration sites supports the idea that insertional mutagenesis does not play a role. Most likely, the leukemic cells do not express viral positive strand RNA until after they are cultured,⁹⁸ indicating that by the time the cells are leukemic, they no longer require viral expression and suggesting there must be subsequent genetic steps in ATL leukemogenesis.

A better understanding has emerged from the signaling pathways used by Tax for transactivation and transformation. Tax associates with members of the ATF/CREB family of transcriptional factors,^{99–103} and the HTLV-I LTR has three ATF/CREB binding sites. Several cellular genes, such as serum responsive factor (SRF) and NF- κ B/Rel, are transactivated by Tax through the same pathway. Tax also transactivates its LTR, as well as some cellular gene promoters such as those for IL-2 and the IL-2 receptor, directly through NF- κ B.^{62, 104, 105} This depends upon an interaction of Tax and MEKK1, which leads to phosphorylation of the NF- κ B inhibitor I κ B. Phosphorylation of I κ B targets its removal by ubiquitination and degradation in the proteasome, which unmasks the nuclear localization signal of NF- κ B. This allows it to be transported to the nucleus, where it activates gene expression by binding to NF- κ B enhancer elements present in the viral LTR. Tax also appears to directly affect the cell cycle. Tax can bind to the cell cycle inhibitor p16/INK4a and interfere with its ability to inhibit the activity of CDK4, a cyclin kinase important for G1-S progression.^{106, 107} Tax also mediates the phosphorylation of cyclin D3¹⁰⁸ and upregulates the expression of E2F^{107, 109} through ATF/CREB signaling, both of which likely contribute to dysregulation of the cell cycle. Cell cycle dysregulation often leads to p53-mediated apoptosis.¹¹⁰ Tax also dysregulates activities of p53 required for cell cycle arrest and apoptosis,^{111–113} which allows unregulated hyperproliferation and immortalization of cells expressing Tax. Tax appears to inhibit p53 functions in part by an NF- κ B-dependent mechanism and in part by competing with p53 for binding to CBP/p300. Tax also has been reported to inhibit MAD1, a protein involved in G2/M transition.¹¹⁴ It is interesting that Tax interferes with the p16/INK4a and p53 pathways, as alteration of these genes or their activities are quite common in naturally occurring cancers.

The HBZ protein, translated from the negative strand of viral RNA, could also be a determinant of HTLV-I leukemogenesis. HBZ appears to be the only viral gene product consistently expressed in ATL cells.¹¹⁵ HBZ heterodimerizes with members of the CREB and Jun families³¹ and supports proliferation of ATL cells.¹¹⁵ HBZ transgenic mice developed skin lesions and T-cell lymphomas resembling ATL.¹¹⁶ The phenotype of Tax/HBZ double transgenic mice did not differ appreciably from HBZ single transgenic mice.¹¹⁷ HBZ protein and transcripts appear to have nonoverlapping functions. HBZ mRNA supports proliferation of ATL cells in the absence of HBZ protein.¹¹⁵ HBZ transcripts have splice variants called SP1, the shorter of the two, and SP2.³² The SP1 isoform negatively regulates Tax- and c-Jun-dependent transcription. Thus, one function of HBZ protein appears to be to inhibit expression of viral proteins. Conversely, HBZ protein cooperates with JunD to upregulate expression of telomerase (hTERT).¹¹⁸ To add to the complexity of regulation of viral gene expression, Tax upregulates expression of HBZ.¹¹⁹

Human immunodeficiency virus

Infection with HIV, although not considered a tumor virus, results in a greatly increased incidence of several types of tumors, most of which are linked to coinfection with other viruses such as human papillomavirus (HPV) or Epstein–Barr virus (EBV).^{120, 121} Retroviruses are also associated with immunodeficiency in infected animals, as in the case of FeLV. The best known example of an immunopathogenic virus is, of course, HIV-1, which is the cause of AIDS. Because HIV-1 is not found in tumor cells, the mechanism must be indirect. One of the clearest examples is its effect on pathogenesis by human herpesvirus 8 (HHV-8) [also known as Kaposi sarcoma (KS) herpesvirus (KSHV)].¹²² HHV-8 is clearly the cause of KS and a B-cell lymphoma called peripheral effusion lymphoma (PEL).¹²³ In the absence of HIV-1 or other immunosuppressive conditions, HHV-8 appears to cause these diseases only rarely. HIV-1 infection raises the risk of these diseases by many orders of magnitude,^{120, 121} but it is not found in the tumor cells. Since the advent of effective viral suppressive therapies, the incidence of KS has decreased precipitously, further confirming the role of HIV infection as a cofactor. A greatly elevated incidence of non-Hodgkin lymphoma (NHL) is also seen in a setting of HIV infection,^{120, 121} and a substantial portion of these AIDS–NHL cases is associated with EBV infection. Infection with HIV-1 also appears to increase the risk of childhood leiomyosarcomas¹²¹ (associated with EBV) and of cervical cancer and hepatocarcinoma (associated with HPV and hepatitis B and C virus infections, respectively). Infection with these viruses tends to be higher in HIV-infected people, but there also appears to be a higher risk of cancer in people who are coinfecting with HIV and one of these viruses. As with KS, the tumor cells are not infected with HIV-1, indicating an indirect role.

Immunodeficiency likely plays an important role in elevated cancer rates in the setting of HIV infection, most clearly in the case of cancers with a viral etiology. It is also possible, however, that HIV may play a more direct role in tumorigenesis. Mice that are transgenic for Tat, the HIV transactivator protein that is functionally homologous to HTLV-I Tax, develop KS-like lesions.¹²⁴ Also, Tat accelerates tumorigenesis in a murine xenotransplant model of KS in a paracrine manner.¹²⁵ A subset of AIDS–NHL is not associated with EBV, and the reasons for its increased incidence are not clear. Some suggestive evidence has pointed to a role for HIV viral proteins, perhaps especially the p17 matrix protein. Viral proteins persist for extended time periods in lymph nodes of infected people, even in the absence of detectable viral RNA or replication.¹²⁶ HIV transgenic mice have a significantly elevated incidence of B-cell lymphoma.¹²⁷ The viral transgene, although deleted for parts of the *gag* and *pol* genes, expresses many viral proteins, including p17. Recently, p17 was shown to promote lymphangiogenesis *in vitro*, reportedly through binding to and activation of the chemokine receptors CXCR1 and 2.¹²⁸

Endogenous retroviruses

Endogenous retroviruses are part of the normal genetic complement of species and make up an extremely large fraction (up to 5%) of various mammalian genomes. Many of these appear to have emerged after speciation, based on differences in their type and number among species. As retroviruses insert at random and as there are so many present, it is clear that they have played a profound if unclear role in evolution. It is less clear whether any endogenous retroviruses play a role in human cancer or other diseases. First, they are for the most part defective because of large deletions, although some only have a few point mutations and a very few may be replication competent. Second, endogenous retroviruses are generally not expressed even at the RNA level. This may be because of mutations in the regulatory regions of their LTRs, because of their location in transcriptionally inactive areas of the chromatin, or because of methylation of promoter sequences in the LTR. When endogenous viruses are expressed as RNA, protein, or virions, it is usually in normal placentas or in teratomas, which may reflect the presence of hormone-

responsive elements in the LTRs of many endogenous retroviruses. It is possible that integration of endogenous retroviruses may result in recessive mutations. The Hr (hairless) and D (dilute brown) recessive phenotypes in mice are associated with the presence of endogenous retroviruses at the affected loci,^{129–131} and reversion of the mutation is associated with proviral deletion, raising the possibility that there may be analogous situations in humans. Indeed, insertion of a GaLV-related provirus upstream from a duplicated pancreatic amylase gene appears to have allowed its expression in saliva^{132–134} and may have led to the inclusion of starch-rich foods in the human diet.

One specific endogenous retroviral RNA is highly expressed in placenta. Its protein product, syncytin, may be important in human placental morphogenesis, and dysregulation of its expression is associated with preeclampsia.^{135, 136} In general, the expression or the lack of expression of endogenous retroviral genes has not been associated with human diseases, although the AKR strain of mice develops leukemia by a complex process that involves expression and recombination of endogenous MuLVs.^{137–139}

Recently, koala retrovirus (KoRV) has attracted interest. Discovered in 1988,^{140, 141} it has apparently occurred in koala populations for several centuries¹⁴² and has become endogenous in north Australia, while it is primarily exogenous in the south. KoRV causes immunodeficiencies and lymphomas in infected koalas^{143–145} (to the point of endangering koala populations) and appears to be invading the koala germ line in real time.^{144, 146} It is most closely related to GaLV,¹⁴¹ and apparently originated as a cross-species transmission from an Asian mouse species.¹⁴⁷

The integration pattern and the content of endogenous retroviruses can differ among members of the same species, suggesting that they are not entirely stable and that many are not currently essential to their hosts. Their existence as fixed genetic elements, however, suggests that they were important at one time. Retroviruses that use the same receptor exhibit interference with each other, because infection either blocks or downregulates the cell surface expression of the receptor, rendering the cell refractory to superinfection. It may be that endogenous retroviruses provided protection by interference against pathogenic retroviruses that no longer exist and are therefore no longer important.

Retroviral vectors and gene therapy

As the understanding of the roles of specific genes in different diseases has evolved, treatment of diseases by gene therapy, or the delivery of desired genes, has become more of a possibility. One of the main obstacles has been efficient and specific delivery of a gene to the appropriate tissue and cell type. Delivery by transfection of DNA, or introduction into cells in which the membrane has been partially permeabilized by chemicals or an electrical charge, is relatively inefficient, not very specific, and not generally suitable for delivery *in vivo*. Delivery by gene gun, which shoots DNA on the surface of gold microparticles into skin and muscle, and direct injection of DNA result in expression of proteins *in vivo*, but these methods are not very specific and may be best suited for the delivery of DNA vaccines.

An alternative is to use a recombinant virus to deliver the gene of interest into the appropriate tissue. This method of gene delivery is called transduction. Viruses can be highly tissue-specific and, in principle, transduction of cells with a recombinant virus may be the best approach to gene delivery. Different viruses have been used for gene delivery, including adenovirus, which has disadvantages of a lack of persistence and the likelihood of immune responses against viral proteins upon repeated administration. Retroviral vectors are perhaps the best studied and most promising transducing vectors.^{148–151} They integrate, so they theoretically only need to be administered once. In addition, as seen with the acutely transforming replication-defective retroviruses, the vector genome does not need to be able to code for

any viral proteins to be integrated. The only requirements for transduction of the gene of interest are that the vector RNA contains the proper packaging signal and has LTRs at both its ends. Tissue and cell tropisms can be altered by pseudotyping with different envelope proteins.¹⁵² The proteins required to form virions are provided by cell lines that express all the viral proteins from genes that cannot themselves be packaged. When the vector RNA containing the gene of interest is transfected into a packaging cell line, only the vector RNA is packaged into the virion. As the pseudotyped RNA does not code for viral proteins, the virions are only capable of a single round of infection and integration. This allows the stable expression of the gene of interest in the absence of any retroviral proteins, which would be likely to elicit an immune response that would eliminate the genetically altered cells. The majority of retroviral vectors to date have been based on the Moloney strain of MuLV (Mo-MuLV).^{148–151} Mo-MuLV vectors efficiently infect a wide variety of cell types, including those of human origin. More recently, retroviral vectors based on lentiviruses have shown promise. These have the advantage of being able to transduce nondividing cells by the same mechanisms that allow natural lentiviruses to infect resting cells.^{153, 154}

There are several potential problems with retroviral vectors. One is the possible generation of replication-competent helper viruses during the packaging of the vector, which can occur by homologous recombination. Two approaches have been used to minimize this possibility. One is to place the viral structural genes on different genetic units, so that multiple recombination events must occur before a replication-competent helper virus is generated. A second approach, not mutually exclusive with the first, is to minimize areas of homology among the units expressing the helper virus proteins and the vector by, for example, using heterologous promoters for helper virus RNA transcription. Another potential problem derives from the risk that integration in the vicinity of a proto-oncogene could lead to tumorigenesis. Although the risk appears small, it is not zero. This was the apparent reason for three of seven monkeys developing lymphomas in one gene therapy study.¹⁵⁵ Mo-MuLV does not replicate well in human cells, but this is not the case for other potential retroviral vectors. Minimizing integration events by rigorously excluding the presence of replication-competent helper viruses somewhat avoids this problem, but does not completely eliminate it. Indeed, treatment of young severe combined immunotherapy X1 patients with a lentiviral vector devoid of replicating helper virus appears to have resulted in insertion near the LMO2 proto-oncogene promoter followed by a leukemia-like clonal T-cell outgrowth in several of the patients.¹⁵⁶ Another problem is that expression is not maintained indefinitely; retroviral promoters have a tendency to become inactivated over time. A further limitation is that the genetic capacity of retroviruses is only about 8–9 kb, which restricts their ability to deliver genes to only a single gene or two.

Conclusions

The study of retroviruses has led to much of today's techniques and understanding of molecular biology. This is obviously especially true in the case of cell transformation and tumorigenesis, as many retroviruses either cause cancers or (in the case of acutely transforming viruses) capture cellular genes that have the potential to contribute to neoplastic transformation. Retroviruses were the first example of a reversal of the normal order of the flow of genetic information, that is, from RNA to DNA. The identification and elucidation of reverse transcription provided the means for cloning and characterizing mRNA, which greatly facilitated understanding gene expression and function. Furthermore, studies of the regulation of viral transcription, retroviral RNA processing, viral entry mechanisms, viral protein processing, and virion assembly have greatly increased our knowledge in the areas of transcriptional regulation, RNA splicing and translational regulation, membrane biochemistry and fusion, and protein processing and protein–protein interactions, respectively. An understanding of how retroviruses package

and deliver genetic material holds promise that these viruses will be successfully used in the clinic to deliver therapeutic genes to appropriate cells and tissues in human diseases. New generations of vectors currently being developed are bringing us closer to realizing this goal.

Perhaps among the most important contributions of retroviral research to human health were the discovery of HTLV-I and HIV-1, two pathogenic human retroviruses. During the 1970s, much of the research carried out with retroviruses came under the aegis of the Virus Cancer Program (VCP) as part of President Nixon's War on Cancer. The VCP was ended because of a lack of discovery of human cancer viruses and the growing feeling that human retroviruses did not exist. Shortly thereafter, however, HTLV-I was discovered and linked to ATL. Although this discovery has not led so far to better treatment for ATL, it has led to better prevention of infection by, for example, screening blood samples and by avoiding transmission by breast-feeding, a common route of infection of babies. Ironically, the most important consequence of the VCP and retroviral research was the relatively rapid discovery and characterization of a virus not directly linked with cancer, but with immunodeficiency. HIV-1 was discovered and shown to be the cause of AIDS and a blood test was developed in a relatively short span of time, and therapies based on structural determinations of its RT and protease were developed and are being successfully used. This rapid progress would have been far slower had the means for isolating, culturing, and characterizing retroviruses not already been in place.

Chapter 29

Herpesviruses

Jeffrey I. Cohen, MD

Overview

Eight herpesviruses have been isolated from humans: two of these, Epstein–Barr virus (EBV) and Kaposi sarcoma-associated herpesvirus (KSHV), are associated with human tumors. EBV has been detected in lesions from patients with post-transplant lymphoproliferative disease, nasopharyngeal and some types of gastric carcinoma, Burkitt lymphoma, Hodgkin lymphoma, and certain other lymphoid tumors. KSHV is associated with Kaposi sarcoma, primary effusion lymphoma, and Castleman disease. Each of these viruses encodes proteins important for establishment of latency, transforming cells, and evading the immune system.

Properties of herpesviruses

Herpesviruses are enveloped DNA viruses that have the capacity to establish latent infection as well as to undergo lytic infection. The ability to establish latent infection *in vivo* and to reactivate from latency ensures a source of virus to infect previously uninfected individuals. Most adults latently harbor herpes simplex 1, varicella-zoster virus, human herpesviruses 6 and 7, and Epstein–Barr virus (EBV). Several features of herpesvirus replication are important for the maintenance of latency and for oncogenicity; EBV will serve as an example to illustrate the principles of herpesvirus infection relevant to oncogenicity.

First, viral DNA must be maintained in the cell. The EBV genome is usually maintained in latently infected B cells as a multicopy circular episome in the host cell. Second, a cell transformed by a virus must avoid immune clearance. Replication of EBV requires up to 100 viral proteins; however, latent infection of B cells with EBV results in expression of 12 or fewer genes.^{1–3} This limited repertoire of gene products prevents frequent virus replication, avoiding death of the infected cell, and restricts the ability of the immune system to recognize and destroy cells latently infected with the virus. Third, specific viral proteins interact with other cell proteins or directly transactivate other cell genes to provide additional functions necessary for cell proliferation and immortalization. Several EBV proteins interact with cellular proteins to activate transcription of viral and cellular genes or to engage signal transduction pathways in the cell.

EBV: an oncogenic human herpesvirus

EBV gene expression in transformed lymphocytes

Infection of primary B cells with EBV *in vitro* results in transformation of the cells, which can then proliferate indefinitely. Eight EBV proteins and several nontranslated RNAs are expressed in latently infected B lymphocytes that have been growth transformed by EBV *in vitro* ([Table 1](#)). The EBV nuclear proteins EBNA-1, EBNA-2, EBNA-LP, EBNA-3A, EBNA-3B, and EBNA-3C comprise the EBV nuclear

antigen complex. EBNA-1 binds to the oriP sequence (origin of viral DNA replication) on EBV DNA and allows the virus genome to be maintained as an episome in transformed B cells.⁴ EBNA-1 also transactivates its own expression. EBNA-1 transcripts are initiated from one of four different promoters. The Cp and Wp promoters are used to express EBNA-1 in lymphoblastoid cell lines *in vitro*; the Qp promoter is used in tissues from Burkitt lymphoma, nasopharyngeal carcinoma, and Hodgkin lymphoma; and the Fp promoter is used during lytic replication.⁵ EBNA-1 inhibits its own protein degradation by proteasomes⁶ and limits its own translation,⁷ both of which may reduce its presentation to CD8+ cytotoxic T cells; however, EBNA-1 remains a target for CD4+ cells.^{8–11} EBNA-1 inhibits apoptosis induced by expression of p53.¹²

Table 1 Selected EBV genes and their cellular homologs and activities

Gene	Expression class	Cellular homolog	Activity
EBNA-1	Latent, lytic	None	Episome maintenance, transactivates viral genes, inhibits apoptosis
EBNA-2	Latent	Notch	Transactivates viral and cellular genes, inhibits apoptosis
EBNA-3A, B, C	Latent	None	Regulates EBNA-2 activity, transactivates cellular genes
EBNA-LP	Latent	None	Increases EBNA-2 activity
LMP1	Latent, lytic	CD40	Transactivates cellular genes, inhibits apoptosis
LMP2	Latent	None	Prevents EBV reactivation, transactivates Akt
EBERs	Latent	None	Upregulates cellular genes
BARF-1	Lytic	CSF-1R	Inhibits IFN-α
BCFR1	Lytic	IL-10	Inhibits IFN-γ and IL-12
BNLF2a	Lytic	None	Blocks antigen-specific CD8 T-cell recognition
BHRF1	Lytic	Bcl-2	Inhibits apoptosis
BALF1	Lytic	Bcl-2	Regulates BHRF1 activity
BGFL5	Lytic	None	Blocks synthesis of MHC class I and II
BILF1	Lytic	GPCR	Removes MHC class I from cell surface
BLLF3	Lytic	None	Upregulates IL-10, TNF-α, and IL-1β
BPLFI	Lytic	None	Inhibits toll-like receptor signaling
BZLF1	Lytic	None	Inhibits IFN-γ effects, inhibits function of p53, inhibits TNF-α, initiates lytic infection

EBNA-2 transactivates expression of EBV LMP1¹³ and LMP2,¹⁴ and the cellular genes *CD21*, *CD23*, *c-myc*, and *c-fgr*.^{15, 16} EBNA-2 is targeted to the LMP1, LMP2, Cp EBNA, and CD23 promoters by the GTGGGAA-binding protein Jκ, and thereby activates these promoters.¹⁷ EBNA-2 is a functional homolog of the Notch receptor, which uses Jκ to regulate gene expression during development.¹⁸ EBNA-2 also interacts with the DNA-binding protein PU-1 to transactivate the LMP1 promoter¹⁹ and with AUF to transactivate the EBNA Cp promoter.²⁰ The transactivation domain of EBNA-2 is essential for B-lymphocyte transformation.²¹ This domain interacts with transcription factors TFIIB and the TATA-

binding protein-associated factor TAF40.²² EBNA-2 inhibits apoptosis mediated by Nur77.²³

EBNA-LP interacts with and enhances the ability of EBNA-2 to transactivate LMP1 and LMP2.²⁴ Although EBNA-LP binds to Rb and p53 *in vitro*,²⁵ the significance of these interactions is uncertain. Deletion of the carboxy terminus of EBNA-LP markedly reduces the ability of the virus to transform B lymphocytes.²⁶

EBNA-3A, EBNA-3B, and EBNA-3C are distantly related to each other. The EBNA-3 proteins bind to Jk preventing it from binding DNA, thereby inhibiting transactivation by EBNA-2.²⁷ EBNA-3C upregulates expression of LMP1 and CD21. EBNA-3C binds to Nm23-H1, a human metastasis suppressor protein, and inhibits the protein's ability to suppress migration of Burkitt lymphoma cells.²⁸ EBNA-3C degrades Rb and enhances kinase activity by disrupting p27.^{29, 30} EBNA-3A and EBNA-3C are essential for B-lymphocyte transformation *in vitro*, while EBNA-3B is dispensable.^{31, 32}

LMP1 functions as a transforming oncogene in nude mice.³³ Expression of LMP1 in EBV-negative Burkitt lymphoma cells results in B-cell clumping and increased villous projections. Upregulation of bcl-2, bfl-1, and A20, and inhibition of Bax, by LMP1 in B cells protects the cells from apoptosis.^{34, 35} Expression of LMP1 in epithelial cells inhibits differentiation of the cells.³⁶

LMP1 is a functional homolog of CD40, a member of the tumor necrosis factor receptor (TNFR) family.³⁷ The carboxy terminus of LMP1 interacts with the TNFR-associated factors (TRAFs) 1, 2, 3, and 5, TRADD, RIP, and JAK3 *in vitro*.³⁸ LMP1 functions as a constitutively active form of CD40 resulting in activation of NF- κ B, stress-activated protein kinases, STATs, adhesion molecules, the B7 co-stimulatory molecule, JNK, and B-cell proliferation.³⁹ LMP1 upregulates expression of intracellular adhesion molecules, Fas, CD40, and MMP-9⁴⁰ in B cells and EGF in epithelial cells.⁴¹ LMP1 inhibits phosphorylation of Tyk2 resulting in inhibition of interferon (IFN)- α signaling.⁴² LMP1 is essential for transformation of B lymphocytes by EBV.⁴³ Analysis of EBV-containing human lymphomas shows that LMP1 localizes with TRAF-1, TRAF-3, and that activated NF- κ B is present.⁴⁴

LMP2 is dispensable for transformation of B cells,⁴⁵ but induces a transforming phenotype in epithelial cells and promotes their motility.^{46, 47} LMP2 prevents lytic reactivation of EBV-infected primary B cells in response to activation of the B-cell receptor complex by cross-linking of surface immunoglobulin. LMP2 associates with the *src* family and *syk* protein-tyrosine kinases that are coupled to the B-cell receptor complex.⁴⁸ Binding of LMP2 to these proteins results in their constitutive phosphorylation, which inhibits their ability to mediate signaling for virus reactivation.^{48, 49} B cells from transgenic mice expressing LMP2 survive even without normal B-cell receptor signaling activity.⁵⁰ LMP2 activates β -catenin and Ras/PI3K/Akt signaling pathways in epithelial cells resulting in transformation of the cells.^{51, 52} LMP2 also activates mTOR and increases c-myc expression.⁵³

The two EBV-encoded RNAs, EBER-1 and EBER-2, are the most abundant EBV RNAs in latently infected B cells; however, they are not required for latent or lytic EBV infection, but may contribute to B-cell transformation.^{54, 55} The EBERs upregulate expression of bcl-2 and IL-10⁵⁶ and interact with the double-stranded RNA-activated protein kinase, and IFN-inducible oligoadenylate synthetase.^{57, 58}

EBV encodes at least 44 miRNAs from the BART and BHRF1 regions of the genome; both BART and BHRF1 microRNAs downregulate cellular genes and inhibit apoptosis and enhance B-cell proliferation.⁵⁹ EBV also encodes cellular RNAs that enhance transformation.⁶⁰ Both EBV microRNAs and LMP1 are secreted from infected cells in exosomes, which may enhance tumorigenicity.^{61, 62}

EBV genes expressed during productive infection

Infection of epithelial cells with EBV results in productive infection, with replication of virus and lysis of infected cells. Immediate-early genes encode regulators of virus gene expression, including the BZLF1 and BRLF1 proteins, which act as switches to initiate lytic infection. The BZLF1 protein inhibits TNF- α signaling⁶³ and helps the virus evade T-cell responses.⁶⁴ BZLF1 protein also inhibits the expression of the IFN- γ receptor⁶⁵ and inhibits the function of p53.⁶⁶ Early genes encode proteins involved in viral DNA synthesis, while late genes encode structural proteins.

Three viral genes expressed during productive infection are functional homologs of cellular genes and are important for the survival of EBV-infected B cells.^{67, 68} The EBV BCRF-1 protein is homologous to IL-10 and has IL-10 activity.⁶⁹ BCRF-1 is a B-cell growth factor and inhibits IFN- γ release from activated peripheral blood mononuclear cells and secretion of IL-12 from macrophages.

The EBV BARF-1 protein acts as a soluble receptor for CSF-1.⁷⁰ BARF-1 inhibits IFN- α secretion by human monocytes. The EBV BNLF2a protein interacts with the TAP complex to block antigen-specific CD8 T-cell recognition.⁷¹ The EBV BHRF1 protein is homologous to bcl-2 and protects cells from apoptosis.⁷² EBV BALF1 is also homologous to bcl-2 and antagonizes the antiapoptotic effect of BHRF1.⁷³

Clinical aspects

EBV infection is usually spread by saliva. The virus infects B cells directly, or oropharyngeal epithelial cells and then spreads to subepithelial B cells.⁷⁴ During primary infection, up to a few percent of peripheral blood B lymphocytes are infected with EBV and have the capacity to proliferate indefinitely *in vitro*. Natural killer (NK) cells, CD4 T cells, and HLA- and EBNA- or LMP-restricted cytotoxic T cells control the latently infected B lymphocytes.⁸ T- and B-cell interactions release lymphokines and cytokines, giving rise to many of the clinical manifestations of acute infectious mononucleosis. After recovery, the fraction of B cells latently infected with EBV in the peripheral blood remains at 1 in 10⁵ to 1 in 10⁶. These lymphocytes are the primary site of EBV persistence and a source of virus for persistent infection of epithelial surfaces.

B-cell tumors that occur early after EBV infection are usually lymphoproliferative processes, in which latent virus infection in B cells is the principal cause of proliferation. In contrast, nasopharyngeal carcinoma occurs long after primary EBV infection and viral gene expression is less important to the growth of the malignant cells.

Lymphoproliferative disease

EBV is associated with B-cell lymphoproliferative disease in patients with congenital or acquired immunodeficiency. X-linked lymphoproliferative syndrome is an inherited immunodeficiency of males; most patients die of a fatal lymphoproliferative disorder or fulminant hepatitis, but some survive with hypogammaglobulinemia or develop EBV-positive lymphomas. The gene mutated in X-linked lymphoproliferative syndrome has been identified as *SAP*,⁷⁵ which encodes an SH2-containing protein that interacts with SLAM on B and T cells, and with 2B4 on NK and T cells. Anti-CD20 antibody (rituximab) has been effective in treating some patients with X-linked lymphoproliferative disease and acute EBV infection.⁷⁶ Mutations in additional cellular proteins including XIAP, ITK, CD27, MagT1, CTP synthase 1, and PI3K 110 δ predispose to severe EBV infections.

EBV lymphoproliferative disease occurs in patients who are immunosuppressed as a result of transplantation or AIDS.^{77–79} Risk factors for development of lymphoproliferative disease include EBV-seronegativity prior to transplant and receipt of T-cell-depleted bone marrow or antilymphocyte antibody. Lymphoproliferative lesions are most commonly seen in the lymph nodes, liver, lungs, kidney, bone marrow, or small intestine. Tumors in transplant patients are usually classified as lymphomas; some patients have hyperplastic lesions. The proliferating lymphocytes in these tumors generally do not have chromosomal translocations.

AIDS-related lymphomas may be systemic (nodal or extranodal) lymphomas or primary central nervous system lymphomas. Although most B-cell tumors in transplant recipients and central nervous system lymphomas in AIDS patients contain EBV, about 50% of other lymphomas in AIDS patients contain EBV. Tumors in patients with AIDS are usually either immunoblastic lymphomas or Burkitt lymphomas; most of the latter have *c-myc* translocations.

Tissues from transplant recipients or AIDS patients with EBV lymphoproliferative disease show expression of EBERs, EBNA-1, EBNA-2, and LMP1 ([Table 2](#)). The EBV viral load in the peripheral blood has been used to predict development of disease and to follow patients after therapy. The expression of EBV genes, which are targets for cytotoxic T cells, has important implications for therapy. Infusion of EBV-specific cytotoxic T cells, nonirradiated donor leukocytes, or HLA-matched allogeneic cytotoxic T cells have been effective in many cases for treatment of EBV lymphoproliferative disease.^{80–86} Anti-CD20 antibody (rituximab) has induced remissions in some patients and has been used in some studies as pre-emptive therapy when EBV viral DNA in the blood is rising in transplant recipients at risk of lymphoproliferative disease,⁸⁷ although other studies suggest that pre-emptive therapy may be unnecessary.⁸⁸

Table 2 Diseases associated with EBV latent gene expression

Disease	BARTs	EBERs	EBNA-1	EBNA-2	LMP1	LMP2
Burkitt lymphoma	+	+	+	–	–	–
Nasopharyngeal carcinoma	+	+	+	–	+	+
Hodgkin lymphoma	+	+	+	–	+	+
Peripheral T-cell lymphoma	+	+	+	–	+	+
Lymphoproliferative disease	+	+	+	+	+	+

Burkitt lymphoma

Seroepidemiologic studies show a strong association between Burkitt lymphoma and EBV in Africa.^{89, 90} More than 90% of African Burkitt lymphomas are associated with EBV, whereas only approximately 20% of Burkitt lymphomas in the United States are associated with the virus. African patients with Burkitt lymphoma often have high levels of antibody to EBV antigens, and the virus can be recovered from the tissue.

Burkitt lymphomas contain chromosomal translocations that result in *c-myc* dysregulation. The most common chromosomal translocation, t(8;14), places a portion of the *c-myc* oncogene adjacent to an immunoglobulin heavy chain gene. Less common translocations involve the *c-myc* oncogene and the κ or λ immunoglobulin light chain genes t(2;8) and t(8;22), respectively. These translocations result in high constitutive expression of *c-myc*. New approaches to treating Burkitt lymphoma based on inhibition of *c-myc* are in development.⁹¹

EBV-associated endemic Burkitt lymphoma is thought to develop in steps. First, EBV infection may expand the pool of differentiating and proliferating B cells. Second, chronic endemic malaria may cause T-cell suppression and B-cell proliferation. Third, enhanced proliferation of differentiating B cells may favor the chance occurrence of a reciprocal c-*myc* (t[8;14] or t[8;22]) translocation placing c-*myc* partially under the control of immunoglobulin-related transcriptional enhancers, with development of a monoclonal tumor.

Nasopharyngeal carcinoma

The nonkeratinizing nasopharyngeal carcinomas are uniformly associated with EBV. Patients with nasopharyngeal carcinoma have high levels of antibodies to EBV antigens. A prospective study of Taiwanese men showed that those with IgA antibodies to EBV viral capsid antigen (VCA) and anti-EBV deoxyribonuclease antibodies had an increased risk for developing nasopharyngeal carcinoma when compared to men without these antibodies.⁹² These antibodies are useful in screening patients for early detection of nasopharyngeal carcinoma and are prognostic for patients after treatment. Another study showed that quantifying the level of EBV DNA in plasma of patients with advanced nasopharyngeal carcinoma was useful for monitoring patients and predicting outcomes.⁹³ Nasopharyngeal carcinoma tissue contains EBV genomes in every cell. These tumors are monoclonal with regard to EBV infection, indicating that EBV infection precedes malignant cell outgrowth at the cellular level. Unlike Burkitt lymphoma, the association of EBV with nasopharyngeal carcinoma is uniform and universal. Infusions of EBV-specific cytotoxic T cells resulted in remissions in some patients with refractory nasopharyngeal carcinoma.⁹⁴

Hodgkin lymphoma

Persons with a history of infectious mononucleosis are at a greater risk of developing Hodgkin lymphoma.⁹⁵ Patients with Hodgkin lymphoma generally have higher titers of antibody to EBV VCA than does the general population. Tissues from ~40% to 60% of patients with Hodgkin lymphoma contain EBV genomes. Cases of Hodgkin lymphoma in patients with HIV or from developing countries are more likely to contain EBV genomes than persons without HIV or from developed countries.⁹⁶ The EBV genome is monoclonal and present in Reed–Sternberg cells. EBV is more often associated with aggressive subtypes (especially mixed cellularity) of Hodgkin lymphoma. Tumors from patients with EBV+ Hodgkin lymphoma and some from patients with lymphoproliferative disease arise from postgerminal center cells.⁹⁷ Infusion of cytotoxic T cells generated from 11 patients with relapsed Hodgkin lymphoma and measurable disease resulted in complete remissions in two patients, partial remission in one patient, stable disease in five patients, and no response in three patients.⁹⁸ Infusion of arginine butyrate and ganciclovir to induce EBV thymidine kinase expression with phosphorylation of ganciclovir and induction of apoptosis resulted in antitumor responses in some patients with EBV B-cell malignancies.⁹⁹

Other tumors associated with EBV

EBV has also been detected in non-Hodgkin's lymphomas. EBV-positive diffuse large B-cell lymphoma has a poorer prognosis than EBV-negative lymphoma.¹⁰⁰ Treatment of patients with EBV+ non-Hodgkin's lymphoma in remission with autologous antigen-presenting cells transduced with LMP2 resulted in increased frequencies of LMP2-specific cytotoxic T cells and tumor responses in several patients with relapsed disease.¹⁰¹ EBV DNA and latency proteins have been detected in tissues from patients with peripheral T-cell lymphomas.¹⁰² EBV DNA has also been detected in central nervous system lymphomas from patients with no underlying immunodeficiency, T cells in patients with virus-associated

hemophagocytic syndrome, nasal T-cell lymphoma, carcinoma of the palatine tonsil, laryngeal carcinoma, and angioimmunoblastic T-cell lymphoma. EBV DNA and nuclear antigens have been detected in thymic carcinomas and in B-cell lesions from patients with lymphomatoid granulomatosis.

EBV DNA has been found in leiomyosarcomas in AIDS patients,¹⁰³ and viral RNA and EBNA-2 have been detected in smooth muscle tumors in organ transplant recipients.¹⁰⁴ About 7% of primary gastric carcinomas are EBV+, especially in undifferentiated lymphoepithelioma-like carcinomas.

KSHV and malignancies

In 1994, Chang et al.¹⁰⁵ detected sequences of a new human herpesvirus, Kaposi-sarcoma-associated herpesvirus (KSHV) in Kaposi sarcoma tissues from patients with AIDS. KSHV is present in B cells in asymptomatic persons. B-cell lines derived from primary effusion lymphomas maintain KSHV in a latent state and can be induced to undergo lytic virus replication by the addition of phorbol ester or butyrate. Infection of dermal microvascular endothelial cells *in vitro* with KSHV results in transformation of the cells with maintenance of long-term infection. The cells become spindle-shaped and show loss of contact inhibition with anchorage-independent growth.¹⁰⁶ Although KSHV transforms bone-marrow-derived endothelial cells, virus is present in only a small fraction of the cells.¹⁰⁷

Viral proteins

Several KSHV proteins are important for transformation, establishing latency, and modulating the immune response to the virus.^{108–110} KSHV encodes a large number of cellular homologs ([Table 3](#)) that have been grouped into different classes, depending on when they are expressed in primary effusion lymphoma cell lines.¹¹¹ Expression of the KSHV K1 gene in rodent fibroblasts results in transformation of the cells.¹¹² The K1 protein induces tyrosine phosphorylation in cells¹¹³ and activates the Akt signaling pathway.¹¹⁴ The K1 protein inhibits apoptosis¹¹⁵ and results in constitutive calcium-dependent signal activation in B cells.¹¹⁶

Table 3 Selected KSHV genes and their cellular homologs and activities

Gene	Expression class	Cellular homolog	Activity
K1	II	ITAM motif	Transformation, activates signaling pathways
K2	II	IL-6	B-cell growth factor, angiogenesis, hematopoiesis
K3	III	None	Reduces surface MHC class I
K4	II	MIP-1 α	Chemokine receptor antagonist; angiogenesis; chemotaxis
K4.1	II	MIP-1 α	Chemokine receptor agonist; angiogenesis; chemotaxis
K5	II	None	Inhibits NK-cell activity; reduces surface MHC class I; increases monocyte proliferation
K6	II	MIP-1 α	Chemokine receptor agonist; angiogenesis; chemotaxis
K8	III	None	Inhibits p53
K9	II	IRF	Represses IFN activity, transformation, inhibits p53
K10.5 (LANA-2)	II	IRF	Represses IFN activity; inhibits apoptosis; inhibits p53
K11.1	I	IRF	Represses IFN activity
K12 (Kaposin A)	II	None	Transformation
K12 (Kaposin B)	II	None	Increases cytokine mRNA stability
K14	II	OX-2	Induces proinflammatory cytokines
K15 (LAMP)	III	None	Binds TRAFs, inhibits B-cell receptor signaling
ORF4	II	CR2	Complement-binding protein
ORF16	II/III	Bcl-2	Inhibits apoptosis
ORF45	III	None	Inhibits IRF7
ORF50	III	None	Increases CD21 and CD23 expression, degrades IRF7
ORF63	III	NLR proteins	Inhibits NLRP1
ORF71	I	FLIP	Inhibits apoptosis; activates NF- κ B
ORF72	I	Cyclin D	Cell-cycle progression, inhibits Rb
ORF73 (LANA-1)	I	None	Episome maintenance, inhibits p53 and Rb
ORF74	II	GPCR	Angiogenesis, transformation, and proliferation

Expression class I = latent gene, expressed in uninduced primary effusion lymphoma cells, not induced by phorbol ester; class II = expressed in uninduced cells, induced by TPA; class III = lytic gene, expressed only after induction by TPA (includes many structural proteins and DNA replication enzymes). FLIP = FLICE inhibitory protein; GPCR = G-protein-coupled receptor; IRF = interferon regulatory factor; ITAM = immunoreceptor tyrosine-based activation motif; MHC = major histocompatibility complex; MIP = macrophage inflammatory protein; NK = natural killer; Rb = retinoblastoma protein; TRAFs = TNFR-associated factors.

The KSHV K2 gene encodes an IL-6 homolog (vIL-6). IL-6 is a B-cell growth factor and acts as an autocrine growth factor for lymphoid tumors resulting in proliferation.¹¹⁷ vIL-6 prevents death of IL-6-dependent B9 cells *in vitro*,¹¹⁸ promotes hematopoiesis, and induces VEGF to promote angiogenesis.¹¹⁹ The K3 [modulator of immune recognition 1 (MIR1)] and K5 (MIR2) proteins induce rapid endocytosis of MHC (major histocompatibility complex) class I molecules and IFN- γ receptor 1 from the surface of cells by ubiquitination of these proteins.^{120–122} The K5 protein also downregulates ICAM-1 and B7.2, which results in inhibition of NK-cell-mediated cytotoxicity,¹²³ and removes CD31 from the surface of endothelial cells.¹²⁴

The KSHV K4, K4.1, and K6 genes encode three chemokines: the viral macrophage inflammatory proteins (MIP)-II, -III, and -I, respectively. vMIP-I inhibits replication of HIV strains dependent on CCR5.¹¹⁸ vMIP-I and vMIP-III are chemokine receptor agonists for CCR8¹²⁵ and CCR4,¹²⁶ respectively, while vMIP-II is a broad-spectrum chemokine receptor antagonist. vMIP-II is a chemoattractant for eosinophils,¹²⁷ binds to both CC and CXC chemokines, and blocks calcium mobilization induced by chemokines.¹²⁸

The KSHV K9, K11.1, and K10.5 proteins are referred to as viral IFN regulatory factor (vIRF)-1, -2, and -3, respectively. Each of these proteins inhibits virus-mediated activation of the IFN- α promoter.¹²⁹ vIRF1 inhibits MHC-1 transcription and surface expression.¹³⁰ vIRF1 and vIRF3 inhibit p53-mediated apoptosis^{131, 132} and transform NIH 3T3 cells.¹³³ vIRF3 (also called LANA2) protects cells from p53-induced apoptosis.^{134, 135} KSHV ORF45 blocks the activity of IRF7 and inhibits the activation of IFN- α and - β .¹³⁶

The KSHV K12 locus encodes several proteins termed kaposins. Kaposin A induces transformation of cells.¹³⁷ Kaposin B increases expression of cytokines by activating MAP-kinase-associated protein kinase 2 and inhibiting the degradation of cytokine mRNA.^{138, 139} The KSHV K14 protein, a homolog of the cellular OX2 protein, stimulates monocytes to produce proinflammatory cytokines such as TNF- α , IL-1 β , and IL-6.¹⁴⁰ KSHV ORF4 protein inhibits the complement system.¹⁴¹ KSHV ORF16 encodes a homolog of bcl-2 and inhibits bax-induced apoptosis.¹⁴² The ORF71 gene encodes a homolog of cellular FLIP that blocks apoptosis. ORF71 binds to Atg3 and protects cells from autophagy. KSHV ORF71 activates NF- κ B, promotes tumor growth, and is required for survival of KSHV-infected lymphoma cells.^{143–147} KSHV ORF72 encodes a cyclin D homolog that binds to and activates cdk6 and phosphorylates p27, and stimulates cell-cycle progression in normally quiescent fibroblasts.^{148, 149} The viral cyclin protein phosphorylates and thereby inactivates Rb.¹⁵⁰

KSHV ORF73 encodes LANA1 that localizes with viral DNA episomes and tethers them to chromosomes during cell division.¹⁵¹ KSHV LANA1 is required for persistence of the episome in dividing cells and transactivates its own promoter. In addition, LANA1 inhibits the activity of both p53 and Rb,^{152, 153} upregulates expression and stabilizes β -catenin,¹⁵⁴ upregulates and activates survivin,¹⁵⁵ induces nuclear accumulation of HIF,¹⁵⁶ and activates c-myc.¹⁵⁷ Expression of LANA in transgenic mice results in development of lymphomas.¹⁵⁸ LANA inhibits TGF- β signaling.¹⁵⁹ KSHV ORF74 encodes a G-protein-coupled receptor that is homologous to the cellular IL-8 receptor; unlike the latter protein, however, the KSHV receptor is constitutively active and induces cellular proliferation.¹⁶⁰ ORF74 protein induces angiogenesis,¹⁶¹ activates the Akt signaling pathway,¹⁶² and induces proliferation and vascular permeability of endothelial cells.^{163–165} ORF74 activates NF- κ B and JNK, and upregulates IL-1, IL-8, TNF- α , and FGF, and inhibits viral lytic gene expression.¹⁶⁶

KSHV K15 encodes the latency-associated membrane protein (LAMP) and interacts with TRAFs 1, 2, and 3.¹⁶⁷ K15 suppresses tyrosine phosphorylation and intracellular calcium mobilization, inhibiting B-cell receptor signaling.¹⁶⁸ KSHV encodes several microRNAs located between K12 and ORF71 or within K12 that are expressed during latency and detected in patient plasma.¹⁶⁹ These microRNAs are important for NF- κ B activation and blocking cell-cycle arrest of latently infected cells.^{109, 170} KSHV microRNAs also target cellular genes.¹⁷¹

Clinical aspects

Seroprevalence rates for KSHV vary from <5% in normal blood donors in the United States or United Kingdom to 30–35% in HIV-positive homosexual men.¹⁷² Antibody to KSHV is more common in African and Mediterranean populations. At least 85% of patients with Kaposi sarcoma have antibodies to KSHV.¹⁷³ The prevalence of Kaposi sarcoma is lower in women than in men, and HIV-seropositive women have a much lower incidence of antibody to KSHV than do seropositive men. KSHV seropositivity in HIV-positive homosexual men is predictive of subsequent development of Kaposi sarcoma.¹⁷⁴ Levels of KSHV DNA are higher in patients with active Kaposi sarcoma or multicentric Castleman disease, than in those in remission, and are also elevated in patients with primary effusion lymphoma.¹⁷⁵ The virus is not thought to be pathogenic in most healthy individuals and can persist in a latent phase for life; however, in immunocompromised persons, it is strongly associated with Kaposi sarcoma. Thus, although infection with KSHV appears to be required for development of Kaposi sarcoma, it is probably not sufficient by itself and other cofactors, such as HIV and impaired cellular immunity, are important. KSHV is thought to be sexually transmitted in homosexual men¹⁷² and has been associated with sexual transmission and intravenous drug use in women.¹⁷⁶ In endemic populations (e.g., Africa), KSHV may be transmitted vertically from mother to child and between siblings. KSHV has been transmitted by renal allografts.^{177, 178}

Kaposi sarcoma

KSHV has been found in nearly all biopsies of classic Kaposi sarcoma, African endemic Kaposi sarcoma, Kaposi sarcoma in HIV-seronegative transplant recipients and homosexual men, and Kaposi sarcoma in patients with AIDS.^{179, 180} KSHV is present in the endothelial and spindle cells of the tumor, but not in normal endothelium.¹⁸¹ Most of the tumor cells are latently infected with the virus, but 1–5% of the spindle cells in HIV-positive Kaposi sarcoma show lytic KSHV infection. Kaposi sarcoma can be polyclonal, oligoclonal, or monoclonal. KSHV is also present in the peripheral blood mononuclear cells of approximately 50% of patients with Kaposi sarcoma, and its presence is predictive of development of the malignancy.¹⁷² KSHV has also been detected in the saliva of patients with Kaposi sarcoma, and, infrequently, in semen. Several KSHV proteins are expressed in Kaposi's tissues ([Table 4](#)). Foscarnet and ganciclovir reportedly reduce the frequency of new Kaposi sarcoma lesions in some, but not all, studies.^{182, 183} Cidofovir had no effect on treatment of established lesions.¹⁸⁴ In contrast, HIV protease inhibitors have been reported to induce regression of Kaposi sarcoma lesions.¹⁸⁵ IL-12, in combination with liposomal doxorubicin, resulted in tumor responses in AIDS patients with Kaposi sarcoma receiving HAART; responses were maintained with IL-12 therapy.¹⁸⁶ Sirolimus,¹⁸⁷ imatinib,¹⁸⁸ bevacizumab,¹⁸⁹ and paclitaxel¹⁹⁰ have all been reported to have activity against Kaposi sarcoma.

Table 4 Diseases associated with KSHV gene expression

Gene	Kaposi sarcoma	Primary effusion lymphoma	Castleman disease
LANA (ORF73)	+	+	+
K12 (Kaposin)	+	+	–
ORF72 (v-cyclin)	+	+	–
ORF71 (v-FLIP)	+	+	+
ORF74 (GPCR)	+	–	–
K10.5 (vIRF3)	–	+	+
K9 (vIRF1)	–	–	+
K2 (vIL-6)	–	±	+

Primary effusion lymphoma

KSHV has also been found in primary effusion lymphomas in patients with AIDS.^{180, 181, 191} These body-cavity-based lymphomas of B-cell lineage are located in the pleural, peritoneal, or pericardial space and usually contain EBV as well as KHSV genomes. Some KSHV-positive lymphomas have been found in patients without AIDS.

Multicentric Castleman disease

KSHV has also been detected in biopsies from some patients with multicentric Castleman disease, especially in the variant known as the plasma cell type.^{180, 181, 192–194} This disease is usually polyclonal and presents as generalized lymphadenopathy, fever, and hypergammaglobulinemia. Symptoms are thought to be due to increased levels of IL-6 and vIL-6.¹⁹⁵ KSHV is detected more frequently in biopsies from HIV-positive patients than in biopsies from those patients without HIV. KSHV is present in the immunoblastic B cells of the mantle zone of the lesions. Zidovudine plus valganciclovir showed activity in some patients with KSHV-associated Castleman disease.¹⁹⁶

Summary

- Two herpesviruses, Epstein–Barr virus (EBV) and Kaposi sarcoma-associated herpesvirus (KSHV), are associated with human tumors.
- EBV is associated with Burkitt lymphoma, Hodgkin and non-Hodgkin lymphoma, post-transplant lymphoproliferative disease, T-cell lymphoma, nasopharyngeal carcinoma, and certain types of gastric carcinoma.
- EBV transformed B cells and EBV post-transplant lymphoproliferative lesions express EBNA-1, -2, -3s, and -LP and LMP1 and LMP2 and RNAs including EBERs and BARTs in culture. Burkitt lymphomas express only EBNA-1, EBERs, and BARTs. Hodgkin lymphomas and nasopharyngeal carcinomas express EBNA-1, LMP1, LMP2, EBERs, and BARTs.
- EBV EBNA-1 is important for maintaining the viral episome during replication of the cells. EBNA-2 transactivates several virus and cellular promoters and is a functional homolog of the Notch receptor. EBNA-3's regulate the activity of EBNA-2 and also transactivate viral genes.

LMP1 is a functional homolog of CD40 and binds to TNFR-associated factors to upregulate NF- κ B, STATs, JNK, and stress-activated protein kinases.

- KSHV is associated with primary effusion lymphoma, Kaposi sarcoma, and Castleman disease.
- Each of the three KSHV-associated tumors express LANA (ORF73) and v-FLIP (ORF71). Other KSHV proteins, including Kaposin (K12), v-cyclin (ORF72), a G-protein-coupled receptor (GPCR, ORF74), v-IRF3 (K10.5), v-IRF1 (K9), and v-IL-6 (K2) are expressed in some, both not all virus-associated malignancies.
- LANA maintains the viral episome during replication and inhibits the activity of Rb and p53. KSHV v-FLIP is a homolog of cellular FLIP and inhibits apoptosis and activates NF- κ B. Kaposin increases the activity of cytokines, v-cyclin inhibits Rb and helps virus-infected cells to progress through the cell cycle, and the viral GPCR contributes to proliferation of KSHV-infected cells. v-IRF1 and v-IRF3 inhibit the activity of interferon and p53, while v-IL-6 functions as a B-cell growth factor.

Chapter 30

Papillomaviruses and cervical neoplasia

Michael F. Herfs, PhD ■ Martin C. Chang, MD, PhD, FCAP, FRCPC ■ Christopher P. Crum, MD, FRCP

Overview

The field of HPV continues to move forward with new insights into pathogenesis, refined screening approaches using HPV testing, and the evolution of vaccines to include a wider range of HPV types covered. The squamocolumnar junction has been more precisely characterized, and its potential as a target for prevention in women beyond optimal age for vaccination is being discussed. HPV testing is assuming a major role in screening women over age 30, to the expense of the Papanicolaou smear, which will be largely limited to women between age 20 and 30, with reduction or elimination of cervical screening for women under age 20. For prevention of cervical neoplasia, the expansion of the range of HPV types targeted is now a reality, with new broader spectrum vaccines (such as 9-valent vaccines) being introduced.

The causal relationship between human papillomaviruses (HPVs) and cervical neoplasia is an accepted fact, and this virus has been the focus of strategies designed to elucidate mechanisms of virus-induced tumorigenesis, to improve the diagnosis and screening of uterine cervical neoplasms, and to exploit the host immune response to prevent these diseases. Technological advances have dictated both the tempo and the direction of this research, which began with descriptive and experimental pathology, progressed to molecular biology, and finally involved molecular immunology in efforts both to implicate the virus directly in producing neoplasia and to unravel the mechanisms of host response and prevention with vaccines.

Definitions, HPV-target cells, and mechanisms of infection and transformation

Definitions

Genital “infections” are best defined by the presence of clinically or colposcopically identifiable flat or raised lesions that contain papillomaviral deoxyribonucleic acid (DNA), the prototype of which is genital warts. In this instance, infectious virus is likely to be identified within the epithelium ([Figure 1](#)). More recently, the term infection has been expanded to include HPV-related precancerous lesions, or even cancers—the term being used loosely to denote the presence of viral DNA. However, integrated viral DNA rather than virions is more likely to be identified in advanced lesions ([Figure 2](#)).¹ As is detailed subsequently (see the section titled “Risk Factors”), HPV DNA may be associated with no visible abnormality; active, clinically, or morphologically conspicuous infection; and advanced neoplasia ([Tables 1](#) and [2](#)). The hallmark of significant HPV infection is a morphologic transformation of the target tissue. This is not synonymous with the term transformation as classically applied to changes in cultured cells produced after introduction of HPV nucleic acids. Rather, it defines the morphologic alterations that

can be most consistently associated with the presence of HPV nucleic acids. Depending on host factors and HPV type involved in the infection, it may be defined as a low- or high-grade genital precancer, either of which is distinct from the normal epithelium ([Figures 1](#) and [2](#)).

Figure 1 Histopathology of a classic human papillomavirus (HPV) infection (condyloma) of the cervix associated with low-risk HPV types (HPV type 6 or 11). (a) Morphologic features of HPV infection include nuclear atypia in the superficial epithelial cells with prominent cytoplasmic halos (*arrowheads*). The lower cell layers contain minimal cytologic atypia. (b) Appearance following *in situ* hybridization with a biotin-labeled mixed deoxyribonucleic acid (DNA) probe containing HPV types 6 and 11 (VIRATYPE, Life Technologies, Gaithersburg, MD). The dark staining in the superficial cell nuclei and cytoplasm represents viral DNA and ribonucleic acid produced during viral replication. (c) An immunoperoxidase stain for HPV capsid proteins, highlighting several dark-staining nuclei in the superficial epithelium (*arrowheads*).

Figure 2 Histopathology of cervical intraepithelial neoplasm associated with high-risk human papillomavirus (HPV) types (i.e., 16, 31, 33, and 35). (a) Lesion involving the superficial and crypt (gland) epithelium (*large arrowhead*). Koilocytotic atypia is present (upper right), but, in addition, nuclear atypia is conspicuous in the lower cell layers (*small arrows*). (b) Appearance following *in situ* hybridization with a mixed probe containing HPV types 31, 33, and 35. Note the similar distribution of staining as in [Figure 1b](#). (c) In contrast to [Figure 1c](#), capsid proteins are infrequently identified by immunostaining, with rare positive nuclei observed (*arrowheads*).

Table 1 Definitions

HPV, human papillomavirus
CIN, cervical intraepithelial neoplasia, synonymous with papillomavirus-related squamous intraepithelial lesions. Low-grade CIN (CIN I) is synonymous with flat or exophytic condyloma and exhibits nuclear atypia, principally in the upper epithelial layers. High-grade CIN (CIN II or III) is characterized by atypia in all epithelial layers. HPV-related lesion includes HPV infections such as condylomata and also any lesion associated with papillomaviruses, including high-grade CIN and various invasive carcinomas
Occult or latent HPV, defined as the presence of HPV DNA in the absence of morphologic evidence of HPV infection (i.e., no lesion is present)
High-risk HPV, HPV with documented association with cancer (this is not an assessment of cancer risk and will vary between high-risk HPVs)
Low-risk HPV, HPV with no association with cancer
VLP, viral-like particle; pertains to papillomavirus-like particles generated <i>in vitro</i>

Table 2 Genital HPVs and relationship to disease

HPV(s)	Associated diseases
16	More than 50% of high-grade CIN and carcinomas (both squamous and adenocarcinoma)
18	10% of squamous carcinomas, 50% of adenocarcinomas and adenocarcinomas <i>in situ</i> , and 90% of neuroendocrine carcinomas
31, 45	5–10% of CIN, squamous carcinomas
33, 39, 51, 52, 55, 56, 58, 59, 68	Less than 3% (each) of CIN, squamous carcinomas
6, 11, 40, 42, 53, 54, 57, 66, 84	Low-risk HPVs, essentially never detected in carcinoma
61, 62, 64, 67, 69–72, 81, cp6108, iso39	Insufficient data to ascertain risk

HPV-target cells and mechanism of infection

The cells initially infected by HPV have traditionally been presumed to be in the basal layer of the squamous epithelium lining the ectocervix and the region of the cervix where the columnar epithelium has been replaced by squamous mucosa (transformation zone). According to this theory, it is presumed that the virus gains access to the basal proliferating epithelial cells through microtraumas or abrasions in the stratified mucosa that expose these latter cells to virion particles.⁵ In support of this hypothesis is the demonstration of HPV DNA and ribonucleic acids in basal cells and the observation that experimental infection of the squamous mucosa by pseudovirions is enhanced by disturbing the epithelial surface (and hence exposing the basal cells) before exposure.⁶ Although basal keratinocyte infection is likely to result in productive infections and subsequent (pre)neoplastic lesions developing in the outer part of the cervix and other mucosal sites (vagina, vulva), this hypothesis is inconsistent with the long-term observation that

about 90% of cervical (pre)cancer develops specifically in the squamocolumnar junction (SCJ).⁷ For several years, this specific microenvironment has been speculated to contain multipotent cells that by virtue of their biology or location render them uniquely vulnerable to HPV infection. A discrete population of residual embryonic (Müllerian) cells has been recently discovered in the cervical SCJ.⁸ In addition to being involved in adult cervical remodeling (metaplasia, hyperplasia),⁹ these SCJ cells are proposed to be targeted by HPV and are thus the progenitors to cervical neoplasia. In this model, the basal keratinocytes are still susceptible to HPV, but less so relative to the SCJ cells.

Whatever the cell initially infected by HPV, host cell entry of HPV is initiated by binding of the mature viral capsid to heparan sulfate proteoglycans on the basement membrane. Then, a cleavage of the HPV minor capsid protein L2 at a furin (convertase) consensus site induces a capsid conformation change allowing HPV capsid endocytosis.¹⁰ Endocytic pathways and HPV cellular receptor are, however, still controversial and several candidates such as α 6 integrin have been proposed.¹¹

Mechanisms of neoplastic transformation

The mechanism by which HPV infection produces neoplastic transformation has been progressively elucidated and consists of at least four components ([Figure 3](#)).¹² The first is the direct effects of the viral oncoproteins on the cell cycle, mediated via interactions between E6 and E7 oncoproteins of cancer-associated (high-risk) HPVs and the tp53 and Rb proteins, respectively ([Figure 3](#)). A direct influence of these oncoproteins on other cell-cycle regulators, such as cyclin E, has also been demonstrated.¹³ Compensatory elevation in expression of the cyclin-dependent kinase inhibitor p16 results from the above disturbances.^{14, 15} The second effect is also mediated via viral oncoproteins and consists of abnormalities in centrosome duplication, leading to genomic instability, subsequently reflected in progressive allelic imbalance.^{2, 16} The latter include alterations in 3p and specific amplifications at 3q25–27.^{17, 18} The third component is mediated via E6 and consists of telomerase upregulation and a disruption of normal replicative senescence.¹⁹ These events occur ultimately as a function of expression of viral oncoproteins (E6 and E7). A fourth mechanism is the inactivation of tumor suppressor genes by methylation.²⁰ For example, the epigenetic repression of E-cadherin by E7 protein has been shown to increase the migratory properties of HPV-infected cells.²¹

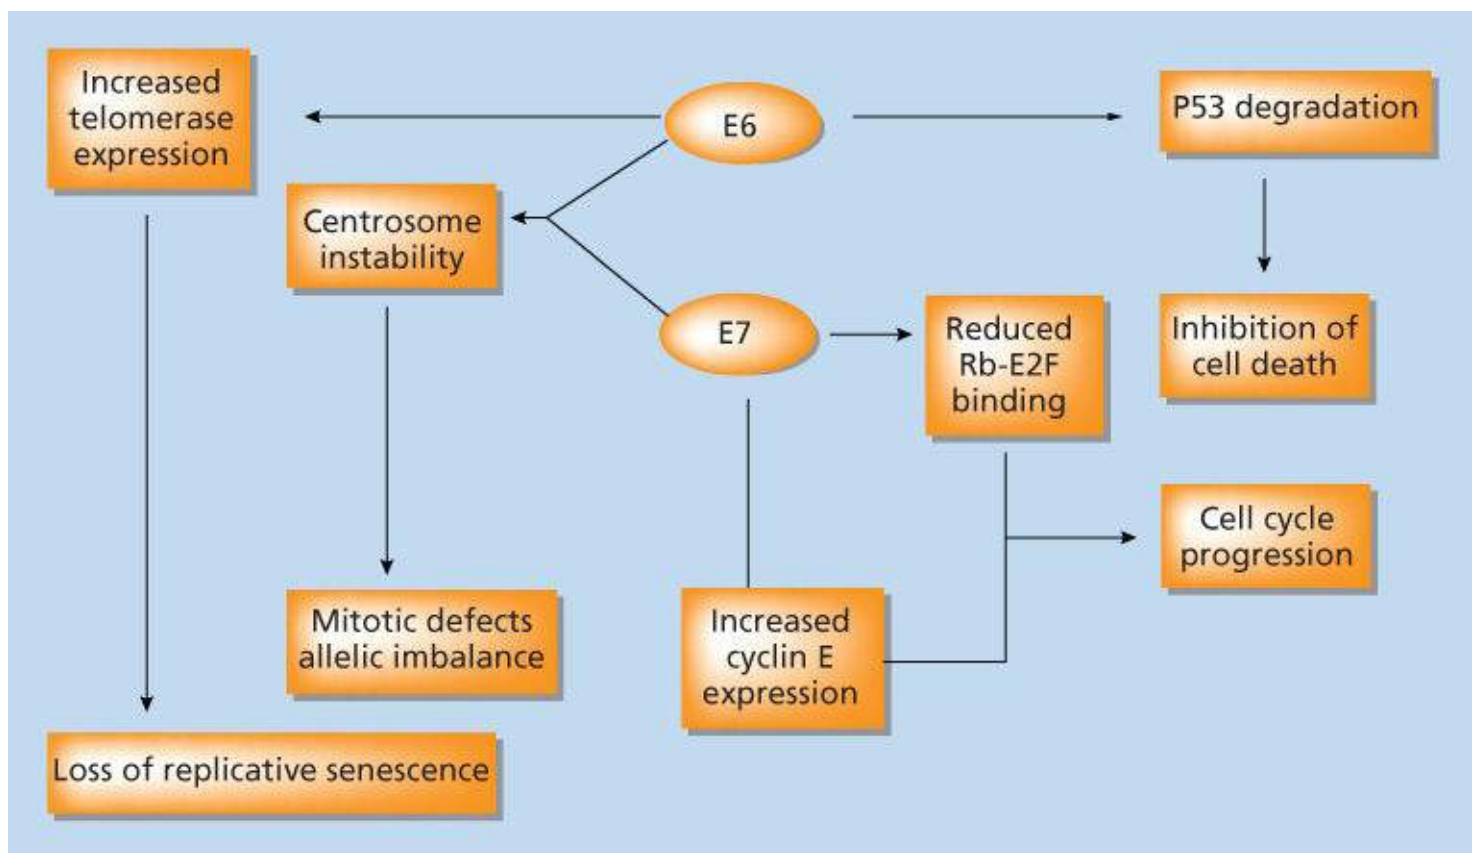

Figure 3 Schematic of potential mechanisms of human papillomavirus-related neoplastic transformation.

HPV and human genital neoplasia

Risk factors

HPV infection is ubiquitous in the young, sexually active population, peaks in the early reproductive years, is often transient, and becomes increasingly less prevalent with increasing age.^{22, 23} However, persistent infection by the same HPV type is strongly associated with the risk of a current or subsequent cervical neoplasm.²⁴ At least 30 HPV types are associated with cervical neoplasia, with a broad gradient of risk imposed by these HPV types. Types 6 and 11 are prototypical “low-risk” HPVs associated with genital warts (condylomata).^{25, 26} In contrast, type 16 is the prototypical “high-risk” HPV, present in more than 50% of cervical carcinomas.²⁷ HPV 18 predominates in glandular and neuroendocrine carcinomas.^{28, 29} However, all of these HPVs may be found in women with normal cytology. A variety of other HPVs are associated with cancer at a lower frequency. Currently, these “intermediate-risk” and the high-risk types are combined into a single category. The presence of any HPV, high- or low-risk, does not exclude the subsequent emergence of another HPV infection of different risk, meaning that infection with one virus may serve as a surrogate marker for subsequent infection by a high-risk HPV. Predictably, most HPVs detected in women with normal Pap smears have some association with cancer risk, albeit low.³

If a woman is found to harbor a high-risk HPV in her genital tract, what is her risk of developing a high-grade squamous intraepithelial lesion (HSIL)? In general, approximately 15% of reproductive-age women will score positive for high-risk HPVs. The risk of HSIL ranges from less than 5% to over 80%, depending on whether the Pap smear is normal, contains a minor or nondiagnostic atypia (atypical squamous cells of undetermined significance [ASCUS]), or is HSIL. Repeated detection of the same HPV type—even in the presence of a normal Pap smear—increases the risk to nearly 20%.³⁰ There is a strong theoretic basis for assuming that intratypal sequence variants influence outcome following infections by

HPV 16.³¹ However, the use of this information in patient management awaits greater consistency in study design and outcome and a clearer understanding of the mechanisms influencing the relationship between intratypical variants and the risk of developing high-grade cervical intraepithelial neoplasia (CIN) or cancer.

Young, sexually active women are at greatest risk of HPV infection and preinvasive cervical neoplasia, and this risk drops significantly with increasing age. As many as 39% of adolescents may score positive at a single visit.²² The index of HPV detection drops further with the approach of menopause, presumably signifying a long-standing and effective immune response to the virus that follows the onset of sexual activity and exposure to HPVs in early life.^{23, 24}

The risk of anogenital neoplasia or HPV infection in immunosuppressed individuals is well documented, particularly in transplantation patients.³² Human immunodeficiency virus (HIV) infection has been the most intensively studied. The risk of HPV positivity and persistent positivity is increased in women who are HIV positive.³³ Furthermore, persistence was 1.9 (95% confidence interval [CI] 1.5–2.3) times greater if the subject had a CD4 cell count <200 cells/ μ L (vs >500 cells/ μ L) in one study.³³ The risk of a subsequent squamous intraepithelial lesion is significantly higher in HIV-infected women.³⁴ The proportion of advanced precursor lesions is not significantly higher, but the risk of lesion persistence is.^{34, 35} The risk of invasive carcinoma in HIV-infected women is controversial but may be influenced by the level and duration of immunosuppression.³⁶ This is in contrast to gay men, who have a high risk of anal cancer that is greatest in the HIV-infected group, particularly since the initiation of antiretroviral therapy.³⁷

In summary, a multitude of factors, virus and host related, influence the risk of papillomavirus-related anogenital neoplasia before, during, and following exposure and lesion progression.

Applications to clinical medicine

The prevention of cervical cancer is based on the Pap test. Because the majority of cervical cancers are preceded by a cervical precursor (CIN) lesion, often by many years, the detection of these precursors is fundamental to cancer prevention. The Pap test recommendations have undergone revision recently, in concert with recommendations for the use of HPV testing in screening. These are discussed together in the next segment. Precursor lesions are recognized clinically on colposcopy, where precursor lesions can be identified following the application of acetic acid.³⁸ The use of colposcopy has maximized the targeting of lesions for biopsy, and outpatient removal is the usual approach, including cryotherapy, laser, and, recently, loop electrical excision.³⁹ The latter procedures target the entire transformation zone, removing the lesion and replacing the process of chronic repair with a brief period of re-epithelialization. Recurrence after removal or ablation is linked to either inadequate excision or infection by another HPV following therapy. The former is increased when margins are positive. Infection with new HPV types appears to explain why many “recurrences” following ablation for high-grade precursors are low grade in nature. Reinfection with the same HPV type is uncommon except in immunosuppressed women. The potential significance of these findings in cancer prevention is discussed at the end of this chapter.

HPV testing in management of the abnormal Pap smear and primary screening

HPV testing has emerged as a viable management tool for a subset of women with abnormal cervical cytology. Because HPV is so strongly linked to cervical neoplasia and because high-risk HPV types

predominate in the cervix, a substantial proportion of women with a cytologic diagnosis of low- or high-grade precancerous changes will score positive. For this reason, HPV testing is of limited value in this population. However, women with nondiagnostic squamous atypias (ASCUS) present a management dilemma in which the clinician must decide between colposcopy and Pap smear follow-up.

HPV testing offers the additional opportunity to triage the patient into colposcopy and follow-up groups by immediately testing the cytologic sample, which is possible with the newer liquid-based technologies. Newer generations of HPV testing, such as the Hybrid Capture II test, are extremely sensitive and will detect more than 95% of women with histologically proven preinvasive disease.⁴⁰ If HPV negative, women with ASCUS have a <1% risk of high-grade CIN, in contrast to a 20% risk if they are HPV positive.⁴⁰ Similar results have been seen with the management of abnormal glandular cells on the smear.⁴¹ Recently, the test has been approved as an adjunct to the Pap smear for screening women over age 30. The basis for this approach lies in the high negative predictive value of both a normal smear and negative HPV assay, which may permit a longer cytology screening interval. Recently, the American Cancer Society and United States Preventative Task Force have made the following recommendations that will impact on reimbursement. First screening of women under age 21 and over age 65 will not be recommended unless there is a history of cervical neoplasia. Second, screening interval of women age 21–65 will be lengthened to 3 years. Third, screening of women over age 30 can be lengthened to 5 years if accompanied by HPV testing (see <http://www.uspreventiveservicestaskforce.org/uspstf/uspsscerv.htm>, <http://www.cancer.org/Cancer/news/News/new-screening-guidelines-for-cervical-cancer>).⁴²

Surrogate markers of HPV infections for diagnosis

The laboratory management of early cervical neoplasia is based on criteria derived in part from prior studies correlating the high-risk prototypes (such as type 16) with HSIL (CIN grades II and III). However, the distinction of a preinvasive lesion from a benign inflammatory process may be difficult and can influence management decisions.

Improving the precision of these diagnoses has been the focus of studies designed to identify biomarkers that may simplify the distinction of HPV-related neoplasia from its mimics. Because HPVs disrupt cell function, it is logical to presume that alterations in host genes may serve as “surrogate markers” for HPV infection. Host genes reported to be upregulated in cervical neoplasia include telomerase, p16ink4, cyclin E, Ki-67, MN, and others.¹⁴ Some of these, such as Ki-67, cyclin E, and p16ink4, have practical value in triaging histologic abnormalities.^{14, 15} The lower anogenital tract task force has recently recommended p16 staining as an adjunct to histologic evaluation, a positive test being continuous horizontal linear (or block) staining.⁴³ The most appropriate use of this biomarker is to solidify a CIN2 or CIN3 diagnosis on histologic exam by inferring the presence of a carcinogenic HPV. However, because up to 70% of CIN1 lesions will stain positive for this marker, p16 immunostaining cannot be used in a vacuum to make a diagnosis of CIN2 or CIN3.⁴⁴ Moreover, strong p16 staining is no guarantee of lesion progression; up to 67% of histologically verified CIN2 lesions will regress in 3 years.⁴⁵

Clinical management

Management of HPV-related cervical neoplasms continues to be defined and redefined, in step with the methods used for lesion removal. Most women with low- or high-grade CIN on Pap smear or an atypical smear that is HPV positive will be referred to colposcopic examination. Of those who have a negative examination or a low-grade CIN on biopsy, 10–13% will develop a biopsy-proven high-grade CIN within 2 years. Many practitioners will follow patients with low-grade abnormalities and negative

colposcopy by repeat cytology in 6–12 months, with attention to this risk.

Biopsy-proven high-grade CIN is typically managed by the loop electrical excision procedure or cone biopsy. Thus, the outcome of a given case will be dependent on the application of the histologic criteria for distinguishing low- from high-grade squamous intraepithelial lesions.⁴⁴ Long-term follow-up of all women with cervical abnormalities, treated or otherwise, customarily includes Pap smear evaluations but may eventually include periodic HPV testing as well.

Prevention

Efforts to elucidate the immune response to HPV have evolved from studies of fusion proteins and linear epitopes to the production *in vitro* of virus-like particles (VLPs) ([Figure 4](#)).^{45–48} VLPs are produced by expressing the entire late region of papillomaviruses in eukaryotic systems, contain the conformational epitopes operative in generating host immunity, and can be used to study (or generate) host immunity.^{49, 50} This avenue of investigation was the most promising because it offered the advantage of intact particles that were highly immunogenic. Recent large-scale trials have validated the merits of VLP vaccination, demonstrating high efficacy for both preventing infection and lesions attributed to the HPV type(s) targeted in the vaccine.^{51, 52} Trials are ongoing that test multivalent vaccines containing not only HPV 16 but also HPVs 18, 6, and 11 (the latter two target genital warts). These trials have shown a high efficacy (95% or higher) for preventing both cervical and genital infection by the HPV types targeted in women who have not been exposed.⁵³ Predictably, efficacies in women who have been exposed are lower, and the overall reduction in HPV-related disease is under 20%.⁵⁴ However, vaccine efficacy against nonvaccine types has been recorded to be 27% and cross protection against specific types such as 31, 45, and 52 has been reported. Thus, the benefit obtained by the vaccination with HPV 16 and 18 is substantial.⁵⁵ Moreover, more broad-based vaccines employing HPV L2 are under investigation.⁵⁶ The value of these newer more broadly inclusive vaccines will hopefully address the regional variations in prevalence of certain HPV types.

The strong association between the squamocolumnar junction and cervical carcinoma and the discovery of a putative cell of origin in this site have raised the possibility that prophylactic ablation of this small region might significantly reduce the risk of cervical cancer. The yearly incidence of cervical cancer worldwide exceeds that of vaginal/vulvar carcinoma by nearly 20-fold, further evidence of the potential influence of the SC junction on cancer risk.⁵⁷ Anecdotes, studies of HPV infection following cryoablation, and topographic recurrence patterns and differences in CIN grade following SC junction excision or

ablation have all pointed to the possibility of a profound change in precancer risk imposed by removal of the SC junction. Whether this information can be translated into a viable cancer prevention program is unclear and awaits further study.⁵⁸

Chapter 31

Hepatitis viruses and hepatoma

Hongyang Wang, MD ■ Guangwen Cao, MD, PhD ■ Jing Fu, MD, PhD ■ Guishuai Lv, MD

Overview

Hepatitis is an inflammation of the liver, occurring as the result of a viral infection or the exposure of liver to toxic substances such as alcohol or aflatoxin B. Hepatitis viruses are the most common cause of hepatitis in the world, of which HBV and HCV can cause persistent liver infection, frequently resulting in chronic hepatitis, liver cirrhosis, and eventually hepatocellular carcinoma (HCC). HBV belongs to the genus *Orthohepadnavirus* of the *Hepadnaviridae* with a circular incomplete double-stranded DNA genome, containing four overlapping open reading frames (ORFs) that encode the surface envelope protein (HBsAg), the core protein (HBcAg and HBeAg), a polymerase, and a multifunctional nonstructural protein termed X (HBx), respectively. HBV genotypes and subgenotypes have distinct geographical distributions. In East Asia, HBV genotypes B and C are endemic. Accordingly, any differences in its global incidence may be explained by differences in the HCV and HBV prevalence. It has been estimated that 57% of cirrhosis is attributable to either HBV (30%) or HCV (27%) and 78% of HCC is attributable to HBV (53%) or HCV (25%). In China, up to 80% of HCC cases are attributable to HBV, and approximately 20% of HCC patients test positive for HCV-RNA. Besides the oncogenic function of HBV-encoding protein, the HBV infection-induced virus or host DNA mutation has been found contribution for HCC development. Unlike to HBV, HCV belongs to the genus *Hepacivirus* of the *Flaviviridae* family, with a single-stranded positive-sense RNA genome. There is no host genome integration, nor does HCV contain any known oncogenes. The major mechanisms of HCV-induced hepatocarcinogenesis include the oncogenic effect of HCV viral proteins, steatosis and insulin resistance, chronic inflammation and fibrosis, oxidative stress, and chromosomal instability. This chapter exclusively focuses on hepatitis and hepatoma caused mainly by HBV and HCV infection, discussing epidemiologic considerations, construction and genotype, role of virus in performing HCC, and early diagnosis and prophylaxis. Still, viruses that selectively infect endemic host predispose patients to malignant hepatoma, to some extent, placing a burden on the healthcare worldwide. Therefore, an upturn in morbidity of hepatitis and hepatoma will be of great importance in public health.

Hepatitis and hepatoma

Liver diseases, including hepatitis B virus (HBV) and hepatitis C virus (HCV) infections, alcoholic liver disease (ALD), nonalcoholic fatty liver disease (NAFLD) and associated cirrhosis, and HCC, are major causes of illness and death worldwide.¹ Liver disease causes serious public health problems because of its high prevalence worldwide and poor long-term clinical outcome, including premature deaths from liver decompensation, cirrhosis, and HCC. Among liver diseases, hepatitis and HCC harm to people's health seriously due to the disease susceptibility, cryptobiosis, and refractoriness, respectively.¹

Human hepatitis viruses

Human viruses that selectively infect human hepatocytes and cause liver diseases are termed as human hepatitis viruses including hepatitis A virus (HAV, HBV, HCV, hepatitis D virus (HDV), and hepatitis E virus (HEV). Through fecal-to-mouth transmission, HAV or HEV causes temporary hepatic infection, varying from an asymptomatic infection to a fulminant disease. HAV, a single-stranded RNA virus, is a major cause of acute viral hepatitis worldwide. It occasionally causes an acute liver failure. HEV, a single-stranded, non-enveloped RNA virus, is endemic in several Asian and African countries. Pregnant women and patients with pre-existing chronic liver diseases are at a high risk of fulminant liver failure upon HEV infection.² HBV (alone or co-infected with HDV or super-infected with HDV) and HCV can cause persistent liver infection, frequently resulting in chronic hepatitis, liver cirrhosis, and eventually HCC.

Hepatitis B virus

HBV belongs to the genus *Orthohepadnavirus* of the *Hepadnaviridae* with a circular incomplete double-stranded DNA genome of about 3.2 kb in length. HBV genome contains four overlapping ORFs that encode the surface envelope protein (HBsAg), the core protein (HBcAg and HBeAg), a polymerase, and a multifunctional nonstructural (NS) protein termed X (HBx). The PreS region that consists of PreS1 (nt.2848-3204) and PreS2 (nt.3205-154) domains overlaps a region encoding the polymerase gene (P gene). The enhancer II (EnhII; nt.1636-1744) and basic core promoter (BCP; nt.1751-1769) regions overlap with the X gene (nt.1374-1835). HBV genome contains two viral enhancers that regulate transcription of the HBV promoters, including the BCP that controls the transcription of the pre-core and core regions. Following the entry into hepatocytes, HBV enters the nuclei of hepatocytes. HBV genome forms a relaxed circular DNA that is converted into covalently closed circular DNA (cccDNA) in the nuclei. The cccDNA transcribes all viral RNAs including pregenomic (pg) RNA as a replicative RNA intermediate. The pgRNA, viral core, and polymerase proteins are assembled into the nucleocapsid in the cytoplasm and then the pgRNA is converted into an HBV DNA by viral polymerase. Approximately 10^{11} viral particles are released into the circulation of the individuals with chronic HBV infection per day, and HBV particles are cleared from the plasma with a half-life of approximately 1.2 day. During viral replication, the partially double-stranded HBV DNA is generated from an intermediate RNA via reverse transcription activity of the viral polymerase. HBV reverse transcriptase lacks proofreading capacity, resulting in mutation rates of 1.5×10^{-5} to 5×10^{-5} nucleotide substitutions/site/year in HBV-infected subjects at their HBeAg-positive stage.^{3, 4} However, owing to the extreme overlapping ORFs, HBV genome evolution is constrained to maintain essential protein functions required for viral replication.⁵ This plasticity of HBV genome allows the generation of viral mutants that can occur under the pressures of immune selection.

Eight genotypes (genotypes A–H) have been determined according to a sequence divergence >8% in the entire HBV genome or a sequence divergence >4% in the S region. Genotypes have further been classified into subgenotypes if the divergence in whole nucleotide sequence is between 4% and 8%. Subgenotypes 1–5 of genotype A, subgenotypes 1–8 of genotype B, subgenotypes 1–8 of genotype C, and subgenotypes 1–7 of genotype D have been recently nominated. HBV genotypes and subgenotypes have distinct geographical distributions.^{3, 6, 7} HBV genotypes A1, A3, A4, and A5 are endemic in Africa, especially in West Africa, whereas genotype A2 is endemic in Europe. Genotypes B and C are endemic in Asia. Of HBV genotypes B and C, subgenotypes B2 and C2 are endemic in most parts of Asia. Subgenotype C4 is encountered in Aborigines from Australia and frequently termed as the Australian aboriginal strain. Subgenotypes B3–B8, C1, C3, and C5–C8 are present in Indonesia and the Philippines.

Genotype D is endemic in the entire Old World including Northern Africa, Northern and South Asia, the Mediterranean area, and most European countries. Subgenotype D1 is predominant in Moslem ethnicity. Subgenotype D2 is endemic in Russia and the Baltic region. Subgenotypes D4 and D6 are endemic in Oceania and Indonesia, respectively. HBV genotype E is endemic in Western and Central Africa. HBV genotypes F, G, and H are endemic in Middle and Southern America. HBV genotype and subgenotype correlate not only with the clinical outcomes but also with the response to interferon- α treatment.^{7, 8} In East Asia where HBV genotypes B and C are endemic, genotype B is more apt to cause acute infection in young people and to be more easily cleared than genotype C, whereas genotype C leads to higher persistence following an acute course and is more apt to cause cirrhosis and HCC than genotype B.^{8–11} Thus, HBV genotyping is not only important in reconstructing the evolutionary history of HBV and humans but also helpful in indicating clinical outcomes of HBV infection and responses to antiviral treatments.

Chronic HBV infection frequently occurs in individuals infected perinatally or during early childhood, when the immune system is immature. HBV infection in adults is mostly asymptomatic or experiences an acute course. Invasive medical procedures, household contact with HBV carriers, body care and beauty treatments, and lack of HBV vaccination are the major risk factors of acute hepatitis B in adults. About 8.5% of adult patients with acute hepatitis B in mainland China will develop a chronic infection.⁹ HBV genotype C (vs genotype B) and genotype D (vs other HBV genotypes) are more apt to cause persistent infection following an acute course.^{9, 11} Genetic polymorphisms of human leukocyte antigen (HLA) in the *HLA-DP* and *HLA-DQ* regions contribute to immune imbalance (such as Th1/Th2 cells or Th17/Treg cells, neutrophil/lymphocyte, neutrophil/CD8⁺ T cell, and Th1/Th2 cytokines balances) upon HBV infection, resulting in HBV persistence and possible chronic liver inflammation.^{12–14} Allelic frequencies of the *HLA-DP* polymorphisms differ greatly among races. According to the NCBI database (<http://www.ncbi.nlm.nih.gov/projects/SNP/>), the *HLA-DP* (or *HLA-DQ*) alleles that facilitate chronic HBV infection are the major allele in the Asian population,^{13, 14} whereas they are the variant alleles in the European population. This might be one of the reasons why HBV persistence is more frequent in Asians than in Europeans. These *HLA-II* genetic polymorphisms may predispose the host to maintaining chronic HBV infection, facilitate the immune selection of the disease-related HBV mutants, and affect the risks of cirrhosis and HCC contributed by the HBV mutations.

Hepatitis B virus and hepatocellular carcinoma

In general, without efficient treatment, all types of chronic hepatitis will finally progress into ESLDs (end-stage liver diseases), such as cirrhosis and HCC. Most ESLD displays a poor clinical outcome. HCC is a major cause of cancer mortality worldwide, and any differences in its global incidence may be explained by differences in the HCV and HBV prevalence.¹ In 2013, the World Health Organization reported that primary liver cancer caused 745,517 deaths worldwide and that HCC represented the major histological type of these liver cancers.¹⁵ In another comprehensive review of global mortality, deaths from HCV-related HCC were estimated at 195,700 in 2010. In China, HCC is the second leading cause of cancer mortality, and its annual death rate was 24.15 per 100,000 persons in 2009.¹⁶ Approximately 383,203 persons die from liver cancer every year in China, which accounts for 51% of the deaths from liver cancer worldwide.¹⁶ Up to 80% of HCC cases in China are attributable to HBV, and approximately 20% of HCC patients test positive for HCV-RNA.¹⁷

Epidemiologic considerations

Approximately 2 billion people have ever been exposed to HBV worldwide. Of those, 350 million people are chronically infected with HBV. It has been estimated that 57% of cirrhosis is attributable to

either HBV (30%) or HCV (27%) and 78% of HCC is attributable to HBV (53%) or HCV (25%).¹⁸ A prospective study conducted in Taiwan has proved that the cumulative lifetime (age 30–75 years) incidences of HCC for men and women positive for both HBsAg and antibodies against HCV are 38.35% and 27.40%; for those positive for HBsAg only, 27.38% and 7.99%; and for those positive for neither, 1.55% and 1.03%, respectively.¹⁹ Prospective epidemiological studies have proved that male gender, increasing age, cirrhosis, high viral load, HBeAg positivity, HBV genotype C (vs genotype B), low albumin, alanine aminotransferase (ALT) elevation, and viral mutation A1762T/G1764A independently increase HCC risk in chronic HBV-infected patients.^{11, 19–23} HBV demonstrates “mutation–selection–adaptation,” a viral evolutionary process involved in hepatocarcinogenesis. During this process, especially during HBeAg seroconversion, HBV accumulates HCC-risk mutations, predominantly in the core promoter and preS regions of HBV genome.^{24–26} A1762T/G1764A can predict HCC prospectively, possibly because this mutation is earlier generated during the evolutionary process.²⁷ These demographic, clinical, and viral factors harvested before HCC occurrence should be prognostic and even predictive for HCC in HBV-infected patients.

Role of HBV mutations in HCC development

Insufficient immune responses elicited by HBV antigens select the HCC-related HBV mutations during long-term evolutionary process. Only the HBV strains/variants best adapted to the immune system will survive and thrive in liver. Genetic predispositions of HLA-II antigens and other inflammatory factors such as NF- κ B and STAT3 may contribute to immune imbalance upon HBV infection, leading to persistent infection and chronic inflammation in liver, which facilitate the generation of the HCC-risk HBV mutations.^{13, 28, 29} Inflammatory factors promote HBV mutations, at least partially, via activating cytidine deaminases.⁵

Host somatic mutations

Cytidine deaminases and their analogs, whose expressions and activities can be activated by proinflammatory cytokines generated during the inflammation, not only promote HBV mutagenesis but also facilitate somatic mutations.⁵ Important HCC-related somatic mutations are found in critical genes such as RNA editing genes (*ADAR1*, *ADAR2*, *KHDRBS2*, and *RTL1*), chromatin remodeling genes (*ARID1A*, *ARID1B*, and *ARID2*), DNA-binding genes (*HOXA1*), growth factor signaling pathway genes (*CDH8*, *CDK14*, *CNTN2*, *ERRFI1*, *RPS6KA3*, *P62*, and *PROKR2*), transcriptional regulation genes (*AXIN1*, *CCNG1*, *CTNNB1*, *IRF2*, *NFE2L2*, *PARP4*, *PAX5*, *ST18*, *TP53*, *TRRAP*, and *ZNF717*), cell structure modification genes (*FLNA* and *VCAM1*), epigenetic modification genes (*MLL3*), and JAK/STAT pathway genes (*JAK1* and *JAK2*).³⁰ These somatic mutations should affect major signaling pathways, which can serve as therapeutic targets for HCC aggressiveness.

The roles of HBV-encoding proteins

(1) Excess production of the HBV envelope proteins, or truncated forms of the middle (preS2/S) and large (preS1/preS2/S) envelope protein, can activate cellular signal transduction pathways or endoplasmic reticulum (ER) stress pathways, induce cell proliferation by upregulating cyclin A expression, and activate c-Raf-1 and extracellular regulated kinase (ERK) signaling to stimulate cell proliferation. Accumulation of the S proteins in the ER can activate the unfolded protein response and cause oxidative stress. Epidermal growth factor receptor (EGFR) overexpression, which occurs in 40–70% of human HCCs, has been linked with tumorigenesis.³¹ Aberrant activation of Raf-MEK/ERK and PI3K-Akt pathways driven by EGFR is commonly observed and implicated in the tumor growth and

progression of many human cancer types, including HCC.³² Moreover, activation of EGFR signaling pathways via the high expression of either its cognate ligands or itself is strongly associated with the poor prognosis of HCC. (2) HBx serves as a transactivator of several cellular signaling pathways including Wnt that contributes to HBV-related HCC and also interacts with tumor suppressor adenomatous polyposis coli (APC) to activate Wnt/ β -catenin signaling. HBx promotes the invasive ability and metastatic potential of HCC. For example, as recently reported, using HBx transgenic mice and human HBV-related HCC specimens demonstrates that expression of HBx promotes expansion and tumorigenicity of HPCs (hepatic progenitor cells) that contribute to HBx-mediated tumor formation in a diethyldithiocarbamate (DDC)-induced mouse model. These studies shed novel light on the notorious role of HBx in the relationship between chronic hepatitis infection and liver cancer.³³ Carboxylic acid-terminal truncated HBx protein (Ct-HBx), a common form of HBV DNA integrated into the host genome, can enhance HCC cell invasiveness and metastasis in a manner that is more potent than that evoked by full-length HBx. HBV genome integration in the promoter of the human telomerase reverse transcriptase (TERT) locus is frequently observed in a high clonal proportion, which correlates with increased TERT expression.⁵ Whether the preference of integration into specific host genomic loci and characteristics of the inserted fragments endow HBV integration a greater potential to drive oncogenic transformation remains to be elucidated.

Early diagnosis and prophylaxis of HCC

Across all countries, 5-year overall survival of HCC is approximately 10%. This dismal outcome is due partly to the lack of an effective method for timely diagnosis, which leads to only 30–40% of patients with HCC being suitable for potentially curative treatments at the time of diagnosis. α -Fetoprotein (AFP) has been used as biomarker for diagnosis of HCC, but its sensitivity is low (25–65%) at the commonly used cutoff of 20 ng/mL, particularly in detection of early-stage HCC.³⁴ In addition, many patients with non-malignant chronic liver disease have raised AFP concentrations in serum, including 15–58% of patients with acute-on-chronic hepatitis and 11–47% with liver cirrhosis.³⁴ Therefore, novel and reliable diagnostic biomarkers to complement AFP are urgently needed to improve clinical outcomes.

Glypican-3 (GPC3) is a heparan sulfate glycoprotein that is highly expressed in approximately 70% of HCC cases³⁵ but poorly expressed in pre-neoplastic lesions and in normal liver tissue.³⁶ GPC3 is considered a biomarker for HCC diagnosis, and multiple studies have demonstrated that GPC3 is an attractive liver cancer-specific target.³⁷ Furthermore, GPC3 is one of the most promising markers according to preclinical exploratory studies.³⁸ GPC3 kit has been pathologically utilized to diagnose and classify HCC, especially in antidiastole of liver tumor between carcinoid and malignancy, thereby providing a promising therapeutic intervention for GPC3-positive HCC.³⁷ As it has diagnostic value to cure patients individually and the ability to avoid over-treatment on benign lesion, GPC3 kit has been expectedly approved by China Food and Drug Administration (CFDA) with a forthcoming popularized application in clinic. Dickkopf-1 (DKK1), a secretory antagonist of the canonical Wnt signaling pathway, is overexpressed in HCC tissue but is not detectable in corresponding non-cancerous liver tissue. A large-scale multicenter study shows that DKK1 could complement measurement of AFP in the diagnosis of HCC and improve identification of patients with AFP-negative HCC and distinguish HCC from non-malignant chronic liver diseases.³⁸ A plasma microRNA panels (plasma miR-122, miR-192, miR-21, miR-223, miR-26a, miR-27a, and miR-801) are potential circulating markers for diagnosing HCC with a large number of participants that ranges HCC from healthy, CHB, and cirrhosis with a high degree of accuracy. The microRNA panel with the seven microRNAs from the multivariate logistic regression model demonstrates high accuracy in the diagnosis of HCC, especially for patients with early BCLC

stages (0 and A) who can benefit from the optimal therapy.³⁹

Importantly, receptor-binding region of pre-S1 can specifically interact with sodium taurocholate cotransporting polypeptide (NTCP), a multiple transmembrane transporter predominantly expressed in the liver using near zero distance photo-cross-linking and tandem affinity purification. It is demonstrated that NTCP is a functional receptor for HBV and HDV; therefore, it is of great significance for the therapy of HBV infection and HBV-related HCC in the near future.⁴⁰

HBV vaccination is effective for those without HBV infection. However, for 350 million HBV carriers worldwide, antiviral treatment is effective for those chronically infected with HBV, respectively. Active inflammation stimulated by HBV replication is indispensable for HBV-induced hepatocarcinogenesis. HCC occurs much less in inactive HBV carriers than in active chronic hepatitis B patients even if the patients are treated with antiviral treatment with oral nucleos(t)ide analogs.⁴¹ Standard antiviral treatments with IFN- α and/or nucleos(t)ide analogs can greatly decrease hepatic inflammation and improve liver function, thus significantly reducing HCC occurrence in HBV-infected subjects and increasing the survival of the patients who received curative surgery.^{41–43} Furthermore, the available research suggests that the miR-26 expression status of such patients is associated with survival and response to adjuvant therapy with IFN- α , meanwhile the expression patterns of microRNAs in liver tissue differ between men and women with HCC.⁴⁴ It should be noted that the result involves Chinese patients with a high rate of HBV positivity. HBV replication is the driving force of HCC evolution in inflammatory microenvironment. As approximately 30% of male and 10% of female HBV carriers may develop HCC in their lifetime, it is important to identify the HBV-infected subjects who are more likely to develop HCC and need the cost-effective antiviral treatment and regular screening for early HCC. However, antiviral treatment is effective in normalizing liver function, decreasing HBV–HCC recurrence, and improving postoperative survival. In the RCT (randomized controlled trial) of Eastern Hepatobiliary Surgery Hospital in China, nucleotide/nucleoside analog (NA) significantly decreased HCC recurrence and HCC-related death. Patients who received antiviral treatment had significantly decreased early recurrence and improved liver function 6 months after surgery compared with the controls ($P < 0.001$). Those with recovered liver function had a higher 2-year recurrence-free survival (RFS) rate than those without. Furthermore, Ct-HBx expression in adjacent hepatic tissues significantly predicts an unfavorable RFS in the antiviral group.⁴³

Surgical resection is still the first-line treatment for HCC patients with well-preserved liver function worldwide, but the rate of postoperative recurrence at 5 years is as high as 70%. Some prognostic factors indicating that postoperative recurrence of HCC can be detected in removed tumor tissues, adjacent liver tissues, and peripheral blood. In tumors, high ratios of neutrophil-to-CD8⁺ T cell and Treg-to-CD8⁺ T cell, high expression of pro-angiogenic factors such as hypoxia-inducible factor-1- α and cell growth/survival factors such as CD24, and activation of inflammatory signaling pathways such as Wnt/ β -catenin, NF- κ B, and STAT3 predict early recurrence. In peritumoral hepatic tissues, high HBV DNA, HBV mutations, high densities of macrophages, activated stellates and mast cells, high expression of macrophage colony-stimulating factor/its receptor and placental growth factor, Th1/Th2-like cytokine shift, inflammation-related signature, and activation of carcinogenesis-related pathways predict late recurrence. In preoperative peripheral blood, high HBV DNA and the genotypes and HBV mutations, high neutrophil-to-lymphocyte ratio and high concentrations of macrophage migration inhibitory factor and osteopontin predict poor prognosis.⁴⁵ As a chemotherapeutic agent, at least working in part by the targeted inhibition of the hyperactivated ERK pathway, which is associated with postoperative liver regeneration, sorafenib is the first and only systemic therapy to significantly prolong the survival of HCC patients with advanced-stage disease until now. Recently, it has been proved that use of sorafenib after

surgical resection for early-stage HCC was a promising approach for preventing recurrence and improving postoperative outcomes. Thus, sorafenib is currently used as a standard treatment for patients with HCC in spite of its shortcoming in specificity.⁴⁶

As the population infected with HBV is increasing, inflammation-driven HCC formation has made early diagnosis and timely treatment more important. Even though targeting kinase addiction is an effective strategy for cancers, EGFR inhibitors have shown disappointing clinical results. A crucial role of EGFR signaling in Kupffer cells or macrophages during inflammation-driven HCC formation is reported.⁴⁰ EGFR is required in liver macrophages to transcriptionally induce interleukin-6, which triggers hepatocyte proliferation and HCC. Importantly, the presence of EGFR-positive liver macrophages in HCC patients is associated with poor survival.⁴⁷ This study demonstrates that a tumor-promoting mechanism for EGFR in non-tumor cells, which could lead to more effective precision medicine strategies EGFR-positive Kupffer cells, might constitute a future prognostic marker and could potentially represent a target for HCC therapy.

Hepatitis C virus

HCV is the genus *Hepacivirus* of the Flaviviridae family. It is a small enveloped virus with a single-stranded, positive-sense RNA genome of 9.6 kb. It circulates as a highly lipidated viral particle. There are six known major genotypes and many more subtypes of HCV. This genetic variability promotes viral persistence, generates viral escape mutants from the immune system, and produces resistance to antiviral therapy.

Once the virus enters the cell, the viral RNA genome is uncoated and translated within the cytoplasm into a single, long polypeptide of 3011 amino acids.⁴⁸ The cleavage of the HCV polypeptide, mediated by host and viral proteases, yields 10 viral proteins. These are subclassified as structural proteins (C, E1, and E2) and NS proteins (p7, NS2, NS3, NS4A, NS4B, NS5A, and NS5B). The structural proteins serve the assembly of progeny virions and comprise two envelope glycoproteins (E1 and E2) and a nucleocapsid protein (core protein).^{49, 50} Core protein not only essential for virus particle assembly but also possesses several regulatory functions, including cellular transcription, virus-induced transformation, and signal transduction.⁵¹ The NS proteins are responsible for executing viral replication and propagation.^{52, 53} HCV genome undergoes rapid mutation in a hypervariable region coding for the envelope proteins to escape immune surveillance. Most HCV-infected subjects develop chronic infection and eventually liver cirrhosis.

More than 185 million people were estimated to be HCV-specific antibody positive, representing 2.8% of the world's population in 2005. However, there are marked differences in HCV prevalence among different countries and regional age and risk groups, ranging from 0.1% to 5%. The most affected regions are Central and East Asia and North Africa. In the United States, it is estimated that 3.9 million individuals (or 1.8% of the general population) are infected with HCV. China has been considered a relatively high endemic area for HCV infection in the past. The prevalence of anti-HCV was estimated to average 3.2% in the general population, according to a national epidemiological survey carried out in most regions of China in 1992, with blood or blood product transfusion as the major route of infection. Since 1993, mandatory screening for anti-HCV and other precautions to prevent bloodborne disease transmission have been implemented extensively. New cases of HCV infection have declined dramatically. As shown by a recent national survey in 2006, the prevalence of anti-HCV is only 0.43% in China.⁵⁴

HCV genotypes also display substantial differences worldwide.¹ HCV variants are classified into six

genotypes. HCV-1b is the commonest one worldwide and more prevalent in patients with HCC than in those with cirrhosis and chronic hepatitis. In the United States, genotype 1a predominates, whereas the predominant genotype in Europe and China is 1b. In China, genotype 1b accounts for 68.4%, followed by 2a at 19.5%.⁵⁵ Interestingly, subtype 1b strains are more likely to be associated with transmission by blood transfusion and medical procedures, whereas subtype 6a strains are more likely to be linked to intravenous drug use (IDU) and sexual transmissions.⁵⁶ This genotypic difference in HCV between Western countries and China may be, to some extent, associated with each population's responsiveness to Peg-IFN- α and ribavirin (RBV) treatment.⁵⁷ In addition, single-nucleotide polymorphisms near the interleukin (IL)-28B gene region have also been found to be associated with the treatment efficacy of Peg-IFN- α /RBV in HCV-infected patients.⁵⁸ The frequency of the rs12979860 C allele is higher in Chinese HCV patients than in Caucasian patients. Evaluation of a large cohort of Chinese HCV patients showed that the major HCV genotype is 1b (approximately 60–70%) and the predominant host IL28b genotype of rs12979860 is CC (84%).⁵⁹ These data suggest that the global differences in the IL28B allele frequency and HCV genotypes may explain the better response to Peg-IFN- α /RBV therapy observed in Chinese patients.

Hepatitis C virus and hepatocellular carcinoma

There are 130–150 million individuals chronically infected with HCV worldwide.⁶⁰ Only a minority of those infected spontaneously clear the virus; most HCV-infected subjects, about 55–85% of persons, develop chronic HCV infection and are at increased risk of developing cirrhosis and HCC.^{61–63} Of subjects with chronic HCV infection, the risk of liver cirrhosis is 15–30% within 20 years. Elevated HCV loads significantly increase HCC risk. HCV infection is estimated to increase the risk of HCC up to 17-fold.⁶⁴ The average time from HCV infection to the onset of cirrhosis is 13–25 years, and the time to onset of HCC is 17–32 years.⁶⁵ Annual incidence of HCC in HCV-infected subjects with cirrhosis is approximately 3–5%.⁶⁶ In addition, successful clearance of HCV infection reduces overall liver-related mortality and HCC incidence, suggesting a causal role of HCV.⁶⁷

HCV is an RNA virus with an exclusively cytoplasmic life cycle. Unlike in HBV infection, there is no host genome integration, nor does HCV contain any known oncogenes. The mechanisms of HCV-induced hepatocarcinogenesis are intricate and several of them have been identified, including the oncogenic effect of HCV viral proteins, steatosis and insulin resistance, chronic inflammation and fibrosis, oxidative stress, and chromosomal instability. In experimental animal models, it has been reported that HCV-encoded proteins, core, E2, NS3, and NS5A, are directly involved in the tumorigenic process through interaction with a number of host factors and signaling pathways that affect cell survival, proliferation, migration, and transformation.^{68–71} The HCV core protein can also influence or interact with several molecules that play important role in fatty acid transport and catabolism.^{72–74} The HCV-associated hepatic steatosis, insulin resistance, and oxidative stress could lead to chronic liver inflammation, apoptosis, and fibrogenesis. These mechanisms are central to the development of liver cirrhosis and HCC in patients with chronic HCV.

Prevention and treatment

As there is no vaccine for hepatitis C, the primary prevention of HCV infection mainly depends on reducing the risk of exposure to the virus in higher risk populations. Among HCV-infected persons, about 15–45% of them spontaneously clear the virus within 6 months without any treatment. When treatment is necessary, the current standard treatment for hepatitis C is antiviral therapy with a combination of

interferon and RBV, which are effective against all the genotypes of HCV. Effective treatment with interferon-based regimens has been available for many years, and achievement of sustained virologic response (SVR) to antiviral therapy is associated with improved morbidity and mortality.^{75, 76} In addition, with the rapid development of oral directly acting antiviral agents (DAAs), IFN-free therapeutic regimens for chronic HCV infection are becoming a reality, and they appear to be much more effective, safer, and better tolerated than interferon-based therapies. DAAs therapies also simplify HCV treatment by significantly decreasing monitoring requirements and by increasing cure rates.

It is anticipated that 12-week courses of interferon-free regimens with SVR rates of 90% or higher will soon be available to most HCV patients in whom cirrhosis has not yet developed.^{77, 78} Experience with interferon-free DAA regimens in patients with cirrhosis is limited, and available data indicate that SVR rates are lower with some regimens.⁷⁹ Therefore, early diagnosis and referral for treatment are important.

Chapter 32

Parasites

Mervat Z. El Azzouni, MD, PhD ■ Radwa G. Diab, MD, MBBCH, PhD

Overview

Many parasites were studied for a possible role in oncogenesis. *Schistosoma haematobium* was proved to play an important role in developing urinary bladder cancer. Other *Schistosoma* species, *Schistosoma japonicum* is classified as a colorectal carcinogen especially in the Far East. Other helminths *Clonorchis* and *Opisthorchis* are proved to induce hepatobiliary cancer. In Africa, a strong correlation between Epstein–Barr virus infection and Burkitt lymphoma is present, with an evident enhancing role for *Plasmodium falciparum*. Chronic inflammation was incriminated to be the most accepted mechanism for parasite-induced cancer; however, the roles of certain carcinogens, oncogenes, DNA mutations, and others were all approved as mechanisms enhancing carcinogenesis in parasitic infections. Strikingly, despite the above-mentioned data, it seemed that certain parasites can modulate the host immune response in a manner that could lead to cancer regression or prevention. This is in the prospect of revaluation of the clinical importance of infectious agents; an issue that requires future concern.

The intensity of parasitic infection frequently correlates with its prevalence.¹ Thus, when relatively uncommon neoplasms are noted with undue frequency in countries with a high prevalence of parasitic diseases, the question of the role of parasites arises. In this respect, the two most intriguing examples are probably the relationships of schistosomiasis to bladder cancer (BC) and that of malaria to Burkitt lymphoma (BL). Classic references have been presented before.²

Schistosomiasis and cancer of the bladder

Schistosoma haematobium was first incriminated for a potential role in induction of urinary BC in Egypt in 1911 by Fergusson³; an issue that was finally confirmed by the International Agency of Research on Cancer (IARC) in 1994; which reported the parasite as a carcinogen.⁴ Bilharzial bladder cancer (BBC) is theoretically a preventable malignancy if nationwide preventive strategies, including snail control and mass treatment campaigns, and screening projects could be adopted.⁵

Epidemiologic aspects

The highest incidence rates of BC are found in the countries of Europe, North America, and Northern Africa.⁶ Smoking and occupational exposure are the major risk factors in Western countries; however, the morbidity and mortality due to BC have declined over the past decade owing to changing the habits of cigarette smoking.⁷ Chronic infection with *S. haematobium* in developing countries, particularly Africa and the Middle East, accounts for about 50% of the total burden,⁸ with Egyptian males having the highest mortality rates (16.3/100,000).⁹ The association between *S. haematobium* infection and BC is far greater than that for any other parasitic infection,¹⁰ and it was classified as group 1 carcinogen.¹¹ Association

between *S. haematobium* and BC was initially established through case-controlled studies and close correlation of the incidence of BC with the prevalence of parasite. Clinically, the evidence of association was based on the presence of parasite eggs and *Schistosoma*-induced histopathological changes in cases of BC.¹²

Urinary BC is morphologically heterogeneous. More than 90% of the cancers are of the transitional cell carcinoma type (TCC),¹³ as in case of BC associated with smoking and occupational hazards.¹⁴ In Africa, squamous cell carcinoma (SCC) of the bladder is greatly overrepresented among the fellaheen of Egypt and the Africans of Mozambique, Zimbabwe, and Zambia (formerly Rhodesia), where *S. haematobium* is endemic.^{15–17} However, a shift toward TCC subtype was observed in developing countries owing to shift in risk factors with increased urbanization and industrialization.⁷ In Egypt, following the construction of the High Dam in the 1960s that led to changes in the water flow with direct impact on the intermediate snail host, *S. haematobium* was gradually replaced by *Schistosoma mansoni* that causes intestinal rather than urinary disease.¹⁸ Furthermore, effective oral treatment campaigns in Egypt since 1977 resulted in significant decrease in urinary schistosomiasis.¹⁹ Strikingly, despite the large decline in *S. haematobium* infection in Egypt, BC continues to be the most common cancer among males. This is because the decline in BBC is being offset by increase in smoking-associated BC.²⁰ This is evidenced by the shift in the incidence of SCC in Egypt from 78% in the 1980s to 27% in 2005 with a shift to TCC.²¹ Another retrospective study was conducted in Egypt, from 2001 to 2010, on two groups: group 1 included 1002 patients from 2001 to 2005 and group 2 included 930 patients from 2006 to 2010. The authors found that the incidence of BBC decreased from 80% in group 1 to 50% in group 2. Besides, a significant increase in TCC from 20% to 66% was observed with a significant decrease in SCC from 73% to 25% by comparing the two groups.²² Hamed et al.²³ suggested another cause for the general decline in BBC in Egyptian governorates. Tendency toward warming, with high temperature exceeding 45°C, and increased number of hot days all over the year are incriminated in damaging the effectiveness of the snail host and hence schistosomal transmission.

The association of BC with schistosomal infection seems to become stronger with long standing and more severe infection.²⁴ In Egypt, this association is directly related to the extent of perennial irrigation through canals, which creates a constant risk of reinfection, and inversely related to control measures and availability of safe and effective therapy.²⁵ Children of school age are especially at risk because of their daily contact with infected water in rural areas.²⁶ Besides, it was noted that in endemic areas in Iraq, Coastal Kenya, Ghana, Malawi, Mozambique, Zambia, and Zimbabwe, a high association between *S. haematobium* and BC is present, whereas it was absent in Nigeria and areas in Southern Africa and Saudi Arabia with moderate to high prevalence of *S. haematobium*.²⁷ Typically, schistosomiasis is a disease affecting agricultural communities, particularly those dependent upon irrigation to support their agriculture. The problem became much more significant in the nineteenth century, when the combination of new irrigation projects and population increases led to a higher probability of exposure to the parasite.²⁸

Geographical distribution of *S. haematobium* seems to play an important role in determining the susceptible groups as regards their age and gender. The peak incidence of BC in schistosomiasis-nonendemic areas is in the sixth and seventh decades of life.²⁹ In Egypt, Sudan, Iraq, Zambia, Malawi, and Zimbabwe, the mean age of the highest incidence of BC is between 40 and 49 years.¹⁰ The male : female ratio of BBC incidence in *Schistosoma*-endemic countries is in average 5 : 1,³⁰ and this could be explained by prolonged contact with infected waters during agricultural activities in rural areas, which are normally done by men rather than women.⁵ Recent observation showed that the relative frequency of BBC was increasing among females during the period 1995–2005 in Egypt. This was explained by

increasing migration of male farmers from the Nile Valley and Delta to the Urban and Frontier governorates seeking for jobs. Therefore, the females were expected to take place of their husbands in agricultural work and thus their exposure risk to infection was increased.²³ Another study found that females were more affected by BBC (51.4%) compared to the males in the western part of Tanzania on the shores of Lake Victoria in the period 2000–2010.³¹

Variability in criteria for diagnosing urinary schistosomiasis influences the epidemiological rates for BBC. Ruling out a diagnosis of schistosomiasis because of the absence of ova in the centrifuged urine specimen would be unrealistic in many cases of contracted bladder owing to bilharzial fibrosis, in which the dense scar tissue precludes shedding of ova from the submucosa.²⁵ Thus, by expanding the criteria for diagnosis of bilharzial bladder to include recent imaging and molecular techniques with high sensitivity and specificity, the epidemiological rates for BBC are expected to be more accurate.

Progression of bilharzial bladder cancer

BC cells require the acquisition of certain properties before being able to grow rapidly, invade, and metastasize.⁵

Chronic infection leads to trapping of *Schistosoma* eggs in the bladder wall. Proliferation of cells in the bladder mucosa results from constant irritation and inflammation.¹² This mucosal damage increases the frequency of urinary tract infection.³² Besides, activated macrophages induced at the sites of inflammation are implicated in the generation of carcinogenic *N*-nitrosamines and reactive oxygen radicals.³³ Mucosal fibrosis and dysuria associating chronic inflammation and bacterial infection lead to urinary stasis that, in turn, allows prolonged contact of urothelium with these carcinogens.³⁴

Nitrate-reducing bacterial species accompanying urinary schistosomiasis can mediate the *N*-nitrosation of amines¹⁰ with the liberation of *N*-nitroso compounds.³⁵ At the molecular level, these compounds are implicated in tumorigenic alkylation of specific bases and DNA sequences,^{36–38} leading to mutations in oncogenes, tumor suppressor genes, and genes for cell cycle control.⁵ Molecular events associating BBC include the activation of H-ras gene,³⁹ inactivation of *p53*,⁴⁰ and inactivation of retinoblastoma (Rb) gene.⁴¹ In 2010, Botelho et al.⁴² suggested that the parasite extract had carcinogenic ability through oncogenic mutation of the K-ras gene. The frequency of *p53* mutations varies with the different grades of BBC.⁴³ For BBC in Egypt,⁴⁴ it was reported that about 86% had *p53* mutations in exons 5, 6, 8, and 10 and that the inactivation of *p53* ranged from 0% to 38% at the early stage of the disease, as opposed to 33–86% in the advanced tumor stage.⁴³ On the other hand, habitual smoking in a group of Japanese BC patients did not increase the frequency of *p53* mutations, but caused unusual AT : GC mutation patterns.⁴⁴ Mutations observed in *p53* gene mostly involve transitions at CpG dinucleotides, which are in excess in cases of BBC. These transitions are explained by the effect of nitric oxide produced by the inflammatory response to *Schistosoma* eggs. Nitric oxide, released during the inflammatory response, can cause such mutations directly by deamination of 5-methylcytosine or indirectly via its capacity to form endogenous *N*-nitroso compounds leading to DNA alkylation.⁴⁵ Over representation of the protein encoded by the *MDM2* gene found in the majority of the studied cases may account for the frequent inactivation of the *p53* gene observed in BBC, and hence the accumulation of DNA damage and the aggressive clinical course.⁴⁶

Cancer development is closely related to uncontrolled cell cycles.⁴⁷ Deletions and mutations in the gene coding for p16^{INK4}, a cyclin-dependent kinase (CDK) inhibitor, were found in 53% of BBC.⁴⁸ Moreover, deletions in chromosome 9, where the CDKN2 gene is located, were found in 92% of SCC in Egypt.⁴⁹

Human papilloma virus

The possibility of association between HPV and BBC remained open for long.⁵⁰ A study done by Khaled et al.⁵¹ showed that the virus was present in 23 out of 40 cases of BBC. Recently, a study using the Mass ARRAY technology showed all BBC blood-tested samples to be associated with HPV-16 DNA.⁵²

Metabolic observations during schistosomiasis

In the study of BBC, the metabolism of tryptophan along the formylkynurenine pathway leading to nicotinic acid has elicited considerable interest.⁵³ The justification for this interest originally stemmed from industrial oncology; however, epidemiologic support is also derived from the high prevalence of classic pellagra that used to be observed in Egypt but not in other parts of Africa where SCC is infrequently reported despite endemic schistosomiasis. In pellagra, exaggeration of the pathway from tryptophan to nicotinic acid occurs, producing larger amounts of tryptophan intermediates along the formylkynurenine pathway.²⁵

Our understanding of the role played by *Schistosoma* infection in disturbed tryptophan metabolism is complicated by geographic variations of dietary habits. In fact, serotonin metabolites such as 5-hydroxyindoleacetic acid, which are excreted in large amounts by plantain-eating Africans, are low in Africans on other diets.⁵⁴ Similar differences attributable to dietary habits have been found between bilharzial patients in Mozambique and South Africa. Egyptian peasants are not plantain eaters but subsist mostly on beans, lentils, and rice. Those with bilharzial cancer metabolize tryptophan into 3-hydroxyanthranilic acid, anthranilic acid, 5-hydroxyindoleacetic acid, and kynurenine. The excretion of these metabolites is enhanced by a loading dose of tryptophan. Therefore, schistosomiasis should not be considered the only causal factor in the associated excretion of abnormal tryptophan metabolites because, with or without cancer, urinary schistosomiasis is almost universally accompanied by urinary tract infection. The bacterial flora may, thus, contribute to a spurious accumulation of some metabolites of tryptophan.²⁵

Potentially carcinogenic metabolites of tryptophan, which may be the true oncogenic agent in the presence of bilharzial bladder inflammation, are principally determined by hepatic metabolic patterns. Factors that bear on this are coincident infestation of the liver by *S. mansoni*, pyridoxine deficiency, and chronic protein starvation. In the presence of advanced abnormalities in any of these factors, certain amounts of potential carcinogenic metabolites might be formed owing to lack of hepatic enzymes or cofactors.^{55, 56} The hepatic drug-metabolizing capacity of mice infected with *S. mansoni* is markedly reduced.⁵⁷ The mutagen-inactivating potential of *S. japonicum*-infected mouse liver is similarly reduced,⁵⁸ which results in longer persistence of the mutagen in the host body.⁵⁹ It seems likely that the carcinogen dose is a determining factor in the aggressiveness of a bladder tumor, and that a low-grade carcinoma can be converted into a high-grade one if exposed continuously to low doses of *N*-nitroso compounds. This would explain, at least in part, the overrepresentation of deeply invasive SCC in the bilharzial urinary bladder.⁶⁰

Apoptosis in schistosomal bladder cancer

One negative impact of the several cytogenetic changes that happen in the course of chronic schistosomiasis is decreasing cell apoptosis and thus enhanced oncogenesis.¹² In 2009, Botelho et al.⁶¹

showed that cells exposed to *S. haematobium* total antigen (worm extract) were found to divide faster than those not exposed to the antigen, and died much less. This was explained by increased level of Bcl-2, which is one gene that can contribute to oncogenesis by suppressing apoptosis.⁵ The overexpression of the Bcl-2 gene in BBC patients was found to be upregulated in SCC but not TCC.⁶²

Pathology of benign and preneoplastic schistosomal bladder lesions

An intense, delayed-sensitivity reaction is elicited by viable *Schistosoma* eggs plugging the vesical venules leading to tubercles, nodules, or polyps. In bilharzial cystitis, the papilloma, covered as it is by one or two layers of flattened cells, which merge with the transitional epithelium at its base, is essentially a granuloma and not a precancerous lesion. With recurrent inflammation and fibrosis, some transitional epithelial cells become sequestered in the vesical submucosa and acquire a globular arrangement around a central cavity. When they open into the bladder cavity, the cystic formations become pseudoglandular. These structures, as part of cystitis glandularis, are at times precancerous; an adenocarcinoma may arise from the columnar epithelium, into which their lining has differentiated. In patients with schistosomiasis, squamous metaplasia is frequently encountered because it is a common concomitant of chronic inflammation. This type of metaplasia is a nearly consistent precursor of BC, and for this reason, leukoplakia acquires clinical importance as a precancerous condition.²⁵

Site of origin

In patients in Western countries, BC frequently arises in the trigone; in patients in Egypt, it usually develops in areas remote from the ureters, mostly in the anterior and posterior bladder walls. This peculiarity tends to strengthen its association with schistosomal infection because the scanty or altogether absent submucosal tissue of the trigone discourages significant deposition of ova.²⁵

Histologic classification

Significant changes in the pathological types of schistosomiasis-associated bladder tumors have been found over the past decades.¹⁰ Comparing the periods 1962–1967 and 1987–1992, there was a decrease in the incidence of nodular tumors (83.4% to 58.7%) and of SCC (65.8% to 54.0%) but an increase in the incidence of papillary tumors (4.3% to 34.8%) and TCC (31.0% to 42.0%).^{63–65} Similar results were proved by comparing the periods 2001–2005 and 2006–2010 as was fore-mentioned.²² The extent of *Schistosoma* infection apparently plays a significant role in the induction of different types of carcinoma; SCC is usually associated with moderate and/or high worm burdens, whereas TCC occurs more commonly in areas associated with lower degrees of infection^{63–65} ([Figure 1](#)). Adenocarcinoma of the bilharzial bladder is particularly aggressive owing to its proneness to develop gross chromosomal aberrations combined with high cell proliferation.⁶⁶ Another rare, though distinct, variant of SCC is verrucous carcinoma of the bilharzial bladder ([Figure 2](#)). Despite reports to the contrary, a large proportion develop into invasive SCC, with which they share the same adverse prognosis.⁶⁷

Experimental data for BBC

In a number of nonhuman primates, infection with *S. haematobium* resulted in epithelial proliferation, squamous metaplasia, and TCC of the urinary bladder.⁶⁸ These types of carcinoma were morphologically similar to those observed in human bladders,⁶⁹ and such observations suggest that there is an association between *S. haematobium* and BC. These early experimental observations were important because eggs of *S. haematobium*, lyophilized worms, and urine from bilharzia patients have not been found to be carcinogenic to mice.^{70, 71} However, 2-acetyl-aminofluorene appears to promote malignant and benign bladder neoplasms of mice infested with schistosomes more often than does either agent alone.⁷² Cancer development was thought to have been accelerated by schistosomal infection, presumably acting as a late-stage cocarcinogen by virtue of its direct proliferative effect on the urothelium.⁷³

Schistosomiasis and cancer of other sites

Large intestine

Intestinal infestation with *S. japonicum* in Asia is considered a significant contributory factor to the development of colorectal cancer (CRC). Female *S. japonicum* lays a very large number of eggs (2000 per day per pair of worms), whereas *S. mansoni*'s eggs are considerably less numerous and, thus, cause

fewer pathologic problems.⁷⁴ In Shanghai, patients with intestinal schistosomiasis and cancer of the large intestine are, on average, 6 years younger than patients with spontaneous intestinal cancer. Furthermore, the male-to-female ratio of schistosomal CRC is consistently higher than in nonschistosomal cancer.^{75, 76} Recently, Madbouly et al.⁷⁶ studied the *S. mansoni*-associated CRC and showed that it has distinctive pathological features often similar to those of colitis-induced carcinoma. The parasitism is strongly associated with microsatellite instability, which is a sign of defective DNA repair,⁷⁷ which in turn affects normal colonocyte homeostasis resulting in malignant growth.⁷⁸ Another study showed that *S. mansoni*-associated colorectal tumors are characterized by Bcl-2 overexpression and less apoptotic activity than ordinary colorectal tumors.⁷⁹

The liver

A study of liver cancer and its association with a previous diagnosis of schistosomiasis was performed in rural Sichuan, China. Previous schistosomal infection was found to be significantly associated with liver cancer and that a fraction of the disease (27%) was attributable to schistosomiasis among hepatitis-negative population.⁸⁰ Experimental data showed remnants of schistosomal eggs in the severe granulomatous reaction present within a well-differentiated hepatocellular carcinoma that had developed in a hepatitis-B and -C, seronegative chimpanzee.⁸¹

Lymphoma

The association between schistosomiasis and lymphomas is far less reported.⁸² Occurrence of an isolated, primary T-cell lymphoma of the bladder may represent an unusual immune response to schistosomiasis.⁸³ Discrete case reports of lymphoma in patients with hepatosplenic and chronic intestinal infections with *S. mansoni* and *S. japonicum* have been known. Types detected were histiocytic lymphoma⁸⁴ and large B-cell lymphoma;^{82, 85, 86} where lymphoma cells proliferated around egg emboli and adult worms.⁸⁶

Other organs

Immunohistochemical studies confirmed invasive SCC of the prostate in three prostatic schistosomiasis patients coming from a population where prostatic cancer is uncommon.⁸⁷ Mazigo et al.⁸⁸ reported three cases of adenocarcinoma of the prostate gland associated with *S. haematobium* in Tanzania.

A case report of a 34-year-old white woman was suspected for genital cervical schistosomiasis. A cervical smear showed cytologic changes suggesting dysplasia and *S. haematobium* eggs inside the chorion surrounded by granulomatous inflammation. The patient showed marvelous response to praziquantel, and all clinical and histopathological changes were relieved. It was concluded that cervical schistosomiasis should be considered a curable cause of dysplasia. It was postulated that schistosomiasis of the cervix might play an additional role in HPV-induced cervical dysplasia and cancer.⁸⁹

Evaluation of carcinogenicity of schistosomiasis

According to accepted international criteria, infection with *S. haematobium* is carcinogenic to humans (group 1); infection with *S. mansoni* is not classifiable as to its carcinogenicity to humans (group 3); and infection with *S. japonicum* is possibly carcinogenic to humans (group 2B).⁹⁰

East Asian distomiasis

Liver and pancreas

Clonorchiasis and opisthorchiasis are caused by chronic infection of the human liver flukes in the biliary tree. The three species of flukes *Clonorchis sinensis*, *Opisthorchis viverrini*, and *Opisthorchis felinus* are closely related trematodes that have similar life cycles and they cause the same pathophysiology to the biliary tract.⁹¹ Globally, nearly 35 million people are infected with *C. sinensis*, with approximately 15 million being in China.⁹² Clonorchiasis is predominantly endemic in China, the Republic of Korea, Vietnam, and a part of Russia.⁹³ A similar species, *O. viverrini*, causes distomiasis in Thailand. Cholangiocarcinoma (CCA) is a cancer of the bile ducts that is considered the most severe complication of liver fluke infection. Exceptionally high incidence of CCA in Thailand and Korea is strongly related with the high prevalence of opisthorchiasis and clonorchiasis⁹¹; hence, *C. sinensis* and *O. viverrini* have been classified as “carcinogenic to humans” (Group 1) by the IARC in 2009.^{94, 95} However, infection with *O. felinus* is not classifiable as to its carcinogenicity to humans (group 3).^{94–96} The highest recorded incidence of CCA in the world is present in North-eastern Thailand, where 70–90% of the population are infected with *O. viverrini*. In Korea, where infestation with *C. sinensis* is widely prevalent, CCA accounts for more than 20% of liver cancers.

Intraductal papillary neoplasm of the bile duct is known to be a premalignant condition often associated with mucin over-production. There have been a few recent articles revealing that the disease was related with *C. sinensis* infection. Suh et al.⁹⁷ reported that 5 of 16 (31%) of intraductal papillary tumors of the bile duct were associated with *C. sinensis* infection. Jang et al.⁹⁸ reported that when CCA was associated with *C. sinensis* infection, intraductal papillary neoplasm was much more common than the usual adenocarcinoma.

Human infection results from eating raw or undercooked parasitized freshwater fish. In humans, the ingested parasites excyst in the duodenum and ascend the bile ducts and canaliculi, where they mature, causing biliary epithelial hyperplasia and fibrosis. Promoters of carcinogenesis as nitroso compounds are incriminated. In the Far East, nitrosamines are commonly found in traditional Chinese preserved foods such as salted fish, dried shrimp, and sausage.⁹⁹ Precursors of nitroso compounds have been identified in the body fluid of men infested with *O. viverrini*.¹⁰⁰ Pancreatic ducts may also be infected with *C. sinensis*; this frequently results in squamous metaplasia and mucous gland hyperplasia.

Malaria

The geographic distribution of BL in the classic malarial belt initially suggested the possible role of an arthropod vector in oncogenesis.^{101, 102} BL is a highly aggressive B-cell non-Hodgkin's lymphoma and is the fastest growing human tumor.¹⁰³ Two major epidemiological clues to the pathogenesis of BL are early infection by Epstein–Barr virus (EBV) and the geographical association with malaria. Both agents cause B-cell hyperplasia, which is almost certainly an essential component of lymphomagenesis in BL. Recent figures suggest that the incidence in children in equatorial Africa is similar to that of acute lymphoblastic lymphoma (ALL) in high-income countries—probably of the order of 3–6 per 100,000 in children aged 0–14 per year, accounting for 30–50% of all childhood cancers in equatorial Africa. This correlates with the high frequency and intensity of malaria in young children.¹⁰⁴ Incidence figures from other parts of the world, though limited, are considerably lower than those in equatorial Africa.¹⁰⁵ These data give the disease its name in Africa, endemic Burkitt lymphoma (eBL).

The possibility that drugs taken for malaria prophylaxis could have contributed to the development of BL^{106, 107} was considered unlikely because no increase (and indeed a decrease) in eBL was observed in the Malagasy Republic¹⁰⁸ and in Imesi, West Africa,¹⁰⁹ where intensive antimalarial prophylaxis was practiced. Interestingly, recent studies showed that chloroquine could play a role in cancer prevention.^{110, 111} Within endemic areas, the peak incidence of BL follows closely the incidence of severe *Plasmodium falciparum* malaria, and malarial prophylaxis reduces the incidence of the lymphoma.^{108, 109}

Of considerable interest are studies on the frequency of sickle-cell trait in eBL patients and controls. Persons with sickle trait are protected against the lethal effect of overwhelming *P. falciparum* malaria in early childhood and from the intense reticuloendothelial stimulation that sometimes progresses to hyper-reactive malarial splenomegaly.¹¹² Sickle cells exposed to low oxygen tension do not support the growth of parasites *in vitro*. A similar phenomenon may explain why children with the sickle-cell trait have a lower *P. falciparum* parasitemia. As a result, a lower mortality rate, lower IgM levels, and reduced lymphoproliferation (as measured by spleen size) are found among individuals with hemoglobin AS genotype. However, most studies attempting to relate eBL to AS hemoglobinopathy have failed to reach statistical significance.^{113, 114} Other hemoglobinopathies, such as hereditary ovalocytosis, also protect against malaria. If eBL turns out to be underrepresented in populations where both ovalocytosis is prevalent, as in Papua, New Guinea,¹¹⁵ such information would provide strong supporting evidence for malaria as a cofactor in the genesis of eBL.¹¹³

One way of explaining the observation that the malaria patient harboring a multitude of parasite-derived antigens becomes a host susceptible to eBL is the suggestion that malaria patients produce so many nonspecific and “useless” antibodies that they are unable to recognize and respond to the threat posed by a small clone of malignant lymphoid cells.¹¹⁶

Malaria and EBV

More significant are the epidemiologic observations that have linked eBL to the potentiating effect of malaria on EBV infection.¹¹⁷ Endemic BL is only found in areas where malaria is holoendemic or hyperendemic; and within these areas, it is absent in malaria-free pockets, such as urban centers. Vigorous cellular and serologic responses occur during malarial infection.¹¹⁸ This renders the plausible argument that persistent reticuloendothelial stimulation experienced among malarial populations conditions the EBV-infected African patient to develop a neoplasm rather than a self-limited disease, such as infectious mononucleosis.¹¹⁹ The potentiation effect adopted by malaria to induce BL is B-cell hyperplasia. A cystein-rich-inter-domain-region1alpha (CIDR1a) of the *Plasmodium falciparum* erythrocyte membrane protein 1 (PfEMP1) is expressed on the surface of infected erythrocytes. This protein was shown to cause an increase in the number of circulating B cells carrying the EBV in acute malaria.^{120, 121} This was explained by two mechanisms; first, the protein stimulates B memory cell replication, including the B-cell compartment where EBV resides.¹²² Second, CIDR1a can induce virus production from infected B cells, which in turn leads to infection of other B cells.^{122–124} Acute malaria, which increases B-cell proliferation, also impairs EBV-specific T-cell responses.^{101, 113, 125} This results in a larger pool of EBV-infected cells with increased likelihood for chromosomal translocation and lymphomagenesis.¹²⁶ Chattopadhyay et al.¹²⁷ defined a malaria-associated aberration localized to the EBV-specific CD8+ T-cell compartment.

African children with eBL develop autoantibodies, the elevated titers of which show no linear correlation with EBV titers for viral capsid antigen (VCA) or EBNA¹²⁸ suggesting that a factor independent of EBV

causes an immunologic imbalance and autoantibody production. The notion that this could be due to malaria is supported by the observation that Caucasians suffering from acute *P. falciparum* malaria develop autoantibodies,^{129, 130} and *in vitro* experiments that demonstrated that normal human lymphocytes can produce autoantibodies as a response to malarial antigens.¹³¹

Chromosomal aberrations and lymphomagenesis

Overexpression of *c-myc* appears to be central to the pathogenesis of typical and atypical BL. Although *c-myc* translocation occurs in all cases of BL, differences are seen in the translocation patterns in the endemic and sporadic varieties of the disease. Typically, sporadic BL has translocations involving sequences within or immediately 5' to *myc* on chromosome 8 and sequences within or near the immunoglobulin heavy chain S region on chromosome 14. In contrast, eBL tends to be characterized by a translocation involving sequences on chromosome 8 further upstream from *myc* and sequences within or near the JH region on chromosome 14.¹³¹ A mechanism by which malaria can directly produce chromosomal translocations associated with BL is the interaction with toll-like receptors (TLRs),¹⁰⁴ which are stimulated in malaria infection by certain agonists such as haemozoin and CpG-enriched DNA, and, in turn, activate the adaptive immune system. This is explained by their ability to induce activation-induced cytidine deaminase (AID) in B cells, an enzyme that induces hyper-variable region mutations and class switch recombination as well as activating B lymphocytes.^{132–134}

Recent evidences

Several studies demonstrated the relationship between several parasites and oncogenesis, for example, the relation between cryptosporidiosis and intestinal cancer.^{135, 136} The study done by Certad et al.¹³⁵ was the first to record that a human-derived *Cryptosporidium parvum* isolate can induce cancer in mice. Another protozoan *Trichomonas vaginalis* was incriminated. Although the latter has a possible role in cancer of the cervix, its role in prostatic cancer is still arguable.¹³⁷ Neurocysticercosis was also incriminated in hematological malignancies.¹³⁸ Parasite-induced immunomodulation, DNA damage, and nitric oxide release due to chronic inflammation were the mechanisms proposed.¹³⁹ The relationship of the nematode *Strongyloides stercoralis* to hepatobiliary cancer¹⁴⁰ and Kaposi sarcoma¹⁴¹ was studied, as well as the role of *Toxoplasma gondii* in brain cancer^{142, 143} and lymphoma.¹⁴⁴ These parasites and others were incriminated in cancer development; however, clues are not yet sufficient to include them in the IARC roster.¹³⁷

In view of recent revaluation of the role of parasites, it was found that infectious agents and their products can orchestrate a wide range of host immune responses, through which they may positively or negatively modulate cancer development and/or progression. Interestingly, certain types of pathogens, including parasites, can decrease the risk of tumorigenesis or lead to cancer regression.¹⁴⁵ *Trypanosoma cruzi* was found to decrease the incidence of experimentally induced rodent colon cancer.¹⁴⁶ The nematode *Trichuris suis* was investigated clinically and experimentally for its ability to alleviate diseases, such as inflammatory bowel disease (ulcerative colitis, Crohn disease), multiple sclerosis, and allergy.^{147, 148} The applicability of this to cancer pathology, and more specifically to tumors of the gastrointestinal system, is a question open to future investigations.¹⁴⁵

When uncommon neoplasms are noted with undue frequency in countries with a high prevalence of parasitic diseases, parasites become incriminated. Many parasites were studied for a possible role in oncogenesis; however, not all of them were registered as true carcinogens by the IARC. Chronic inflammation, immunomodulation, overexpression of certain carcinogens, DNA mutations, and suppression of apoptosis are the frequent well-common mechanisms for parasite-induced oncogenesis. Besides, concomitant presence of other infectious agents is proved to be an enhancing factor in many situations. Epidemiological, cytogenetic, and animal studies were used to prove the relationship between parasites and cancer. In this view, *S. haematobium* was proved to play an important role in developing urinary BC due to chronic irritation by submucosal egg deposition, constant high levels of *N*-nitroso compounds that lead to DNA mutations, suppression of apoptosis, and, hence, histopathological changes in the urinary epithelium. Human papilloma virus is still suspected to play an assistant role in this sequence. Other *Schistosoma* species *S. japonicum* is classified as a colorectal carcinogen especially in the Far East. Other helminthes *Clonorchis* and *Opisthorchis* are proved to induce hepatobiliary cancer. In Africa, a strong correlation between BL and EBV infection is present, with an evident enhancing role for *P. falciparum*. These and more can be viewed as possible human carcinogens in respect of chronic inflammatory process associating several parasitic infections. However, strong evidences, especially cytogenetic, are usually required. Strikingly, despite the above-mentioned data, it seemed that certain parasites can modulate the host immune response in a manner that could lead to cancer regression or prevention. This is in the prospect of revaluation of the clinical importance of infectious agents; an issue that requires future concern.

Part 5

Epidemiology, Prevention and Detection

Chapter 33

The burden of cancer worldwide: current and future perspectives

Jacques Ferlay, MSc, ME, ■ Christopher P. Wild, PhD ■ Freddie Bray, PhD

Overview

Cancer, once seen as a problem only of high-income countries, is now a leading global cause of death responsible for one in three premature deaths from non-communicable diseases. The global trend is set to continue over the next decades through population and lifestyle changes, part of an ongoing demographic and epidemiologic transition that will see the 14 million new cancer cases and 8 million cancer deaths estimated worldwide in 2012 rise by 55% by 2030. This chapter has three main aims. The first is to portray the marked diversity in the scale and profile of cancer in different regions of the world. Secondly, we point to the transitional nature of cancer incidence, showing that the rising incidence rates and shifting profiles of common cancers are linked to societal and economic change. Thirdly, present inequities are highlighted in countries undergoing transition, where a rising cancer incidence and mortality burden is often matched by limited data for planning purposes and an absence of operational national cancer plans. We conclude by discussing the means to improve data in resource-constrained settings for cancer control action through the planning and development of population-based cancer registries.

Introduction

Cancer, once seen as a problem of the industrialized world and high-income countries, is now a leading cause of morbidity and mortality in the majority of countries of the world. Mortality statistics from the World Health Organization (WHO) for 2011 reveal that cancer is of greater frequency as a cause of death than either ischemic heart disease or stroke, or chronic obstructive pulmonary disease and lower respiratory infections combined. The disease now constitutes one in four NCD (non-communicable disease)-related deaths overall and one in three-related NCD deaths below the age of 70. The global trend is set to intensify over the next two or three decades as population and lifestyle changes, part of an ongoing demographic and epidemiologic transition, continue to take hold. The 14 million new cancer cases and 8 million cancer deaths estimated worldwide in 2012 is projected to rise by 55% by 2030.

The impact will be greatest in the so-called developing world and countries undergoing rapid social and economic changes. An increasingly disproportionate burden of cancer will therefore fall in Africa, Asia, and Latin America, putting strain on lower-resource countries in these regions already ill-equipped at present to deal with the need for cancer services for an increasing number of cancer patients.

This chapter has three primary aims. The first is to highlight, using such global statistics, the marked diversity of cancer in terms of its scale and the range of frequent cancer forms observed in different regions of the world. Seen at the country level, 20 different cancer types rank within the five most frequent causes of cancer incidence or mortality by sex, and we briefly review and elucidate the cancer-specific patterns. Secondly, we point to the transitional nature of the cancer burden from a temporal

perspective, showing that the rising incidence and shifting profiles of cancer are linked to societal and economic changes within countries and utilize trends in the human development index (HDI) as a national proxy for such changes. Thirdly, we link the estimation and interpretation back to the express purpose of these descriptive results, to advocate for, and support the implementation of cancer control actions. We underline the present inequities seen in countries under transition where the rising cancer burden is often matched by a lack of data fit for cancer control purposes and an absence of operational national cancer plans. We discuss the means to improve the cancer data in resource-constrained settings to inform planning through the development of population-based cancer registries (PBCR). We conclude by stressing the need to implement prevention strategies alongside those of cancer treatment, management, and palliative care and integrate these into NCD plans.

Following this introduction, the next section reviews the definitions of the key indicators for cancer, the available data sources, and the methods of estimation used to derive cancer incidence, mortality, and prevalence at the national level and the global estimates within GLOBOCAN. The third section examines the key aspects of the cancer burden by development level and the patterns of the eight most frequent cancers worldwide, briefly noting the major causes for the variations observed. The fourth section focuses on human development and the extent to which socioeconomic transitions are changing the scale and profile of cancer worldwide. The final section links these findings to the equitable delivery of national cancer control policies to avert the increasing burden. We discuss the overwhelming need for better data for cancer planning in resource-constrained settings, as an integral part of global cancer control strategies. The descriptive epidemiology contained in this chapter provides strong support for prioritizing primary and secondary preventions, as an essential means to ameliorate the rising future cancer burden.

Definitions, data sources, and methods

The International Agency for Research on Cancer (IARC) is recognized as a definitive reference source for global cancer information; in addition, over the past 40 years, the Agency has prepared updated estimates of the worldwide burden from cancer. Beginning in 1975 with broad estimates of numbers of new cases for 12 common types of cancer in different areas of the world,¹ IARC now provides detailed country-specific estimates of incidence, mortality, and prevalence, by sex and age group for 27 types of cancer through the GLOBOCAN series.² An emphasis has been consistently placed on directly estimating the magnitude of cancer using locally recorded data at the country level, either from PBCR (new cancer cases) or from vital registration systems (cancer deaths), wherever the source information is available. Methods of estimation are refined with every iteration of GLOBOCAN as the quality and availability of the data increases. The latest release contains estimates for the year 2012,² with online facilities for the tabulation and graphical description of the full dataset for 184 countries and 30 world regions by sex (<http://globocan.iarc.fr>). In the following discussion, we define the core measures of incidence, mortality, and prevalence used in this chapter and the underlying data sources that build up the global profile of cancer.

Incidence, the number of new cases occurring, can be expressed as an absolute number of cases per unit time (commonly in years), as a rate per 100,000 person-time, or as a cumulative risk (expressed as a percentage) of developing a cancer up to a certain age (commonly up to 75 years), assuming an absence of competing causes of death. Incidence data are produced by PBCR, which routinely and systematically collect information on all new cases of cancer within a defined population. PBCR may cover entire national populations but more often cover smaller, subnational areas, and particularly in less developed

countries, only major urban areas (cities). Less than one-quarter of the world population is covered by population-based cancer registries currently, with sparse registration in Asia (8% of the total population) and in Africa (11%).³ When considering data of high quality [e.g., datasets included in the latest volume (X) of the *Cancer Incidence in Five Continents* (CI5) series,^{4,5}] these percentages are lower, and only 14% of the world population is covered with cancer registries that match the CI5 inclusion criteria. Presently, about one in every three (mainly higher-income) countries have high-quality PBCR. While the information from some registries in lower resource settings does not currently meet the quality standards of CI5, it is still of unique importance as a relatively unbiased source of data for cancer control purposes (see section titled “Integrating Population-Based Cancer Registries”). PBCR may also produce survival statistics by following up the vital status of registered cancer patients. Survival represents the probability that an individual with cancer will not die from it and can be used to estimate mortality from incidence in the absence of mortality data and vice versa.

Mortality is the number of deaths occurring and, as with incidence, is expressed in terms of numbers of deaths, or as a rate or cumulative risk. Mortality is the product of incidence and the *case fatality* (the inverse of survival). Mortality statistics are collected and made available by the WHO. Their advantages are national coverage and long-term availability, although for some countries, coverage of the population is incomplete, so that the mortality rates produced are implausibly low, while in others, the reliability of cause of death information is questionable. By 2003, around one-third of the world population was covered by mortality statistics,⁶ although less than half of the countries producing data currently report statistics of high quality to WHO. While almost all European and American countries have comprehensive death registration systems, most African and Asian countries (including the populous countries of Nigeria, India, Indonesia, and Pakistan) do not. The mortality data used to estimate the burden of cancer in China is available from a sample survey based on the “disease surveillance points” project covering around 6% of the total Chinese population. These statistics are considered nationally representative given the samples include both urban and rural areas.

Prevalence measures the absolute number (or relative proportion) of individuals alive in the population at a particular point in time and affected by the disease. Although incidence and mortality are considered the key measurements of cancer burden, prevalence is an important supplementary indicator for developing strategies for service provision. Unlike incidence and mortality, however, there is no clear definition of cancer prevalence. Total (or complete) prevalence is the number of persons in a defined population alive at a given time who have had cancer diagnosed at some time in the past, even if this was many years ago, and the person is cured. Beyond measures of numbers of persons living with cancer, prevalence is usually of greater utility for planning purposes to consider only those persons requiring some form of cancer services and by partitioning prevalence into defined phases of cancer care. Therefore, cancer prevalence is generally presented as the number of persons still alive after a given number of years following diagnosis.⁷ We use 5-year prevalence in this chapter and define it as the number of persons alive at the end of 2012 who had been diagnosed with cancer in the previous 5 years, a surrogate for care requirements (diagnosis, initial treatment, and follow-up) before the point of cure; this may be less useful for cancer survivors who require some form of care beyond 5 years, such as for female breast cancer where the disease remains a chronic condition affecting average prognosis decades after initial diagnosis.⁸

The global incidence, mortality, and prevalence estimates in GLOBOCAN are built up from within-country data sources considered the most recent and reliable in a given country. The methods used in the estimation process have been described in detail in various reports^{2,7,9} and are summarized in [Table 1](#).

Incidence

Mortality

Prevalence (5 years)

Figure 1 Global burden of cancer in 2012: estimated incidence, mortality, and 5-year prevalence by continent.

Source: GLOBOCAN 2012.

Lung cancer remains the most common cancer worldwide, both in terms of numbers of new cases (1.8 million) and deaths (1.6 million deaths). Breast cancer is the second most common cancer overall (1.7 million cases) but ranks fifth as a cause of cancer death (522,000 deaths) reflecting a more favorable average prognosis. These two neoplasms are followed, in terms of incidence, by colorectal cancer (1.4 million cases, 694,000 deaths), prostate cancer (1.1 million cases, 307,000 deaths), and stomach cancer (952,000 cases, 723,000 deaths). These five cancers represent almost half the global incidence burden in 2012.

Around 32.5 million people were alive and living with a cancer diagnosed in the previous 5 years at the end of 2012 ([Table 2](#)). By far, the most prevalent cancer (in both sexes) is female breast cancer ([Figure 2](#)), with an estimated 6.3 million women living with the disease. The second most prevalent cancer is prostate affecting 3.9 million men, closely followed by colorectal cancer (3.5 million). Prevalence reflects the integration of incidence and prognosis, and lung cancer, the most frequent cancer globally but one associated with a poor prognosis, has a 5-year prevalence (1.9 million) rather close to the annual mortality figure, ranking in fourth place.

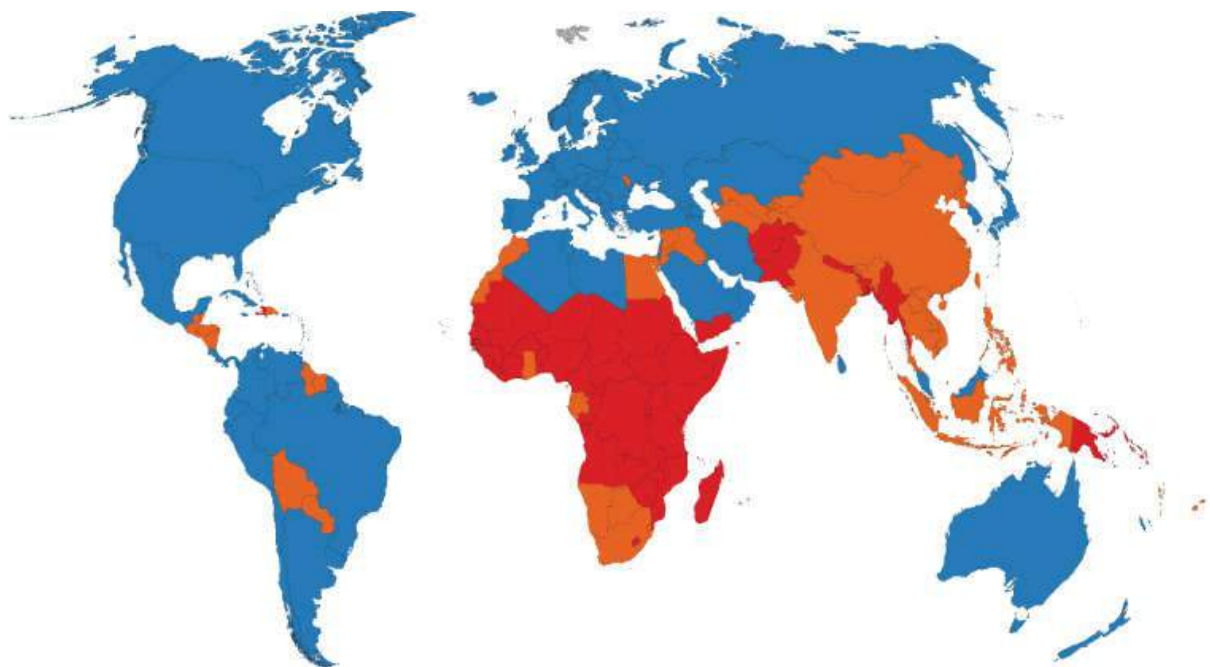

Figure 2 Bar chart of global 5-year cancer prevalence (millions) by cancer site; stacked bars denote prevalence among patients alive at end-2012 diagnosed in 2012, 2010–2011, and 2008–2009, respectively; for example, <1 year, 2–3, and 4–5 years after diagnosis. Both sexes and ages 15 years and above, sorted by magnitude of prevalence.

Patterns of cancer by level of development

In the following discussion, we use four levels of HDI, (low, medium, high, and very high) as a proxy for social and economic development (Ref. 10; <http://hdr.undp.org/en>). HDI is a composite measure of life expectancy at birth, access to education, and income [GDP (gross domestic product) per capita]. While HDI is highly correlated with GNI (gross national income), HDI additionally provides an indication as to how income is spent in a country, at least in the areas of health and education ([Figure 3a](#)).

Source: GLOBOCAN 2012.

Figure 3b–e draws attention to the diverse cancer incidence and mortality profiles globally and according to broad levels of HDI. The relative frequency of different cancers is determined by key reproductive and lifestyle determinants of cancer and the availability of health services including early detection and clinical interventions driven by the level of resources and extent of inequalities in individual countries, and thus, the degree of societal and economic transition. In regions with either high or very high HDI levels (**Figure 3c**), breast, lung, colorectal, and prostate cancer explain half the overall cancer incidence burden, with stomach cancer in fifth; this is a common “top five” profile in many high-income countries, and because of the relative contribution of these geographic areas to the burden worldwide (56%), it is equivalent to the world profile for incidence (**Figure 3b**); it is also worth noting that pancreatic cancer, a tumor associated with a very dismal prognosis, now lies in fifth place as a cause of cancer deaths in high and very high HDI countries. In low HDI (**Figure 3e**) and medium HDI (**Figure 3d**) regions, esophageal, stomach, liver, and cervical cancer remain common cancers. The profile in medium HDI settings is not dissimilar to that of China, which, given its population size (1.35 billion inhabitants), comprises two-fifths of the medium HDI burden. In low HDI settings including many Eastern African and other sub-Saharan African countries, there is a residual burden from cancer associated with the HIV/AIDS (human immunodeficiency virus infection and acquired immune deficiency syndrome) epidemic, including Kaposi sarcoma, an HIV-associated cancer caused by human herpes virus-8; rates are however declining due to a decline in HIV prevalence and an increasing availability of highly active antiretroviral therapy.^{11–13}

Figure 4a and **b** shows the global distribution of the estimated risk of dying from cancer (before the age of 75 years) in men and women. High risks of cancer mortality in men are seen in Europe and the Americas (**Figure 4a**), and mortality is also elevated in a number of Central and Eastern Asian countries including Kazakhstan and China, where lung cancer is the most frequent cause of male cancer incidence and mortality (**Figure 5a**). In women, there are substantive mortality risks in Eastern and Southern Africa, where the burden from both cervical cancer and breast cancer is high in many countries in these regions.

Patterns for eight major cancer types

A brief description of the global patterns of the eight most common cancers globally follows.

Lung

Lung cancer remains the most frequent cancer worldwide. There were more than 1.8 million new cases (13% of total cancer incidence) and almost 1.6 million deaths (20% of total cancer mortality). More than one-third of all newly diagnosed cases occurred in China. Lung cancer is the leading cause of cancer incidence in 38 countries in men ([Figure 5a](#)), but it is the leading cause of cancer mortality in men (89 countries) and the most common cause of cancer death in women in 26 countries. Owing to a high and rather stable case fatality rate, patterns and trends for mortality rates are similar to those for incidence rates, irrespective of level of resource within a given country. Recent trends in lung cancer reflect the evolution of the smoking epidemic,¹⁴ and in men, incidence rates have peaked and begun to decline in a number of highly developed countries at a late stage of the epidemic, while rates continue to rise among women. Only in a few countries (in Northern Europe, Australia, and the United States), where the epidemic is most advanced and smoking prevalence has been declining for several decades are there recent peaks or downward turns in female incidence rates. The prevalence of smoking in men has however increased sharply in many middle income countries, including China and Indonesia.¹⁵ The future burden of lung cancer and other smoking-related cancers will largely depend on future sex-specific smoking patterns, including the smoking duration, the extent of cessation, and the types of tobacco smoked.¹⁶

Breast

Breast cancer is by far the most frequently diagnosed cancer and cause of cancer death among women. There were an estimated 1.7 million new cases (25% of all cancers in women) and 0.5 million cancer deaths (15% of all cancer deaths in women). Breast cancer is the most common cancer diagnosis in women in 140 countries ([Figure 5](#)) and the most frequent cause of cancer mortality in 101. About 42% of the estimated new cases and 34% of the cancer deaths occurred in Europe and North America. Mortality rates vary approximately 2.5-fold worldwide, with the case fatality rate higher in lesser developed countries. While incidence has been generally increasing in most areas of the world ([Figure 6a](#)), breast cancer has peaked and declined over the past decade or so in a number of highly developed countries, part-linked to the impact of national screening and in some, to a population-wide reduction in the prevalence of HRT (hormone replacement therapy) use. Mortality rates have been declining in a number of highly developed countries since the late 1980s and early 1990s, a result of a combination of earlier diagnosis and treatment including a number of breakthroughs in effective therapeutics.

Rates are smoothed using lowess regression.

Prostate

Globally, prostate cancer is the second most frequently diagnosed cancer and the fifth most common cause of cancer death among men, with an estimated 1.1 million new cases (15% of all cancers in men) and 0.3 million cancer deaths (7% of all cancer deaths in men). In 2012, 60% of the estimated new cases but only 41% of the cancer deaths occurred in Europe and North America. Mortality rates are highest in countries and areas with predominantly black populations—in the Caribbean and in parts of sub-Saharan Africa—but mortality rates are also high in certain northern European countries, such as the Nordic countries. Incidence rates of prostate cancer vary more than 25-fold worldwide. The highest rates are in Australia and New Zealand, Northern and Western Europe, and North America. Prostate cancer is the most frequent type of cancer among men in 87 countries worldwide in 2012, largely in countries that have attained high or very high levels of human development, but also in several countries in Central and Southern Africa (Figure 5a). Incidence rates increased dramatically in the late-1980s in North America and the Nordic countries as prostate-specific antigen (PSA) testing became available; a similar pattern developed in

many of the highest-resource countries during the 1990s ([Figure 6b](#)). Incidence rates have leveled off in some of these countries but continue to uniformly increase in countries transitioning toward higher levels of human development.

Colon and rectum

Colorectal cancer represents almost 10% of the global cancer incidence burden and is the third most common cancer in men (an estimated 746,000 cases) and the second most common in women (614,000 cases). The disease is the fourth most common cause of death from cancer worldwide, with an estimated 694,000 deaths. Almost two-thirds of new cases occur in countries with high or very high levels of human development, with half of these occurring in Europe and the Americas. Colorectal cancer is now a common cancer in countries that have attained high levels of human development, and elevated incidence rates are seen in men in Eastern Europe (Slovakia, Hungary, and the Czech Republic) and in the Republic of Korea; incidence rates in women tend to rank second to breast cancer in countries where cervical cancer has been historically low such as in the Eastern Mediterranean region. Incidence varies 10-fold between countries worldwide, in both sexes, and rates tend to be relatively low in most African countries. As with incidence, mortality rates are lower in women than in men, except in the Caribbean. The scale of the colorectal cancer incidence and its temporal development are key markers of human development transitions in a given country. Incidence is increasing in many countries transitioning toward higher levels of development, whereas trends appear to be stabilizing or declining in countries that have attained the highest levels of human development ([Figure 6c](#)).

Stomach

Stomach cancer is the fifth most common cancer worldwide, with an estimated 952,000 new cases (7% of total cancer incidence) and 723,000 deaths (9% of total cancer mortality). Almost three quarters of the new cases occurred in Asia, and more than two-fifths occurred in China. There is a 10-fold international variation in stomach cancer incidence; rates in men are approximately double those observed in women. The highest age-standardized incidence rates are in Eastern Asia and in Central and Eastern Europe. Incidence rates remain relatively low in Africa and North America. Over the past 50 years, incidence and mortality rates of stomach cancer have been uniformly decreasing in almost all countries ([Figure 6d](#)). This may be related to changing prevalence of *Helicobacter pylori* infection, a major risk factor for gastric cancer and for which trials are underway to inform the best public health approach to prevention.¹⁷ Overall rates largely comprise the non-cardia type of gastric cancer: rates of gastric cardia cancer have, in contrast, been stable or have been increasing in recent two to three decades in the same populations.

Liver

Liver cancer represents 6% and 9% of the global cancer incidence and mortality burden, respectively. With an estimated 746,000 deaths, liver cancer is the second most common cause of death from cancer worldwide. Liver cancer is the fifth most common cancer in men (554,000 new cases, 8% of the total) and the ninth most common in women (228,000 cases, 3% of the total). Almost three quarters of the new cases occur in areas with low and medium human development; more than half of the global incidence and mortality is in China. Given the high fatality of liver cancer (overall mortality-to-incidence ratio, 0.95), the geographical patterns and trends for mortality are very similar to those observed for incidence. By far, the highest age-standardized incidence rate is seen in Mongolia. There are elevated incidence rates in East and South-East Asia, Africa, and Melanesia. Incidence rates tend to be lower in most highly developed regions. A higher prevalence of chronic infection with hepatitis B is one of the explanations for high incidence in lower resource countries as is widespread dietary exposure to aflatoxins, which

occurs in many of the same geographic regions. There is the promise of reductions in hepatocellular carcinoma incidence in the coming decades in countries where the hepatitis B vaccine was introduced (from the early-1980s) and attained complete population coverage. For aflatoxins, reductions in exposure are occurring in some countries owing to economic development (e.g., parts of China), and new emphasis is being placed on effective interventions at the level of small farmers in developing countries.¹⁸ There are concerns regarding a possible rise of liver cancer resulting from increasing infection with the hepatitis C virus, alongside the rising prevalence of obesity rates, and misuse of alcohol.¹⁹

Cervix uteri

Cervical cancer is the seventh most common cancer overall worldwide and is fourth most common in women in terms of both incidence (528,000 new cases) and mortality (266,000 deaths). Almost 70% of the global burden occurs in areas with low or medium levels of human development, and more than one-fifth of all new cases of cervical cancer are diagnosed in India. Incidence rates of cervical cancer vary greatly from country to country. The disease is still the most common cancer among women in 39 of the 184 countries worldwide ([Figure 5b](#)) and is the leading cause of cancer death in women in 45 countries. Risk is elevated mainly in sub-Saharan Africa, parts of Asia, and some countries in Central and South America. The lowest incidence rates tend to be in Western Europe, North America, Australia, New Zealand, and the eastern Mediterranean. Over the past 30 years, cervical cancer incidence rates have declined in many countries with notable exceptions ([Figure 6e](#)). This trend reflects changing societal factors linked to economic progress in countries in transition but in highly resourced countries reductions have been hastened by the implementation of effective screening programs. In contrast, however, there is little evidence for declines in incidence in recent years in Uganda, whereas rates are also increasing in several Eastern European and Central Asian countries. Recent changes in sexual behavior have led to an increase in the risk of infection with high-risk human papillomavirus types and, consequently, to increasing incidence rates in the absence of effective screening programs.²⁰

Esophagus

Esophageal cancer is the eighth most common cancer worldwide, with an estimated 456,000 new cases (3% of all cancers) and 0.4 million cancer deaths (5% of all cancer deaths). About 73% of all new cases occurred in countries at low or medium levels of human development, and 49% of all new cases occurred in China. Incidence and mortality rates are elevated in Central and East Asia as well as in Eastern Africa. Incidence rates tend to be relatively low in Western Africa and some Latin American countries. While alcohol and tobacco are common causes of esophageal cancer in high income countries, these risk factors explain far less of the burden in the high incidence, low- and middle-income countries. Incidence varies 15-fold between countries worldwide in men and almost 20-fold in women. Incidence and mortality rates are 2–4 times as high in men as in women. Owing to the high fatality rate, mortality rates are close to incidence rates, whereas trends are variable, reflecting the changing prevalence and distribution of the underlying risk factors for esophageal cancer and its main histological subtypes (adenocarcinoma and squamous cell carcinoma). A recent study²¹ providing global estimates of esophageal cancer incidence by histology suggested a high concentration of adenocarcinoma in high-income countries, with men at greater risk and a link to increasing obesity rates. An increasing tendency to classify cancers located at the gastro-esophageal junction as adenocarcinoma (rather than gastric cardia cancer) may also have had a distortive impact on the overall trends and the cancer burden.

Global cancer transitions

The changing scale of cancer

NCDs were responsible for 36 million deaths in 2011 (with cancer, cardiovascular diseases, diabetes, and chronic respiratory diseases comprising 82% of all NCD deaths), a mortality figure surpassing all other causes combined, with NCD deaths expected to rapidly rise to over 50 million by 2030. Such changes in societies result from a complex interaction between health and disease patterns and their demographic, social, and economic determinants, but the rise of NCD may be considered part of the epidemiologic transition.²² In this late stage of the transition, malnutrition and pandemics of infection (e.g., through the control of TB and malaria) are displaced by NCD—“degenerative and man-made diseases”—as the major causes of morbidity and mortality as societies increase their average life expectancy; overall, global mortality is generally lower but becomes concentrated at older ages.

Declines in all-cause mortality trigger fertility declines, and the rapid declines in high fertility rates projected over the next decades coupled with increasing longevity are the key contributors to population growth and population ageing worldwide. The global population of 7 billion in 2012 will reach 8.3 billion by 2030.²³ The population expansion is expected to be particularly dramatic in rapidly transitioning countries currently classified as low and medium HDI countries; as population aging is much less advanced, many are poised to enter a period of rapid increases in this parameter. Such demographic transitions are the major drivers of the increasing global cancer burden, assuming that incidence rates remain unchanged: when rates are allowed to vary and trends in major cancers are incorporated into projections, further increases in the future burden are expected. This is particularly so in countries in transition where the most rapid increasing incidence in major cancers is observed. In any case, the changes in population structure and those in the underlying rates contribute to the rise in a ratio of 4 : 1⁹; the demographic component alone translates to a predicted global burden of almost 19 million new cases of cancer in 2025 and 21.6 million cases by 2030, compared with the estimated 14.1 million cases in 2012 ([Figure 7](#)). The proportional growth in population and corresponding number of future cancer cases are inversely related to current level of development, with the biggest relative increases seen in low HDI areas. Medium HDI countries will experience the greatest absolute population growth and thus the greatest absolute increase in the future cancer burden in 2025. Increases of 60–70% in the cancer incidence are forecast in Latin America, Asia, and Africa by 2030.

Figure 7 Bar charts depicting (a) the percentage increase in cancer incidence 2012–2025 by HDI and (b) the percentage increase in cancer incidence 2012–2030 in five world regions.

Source: GLOBOCAN 2012.

The changing profile of cancer

Cancer has emerged as one of major causes of death in human populations, and the lowering of death rates of degenerative diseases among the aged, such as cerebrovascular disease and stroke, signify that cancer is also one of the major barriers to a longer average life expectancy. The disease burden is changing in its profile as well as scale as countries transit towards higher levels of human development, and the disease has transitional hallmarks as noted earlier: cancers associated with infection (e.g., cervical and stomach cancer above) have, from a global perspective, been surpassed by cancers more associated with affluence (e.g., breast, colorectal, and prostate cancer). For colorectal cancer in particular, the rapid increases in countries that have attained medium or higher levels of human development are indicative of a westernization effect: a changing population prevalence of a number of reproductive, dietary, metabolic and hormonal risk factors—toward levels more akin to those more commonly observed in the west—and a corresponding increase in risk of the disease.²⁴

Kuwait, a highly resourced country that has scored highest of all Arab countries in the HDI, now has a similar cancer profile to many countries in the west (personal communication, Dr. Amani Elbasmy), with high frequencies of breast, prostate, and colorectal cancer (similar to Australian registries despite an overall rate three times lower) and a rising and increasing relative importance of certain types of cancer—leukemia and non-Hodgkin lymphoma, and in 10th place in men, testicular cancer—for which there remains only limited understanding of the respective causative factors.²⁵

It has been noted that the basic models of Omran's epidemiological transition fail to grasp the global nature and therefore heterogeneity of the mortality transition and that “there are probably as many models as there are societies.”²⁶ For cancer, the description of a *cancer transition* and indeed the disease as purely non-communicable is an over simplification, particularly as it fails to address the importance of infection as an important and persistent cause of cancer.²⁷ It has been estimated that around one-third of all cancers in Sub-Saharan Africa are caused by infectious agents including cancers of the cervix, liver, stomach, bladder, and Kaposi sarcoma.²⁸ While rapid increases in the incidence of breast, prostate and colorectal cancer are observed in high-quality cancer registries in Kampala, Uganda, and among Harare blacks in Zimbabwe,^{12, 13} corresponding rates of cervical cancer also show increases in incidence. In low HDI Eastern Africa, infection- and poverty-related cancers are the major forms diagnosed. In Blantyre, Malawi, cervical cancer, Kaposi sarcoma, non-Hodgkin lymphoma, and esophageal cancer are ahead of female breast cancer as the top five incidence cancers. In high and very high HDI Eastern Europe and Central Asia, many countries have observed increasing cervical cancer mortality rates in young women. In the absence of effective screening programs, trends in Belarus, Tajikistan, Kyrgyzstan, Armenia, Azerbaijan, Ukraine, the Russian Federation, and Kazakhstan are linked to changing sexual behavior and increasing risk of persistent HPV infection in successive generations of women born around 1940–1950.²⁹

Using descriptive epidemiology to inform cancer control policy

Clearly, a step-change in investment in the control of cancer and other major NCD is necessary to stem the rising burden. In developing national cancer control strategies and integrating these into NCD planning, strengthening surveillance systems, including population-based cancer registries and implementing population-level primary prevention and early detection policies are critical aspects, and development agencies and international partners have a distinct role to play in supporting activities in resource-challenged countries. We close by discussing the need to enhance cancer surveillance systems to inform cancer control action, notably in lower resource settings.

Integrating population-based cancer registries

In order to plan and evaluate health services, we need to know what is happening at a population level—at the national level or within a province or a substantial sector. Cancer planning is equally impossible without first identifying the scale and the profile of cancer in the community. While the use of good quality cancer surveillance data, including cancer incidence and mortality used in conjunction is ideal, for many developing countries (as discussed in section titled “Definitions, Data Sources, and Methods”), the respective sources, population-based cancer registries and vital registration systems are very limited in availability, quality, and population coverage outside of Europe, North America, and Australia/New Zealand. In particular, PBCR are feasible to implement even in lower resource settings, and guidance for planning and developing such registries is available.³⁰ It is of acute concern that currently only 67 (mainly high-income) countries are equipped with high-quality PBCR, whereas in 62 (mainly low-income) countries, no reliable data are available. Many developing countries endure the very same obstacles facing other health services including a lack of financial resources and expertise.

The political recognition of NCD has changed however recently and world leaders agreed in 2011 to a roadmap to address the global burden, including a time-bound commitment to establish policies for the prevention and control of NCDs by 2013, and the adoption of nine global targets for 2025 (including a 25% reduction in premature mortality from NCDs). Importantly, all countries agreed to collect cancer incidence data as one of 25 indicators to monitor progress, and the IARC-led *Global Initiative for Cancer Registry Development (GICR)* partnership (<http://gicr.iarc.fr>) aims to support this high-level commitment by aiding and accelerating the availability of PBCRs for national cancer control purposes. The key instrument through which the ambitions are realized is the formation of six IARC Regional Hubs for Cancer Registration in Africa, Asia, Latin America, the Caribbean, and the Pacific Islands, which provide localized programs of training, support, and advocacy to targeted countries within defined regions. A key medium-term aim of IARC and GICR is to support 50 countries in resource-challenged settings in providing measurable improvements in cancer surveillance for cancer control action by 2018, via the planning and development of PBCR.

Conclusions

Cancer registration and the descriptive epidemiology using the collected data are essential foundations for evidence-based cancer control at a national, regional, and global level. The markedly different rates and patterns of cancer across the world, and their trends over time have been and continue to be a source of hypotheses on cancer causation and a mechanism to measure the impact of preventive interventions. Information on the burden of the disease and its changing patterns should also underpin the planning of health service provision. Furthermore, cancer registries make valuable research partners, for example, in the identification of cancer cases in population-based studies.

The observations summarized briefly in this chapter demonstrate the different and changing challenge of cancer control internationally. The increased importance of cancer as a cause of premature mortality in low- and middle-income countries must translate to increased investment in cancer control if this disease is not to become a major barrier to sustainable human development throughout the twenty-first century.

Chapter 34

Cancer epidemiology

Xifeng Wu, MD, PhD ■ Xia Pu, PhD ■ Stephanie C. Melkonian PhD ■ Margaret R. Spitz MD, MPH

Overview

According to the World Health Organization (WHO) there are over 14 million new cancer cases per year worldwide. As the epidemiologic transition continues, we see increases in cancer incidence in developing nations with more than 50% of all new cancers occurring in low- and middle-income countries. This chapter will review cancer disparities in developed and developing nations, as well as traditional and emerging risk factors, particularly tobacco smoking and factors related to energy balance. It will also summarize the novel and emerging wealth of genomic, epigenomic, metabolomic, and transcriptomic information for the prediction of cancer risk and outcomes.

Descriptive cancer statistics

Global cancer statistics

According to the ¹ World Health Organization (WHO), there are over 14 million new cancer cases and 8 million cancer-related deaths per year worldwide.¹ The top 10 commonly diagnosed cancers worldwide are lung (13%), breast (11.9%), colorectal (9.7%), prostate (8%), stomach (6.8%), liver (5.5%), cervical (3.7%), esophageal (3.2%), and bladder (3%) cancers, and non-Hodgkin lymphoma (2.7%).¹ The most frequently diagnosed cancers differ between men and women; lung (16.7%), prostate (15%), colorectal (10%), stomach (8.5%), and liver (7.5%) cancers are the most commonly diagnosed cancers in men, whereas breast (25.2%), colorectal (9.2%), lung (8.8%), cervical (8%), and endometrial (5%) cancers are the most common cancers in women (excluding nonmelanoma skin cancers) worldwide.¹ It has been suggested that if the recent trends in cancer incidence continue, then the burden of cancer will increase to 23.6 million new cases each year by 2030. In 2013, there were an estimated 8.2 million deaths from cancer in the world—4.7 million (57%) in males and 3.5 million (43%) in females, giving a male to female ratio of 10 : 8.¹

US cancer statistics

In 2014, there were over 1.6 million new cancer cases in the United States with nearly 600,000 cancer-related deaths.² According to Surveillance, Epidemiology, and End Results (SEER) program data, the top incident cancers in the United States excluding nonmelanoma skin cancers) are cancers of the prostate (27%), lung (14%), colorectum (8%), bladder (6.6%), melanoma of the skin (5.1%), kidney (4.6%), non-Hodgkin lymphoma (4.5%), oral cavity (3.5%), leukemia (3.5%), and pancreas (2.8%) in men and cancers of the breast (29%), lung (13%) colorectum (8%), endometrium (6.5%), thyroid (5.9%), melanoma (4%), non-Hodgkin's lymphoma (4%), kidney (3.1%), pancreas (2.8%), and ovary (2.7%) in women.³ The overall cancer incidence rate is 529.4 per 100,000 in men and 411.3 per 100,000 in women; however, the rates have been decreasing in recent years due to rapid declines in colorectal, prostate, and

lung cancers, largely due to improvements in primary prevention and screening.³ However, incidence rates for cancers such as melanoma of the skin, esophageal adenocarcinoma; cancers of the thyroid, liver, kidney, anus, and pancreas; and human papillomavirus-positive oropharyngeal cancers are increasing.⁴ Although the overall cancer death rate rose for a good portion of the twentieth century, there has been a steady decline in cancer death rates over the past 20 years (from 215.1 deaths per 100,000 population in 1991 to 171.8 per 100,000 deaths per 100,000 population in 2010).^{2, 3}

Cancer sites include invasive cases only unless otherwise noted.

Rates for American Indian/Alaska native are based on the CHSDA (Contract Health Service Delivery Area) counties.

Hispanics and non-Hispanics are not mutually exclusive from whites, blacks, Asian/Pacific Islanders, and American Indians/Alaska natives.

Incidence data for Hispanics and non-Hispanics are based on NAACCR (The North American Association of Central Cancer Registries)

Hispanic Identification Algorithm and exclude cases from the Alaska native registry.

Rates are per 100,000 and are age-adjusted to the 2000 US standard population (19 age groups –Census P25-1130).

Regression lines are calculated using the Joinpoint Regression Program Version 4.1.0, April 2014, National Cancer Institute.

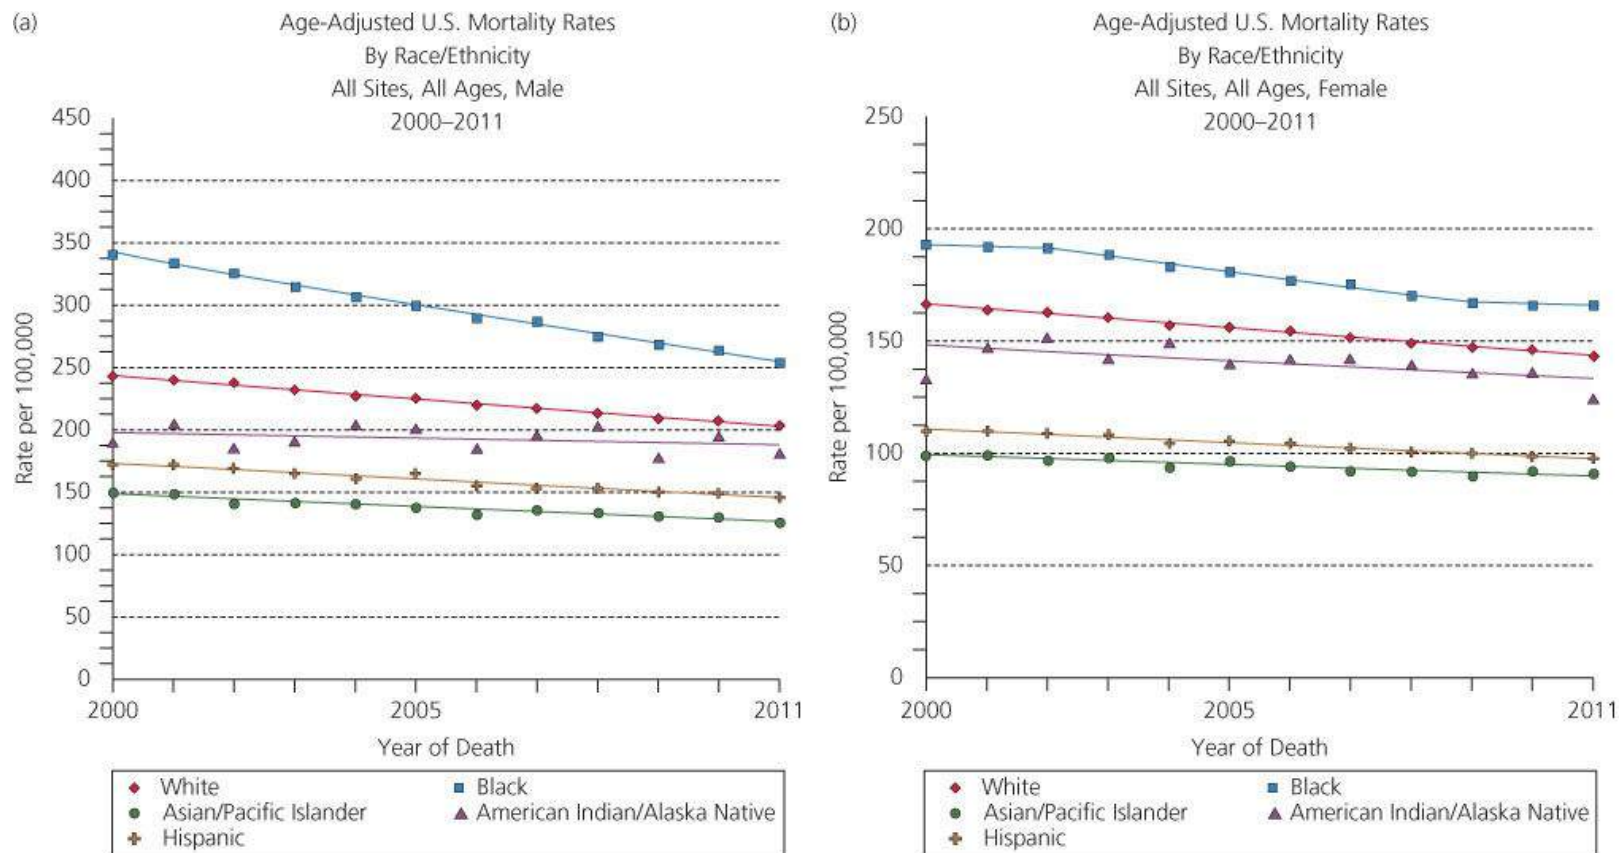

Incidence source: SEER 18 areas (San Francisco, Connecticut, Detroit, Hawaii, Iowa, New Mexico, Seattle, Utah, Atlanta,

San Jose-Monterey, Los Angeles, Alaska native registry, Rural Georgia, California excluding SF/SJM/LA,

Kentucky, Louisiana, New Jersey and Georgia excluding ATL/RG).

Rates of cancer incidence and mortality also vary significantly by ethnicity, race, and socioeconomic status (SES). These variations, both in the United States and worldwide, contribute to a growing concern regarding cancer health disparities.

Cancer health disparities

Cancer health disparities represent differences in cancer incidence, prevalence, and mortality among different populations based on factors such as race, ethnicity, poverty, SES, inadequate education, lack of access to care, and various behavioral, environmental, lifestyle, and occupational exposures.^{5–7} The elimination of disparities in the burden of cancer is a primary concern worldwide.

Variation in cancer incidence and mortality by race and ethnicity in the United States

Cancer incidence and death rates vary fairly dramatically between racial and ethnic groups in the United States (broadly defined as non-Hispanic White, Black, Asian American/Pacific Islander, American Indian/Alaska native, and Hispanic). Cancer incidence rates are highest among African-American (AA)

men (554.5 per 100,000 population) followed by whites (499.7 per 100,000), Hispanics (393.5 per 100,000), Asian/Pacific Islanders (310.1 per 100,000), and American Indian/Alaska natives (293.5 per 100,000) ([Figure 1a](#)).⁴ AA men also have the highest cancer death rates (253.9 per 100,000), nearly double those of Asian Americans (131.1 per 100,000), who have the lowest out of the five racial/ethnic groups ([Figure 2a](#)).^{2, 4} Cancer incidence and death rates are higher among black men than white men for almost every cancer site, except for kidney cancer.^{4, 8}

Among women, cancer incidence rates are highest among whites (414.8 per 100,000 population), followed by AA (393.8 per 100,000), Hispanics (324.2 per 100,000), Asian/Pacific Islanders (279.8 per 100,000), and American Indian/Alaska natives (261.0 per 100,000) women ([Figure 1b](#)). Black women have the highest cancer death rates (166.2 per 100,000) versus Asian/Pacific Islanders (91.1 per 100,000) ([Figure 2b](#)). Overall, cancer incidence and death rates are lower among Asian Americans/Pacific Islanders, American Indians/Alaska natives, and Hispanics than whites for all cancer sites combined and for the four most common cancer sites.³ However, cancers associated with infectious agents (uterine cervix, stomach, and liver) are generally more common in nonwhite populations. Asian Americans/Pacific Islanders having the highest incidence of stomach and liver cancer and Hispanics with the highest incidence of cervical cancer.⁹

In developed nations such as the United States, lower SES groups tend to have poorer access to care and resources for cancer prevention, detection, and control, resulting in a disproportionate burden of cancer in poorer communities.^{5, 7, 9} Although there is commonly an overlap between minority status and lower SES, it has been noted that even after taking into account factors related to SES, minority populations and medically underserved groups tend to be differentially burdened by cancer incidence and mortality.⁹ These groups tend to enter the healthcare system with later-stage disease, which negatively impacts cancer morbidity and mortality in those populations.^{7, 9}

Cancer disparities in developing nations

Cancer is often overlooked as a major source of disease burden in developing nations where infectious disease and perinatal and maternal mortality are primary health concerns.⁶ However, large declines in mortality have been observed and are expected to continue for all the principal communicable diseases (with the exception of HIV/AIDS) and noncommunicable diseases such as cancer are projected to increase over the next 30 years.^{6, 7, 10, 11} More than 50% of all new cancers and two-thirds of annual cancer mortality worldwide occur in low- and middle-income countries.^{1, 11} The cancer burden in these countries disproportionately affects the poor, who are more likely to use tobacco, have poorer diets, have higher exposure to sunlight and other occupational exposures, and are at higher risk for infection-related cancers and have limited access to care.¹²

Although higher income countries have long-term survival rates for cancer upwards of 60%, these rates are closer to 20% for developing nations. Likely due to the lack of infrastructure, and available channels for early detection, approximately 70% of cancers diagnosed in developing nations are diagnosed in a late stage.^{1, 12} Incidence of infection-related cancers, such as cervical cancer and hepatocellular cancer, remain high in low- and middle-income countries.^{1, 7} However, as these nations become more industrialized and modifiable risk factors such as sedentary lifestyle and Westernized diets become more prominent, cancers more prevalent in Western nations, such as breast and colorectal cancer, will also become more common.⁷

Emerging cancer risk factors

Although factors such as genetic susceptibility and family history play an important role in cancer etiology, they only explain part of the variance observed in cancer risk across different populations and subgroups. For example, evidence suggests that in the United States, for those individuals who do not use tobacco, the most important modifiable determinants of cancer risk are associated with energy balance—the integrated effects of diet, physical activity, and genetics on body weight over an individual's lifetime.^{13, 14} Together these factors contribute to approximately one-third of preventable cancers each year, equal to the number of preventable cancers due to smoking, and are responsible for the same number of cancer-related deaths.^{15, 16} The carcinogens in different cancer etiologic risk factors may cause specific molecular (e.g., nucleic acids and protein) defects that eventually lead to cancer development.

Energy balance

Obesity: According to the WHO, the rates of obesity have doubled worldwide since 1980.¹⁷ Globally, between 1980 and 2008, obesity prevalence rose from 4.8% to 9.8% in men and from 7.9% to 13.8% in women.^{17, 18} The WHO estimates that by 2008, more than 1.4 billion adults over the age of 20 were overweight, and of these overweight adults, nearly 500 million were obese.¹⁷ The United States has the highest prevalence of obesity. More than one-third (34.9%) of adults are considered obese with rates of obesity varying drastically by racial and socioeconomic subgroups.¹⁹ For example, non-Hispanic blacks have the highest age-adjusted rates of obesity (47.8%), followed by Hispanics (42.5%). Obesity and cancer may be linked via mechanisms related to insulin and insulin-like growth factors, sex steroid levels, and the adipocyte-derived cytokines, or adipokines.^{20–22} Adipose tissue has in recent years been recognized as an active and major endocrine and metabolic organ, important in regulation of energy balance and lipid metabolism through the release of peptide hormones such as leptin, adiponectin, and the cytokine TNF α . Depending on the cancer site and population in question, population attributable fractions due to obesity range from 14% for colorectal cancer (CRC) and over 50% for endometrial cancer.²³ The heritability of body weight is high, estimated to range between 40% and 70%.^{24–26} Studies have suggested that genetic variation, particularly in genes such as *FTO*, *MC4R*, and *TMEM18*, plays a major role in determining interindividual differences in susceptibility or resistance to the obesogenic environment.²⁷

Once considered to be a concern only in high-income westernized nations, obesity has become a major contributor to the global burden of disease.¹⁸ Over the next two decades, some of the largest proportional increases in the number of adults classified as overweight or obese are expected to occur in low- to middle-income nations including South Asia, East Africa, Southeast Asia, West Africa, and the Caribbean.^{18, 28} The rapid increase in rates of obesity in developing nations has been driven by urbanization and economic growth, which continue to fuel dramatic changes in living and labor environments as well as diet and lifestyle.^{18, 28} Studies to date indicate a role for obesity in several cancers including colon, breast, endometrium, kidney (renal cell), gastric cardia, pancreas, gallbladder, and liver.²⁰

Physical activity and energy intake

Numerous observational studies have examined the relationship between physical activity and cancer risk at various cancer sites.²⁹ The most definitive epidemiologic evidence for the association between physical activity and cancer risk exists for CRC.³⁰ Studies suggest a risk reduction of approximately 30% when comparing individuals with the highest versus lowest activity levels.³⁰ The evidence for the

association between physical activity and other cancers such as prostate, endometrial, breast, lung, and renal cancers is less consistent and suggests that these associations may be jointly impacted by factors such as body mass index (BMI) and family history.³¹

Total caloric intake, or energy intake, has also been proposed to be a major cancer risk factor.³² Early evidence from animal models suggest that a 15–53% reduction in caloric intake can result in a 20–62% reduction in incidence of spontaneous, chemically induced, and radiation-induced tumors.^{32–34} Long-term follow-up of previously morbid obese bariatric surgery patients demonstrates significant reduction in the incidence and mortality of cancer, especially those related to obesity.³⁵ Although it currently remains unclear if this reduction in incidence is due to the profound metabolic changes related to weight loss, this evidence is supported by well-known pathophysiological consequences of obesity including chronic inflammation and hormonal changes.³⁵ Caloric restriction-mediated benefits on cancer are thought to involve metabolic adaptations including decreased production of growth factors and anabolic hormones, decreased reactive oxygen species production, decreased levels of inflammatory cytokines, and the potential impact on cellular processes including apoptosis and DNA repair.³²

Recent epidemiologic evidence has suggested that high total caloric intake is associated with increased cancer risks, particularly for CRC.³⁶ For example, a large population-based case–control study of CRC concluded that total energy intake was associated with an approximately 56% increased risk of cancer for those in the highest versus lowest category of total energy intake. Similarly, a familial study of breast cancer risk identified a nearly 60% increased risk associated with high versus low caloric intake.³⁷ Other case–control studies of prostate cancer and kidney cancer have also suggested that high caloric intake is associated with increased cancer risks.^{38, 39} However, measures of total caloric intake in epidemiologic studies are often prone to recall bias and misclassification due to the use of self-reported data, and findings regarding energy intake and physical activity have been inconsistent.^{38, 39}

Metabolic, hormonal, and growth factor alterations that affect the regulation and expression of genes involved in DNA repair, cell proliferation, and apoptosis have been associated with increased food consumption and decreased physical activity.⁴⁰ Regular physical activity and caloric restriction have been shown to significantly lower levels of insulin and insulin-like growth factors.⁴¹ Physical activity may play a role in cancer etiology through changes in endogenous sexual and metabolic hormone levels and growth factors, decreasing obesity and central adiposity and by potentially impacting immune function and response.⁴⁰

Diet

Dietary factors are believed to account for nearly one-third of all cancers in Western countries.⁴² Early studies linking diet to cancer etiology observed that dietary intake patterns and cancer rates varied by populations around the world, suggesting that these dietary patterns may be linked with cancer etiology. In order to further investigate this association, hundreds of case–control as well as prospective studies have evaluated the role of diet in cancer risk. Several reviews have summarized the association between dietary intake and cancer risk.^{42–45}

Briefly, dietary factors such as meat intake, dietary fat consumption, and fruit and vegetable intake have all been studied extensively with regard to cancer risk. A meta-analysis suggested that high red meat intakes were associated with 28–35% increased risk of CRC, whereas processed meats were associated with 20–40% increased risk.^{46, 47} Meat intake has also been associated to a lesser degree with stomach cancer risk, and less consistently with cancers of the bladder, breast, endometrium, glioma, pancreas,

prostate, and renal cell.⁴⁶ Case–control studies have suggested up to a 35% increased risk of breast cancer associated with high dietary fat intake; however, prospective studies, which are less prone to the sources of bias common in case–control studies (i.e., recall bias), have largely found no association between dietary fat intake and cancer risk, suggesting that methodological biases are potentially the cause of some of the results of case–control studies.⁴⁸ Studies also suggest that high fruit and vegetable intake could potentially prevent 5–12% of cancers.⁴⁹ Substances present in fruits and vegetables may have anticarcinogenic effects—these include dithiolthiones, isothiocyanates, indole-3-carbinol, allium compounds, isoflavones, protease inhibitors, saponins, phytosterols, inositol hexaphosphate, vitamin C, D-limonene, lutein, folic acid, β carotene, lycopene, selenium, vitamin E, flavonoids, and dietary fiber.⁵⁰ These substances have been shown to play a role in estrogen metabolism, protecting DNA from oxidative damage, DNA methylation, and cell proliferation.⁵¹

Electronic cigarettes (E-cigarettes)

E-cigarette use, also called “vaping,” employs battery-powered devices that deliver nicotine-containing vapor rather than inhaled smoke of traditional cigarettes.⁵² E-cigarettes constitute a growing market with around \$2.2 billion estimated in 2014.⁵³ E-cigarettes are controversial in their role as a smoking cessation aid and in tobacco harm reduction as a substitute for traditional cigarettes. There is evidence that the convenient features of e-cigarettes make it more difficult to quit compared with traditional cigarettes.⁵² The US Food and Drug Administration (FDA) reported that e-cigarettes contained many dangerous chemicals that are carcinogenic.⁵⁴ In April 2014, FDA announced its intention to regulate e-cigarette devices to make them subject to the established regulation terms of tobacco products.⁵³ It remains to be seen what the long-term adverse effects of e-cigarette use are.

Genetic susceptibility

Although cancer is mainly caused by environmental exposures, genetic susceptibility also plays an important role.⁵⁵ Susceptibility genes are categorized as rare high penetrant variants [odds ratio (OR)] > 10, moderate penetrant variants (OR = 2–5), or common low penetrant variants (OR = 1.2–1.5). The known hereditary cancers are uncommon and are usually associated with highly penetrant genes. For example, germline mutations in *BRAC1* and *BRCA2* genes are responsible for the majority of hereditary breast/ovarian cancer syndromes and can also increase the risk of several other cancers, such as prostate and pancreas cancers.⁵⁶ The *MLH1* and *MLH2* genes cause the majority of hereditary nonpolyposis colorectal cancer (HNPCC) cases.⁵⁷ Children with two copies of mutated *RB1* genes are at 90% risk of developing pediatric retinoblastoma.⁵⁸

Although the penetrance for these inherited cancer syndromes is high, they only represent a very small portion of all cancer cases. The majority of cancers are sporadic, attributed to a large number of common, low-penetrance genes. Historically, the candidate gene approach only identified a handful of true cancer susceptibility loci, such as *GSTM1* and *NAT2* for bladder cancer and *CASP* for breast cancer.^{59–61} The problems associated with such studies included low throughput of platforms, limited study size and power, nonreproducibility of gene–environmental interactions, and, above all, the failure to pick functional variants to evaluate. The explosion of genome-wide association studies (GWAS) in recent years has revolutionized studies of genetic susceptibility. To date, there are over 250 publications on GWAS of cancer risks that have identified hundreds of single nucleotide polymorphisms (SNPs) as genetic susceptibility variants for 35 cancer sites, including 95 SNPs in 48 regions for prostate cancer, 81

SNPs in 28 regions for breast cancer, and 17 SNPs in 12 regions for lung cancer (a catalog of published GWAS is available at <http://www.genome.gov/gwastudies>). These genetic variants are often located in gene deserts and intergenic regions. However, some identified susceptibility genes have provided important biological insights into the etiology of cancers, such as the lung cancer susceptibility loci at chromosome 15q25.1 containing nicotinic acetylcholine receptor genes,^{62–64} breast cancer susceptibility loci at 6q25.1 containing estrogen receptor 1 gene,^{65, 66} and multiple prostate cancer susceptibility loci containing androgen-receptor-binding regions.⁶⁷ In addition to these specific cancer susceptibility regions, many “hot-spot” regions have been found to harbor susceptibility loci for multiple cancers. For example, the chromosome 8q24 region flanking the oncogene *MYC* harbors susceptibility loci for five cancers, including breast, colorectal, bladder, prostate, and ovarian cancers. Chromosome 5p15.33, which maps to the *TERT-CLPTM1L* region, harbors susceptibility loci for at least six cancers, including melanoma, basal cell carcinoma, glioma, lung, bladder, breast, prostate, pancreas, and testicular cancers. A third region chromosome 11q13 contains susceptibility loci for at least four cancers, including prostate, kidney, colorectal, and breast cancer. The major signal mapped in this region is an intergenic region near *TPCN2* and *MYEOV*.^{68, 69}

Despite the success of the GWAS approach in identifying cancer susceptibility loci, each region only confers a small OR for cancer risk, and the clinical application of these low-penetrance loci is unclear. The biological mechanisms underlying these GWAS hits are largely unknown. Future studies are warranted to decipher gene–environment interactions, explore the functional relevance of the hot spots identified, and pinpoint the biological mechanisms of these loci.

Emerging methods and technologies

The rapid technological advancement over the past decade has had a tremendous impact on the practice of cancer epidemiology. In particular, various “omics” technologies are changing the landscape of epidemiologic research at an unprecedented pace. In addition to genomics, epigenomics, transcriptomics, proteomics, and metabolomics are all being applied to cancer epidemiological research. However, there has been limited success to date applying these technologies in cancer epidemiology due to study design and confounding issues. Unlike inherited genetic variations that are a stable trait, molecular features at the epigenetic, RNA, protein, and metabolite level are influenced by environmental exposures, pathological status, sample collection and processing, and technical reproducibility. With proper study design (e.g., prospective, longitudinal study), standardized data collection, well-controlled sample collection and processing procedures, and maturing technology, these “omics” approaches have the potential to identify novel biomarkers for cancer risk and outcome in cancer epidemiology research.

Next-generation sequencing (NGS)

The success of GWAS in identifying genetic susceptibility loci has benefited from advances in genomic technology, and the human genome and HapMap projects. GWAS have been fruitful in identifying new genetic susceptibility loci; however, GWAS only test common alleles and GWAS hits so far only explain a small fraction of the heritability of cancer.⁷⁰ Next-generation sequencing (NGS) (e.g., exome or whole genome sequencing) has facilitated the effort to identify the missing heritability of cancer. There have been success stories in using NGS in cancer association studies. The identification of a germline mutation in *PALB2* as a familial pancreatic cancer susceptibility gene was among the early efforts in the application of NGS in cancer gene discovery.⁷¹ The *POLE* and *POLD1* germline variations, which result in a defective protein, have been identified by NGS as high-penetrance susceptibility genes for colorectal

adenomas and carcinomas, improving our understanding of the etiology of these diseases.⁷² Earlier this year, NGS found a significant enrichment of novel and rare germline variants in *JMJD1C*, which codes for a histone demethylase and is a coactivator of the androgen receptor, among patients with intracranial germ cell tumors (IGCTs), suggesting *JMJD1C* as a susceptibility gene for this rare brain tumor.⁷³ Most recently, germline mutations in *POT1*, encoding one member of the telomere shelterin complex, have been identified by NGS as predisposing people to familial melanoma and glioma.^{74, 75}

Epigenome-wide association study (EWAS)

Epigenetic changes refer to changes that may modulate gene expression without affecting DNA sequence. The epigenome sits at the interface between the dynamic external environment and the static human genome. There is extensive interindividual variation in the epigenome. Epigenome-wide association study (EWAS) generally refers to the study of genome-wide epigenetic profiles and represents a novel tool to understand disease etiology and predict treatment response and clinical outcome.⁷⁶ For example, a prospective breast cancer EWAS study identified a blood methylation signature as having higher predictive power for breast cancer risk than eight GWAS-identified SNPs combined.⁷⁷ Likewise, a genome-wide methylation analysis found methylation signatures to be a robust predictor for estrogen receptor subtype and patients' clinical outcome.⁷⁸ Although the epigenome has the advantage of capturing a dynamic picture of cancer processes resulting from the interplay between inherited and environmental factors, there are specific challenges in conducting EWAS studies—including sample selection and handling, meticulous exposure phenotyping, sample size, and population selection. Therefore, the results should be interpreted with caution, as epigenetic changes could be either causal or consequential for a specific phenotype. MicroRNAs (miRNAs) are another important epigenetic modifier that regulate a third of human genes post-transcriptionally.⁷⁹ Evidence supports the role of miRNAs in many cellular processes critical in carcinogenesis, such as cell proliferation, differentiation, and cell death. MiRNAome is the profile of global miRNAs in the genome. Considering the complex regulation network of miRNA-target genes, the comprehensive analysis of microRNAome could provide insight into cancer etiology, treatment effects, and potential therapeutic molecules.^{79, 80}

The microbiome

Chronic infections contribute to carcinogenesis, with approximately 16% of the global cancer burden being directly attributable to infectious agents. The mechanism through which pathogens, such as viruses, promote cancer has also been well described. For example, *Helicobacter pylori* and hepatitis C virus (HCV) promote cancer development through epithelial injury and inflammation. Recent evidence also suggests, however, that cancer initiation and progression may not be attributable simply to one pathogen, but also potentially to global changes in our microbiome.⁸¹

Microorganisms make up only 1–2% of the mass of the body of a healthy human, but microbial cells are estimated to outnumber human cells by 10 to 1, and the number of microbial genes (i.e., the microbiome) is suggested to outnumber human genes by 100 to 1.^{82, 83} Since metabolic processes coded in the human genome are integrated with those of the associated microbiome, NGS technologies have enabled researchers to explore the bacterial microbiome and the role it plays in metabolism and inflammation, two factors involved in carcinogenesis. The 16S rRNA gene, present in all microbes, is a useful tool for characterizing microbial community structure.⁸³ Early animal models have linked alterations in the microbiota to carcinogenesis, particularly colorectal carcinogenesis. Tumor promoting effects of the microbiota in cancer have been largely attributed to dysbiosis, or the microbial imbalance on or inside

the body, rather than infections with specific pathogens. Interindividual variability in the microbiome is influenced by a variety of factors including host physiology, pathobiology, environment, and lifestyle (diet) and behavioral factors, and microbial community structure in turn has been shown to impact important risk factors for cancer including obesity.^{83–85} This area of research is still novel and the complex relationship between the microbiota and the host in respect to carcinogenesis is just now starting to be described.^{86–88} Future work in this area will provide critical contributions for diagnostic, preventative, and therapeutic approaches.⁸¹

Other omic and digital epidemiology

Cancer is a complex disease contributed by many environmental and host factors along with their interactions. Therefore, to study those interacting factors as a whole instead of separate individual parts is critical to discovering the causal pathways. “Interactome” is a new term that refers to the characterization of a whole network of interactions among different factors (usually biological molecules) in a cell or organism contributing to a condition or disease.⁸⁹ The network is usually depicted by graphs of interconnecting lines. As an example, the interactome for *Notch2* has found a novel tumor suppressor gene *WPP2* as it serves as a negative regulator for *Notch2*,⁹⁰ which could not be discovered by traditional candidate gene approaches. In addition, genome–environment wide interaction studies (GEWIS) could address the joint effect and interactions between genetic and environmental factors.⁹¹ An exploratory GEWIS for CRC uncovered an SNP that had significant interaction with being overweight to increase CRC risk.⁹²

Advances in “digital epidemiology” developed based on communication technology devices, imaging, advanced statistical methods, and bioinformatics tools have also contributed to the advances in cancer epidemiology.⁹³ Traditionally, epidemiological data were collected by personal interview, which is costly and time consuming. With the advancement in digital technology, these data can now be collected using mobile phones and Internet. The digital revolution provides resources for timely computer-based data mining. At the same time, sophisticated statistical and bioinformatics tools are fundamental to analyzing the vast amount of data to draw meaningful conclusions. Unfortunately, many epidemiologists are not equipped with the training to design, conduct, and analyze these data-driven, complex, and expensive high-resolution studies, and team studies and new educational approaches are now being recognized as urgently needed.

Perspective and future direction

In the past, cancer epidemiologists have been too focused on etiologic research and are now being urged to broaden their perspective across the entire translational spectrum.⁹⁴ Khoury et al.⁹⁵ have summarized a roadmap for translational epidemiology as it impacts every step in translation research. Spitz et al.^{96, 97} proposed the concept of “integrative epidemiology,” which expanded the boundary of epidemiology to include a cohesive integration of traditional epidemiological study design with advanced analytic and data-mining tools, to integrate and analyze information from multiple sources, and to examine influence on a wide spectrum of endpoints, from risk assessment to outcomes and treatment effects. These analytical methods for cancer epidemiology require multilevel approaches. Taplin et al.⁹⁸ have proposed a model for multilevel analysis across the cancer continuum based on the assumption that multiple levels of contextual influence affect behaviors through interdependent interactions. Lynch and Rebbeck extended this approach to a “Multilevel Biologic and Social Integrative Construct” (MBASIC) framework to integrate macroenvironment and individual factors with biology to explore multifactorial relationships

and to guide study design and statistical or mechanistic models to study these relationships.⁹⁹

The core implication in cancer epidemiology is knowledge integration, the process of integrating information and accelerating the translation and application of research findings. The process includes three key processes: knowledge management, synthesis, and translation.

Validated risk prediction models that employ such data synthesis and knowledge integration approaches could improve the outcomes of screening efforts and have substantial public health implication. Further, risk prediction tools could be incorporated into the design of smaller, more powerful, and “smarter” prevention trials. The development of risk prediction modeling is based on stringent statistical approaches incorporating information from a wide spectrum of risk factors. By quantifying risk at the individual level, the model provides evidence-based criteria for designing and subject recruitment in cancer surveillance and intervention programs.¹⁰⁰ For breast cancer, the multivariable statistical Gail model is the paradigm that estimates a woman's absolute risk of breast cancer given her current age, age at menarche, age at first live birth, family history of breast cancer, and number of previous breast biopsies. This model has been extended to include more comprehensive exposure and genetic and phenotypic variations.^{101–103} Several studies have added additional breast cancer risk factors, such as BMI, breast density, and nutrition into the model, and provided modest improvement in the discriminative ability.^{104–107} Tammemagi et al.¹⁰⁸ developed a lung cancer risk prediction model with an AUC of 0.8 using the large data set of the Prostate, Lung, Colorectal, Ovarian (PLCO) cancer screening trial and further showed that using their risk prediction model was more sensitive than the National Lung Screening Trial (NLST) criteria for lung cancer detection. Wen et al.¹⁰⁹ developed a series of models for hepatocellular carcinoma that incorporated variables of hepatitis B virus (HBV) and HCV infections as well as a panel of serum biomarkers.

Risk modeling holds great potential as the most efficient tool to implement results from cancer epidemiology studies; however, challenges still exist regarding the generally low-prediction discriminatory ability of the published models, which mostly have an AUC of around 0.55–0.70.¹⁰⁰ There have been continued efforts to improve prediction ability, for example, methylation profiling of DNA has increased AUC of a breast cancer risk model by 9.8%,⁷⁷ and a DNA repair assay could improve AUC of a bladder cancer risk model by 10%.¹¹⁰ The major challenge associated with risk modeling, especially when using high-throughput data and intermediate biomarker data, is model validation. Collaboration is essential to provide external validation to evaluate the utility and generalization of models developed.

Summary

Lam et al.⁹⁴ have outlined four driving forces that are impacting translational cancer epidemiology in the twenty-first century: increasingly large-scale collaborative and team science, emerging novel genomic technology and application into large-scale epidemiology studies, multilevel data analysis and interventions, and the increasing complex analytical techniques to enable effective knowledge integration of large multilevel data. All of these features have allowed cancer epidemiology to evolve rapidly and become a comprehensive research “tool science” for knowledge integration at all aspects of the cancer continuum with the aim to ultimately bridge the gap from discovery to translation.

Chapter 35

Behavioral approaches to cancer prevention

Errol J. Philip, PhD ■ Jamie S. Ostroff, PhD

Overview

Certain health behaviors increase the risk of being diagnosed with cancer. It has been estimated that 35% of cancer deaths throughout the world could be avoided through adoption of health promoting behaviors. This chapter summarizes research on the effects of behavioral risk factors on cancer incidence and behavioral interventions for cancer prevention. Several behavioral risk factors—tobacco use, unhealthy diet, sedentary lifestyle and obesity, sun and UV exposure—have all been associated with cancer etiology, and clinical recommendations for health promoting behavior change interventions have been developed. Physician recommendations and delivery of health promotion counseling are essential for effective dissemination of cancer prevention efforts.

Tobacco use

Tobacco use remains the leading preventable cause of morbidity and mortality. In the United States, tobacco use is responsible for nearly one in five deaths or roughly 480,000 early deaths each year (*US Surgeon General Report 2014*). Tobacco use accounts for at least 30% of all cancer deaths, causing 87% of lung cancer deaths in men and 70% of lung cancer deaths in women. (Source: *Cancer Facts & Figures 2014*.) In addition to lung cancer, cigarette smoking also increases the risk for cancers of the oral cavity, larynx, pharynx, esophagus, stomach, liver, pancreas, kidney, bladder, cervix, colon/rectum, and acute myeloid leukemia. (Source: *Cancer Facts & Figures 2014*.) Secondhand smoke exposure is also considered a risk factor for lung cancer with about 3400 nonsmoking adults dying each year of lung cancer as a result of breathing secondhand smoke. (Sources: *Cancer Facts & Figures 2014*; SGR, 2014.) Cigar smoking causes cancers of the lung, mouth, throat, larynx, and esophagus. (Source: *CDC, Consumption of Cigarettes and Combustible Tobacco—United States, 2000–2011, 2012*.) Smokeless tobacco products increase the risk of developing cancer of the mouth and throat, esophagus, and pancreas.

Although cigarette use has declined dramatically since the release of the first US Surgeon General's Report on Smoking and Health in 1964, 18.1% of all adults or more than 42 million American adults currently smoke cigarettes. (Source: *CDC, Current cigarette smoking among adults—United States, 2005–2012, 2014*.) In 2012, approximately 20.5% of men and 15.8% of women were considered to be current cigarette smokers. African Americans, Native Americans, individuals with lower income, lower education, sexual minorities, and those with comorbid substance abuse and mental illness are more likely to be current smokers. Fortunately, daily consumption of cigarettes has declined with about 22% of smokers reporting nondaily smoking. (Source: *CDC, Current cigarette smoking among adults—United States, 2005–2012, 2014*.)

Fortunately, there have also been noteworthy declines in youth smoking. In 1997, nearly half (48%) of male high school students and more than one-third (36%) of female students reported using some form of tobacco—cigarettes, cigars, or smokeless tobacco—in the past month. In 2012, tobacco use declined to

23% for male students and 18% for female students. (Sources: *Cancer Facts & Figures 2010*; CDC, *Tobacco Product Use Among Middle and High School Students—United States, 2011 and 2012, 2013*.) On the other hand, there are growing concerns about the increasing use of electronic cigarettes, hookah, and other noncigarette tobacco products.^{1, 2}

Tobacco cessation in health care settings

Most recently updated in 2008 and representing current best practices, the US Public Health Service Treating Tobacco Use and Dependence Clinical Practice Guideline (PHS Guideline)³ recommends that evidence-based tobacco treatment be delivered to all smokers in health care settings.

Brief counseling

The PHS Guideline recommends the use of a brief counseling method. As shown in [Table 1](#), physicians are encouraged to: ask, assess, advise, assist, and arrange. Health care providers are encouraged to *ask* their patients about their smoking status at every encounter. Once current smokers are identified, clinicians should *assess* readiness to quit to inform the tobacco treatment plan. Clinicians should strongly advise their patients against smoking, personalizing the cancer and other risks of persistent smoking and the benefits of cessation in relation to their patients' disease and treatment. The next *A*, *assist*, involves providing education, addressing barriers to quitting such as concerns about coping, suggesting behavioral strategies that may help them overcome these barriers, developing a quit plan, and prescribing pharmacotherapy as needed. For patients who are reluctant to quit, clinicians should provide motivational counseling in an effort to encourage them to cut down or reduce their daily cigarette consumption. Finally, clinicians are encouraged to *arrange* follow-up support such as referring smokers to other resources such as Quitlines or onsite tobacco treatment specialists.

Table 1 The “5 A’s” model for treating tobacco use and dependence

Ask about tobacco use	Identify and document tobacco use status for every patient at every visit (<i>Strategy A1</i>)
Advise to quit	In a clear, strong, and personalized manner, urge every tobacco user to quit (<i>Strategy A2</i>)
Assess willingness to make a quit attempt	Is the tobacco user willing to make a quit attempt at this time? (<i>Strategy A3</i>)
Assist in quit attempt	For the patient willing to make a quit attempt, offer medication and provide or refer for counseling or additional treatment to help the patient quit (<i>Strategy A4</i>) For patients unwilling to quit at the time, provide interventions designed to increase future quit attempts (<i>Strategies B1 and B2</i>)
Arrange follow-up	For the patient willing to make a quit attempt, arrange for follow-up contacts, beginning within the first week after the quit date (<i>Strategy A5</i>) For patients unwilling to make a quit attempt at the time, address tobacco dependence and willingness to quit at the next clinic visit

Pharmacotherapy

The guidelines strongly recommend use of pharmacotherapy along with counseling in order to optimize cessation outcomes. There are several safe and effective medications indicated for smoking cessation:

nicotine replacement therapies (NRT) (patch, gum, lozenge, nasal spray, and inhaler), bupropion (Wellbutrin), and varenicline (Chantix). Refer to [Table 2](#) for list of cessation medications, dose, duration, potential contraindications, and side effects. Combination and extended use pharmacotherapy have been shown to enhance effectiveness of tobacco dependence treatment. More research is needed to identify methods for personalizing treatments, including the tailoring of interventions to the smoker's readiness to quit, sociocultural factors, gender, age, and health status. Neuroscience research focusing on the genetic basis of nicotine addiction may also lead to the development of precision interventions for high-risk groups.

Currently, there is much debate and little data as to whether e-cigarettes will facilitate or impede smoking cessation and reduction of known hazards of traditional cigarettes and other combustible tobacco products.⁴ The American Society of Clinical Oncology and the American Association of Cancer Research have recently published a literature summary and policy statement⁵ about electronic cigarettes. Oncologists should advise smokers to quit smoking traditional cigarettes, encourage use of FDA (Food and Drug Administration)-approved cessation medications, refer patients for tobacco cessation counseling, and provide education about the potential risks and lack of known benefits of e-cigarette use with regard to long-term cessation.

Prevention of tobacco use

Preventing tobacco-related cancers requires the development and implementation of effective multipronged tobacco prevention programs. In the most recent Best Practices for Comprehensive Tobacco Control Programs,⁶ the Centers for Disease Control and Prevention (CDC) recommends statewide programs that combine community-based interventions that focus on (1) preventing initiation of tobacco use among youth and young adults through tobacco control policies (i.e., taxation, tobacco-free laws), (2) promoting quitting among adults and youth, (3) eliminating exposure to secondhand smoke, and (4) identifying and eliminating tobacco-related disparities among population groups. Tobacco prevention programs should also consider targeting those children with highest biological susceptibility and sociocultural factors that increase the risk for initiating regular smoking.

Secondary and tertiary cancer prevention

An emerging body of evidence demonstrates that for individuals diagnosed with cancer, smoking is also associated with several adverse outcomes such as increased complications from surgery, increased treatment-related toxicity, decreased treatment effectiveness, poorer quality of life, increased risk of recurrence, increased risk of second primary tumors, increased noncancer-related comorbidity and mortality, and decreased survival.^{7–9} Despite these risks, at least 15.1% of all adult cancer survivors report current cigarette smoking.¹⁰ Continued tobacco use after diagnosis and resumption of smoking after initial quit attempt should be seen as a modifiable clinical problem. In fact, there is a growing consensus among oncology leadership organizations that tobacco use assessment and treatment should be treated as a quality of care metric.^{11–14} Unfortunately, a recent survey of practicing oncologists showed that oncologists provide quitting advice to only 25% of their patients¹⁵ and that only half of National Cancer Institute-designated Comprehensive Cancer Centers offer any type of tobacco treatment program.¹⁶ These survey findings highlight the need to identify and address barriers to tobacco treatment delivery in cancer care. Barriers to addressing tobacco use include patient factors (shame, helplessness, addiction),

physician barriers (lack of training and referral options, beliefs about patients' lack of interest or ability to quit), and systems levels factors (inadequate identification of smokers, costs) that impede the delivery of effective tobacco programs.¹⁷ Further research examining patient, provider, and systems-level strategies for engagement and retention of smokers into evidence-based tobacco treatment is needed.

Energy balance: diet, physical activity, and body weight

Energy balance represents the nexus of diet, physical activity, and body weight and has been shown to be a significant contributor to the global burden of cancer. Although research is ongoing concerning the mechanisms by which these factors relate to cancer and cancer outcomes, there is strong evidence to support an association between energy balance and cancer development and progression.

Obesity and dietary factors are estimated to account of nearly 35% of cancer cases in the United States. Strong evidence exists regarding an association between excess weight and an increased risk of many common cancer types, as well as emerging evidence of a link to poorer disease outcomes. The greatest consistency in research examining diet and cancer has been established in regard to broader dietary patterns, with prudent plant-based diets that limit meat and dairy intake generally associated with reduced cancer risk. Engagement in physical activity has been consistently shown to confer a protective effect across common cancer types.

This expansive literature has provided a foundation for lifestyle-based cancer prevention and control guidelines that all patients and survivors should be encouraged to adopt. These include consuming a healthy diet, maintaining or achieving a normal weight, and engaging in regular physical activity, all of which are key components to both cancer prevention and the pursuit of long-term health among those diagnosed with cancer.

Excess weight remains a critical modifiable risk factors linked to cancer risk in the United States,^{18, 19} with further contributions from physical inactivity and dietary factors. These three interrelated factors, collectively referred to as energy balance, represent primary targets of investigation and intervention in cancer prevention and control. An extensive body of research exists concerning components of energy balance and their association with increased risk of primary and secondary cancers, treatment complications, impaired quality of life, and poorer disease outcomes.²⁰

Lifestyle behavior guidelines have been published by national organizations targeting cancer prevention and control. The American Cancer Society notes the importance of maintaining a healthy weight, adopting a healthy diet and engaging in regular exercise.^{21, 22} These recommendations are summarized in [Table 3](#). Importantly, the broad nature of these recommendations align with disease prevention guidelines beyond cancer, and adhering to such advice will serve to also reduce risk of other chronic conditions such as cardiovascular disease, diabetes, and hypertension. Unfortunately, despite a variety of efforts to raise awareness of lifestyle-based recommendations and increase adoption, adherence among the general population and cancer survivors alike remains low.^{23, 24} Recent calls have been made to promote the use of the term energy balance in clinical practice and oncology,²⁵ thus reinforcing the interdependent nature of diet, exercise, and weight, and in turn lessen the potential for patients to focus on such factors in isolation.

Table 3 ACS adult guidelines for energy balance for cancer prevention and control

Achieve and maintain healthy weight	<ul style="list-style-type: none">• Balance energy intake and expenditure through portion control, an emphasis on a plant-based diet and the limiting of high caloric foods and beverages
Engage in regular physical activity	<ul style="list-style-type: none">• Engage in 150 min of moderate activity (e.g., brisk walking) or 75 min of vigorous activity (e.g., jogging) per week and limit sedentary activity
Maintain a healthy diet	<ul style="list-style-type: none">• Emphasize a plant-based diet that includes whole grains and 2.5 cups of fruits and vegetables per day, while limiting intake of processed and red meats• Alcohol consumption should be limited to two standard drinks per day for men and one standard drink for women

A recent study of nearly 112,000 nonsmoking individuals examined the association between adherence to ACS health guidelines and disease outcomes across 14 years of follow-up. The authors reported that greater adherence to health recommendations were associated with reduced risk of both cancer and all-cause mortality.²⁶ The next section will provide an overview of current research findings concerning the relationship between energy balance and cancer. While acknowledging the synergistic and interrelated nature of diet, weight, and physical activity, each will be addressed separately with focus given to the four most common cancers diagnosed in the United States.

Diet and cancer

Breast cancer

The potential association between diet and breast cancer has received extensive empirical attention over the past three decades. The WCRF (World Cancer Research Fund) reported that based on observational studies, certain dietary patterns that include a high intake of fruit and vegetables, along with consumption of poultry, fish, and low-fat dairy products,²⁷ are associated with reduced disease risk. Similar findings were reported by Brennan et al. in a 2010²⁸ systematic review and meta-analysis of 39 case-control and cohort studies examining various dietary patterns. Despite its primary role among prudent dietary patterns, little evidence exists supporting the isolated protective effect of fruit and vegetable intake alone.²⁹ The Women's Health Initiative Trial sought to establish whether reduced fat intake could impact cancer risk in a randomized clinical trial involving nearly 50,000 postmenopausal women. Reduction in fat intake was associated with only a marginal reduction in disease risk, and no difference in invasive breast cancer cases during the 8-year follow-up period.³⁰ Finally, evidence suggests that alcohol consumption may increase risk of breast cancer in a dose–response manner for both pre and postmenopausal women,^{27, 29} while a recent meta-analysis suggested that there currently exists no evidence linking red meat consumption with breast cancer risk across the lifespan.³¹

Prostate cancer

As the literature examining the relationship between diet and prostate cancer has matured, recent studies have suggested that this association may differ based on the aggressiveness of the disease. In their systematic review, Ma and Chapman³² proposed that further work is needed to account for this potential influence, and that there is not yet sufficiently rigorous evidence to provide firm recommendations on the

role of diet in prostate cancer. Despite this, there exists suggestive evidence of a protective effect of vegetable and soy consumption, and an increased risk of disease associated with dairy products. Kirsh et al.³³ reported that men who had a high intake of cruciferous vegetables (e.g., cabbage, broccoli) had a decreased risk of aggressive prostate cancer. Dairy consumption may lead to a possible increased risk of prostate cancer,²⁷ with a further analysis of the PLCO trial, and nearly 30,000 men establishing a modest increase in the risk of nonaggressive cancers among those reporting a higher intake of dairy products.³⁴ There was no association established between dairy intake and more aggressive forms of disease.

Colorectal cancer

Considerable effort has been devoted to examine the potential impact of nutrition on the development and progression of colorectal cancer. A number of recent international reports and meta-analyses noted convincing evidence of an increased risk of colon, colorectal, and rectal cancer associated with the consumption of red meat and processed meat products.^{27, 35} These recent studies, including an updated meta-analysis,³⁶ noted a dose–response relationship between meat consumption and cancer risk, including a 21% increased risk with 50 g/day consumed and a 29% increased risk with 100 g/day consumed.³⁵ For comparative purposes, the recommended serving size for a portion of lean meat is approximately 85 g.

The relationship between fiber and disease risk has also received considerable attention; however, despite plausible biological mechanisms, early reports found little evidence of an association between fiber consumption and colorectal cancer.^{37–39} More recent studies have, however, noted a relationship.^{40, 41} A systematic review of 25 prospective studies reported a dose–response relationship between cereal fiber and whole grains and a reduced risk of colorectal cancer.⁴² The authors reported a statistically significant 10% decrease in cancer risk with 10 g of daily fiber intake. The recommended daily intake of fiber for adults is 25 g.

Alcohol consumption has also been associated with increased risk of colorectal cancer.³⁵ In a review of 103 cohort studies, Huxley found that those reporting the highest levels of alcohol consumption had a 60% increased risk of colorectal cancer compared to non- or light drinkers. This relationship was particularly prominent among male participants.⁴³ Chung et al.⁴⁴ conducted a systematic review and reported inconsistent results concerning the relationship between calcium and vitamin D and colorectal cancer. Importantly, while evidence is evolving and currently suggests that increased calcium intake could reduce risk of colorectal cancer; this benefit must be weighed against potential increase in prostate cancer risk. At present, there exist no recommendations to increase calcium intake as a means of reducing cancer risk.

Lung cancer

The WRCF/AICR (American Institute for Cancer Research) report established that higher rates of fruit and vegetable consumption is consistently associated with reduced risk of lung cancer among both smokers and nonsmoking populations.²⁷ The report notes, however, that despite this consistency, the protective effect of a healthy diet is minimal compared to risk associated with tobacco use.

Obesity and cancer

Obesity rates have increased dramatically over the past 30 years, with over 35% of US adults now considered obese.⁴⁵ A 2003 report estimated 14–20% of all cancer deaths to be attributable to excess weight,⁴⁶ and in combination with the dietary intake, accounts for nearly one in three cancers and may soon overtake tobacco as the primary modifiable risk factor in cancer.^{27, 47} The unprecedented increase in weight of the general population, along with the increased risk of cancer associated with excess weight,

means that an estimated 10 of the 14 million survivors are overweight or obese.^{48–50} A report published by the WCRF/AICR, along with an updated review by Renehan in 2008, noted evidence of a link between excess body weight and many common types of cancer.^{27, 51} These include colon, kidney, pancreatic cancer, and esophageal adenocarcinoma among both sexes, as well as thyroid cancer for men and gallbladder, endometrial, ovarian, and postmenopausal breast cancers among women.

Breast and Prostate Cancer

Excess body weight and weight gain in adulthood have both been consistently associated with risk of breast cancer.^{52, 53} A further meta-analysis by Vrieling et al.⁵⁴ noted a stronger association between weight gain and estrogen-/progesterone-positive breast cancers. The impact of obesity on prostate cancer appears to be moderated by disease severity, and thus, more recent studies have emphasized the importance of examining this relationship in greater detail. Obese weight status has been associated with greater risk of being diagnosed with advanced disease,⁵⁵ increased risk of recurrence,⁵⁶ and poorer prognosis.⁵⁷ In contrast, Wright et al.⁵⁸ reported an inverse association between BMI (body mass index) and risk of early stage disease among a large population of men enrolled in the National Institutes of Health–AARP Diet and Health Study. This complex relationship is believed to be partly due to challenges inherent to screening and diagnosis among obese men, however, research continues.

Colorectal cancer and other notable findings

The majority of studies have supported a positive association between weight and risk of colorectal cancer, most strongly among men,^{35, 46} including a recent meta-analysis over 56 observational studies.⁵⁹ Norat et al.³⁵ noted that this association was more consistent among studies that examined measures of body fat distribution beyond BMI, with excess weight in the abdominal region most predictive of increased cancer risk.

Endometrial cancer remains the most consistent cancer linked to excess weight, with an estimated 60% of new cases attributable to obesity.⁶⁰ Obese women are 2–3.5 times more likely to be diagnosed with this form of cancer,⁶¹ including a large-scale European study that followed one million women for nearly 40 years reporting obese women to be 2.5 times more likely to be diagnosed with cancer of the uterine corpus compared to those of normal weight.⁶²

Physical activity and cancer

Engagement in physical activity remains an important component of health recommendations and has been associated with reduced risk across a number of common cancer types.²²

Breast and prostate cancer

The association between physical activity and breast cancer risk has been extensively researched and deemed convincing.⁶³ This has included a review of more than 70 observational reports that established an absolute risk reduction of between 20% and 30% in breast cancer risk when comparing those who were most active to those who are least active.^{61, 64} In a systematic review and meta-analysis of over 40 reports, including over two million men and nearly 90,000 cases of cancer, Liu et al.⁶⁵ reported an 10% overall risk reduction in prostate cancer associated with engagement in physical activity.

Colorectal and lung cancer

The relationship between physical activity and colorectal cancer has also received considerable empirical attention. A 2009 meta-analysis by Wolin et al.⁶⁶ examined over 50 studies and reported on overall reduction in risk of 24%, with greater risk reduction reported in case-control studies. Similar findings were reported by Harris and Thune in relation to colon cancer, including evidence of a dose–response relationship between physical activity engagement and cancer risk among both genders.^{67, 68} No evidence of a relationship was established, however, among seven studies of rectal cancer.

In a review of predominantly cohort studies, Emaus and Thune⁶⁹ reported a 23% reduction in lung cancer risk among those engaged in physical activity, with a greater rate of 38% once again reported among case-control studies. A further meta-analysis reported similar results, although risk reduction varied based on intensity of activity, with moderate engagement associated with a 13% reduction in risk and rigorous activity associated with 30% reduction in risk.⁷⁰ A recent systematic review noted the need for ongoing research in this arena, particularly among women, with 10 studies reporting an inverse association between physical activity and lung cancer and nearly as many reporting a null association.⁷¹

Energy balance and cancer survivorship

As survival rates across many common cancers have increased; emerging research has begun to address the role of lifestyle in cancer prognosis and survivorship. Research and clinical programs in this domain have sought to build upon the noted potential for a cancer diagnosis to act as a teachable moment,⁷² and to thus seize upon a period in which patients and survivors may be motivated to enact lifestyle changes.^{73–75} In a systematic review of physical activity and cancer survival, authors reported, among 27 published studies, there was sufficient evidence supporting an association between physical activity and a reduction in all-cause mortality, as well as breast and colon-specific cancer mortality.⁷⁶ In a review by Davies et al.,⁷⁷ a healthy or prudent diet pattern low in fat and high in fiber may be broadly associated with a reduced risk of cancer recurrence and progression; however, further research is needed. This is particularly true in regard to establishing whether the protective effects of a healthy diet and/or physical activity may be due to their promotion of a healthy body weight. Finally, Parekh et al.⁷⁸ reported in a systematic review of the literature pertaining to breast, colon, and prostate cancer that the majority of studies suggest a negative effect of excess weight on cancer survival outcomes. However, the authors noted that breast cancer is overrepresented in this literature, and that many studies examining obesity and cancer survival were not initially designed to examine such outcomes. In light of these emerging findings, the American Society of Clinical Oncology has created a toolkit to help oncologists counsel their patients about the importance of weight management for cancer survivors.⁷⁹

Promoting behavioral change in diet and physical activity

Although some individuals may require more intensive intervention, a recommendation from a health care provider can play an important role in promoting energy balance and lifestyle change.²⁰ Evidence-based behavioral lifestyle programs exist for those individuals who require more support. These 6–12-month programs usually adopt a group-based format and include dietary counseling and caloric reduction, along with promotion of physical activity engagement. Such programs routinely result in weight loss of 5–10% of initial body weight⁸⁰ and can provide clinically relevant improvements in many disease markers with plausible downstream benefits for reducing cancer risk.^{81, 82} Maintenance of weight loss remains a challenge and providers should remain supportive of patients seeking to adopt changes.⁸³ Evidence pertaining to the impact of behavior change on cancer-related outcomes is growing, with evidence suggesting that bariatric surgery results in reduced cancer risk⁸⁴ and that changes in diet and physical

activity behavior change can improve biological markers among survivors.⁸⁵

Risk behaviors for skin cancer

Skin cancers are commonly divided into melanoma and nonmelanoma skin cancers. Melanoma is less common but more aggressive than other types of skin cancer, affecting some 68,000 Americans each year.⁸⁶ Exposure to ultraviolet radiation (UVR) from the sun or from indoor tanning devices is a significant risk factor for skin cancer,⁸⁷ and there are well-established behavioral strategies for skin cancer prevention. These recommendations,⁸⁸ include nonuse of artificial tanning beds and limiting unprotected exposure to the sun—especially strong midday sunlight—whenever possible. When exposure to sunlight is not avoidable, individuals should be advised to apply a broad spectrum sunscreen (i.e., effective against both UVA (ultraviolet A) and UVB (ultraviolet B) radiation with a sun protection factor (SPF) of 30 or greater) very liberally, approximately 30 min before going out into the sunlight and then reapplying every 2 h or after any exposure to water. Most importantly, individuals should be advised that sunscreens offer only *partial* protection from UVR and should best be used in combination with avoiding exposure to strong sunlight and wearing sun protective clothing (i.e., hats, long-sleeved garments).

Unfortunately, only 30% of US adults routinely report using sunscreen and/or sun protective clothing.⁸⁹ Remarkably, surveys show that even cancer survivors do not consistently protect themselves from UV light, especially younger survivors who are most likely to be exposed to UVR.^{50, 90, 91}

Summary

The importance of reducing behavioral risks on cancer prevention is well established.⁹² Healthy People 2020⁹³ goals emphasize health promoting behavior change efforts such as not smoking, maintaining a healthy weight, eating a low-fat, high-fiber diet, being physically active, and limiting UVR exposure.

Chapter 36

Diet and nutrition in the etiology and prevention of cancer

Steven K. Clinton, MD, PhD ■ Elizabeth M. Grainger, PhD, RD ■ Edward L. Giovannucci, MD, ScD

Overview

Associations between nutrients, foods, dietary patterns, and cancer risk have been the source of substantial scientific inquiry as improved tools to assess dietary exposures and cancer outcomes have emerged for different populations around the globe. Research includes observational studies, epidemiologic cohort studies, and some human intervention trials that are supported by mechanistic laboratory investigations. These efforts strongly implicate dietary patterns as a major risk factor in the global cancer burden and have resulted in the formulation of dietary guidelines for prevention of cancer by several public health organizations. The dietary recommendations, which also include maintaining a healthy weight and participating in regular physical activity, are interrelated and are intended to guide the development of behavior patterns regarding diet orchestration and exercise that are consistent with reducing the risk of cancer. Those undergoing cancer treatment with diverse therapeutic interventions require personalized consultations with nutrition professionals, such as registered dietitians, in order to maintain optimal health while reducing toxicity and enhancing efficacy of therapy. Increasingly, the role of diet and physical activity in cancer survivorship is being addressed, and the future will likely include more specific survivorship guidelines, personalized for individuals, that reduce the risk of cancer recurrence, lower the long-term consequences of cancer therapy, and promote health and quality of life.

Over the past two centuries, improvements in food production, processing, storage, and distribution have led to major changes in diet composition throughout the world. During this period, life expectancy also dramatically increased within economically developed nations because of a combination of factors, including public health measures, improved occupational safety, and major reductions in nutrient deficiency syndromes. As the populations age, there has been a shift in the major causes of morbidity and mortality toward chronic diseases, such as cancer and cardiovascular disease. In the United States, recent decades are characterized by an increasingly sedentary population with an epidemic of obesity, a trend that is emerging worldwide. Although nutritional deficiencies still plague subpopulations in developed nations such as the poor, the aged, alcoholics, and the chronically ill, we now recognize that the affluent dietary pattern contributes to the pathogenesis of many chronic diseases, including cancer, that afflict the vast majority of the population. Efforts to understand the often complex etiologies of various cancers have led to laboratory, clinical, and epidemiologic studies that strongly implicate specific nutrients and certain dietary patterns in human carcinogenesis.

It is important to establish a conceptual framework for organizing data regarding diet, nutrition, and cancer that will help readers provide guidance to the public and patients. We arbitrarily divide the topic into the realms of prevention, therapy, and survivorship. Organizations such as the National Cancer Institute, the American Cancer Society (ACS), the World Health Organization, and the American Institute for Cancer Research/World Cancer Research Fund have published recommendations defining achievable dietary and nutritional goals for the populations that may help reduce the overall cancer burden through

primary prevention (Table 1). These goals are evidence-based and increasingly utilize a systematic review process. Some individuals, particularly those deemed to be at higher risk of specific types of cancer as a result of environmental exposures, family history, or the presence of premalignant conditions, are more readily pursuing dietary and lifestyle interventions that may be tailored to lower their chances of developing a specific cancer. Patients actively undergoing cancer therapy represent another group profoundly interested in the role of dietary and nutritional interventions to enhance the efficacy of treatment while reducing the frequency and severity of side effects. These issues are diverse and best addressed in the medical clinics with a therapeutic team that includes registered dietitians (RD). Finally, as cancers are detected earlier and treatment interventions become more successful, the number of cancer survivors is increasing rapidly. Those completing cancer therapy are seeking guidance regarding diet and lifestyle interventions that will lower their risk of recurrence (secondary prevention) and reduce the severity of long-term complications of their cancer treatment, including therapy-related second malignancies and long-term organ dysfunction. Thus, those involved in cancer therapy and management of long-term health are ever more being asked to provide evidence-based guidance in an area where scientific studies are few. Thus, vulnerable survivors frequently fall prey to purveyors of alternative diet- or nutrient-based interventions marketed in the absence of scientific data regarding efficacy and safety. Although this chapter focuses upon prevention, we briefly review the therapeutic and survivorship phases and provide information that will assist in counseling individuals and groups interested in dietary and nutritional interventions.

Table 1 Guidelines for nutrition and cancer prevention

	American Institute of Cancer Research¹	American Heart Association and the American College of Cardiology^{2, 3}	Dietary Guidelines for Americans^{4 a}	American Cancer Society⁵
Body weight	Ensure that body weight through childhood and adolescent growth is toward the lower end of normal BMI by age 21 Maintain body weight within the normal range from age 21 on Avoid weight gain	For individuals who are overweight, participation in a professionally-guided lifestyle program (>6 mo duration) promoting a lower-calorie diet is advised Medical team should use NHLBI body mass index (BMI) tables to stratify risk and define interventions	Prevent and/or reduce overweight and obesity through improved eating and physical activity Control calorie intake. For people who are overweight, consume fewer calories from foods and beverages Maintain appropriate calorie balance during each stage of life	Achieve and maintain a healthy weight throughout life Be as lean as possible throughout life without being underweight Avoid excess weight gain at all ages Engage in regular physical activity while limiting high calorie foods

				and beverages
Physical activity	Be moderately physically active for at least 30 min each day As fitness improves, aim for at least 60 min of moderate activity or 30 min of vigorous activity every day Limit sedentary habits	Engage in 2 h and 30 min/wk of moderate intensity or 75 min/wk of vigorous-intensity aerobic physical activity To reduce weight, 150 min/wk of aerobic physical activity. Higher levels (200–300 min/wk) are recommended to maintain weight loss and prevent regain	Increase physical activity and reduce time spent in sedentary behaviors	Adopt a physically active lifestyle Adults: engage in at least 150 min of moderate intensity or 75 min of vigorous intensity activity each week Limit sedentary behavior such as sitting, lying down, watching television, or other screen-based entertainment
Plant-based diet	Eat at least five servings (at least 400 g) of a variety of nonstarchy vegetables and fruits each day Eat relatively unprocessed cereals and legumes with every meal Limit refined starchy foods	Consume a dietary pattern that emphasizes intake of vegetables, fruits, and whole grains and includes low-fat dairy products, poultry, fish, legumes, nontropical vegetable oils, and nuts		Consume a healthy diet with an emphasis on plant foods
Vegetable and fruit	Eat at least five servings (at least 400 g) of a variety of nonstarchy vegetables and	Consume a dietary pattern that emphasizes intake of vegetables and fruits	Increase fruit and vegetable intake Eat a variety of vegetables, especially dark-green, red, and orange vegetables, beans and peas	Eat at least 2.5 cups of vegetables and fruits each day

	fruits each day			
Breads, grains, and cereals	Eat relatively unprocessed cereals and legumes with every meal Limit refined starchy foods	Consume a plant-based dietary pattern that includes whole grains	Consume at least half of all grains as whole grains Increase whole grain intake by replacing refined grains with whole grains	Choose whole grains instead of refined grain products
Animal products	People who choose to eat red meat should consume less than 500 g (18 oz) per week, very little if any to be processed meat	Consume a dietary pattern that includes low-fat dairy products, poultry, and fish; limit intake of red meat	Choose a variety of protein foods, which include seafood, lean meat and poultry, and eggs Increase intake of fat-free or low-fat milk and milk products	Limit consumption of processed meats and red meat
Dietary fat	Consume energy-dense foods sparingly Consume “fast foods” sparingly, if at all	Reduce percent of calories from saturated fat Aim for a dietary pattern that achieves 5–6% of calories from saturated fat Reduce percent of calories from <i>trans</i> -fat	Consume less than 10% of calories from saturated fat Consume less than 300 mg per day of cholesterol Keep <i>trans</i> -fatty acid consumption as low as possible	
Processed foods and refined sugar	Avoid salt-preserved, salted, or salty foods; preserve without using salt Avoid sugary drinks	Limit intake of sweets and sugar-sweetened beverages	Reduce the intake of calories from added sugars	
Salt and sodium	Avoid salt-preserved, salted, or salty foods; preserve without using salt Limit consumption of processed foods with added salt to ensure an intake of less than 6 g (2.4 g	Consume no more than 2400 mg of sodium per day Further reduction of sodium intake to 1500 mg/day can result in even greater reduction in blood pressure	Reduce daily sodium intake to less than 2300 mg. Certain populations of people, including African Americans, persons with diabetes or chronic kidney, disease and all adults 51 years of age and older, should reduce sodium to 1500 mg per day	

	sodium) per day			
Alcohol	If alcoholic drinks are consumed, limit consumption to no more than two drinks a day for men and one drink a day for women		If alcohol is consumed, it should be consumed in moderation—up to 1 drink/day for women and up to 2 drinks/day for men	If you drink alcoholic beverages, limit consumption Drink no more than 1 drink per day for women and 2 per day for men
Miscellaneous	Dietary supplements are not recommended for cancer prevention Unless otherwise advised, cancer survivors should aim to follow the recommendations for diet, healthy weight, and physical activity		Select an eating pattern that meets nutrient needs over time at an appropriate calorie level	Increase access to affordable, healthful foods in communities, worksites, and schools

^a Updated Dietary Guidelines for Americans are scheduled for release in 2016, and will be accessed at <http://health.gov/dietaryguidelines/>.

The vast majority of research conducted in the field of diet, nutrition, and cancer focuses on etiology and prevention. Thus, this chapter emphasizes the public health model and focuses on the interventions that may reduce the overall cancer burden of large populations. We then consider the evidence for prevention of the most commonly occurring cancers involving specific organs. Rather than detailing the complex, often incomplete, and occasionally contradictory literature concerning the role of dietary components in the etiology of specific cancers, this chapter provides a general guide with an emphasis on the major emerging concepts in the area. We conclude with a brief overview of the role of diet and nutrition to enhance therapy and survivorship.

Methodologic issues in diet, nutrition, and cancer studies

It is valuable to briefly consider how evidence-based dietary recommendations are established. The unbiased detection and quantification of risks that are associated with variations in diet and nutrient intake would ideally be achieved through randomized and prospective trials. Unfortunately, the enormous costs of long-term nutrition studies and the scientific difficulties in controlling or measuring dietary patterns and nutrient intake limit their feasibility. Therefore, current nutritional guidelines for disease prevention are based on the integration of information derived from a variety of different epidemiologic approaches and laboratory investigations, and, thus, most guidelines are developed by expert committees convened by

organizations such as the National Cancer Institute, the ACS, the American Institute of Cancer Research (AICR)/World Cancer Research Fund (WCRF), and the World Health Organization, among others.^{1, 2, 5, 6} The evidence derived from epidemiologic studies, clinical investigations, and laboratory studies is reviewed and discussed relative to criteria of causality, defined as a specific occurrence or outcome that is consistently preceded by a known set of circumstances or conditions. In nutritional sciences, clear representations of causality have been the demonstration of single-nutrient deficiency syndromes and their complete reversal by exposure to the nutrient. For example, the lack of fruits and vegetables in the diet leads to scurvy, which is readily reversed by vitamin C. Unfortunately, relationships between diet and cancer are much more complex than simple nutrient-deficiency syndromes. To establish causality, conclusions about the occurrence of an event and its etiologic factors are based on consensus criteria. These criteria have evolved over many years and include consistency, strength of association, biologic gradient, temporality, specificity, biologic plausibility, biologic mechanism, coherence, and experimental evidence.⁷ Precisely quantitating risk due to a dietary variable has been difficult, because the etiologies of most cancers are multifactorial, and the interactions are poorly understood. Human cancers show striking variations based on factors such as age, sex, race, socioeconomic status, and host genetics, as well as many environmental, occupational, and lifestyle variables. The potential for complex interactions between these factors and diet is enormous, and this emphasizes the difficulties in demonstrating causal associations with the same clarity as is demonstrable for high-risk environmental exposures, such as the impact of cigarette smoking on lung cancer.

Assessment of the human diet

Nutritional epidemiology poses some unique obstacles in that food is a universal exposure, in stark contrast to many cancer-causing environmental exposures, such as cigarette smoke. [Table 2](#) details the strengths and limitations of various types of study designs used in nutrition research. The outcomes of interest in epidemiology include nutrients, nonnutrient bioactive components, and dietary patterns. Nutrients are components where known deficiency syndromes have been characterized. These include the energy-supplying macronutrients, which are lipids, carbohydrates, and proteins, and the various constituents, such as essential fatty acids and amino acids, as well as micronutrient vitamins and minerals. Nonnutrient components include thousands of potential bioactives, particularly rich in fruits and vegetables, such as fiber, polyphenols, and carotenoids. Currently, strategies to define dietary patterns, such as a Mediterranean-style, vegetarian, or affluent dietary pattern may provide greater insight into combined effects of multiple variables; nevertheless, standardized definitions and statistical approaches to assessing dietary patterns are lacking.

Table 2 Types of studies used to assess diet and disease relationships

Study type	Methods	Strengths	Limitations
Ecologic/correlational studies	The unit of observation is a population defined by a discriminator location (Japan vs United States, northern vs southern latitudes). Mortality or incidence among groups is compared with estimates of nutrient or food intake	Large differences in cancer incidence and dietary patterns are often identified, and hypotheses can be generated	There are often many diet and lifestyle differences between populations; therefore, correlations between disease incidence, and dietary factors are confounded by known or unknown variables Cancer incidence data

			and diet patterns may not be similarly quantitated among nations
Case–control studies	Individuals experiencing a disease are identified, and a similar group of matched subjects without the disease are identified. Information about past diet and nutrients is obtained from both the cases and controls for comparison	Studies can be conducted over a relatively short period of time	Selection bias can occur if a non-representative control group is selected Recall bias can occur when subjects with a disease alter their perceptions and recall of past dietary habits. This often occurs when participants are familiar with a particular diet/disease hypothesis
Prospective/cohort studies	A study population is identified and diet patterns assessed. The population is followed over time for disease outcome and changes in exposure to dietary risk factors	Dietary intake can be monitored periodically over time Diet assessment does not rely on long-term memory and is less affected by recall bias Biochemical measures can be obtained periodically	Long periods of time may be necessary for a disease to be diagnosed, so cohort studies often require many years of follow-up A large number of subjects are required to compensate for subjects who drop out, subjects lost to follow-up, and/or the possibility that the frequency of the outcome of interest is low Long term, large prospective studies are expensive
Randomized controlled trials	Individuals are screened, and, based on specific characteristics; a proper target population is identified and randomized to a control arm (standard of care) or an intervention arm. The subjects are followed for disease outcome or other biomarkers	Especially useful for testing compounds (vitamins and minerals) that can be incorporated into pills or capsules and provided in a double-blind manner over a period of years	Difficult to implement for many nutrition and cancer hypotheses (weight loss, exercise, dietary fat, fiber, fruits, and vegetables), because trials of dietary change cannot be blinded Manipulation of single dietary components in large-scale intervention studies is difficult, because foods are complex and contain

			many compounds Compliance with food changes may be difficult to determine Randomized, controlled trials can take a long time to complete and can be very expensive
--	--	--	---

The critical limiting feature of most human studies is the imprecision of quantifying dietary intake. Estimating the usual intake of foods or nutrients, as well as accounting for intraindividual variation over time, is a critical area of research.^{8–10} An estimate of human nutrient intake is derived from a two-step process. First, interviews, questionnaires, or food diaries must determine the amounts and types of foods that are consumed.¹¹ This information is then used to calculate nutrient intake if an accurate database has been established that quantifies the amount of each nutrient contained in the foods consumed by the population under investigation. Each step can be associated with significant error and contributes to the challenges in defining nutrient and cancer associations. The human diet is a complex array of foods that exhibits significant day-to-day and seasonal variations. The complexity of diet also differs widely among populations, cultures, and geographic areas. This often requires the development of different assessment methods for each population or subgroup. Future progress will depend, in part, on identifying biomarkers of nutrient exposure. Development of valid and reliable biomarkers of nutrient intake offers the promise of improved precision in epidemiologic studies because of reduced misclassification of participants according to intake estimates.¹² Finally, for many of the bioactive compounds in foods that may impact cancer risk, including the vast array of non-nutrient phytochemicals derived from plants, our ability to estimate exposure remains a challenge, as databases regarding content in foods often do not exist.¹³

Laboratory models

The effects of nutrients or food components and their interactions on carcinogenesis can be rigorously tested in a growing array of animal models. Although the information derived from animal models must be extrapolated to humans with caution, the literature does provide important evidence for the biologic plausibility of relationships suggested by epidemiologic studies. The nutrient requirements of most laboratory animals have been precisely defined, and purified ingredients can be used to formulate diets for cancer studies. The rapid emergence of new animal models based on transgenic and knockout technology has provided new opportunities to examine interactions between specific genetic targets and dietary variables.¹⁴

Public health guidelines for cancer prevention

We begin this section with a synthesis of public health dietary guidelines for cancer prevention and health published by several organizations, including the AICR/WCRF, ACS, and The American Heart Association (AHA).^{1–3, 5} The public health approach is a preventive strategy to decrease the overall disease incidence by reducing the adverse dietary habits of the entire population. Implementation of dietary recommendations requires cooperation among the media, food industry, public health workers, medical practitioners, educators, and government agencies.¹ To achieve success, dietary recommendations must be clear, as well as feasible and have minimal risk, low cost to society, and the potential to benefit the population.¹ In addition, economic issues relative to the food and agricultural

industry are factors that may influence decisions, particularly by government agencies, to define nutritional guidelines. Past efforts have been successful in the area of nutrition. For example, iron fortification of cereals benefits a large number of children and adult women through prevention of anemia, while risk is limited to a small number of individuals with hemochromatosis. The current evidence-based dietary recommendations can be made with a reasonable degree of certainty with the likelihood of minimal risk and the potential for significant public health benefits.^{1, 6, 15–17} [Table 1](#) summarizes the current population-based dietary recommendations that together may lower the risk of chronic diseases, including cancer.^{1, 4, 5} In early 2016, a revision of Dietary Guidelines for America will be published by the National Institutes of Health and should be examined by those interested in disease-prevention strategies.

Public health guidelines for nutrition and cancer prevention

Maintain a healthy weight

Increasingly, studies document that sedentary behavior, weight gain, overweight, and obesity are major risk factors for human cancer.^{1–3, 5, 18–23} Women with a body mass index (BMI) of $>25 \text{ kg/m}^2$ and men with a BMI $> 27 \text{ kg/m}^2$ should make weight loss a priority. Weight loss of just 5–10% is associated with improved health and can reduce the incidence or severity of several cancers.^{20–23} Weight loss is best achieved by reducing total calorie consumption and increasing calorie expenditure to create a negative energy balance, resulting in a modest, but consistent weight loss over time. Maximum weight loss of 1–2 pounds per week is appropriate for most people. Rapid weight loss achieved through fad diets does not encourage individuals to establish healthy eating and physical activity patterns, and weight loss is typically not maintained with these regimens.³ It is increasingly clear that maintaining a healthy weight throughout life may be one of the most critical approaches to protect against many common malignancies.^{1, 2, 5, 18}

Participate in physical activity daily and moderate-to-vigorous intensity exercise several days each week

The energy expenditure associated with physical activity is a critical component of maintaining a healthy body weight and preventing adult weight gain, which is associated with risk of several types of cancer.^{1, 5, 24} Additionally, a combination of daily physical activity and regular bouts of moderate-to-vigorous intensity exercise has been shown in many studies to reduce cancer risk independent of weight and diet.^{25–27} Physical activity should be incorporated into activities of daily living in combination with regular moderate-to-vigorous intensity exercise on most days of the week. There is general agreement that a minimum of 150 min/week of moderate intensity activity or 75 min/week of vigorous physical activity is recommended.^{1, 5, 28}

Consume a plant-based diet that is rich in fruits, vegetables, and a variety of whole grains and cereals

Several hundred studies have examined the relationships between fruit and vegetable intake and cancer risk.¹ The vast majority suggests a significant protective effect of a plant-based diet relative to cancer risk at many sites. Fruits and vegetables not only contain a diverse array of vitamins, minerals, fiber, and phytochemicals, but they are lower in caloric density than most other foods. A variety of nonstarchy fruits and vegetables should be included at every meal with a goal of consuming at least five servings (or at least 400–600 g) of fruits and vegetables per day. Additionally, emphasis should be placed on

consumption of beans and legumes, which provide protein, fiber, B vitamins, and iron, as well as whole grain breads, cereals, and pastas, which provide fiber, B vitamins, and a vast array of phytochemicals. As a plant-based diet is compatible with modest lean meat consumption, it should not be interpreted as a vegetarian dietary pattern.

Minimize consumption of energy-dense foods and sugary drinks

This recommendation has emerged as vital to the overall prevention of weight gain and obesity. Diets that are rich in processed foods are typically high in refined sugars and/or fats that contribute excess calories to the diet and do not provide a concentrated source of vitamins, minerals, and bioactive phytochemicals. Consumption of processed foods with added sugars has significantly increased in recent decades and currently contributes over 15% of total calorie consumption.^{29, 30} The majority of this increase comes from the consumption of sugary beverages, especially soda.¹ Drinks containing added sugars have been associated with an increased risk of overweight and obesity in children, adolescents, and adults. The consumption of sugary beverages should be minimized.

For people who enjoy red meat, moderate portion sizes and reduced intake of highly processed red meats are advisable

Populations consuming plant-based diets are often found to exhibit lower risk for various diseases, including some types of cancer; however, a specific role for meat in promoting cancer, independent of other variables, is not causally established. In addition, meat is an important source of many nutrients, such as protein, iron, and vitamin B12. Thus, modest meat consumption of 18 ounces or less of red meat (beef, lamb, and pork) per week likely does not significantly contribute to an overall significant increase in cancer risk, especially if meat does not displace consumption of fruits, vegetables, and whole grains. The impact of different cooking methods, which lead to the production of carcinogens on cancer, continues to be examined.³¹ Modest exposure to meats cooked for long periods of time and over flames is prudent.³² Historically, populations consuming diets rich in various forms of processed meat, including smoked, cured, or salted meats, have experienced greater risk of various cancers; therefore, limiting consumption of these meat products is advised.^{1, 33} For those choosing meat, it is sensible to select a variety of sources, including fresh chicken, fish, and turkey.¹

Alcohol, if consumed at all, should be limited

The risks and potential benefits of modest alcohol consumption remain a subject of debate. Although the health effects of alcohol or specific types of alcoholic beverages is an active area of research, chronic consumption of alcohol is strongly associated with cancers of the oropharynx, larynx, esophagus, and breast (both pre- and postmenopausal).^{1, 5} Smoking tobacco acts synergistically with alcohol in the pathogenesis of oral and upper aerodigestive cancers. Significant consumption of alcoholic beverages also contributes to liver cancer and perhaps colon cancer.¹ Even a moderate amount of daily alcohol consumption may slightly, but significantly, increase the risk of breast cancer.^{1, 34} Because there is some evidence that alcohol in moderation may reduce the risk of heart disease, individuals need to consider their personal health history and risk profile when deciding whether or not to consume alcohol. For those who choose to drink, alcohol intake should be limited to one drink per day for women and two drinks per day for men.^{1, 2, 5}

Optimal food preservation, processing, and preparation

Salt is vital for human health, but adequate amounts are achieved at levels much lower than those

typically found in the American diet.³⁵ Salt-preserved foods are associated with gastric cancer, a major malignancy worldwide, particularly in developing nations. Although relationships remain uncertain, diets high in salt-rich processed meats are associated with risk of several cancers and, consequently, should be consumed in moderation.^{1, 36} Meat that is cooked at very high temperatures, grilled, and charred favors the formation of certain types of chemical carcinogens and should be consumed in moderation.¹ Microbial contamination of the food supply is a major problem globally. Most critically, the contamination of grains and legumes with fungal aflatoxins contributes significantly to the risk of liver cancer, and public health approaches by government agencies to limit exposures are necessary.

Table 3 World Cancer Research Fund (WCRF)/American Institute for Cancer Research (AICR) Guidelines

AMERICAN INSTITUTE FOR CANCER RESEARCH / WORLD CANCER RESEARCH FUND SUMMARY OF STRONG EVIDENCE ON DIET, NUTRITION, PHYSICAL ACTIVITY AND PREVENTION OF CANCER

¹Includes evidence on foods containing carotenoids for mouth, pharynx, larynx; foods containing beta-carotene for esophagus; foods containing vitamin C for esophagus.

²Includes evidence on foods containing carotenoids for mouth, pharynx, larynx and lung; foods containing beta-carotene for esophagus; foods containing vitamin C for esophagus

³Evidence is from milk and studies using supplements for colorectum

⁴Convincing increased risk for men and probable increased risk for women for colorectum. Evidence applies to adverse effect for kidney

⁵Evidence derived from studies using supplements for lung

⁶Convincing increased risk for colon not rectum

⁷Probable increased risk for advanced not non-advanced prostate cancer

Dietary supplements are probably unnecessary in the context of a healthy diet

An increasing proportion of the American population consumes some type of self-prescribed nutrient or dietary supplement on a regular basis. The public increasingly perceives heavily marketed supplements and alternative medications as an important form of self-therapy for the prevention and treatment of many ailments, including cancer.^{1, 24} Multivitamin and mineral supplements are usually inexpensive, easy to consume, obtained without a prescription, and relatively free of side effects when taken at the dosages approximating the recommended dietary allowance (RDA). There has been very little evidence in support of routine dietary supplements for population-wide cancer prevention.^{5, 37} Although it is clear that Americans can achieve adequate nutrient intake by consuming a diverse diet based on the above recommendations, a standard multivitamin/mineral supplement providing the RDA may be beneficial to some and entails minimal risk. Increasingly, supplements that contain high concentrations of specific nutrients combined with other components, such as herbals, extracts, and concentrates, are being aggressively marketed. Consumers should be aware that regulations regarding implied health claims and requirements that products contain the stated ingredients and have demonstrated safety and efficacy are minimal, and the buyer should maintain skepticism and caution. The Office of Dietary Supplements of the National Institutes of Health provides web-based information for interested consumers.

Summary of research efforts focusing on specific cancers

It is unlikely that any food, nutrient, or dietary pattern will influence all cancers uniformly.^{1, 5, 24} Thus, in reviewing the relationships between nutrition and cancer risk, it is important to examine the data for each tissue or organ separately. It is clear that research will continue to improve our ability to identify individuals at high risk of specific cancers based on genetic tests, family history, exposure to carcinogenic agents, and the presence of premalignant conditions. A future goal is to provide tailored dietary recommendations and chemopreventive strategies for individuals at risk. Additional research will define unique preventive strategies for various cancers. The following is a brief summary of the current understanding of relationships between diet, nutrition, and the risk of specific, commonly occurring cancers. For additional information, please refer to [Table 3](#).

Figure 1 Age-adjusted death rates per 100,000 population from colon and rectal cancer in selected countries.

Source: Data from Boring 1994.³⁹

Colon and rectum

Colorectal cancer is the third most common cancer worldwide and the third leading cause of cancer death in the United States.^{1, 38} Genetic factors and premalignant conditions are being characterized that will define high-risk groups for chemoprevention and diet-intervention studies, which show promise in preclinical testing. The international variation in colorectal cancer is large (Figure 1). Although screening differences may account for some of the international variation, it is unlikely to account for the greater than 10-fold variations that are observed between nations.¹ The lower rates in Asian nations suggest that cultural and lifestyle variables, rather than industrialization, are the critical factors.^{1, 40, 41} Dramatic increases in incidence among Japanese and Chinese migrants to the United States⁴² clearly indicate that

international variations primarily result from environmental influences rather than genetic background.⁴³
⁴⁴ Examination of time trends in colorectal cancer incidence, particularly in Japan since the 1940s, strongly suggests major contributions from diet and lifestyle factors associated with the Westernization of cultures ([Figure 2](#)).¹

Figure 2 Age-standardized colon and rectal cancer incidence per 100,000 men in Japan from 1960 to 1977.

Energy balance, body mass, and physical activity

Energy intake, physical activity, and various measures of body size or obesity are all intimately related and associated with colon cancer risk. It is difficult to quantitate or ascertain the role of each component without considering them as a group. A convincing inverse association between physical activity and risk of colon cancer has been consistently reported.^{1, 45–47} Several studies have found an association between BMI or adiposity and elevated risk of colon cancer.^{1, 44, 48–50} The associations between obesity and inactivity with risk of colon cancer have been observed in several countries (United States, China, Sweden, and Japan), among men and women, and for both occupational and recreational activities.¹ Obesity is also associated with risk of colon adenoma.⁵¹ Some evidence suggests that height (perhaps a proxy of the net energy intake during childhood and adolescence) is related also to a higher risk of colon cancer.^{52–54} Studies in rodent models of colon carcinogenesis have reported enhanced tumorigenesis with greater *ad libitum* intake⁵⁵ and reduced risk with restricted intake.⁵⁶ Overall, the evidence is convincing that physical activity, appropriate energy balance, and maintaining the ideal BMI will decrease the risk of colon cancer.^{1, 47}

Figure 3 The risk of colorectal cancer in Chinese migrants to the United States according to dietary fat intake and level of physical activity.⁴²

Dietary pattern

In general, a Western dietary pattern that is rich in red and processed meat, high in fat, and low in fruits, vegetables, and fiber is associated with an increased risk of colon cancer.^{1, 57, 58} The relationship between total fat intake, fat saturation, or different sources of fat and risk of colon cancer remains an active area of research, but definitive conclusions regarding fat *per se* are not yet possible.^{1, 5, 42, 59–62} For example, [Figure 3](#) illustrates a population-based case–control study suggesting that dietary fat accounts for 60% of colorectal cancer risk among Chinese migrants to the United States. Other cohort studies report that fat from red meats rather than total fat may increase colon cancer risk.^{50, 61, 63–65} Dietary consumption of processed meats, which not only contain fat but also may contain suspected procarcinogens, have emerged as a convincing risk factor for colon cancer.^{1, 47, 66, 67} Thus, moderation in consumption of red meats and processed meats should be considered for those at risk of colorectal cancer. Efforts are underway examining complex dietary patterns, such as the Mediterranean-style diet, rather than single variables, with emerging data supporting benefits of a healthy dietary pattern.^{68, 69}

Fruits, vegetables, and fiber

Dietary patterns rich in plant products, particularly grains and vegetables, are often associated with a lower risk of colon cancer, and many have postulated that the fiber content is one major mediating factor.^{1, 15, 26, 59, 61, 70–73} The chemistry of dietary fiber is exceptionally complex, and, unfortunately, the quantitative and qualitative assessment of fiber intake in human epidemiologic studies is very difficult. However, the majority of studies suggest that a diet rich in diverse fiber-containing foods may be

beneficial. The large European Prospective Investigation into Cancer (EPIC) study involving over 500,000 men and women reported a 13% reduction in colon cancer risk for each 10 g/day increase in dietary fiber derived from cereals, fruit, or vegetables.^{74, 75} A few intervention trials have evaluated interventions focusing upon specific types of dietary fiber and colon cancer risk, and, to date, the results are equivocal.^{76–80} A specific role for any one type or class of fruits, vegetables, or grains has not been established; yet, a diverse plant-based dietary pattern is an advisable strategy.

Alcohol

A positive association between alcohol intake and risk of colon cancer is consistent among many ecologic, cohort, and population-based case–control studies.^{1, 5, 47, 81–83} Alcohol is also related to higher risk of colorectal adenoma.^{1, 5, 47} Overall, the impact is related more to total alcohol intake rather than to the source of alcohol.^{1, 5} Studies suggest that the elevated risk associated with alcohol occurs predominantly in the rectum or distal colon.⁶⁵ Recent studies indicate that high intakes of folate or methionine, both of which are crucial for normal methyl-group metabolism and, particularly, deoxyribonucleic acid (DNA) methylation, appears to mitigate the influence of alcohol.⁸¹ This suggests that alcohol, which has a well-known adverse effect on methyl-group metabolism, increases the risk of colorectal cancer via this mechanism; however, the role of folate during various stages of carcinogenesis remains to be clearly defined.⁸⁴

In summary, increased risk of colorectal cancer is strongly associated with a physically inactive lifestyle, a high BMI, and an affluent or Western dietary pattern, which is rich in simple sugars and high-fat foods (especially red meats and processed meats) and regular alcohol consumption but low in fruits, whole-grains, and vegetables.^{1, 5, 47} The individual contributions of folate, methionine, meats, and specific fiber components require further investigation.^{1, 5} The potential interactions among these components and other factors contributing to risk, such as early life dietary exposures, exercise, the colonic microbiome, and genetics are numerous. At present, it is sensible to consider the combined impact of the total dietary pattern and physical activity when making recommendations for colon cancer prevention, rather than focusing on a single factor.

Breast cancer

Cancer of the breast is most common in the affluent nations of North America and Western Europe and much less common in many parts of Asia and Africa,^{1, 5, 38} and, like colorectal cancer, we observe that migrants from low-risk nations show increasing risk after moving to a high-risk nation,^{1, 5, 38, 43} particularly in succeeding generations. This observation suggests that nutritional or other environmental factors active during youth and adolescence may have a long term and major impact on subsequent risk of breast cancer.^{1, 5, 38} The risk of breast cancer is reduced by early age of pregnancy and lactation.^{1, 23, 85} A number of dietary and nutritional factors characteristic of an affluent culture have also been proposed to enhance risk of breast cancer and are briefly summarized.^{1, 5}

Alcohol use

The accumulated evidence concerning alcohol intake and risk of breast cancer shows a positive and convincing association.^{1, 5, 23} The relative risk (RR) from the consumption of one typical serving of beer, wine, or liquor (~12 g of ethanol) per day is estimated to be 1.4, whereas three drinks per day approximately doubles the risk. Recent analyses have reported a linear relationship between breast cancer risk and each 10 g increase in daily alcohol consumption, even across different

estrogen/progesterone hormone subtypes.^{34, 86}

Energy balance, weight, and obesity

Evidence is accumulating that body fatness, adult weight gain, and a lack of physical activity are important risk factors for breast cancer.^{1, 5, 23, 87, 88} The role of energy intake as a stimulator of mammary carcinogenesis has been well-established by rodent studies using diet or energy restriction^{89, 90} and regression analysis of *ad libitum* feeding.^{55, 91} Overall, higher levels of adult physical activity seem to be associated with a modest protection (~25% risk reduction) against breast cancer risk, and the protective effect may also be independent of BMI or weight gain as an adult.^{88, 92–94} However, the precise relationships between energy intake, energy expenditure, anthropometrics, and risk of breast cancer must be examined for different critical periods in a woman's life cycle. The effects of these factors may vary during adolescence, the reproductive years, and the postmenopausal period.

Figure 4 International correlation of (a) estimated dietary fat intake (percentage of calories as fat) and (b) estimated carbohydrate intake (percentage of calories as carbohydrate) and age-adjusted breast-cancer mortality.

Source: Carroll 1991.⁹⁵ Reproduced with permission of Springer.

Dietary fat

The controversy concerning the contribution of dietary fat concentrations or sources, independent of energy intake, to risk of breast cancer can best be appreciated through examination of the representative data presented in [Figure 4](#). Geographic studies show strong correlations between national rates of breast cancer and the estimated per capita fat consumption.^{60, 96} There are wide international variations in breast cancer rates as well as per capita fat consumption, or the percentage of calories derived from fat. Breast cancer rates have been observed to increase significantly in populations migrating from low-risk areas, such as Japan, where diets were traditionally low in fat, to high-risk areas, such as the United States, where populations consume diets rich in fat.^{43, 97} Time–trend studies also support a dietary fat and breast cancer association. Within Japan, estimates of per capita daily fat intake have risen over the decades following World War II. During this period, breast cancer mortality increased in Japan by >30%. These examples illustrate that correlation does not prove cause and effect, and many investigators argue that fat intake may be an indicator of some other unidentified combination of diet and environmental components that are the truly critical risk factors. The relationship between fat intake and risk of breast cancer has been examined in many case–control and cohort studies with inconsistent results.^{98–101} Although the epidemiologic data have not provided definitive results concerning dietary fat and breast cancer, accumulated evidence from >100 animal studies using chemical carcinogens, hormones, irradiation, or viruses to induce breast cancer indicate that, as a single variable, fat enhances mammary carcinogenesis ([Figure 5](#)).^{1, 55, 91, 102} One randomized intervention study of women who had been treated for breast cancer suggested a 24% risk reduction in breast cancer recurrence among women who were able to reduce their dietary fat consumption to ~33 g/day (vs 51 g/day for the control group).¹⁰³ Although not statistically significant, similar trends were observed in the very large, randomized Women's Health Initiative study.⁹⁸ The large EPIC study followed over 33,000 women for 11.5 years and found diets high in total and saturated fat to be associated with a significantly increased risk of ER(+)PR(+) disease but not with ER(–)PR(–) breast cancer.¹⁰⁴ Overall, the possibility that achievable reductions in fat intake during adulthood will cause an appreciable reduction in breast-cancer risk remains uncertain, and dietary patterns during adolescence and reproductive years may prove to be more critical to future breast cancer risk.¹

Figure 5 The effects of low- and high-fat diets at different levels of caloric intake on spontaneous mammary tumorigenesis in C3H female mice.

Other dietary factors

Overall, a plant-based dietary pattern rich in vegetables, fruits, and grains may have a role in decreasing the risk of breast cancer, but a conclusive and specific role for selected plant components has not been demonstrated.^{1, 5, 23, 101, 105} There are no consistent relationships for the consumption of specific vitamins or minerals and breast-cancer risk, and recommendations regarding supplement use for prevention remain to be defined.^{1, 5} Other bioactive compounds found in the diet, such as soy isoflavones, lignans, and fiber, may play a role in breast cancer, but evidence remains insufficient for recommendations.^{1, 5, 101} In summary, the most well-established recommendations for breast cancer prevention are to engage in vigorous physical activity on a regular basis, avoid or limit intake of alcoholic beverages, and minimize lifetime weight gain and body fatness through physical activity and energy restriction.

Prostate cancer

Cancer of the prostate is one of the most frequently diagnosed malignancies in American men, and it is especially common among the African-American population.^{1, 38} Prostate cancer is a disease of aging men, and the international distribution of prostate cancer is similar to that of colon and breast cancer; therefore, it correlates with affluent dietary patterns.^{1, 106} Relationships between diet and prostate cancer are not clearly defined, and specific recommendations to prevent the disease remain speculative. A role for weight gain and obesity resulting from excess energy intake and a lack of physical activity is accumulating in human studies and is clearly demonstrated in rodent studies.^{1, 18, 106–109} The evidence is most clear for the increase in the risk of advanced prostate cancer.²² International and intracountry correlational studies suggest associations between prostate cancer mortality and the per capita intake of total fat.^{1, 106} Similarly, several analytic epidemiologic studies and case–control studies have reported

associations between prostate cancer and total fat or the consumption of foods high in fat, particularly saturated fats from animal products.^{1, 106–108, 110, 111}

Several studies suggest that specific nutrients such as vitamin E and selenium may influence prostate cancer risk.¹¹² A significantly lower risk of prostate cancer was noted among men randomized to vitamin E supplementation.¹¹² The possible role of selenium in the prevention of prostate cancer has been hypothesized based on various lines of indirect evidence.^{1, 113–116} The largest prostate cancer chemoprevention trial to date, the Selenium and Vitamin E Chemoprevention Trial (SELECT), began randomizing 33,000 men in the fall of 2001. The study design was a 2×2 factorial of vitamin E, selenium, and a placebo. After a median follow-up of 5.4 years, selenium, vitamin E, or a combination of the two were not found to be protective for prostate cancer in a group of healthy men.¹¹⁷

The possibility that calcium and vitamin D are interacting components of a complex network of dietary and endocrine factors modulating prostate cancer risk is under investigation.¹¹⁸ Several large cohort studies suggest that high dietary calcium consumption increases prostate cancer risk.^{1, 22, 118–122} Endogenous production of the active form of vitamin D (1,25(OH)₂) is suppressed with high calcium intake and with reduced exposure to sunlight. Prostate cells express vitamin D receptors, and exposure to a ligand tends to induce differentiation pathways. These complex relationships have spurred many cell culture, animal, and cohort studies, with several suggesting an inverse relationship between vitamin D and prostate cancer risk, although benefits beyond correction of deficient or marginal intake are unknown.^{123–126}

The overall consumption of fruits and vegetables has not been shown to be related to a consistent reduction in the risk of prostate cancer.^{1, 22, 106} However, a reduced risk of prostate cancer associated with the consumption of tomatoes and processed tomato products has been observed repeatedly in the prospectively evaluated Health Professional's Follow-up Study.^{127–131} On the basis of these findings, it has been hypothesized that the carotenoid lycopene may account for some of the anticancer properties of tomato products, although other compounds found in tomato foods may also be important.^{131–137} However, it is very premature to conclude that lycopene mediates a protective effect against prostate cancer or that lycopene is the only component of tomato products that may contribute to the association.¹³⁸ Interestingly, several interventions where subjects have been fed either tomato products or a lycopene supplement have reported modulation of both blood and prostate tissue biomarkers of prostate cancer.^{135, 139–141}

In summary, epidemiologic studies and a limited number of laboratory investigations suggest a role for an affluent dietary pattern in prostate cancer risk. Rates of prostate cancer are higher in nations consuming an affluent dietary pattern coupled with obesity and a sedentary lifestyle, although the contributions of specific components are not well-defined and are being actively investigated.

Lung cancer

Lung cancer is currently the most common worldwide malignancy and the leading cause of cancer-related death.¹ Cigarette smoking accounts for the vast majority of cases, and incidence rates continue to climb in parallel with the globalization of cigarette manufacturing, marketing, and advertising.¹ Certain occupational exposures, such as asbestos or radiation, may act synergistically with cigarette smoking to increase the risk.¹ Compared with the role of tobacco, the potential contribution of diet and nutrition is relatively modest. However, an inverse relationship between the greater intake of fruits and vegetables and lower risk of lung cancer has been a frequent finding in human nutritional epidemiology.^{1, 142–144} Many hypothesized that β -carotene found in fruits and vegetables or vitamin A derived from cleavage of

β -carotene may be the critical active agents in these foods.^{1, 145} However, two randomized controlled intervention trials in high-risk populations found no reduction, and perhaps an increase, in the incidence of lung cancer among male smokers after several years of supplementation with β -carotene at 20 or 30 mg/day.¹⁴⁶ A recent study of over 72,000 Chinese women reported that, among women who were exposed to side-stream smoke, dietary intake of foods rich in tocopherols was inversely related to lung-cancer incidence. In contrast, supplemental vitamin E significantly increased risk of total lung cancers and, in particular, lung adenocarcinoma.¹⁴⁷ These reports emphasize that protective benefits of diets rich in fruits and vegetables probably involve many interacting components and will not be reproduced by providing a single agent.^{1, 148} Overall, elimination of cigarette smoking and occupational risk factors will have the greatest impact on decreasing the incidence of lung cancer. Among high-risk individuals, the frequent consumption of a diverse array of fruits, vegetables, and other plant foods may provide some degree of protection against lung cancer.

Figure 6 The interactions between alcohol intake and cigarette smoking on the relative risk of oral cancer.

Source: Rothman 1972.¹⁴⁹ Reproduced with permission of Elsevier.

Oral cavity, larynx, and oropharynx cancers

Like lung cancer, cancers of the oral cavity and the larynx are strongly related to the use of tobacco products.^{1, 2, 24} Case-control studies completed over several decades have documented associations between the consumption of alcoholic beverages and cancers of these tissues. A dose-response relationship of alcohol and oral cancer, independent of tobacco usage, has been observed in a number of studies (Figure 6).^{150, 151} Additional evidence is derived from studies of populations who exhibit increased risk, such as alcoholics. Seventh-Day Adventists and Mormons in the United States, who refrain from alcohol and have a much lower risk.^{152, 153} It is of interest that feeding pure alcohol as part of a nutritionally sound diet does not produce oral cancers in experimental animals. The extent that this

represents biochemical differences between man and rodents, the lack of a direct carcinogenic effect of ethanol, the presence of carcinogens in alcoholic beverages consumed by man, the passive inhalation of ambient tobacco smoke in the places where ethanol is consumed, or the importance of other interacting carcinogens and nutritional deficits must be further evaluated. Both epidemiologic and laboratory studies provide convincing evidence supporting a protective role for diets rich in fruits and vegetables.^{1, 49, 154} In addition, clinical and laboratory investigation has suggested that vitamin A and analogs or metabolites, as well as certain carotenoids, may serve as inhibitors of carcinogenesis in the oral and respiratory epithelia.¹⁵⁵ In summary, tobacco products are major contributors to cancers of the mouth and pharynx, especially in conjunction with the consumption of alcoholic beverages.¹ Further efforts to better define the roles of vitamin A and derivatives, other phytochemicals, and a diverse plant-based diet for prevention in high-risk groups are warranted.

Esophageal cancer

Squamous cell cancer of the esophagus is the eighth most common cancer worldwide and varies several hundredfold between nations and between geographic regions within nations.^{1, 154} In most developed nations, correlational analyses and case–control studies indicate that the major risk factors are ethanol and cigarette smoking for squamous-type esophageal cancer.¹ Risk increases in proportion to the amount of alcohol consumed.^{1, 156, 157} A number of studies show an alcohol dose–response relationship after controlling for cigarette smoking, although the two factors may show a significant additive effect.¹ Increasing consumption of alcohol generally is associated with the marginal intake of many nutrients, which is thought to predispose individuals to greater risk. For example, alcohol may interact with folate, vitamin B12, and methyl group metabolism to modulate risk.¹⁵⁸ A number of studies suggest an inverse relationship between risk of esophageal cancer and consumption of fresh fruits and vegetables.^{1, 143, 159} In certain parts of Asia where alcohol consumption does not explain the high risk for esophageal cancer, there may be a relationship between esophageal cancer and the indigenous diet, which is low in fresh fruits, vegetables, and animal products, and the estimated intakes of vitamin A, vitamin C, riboflavin, zinc, and several trace elements, such as molybdenum, frequently are cited as being low, as well.^{1, 160, 161} In summary, cigarette smoking and alcohol consumption are the most important etiologic factors. The possibility that marginal intakes of one or more nutrients may contribute to risk in affluent populations has been suggested but not firmly established. The most important protective dietary intervention is a dietary pattern characterized by frequent consumption of fruits and vegetables.¹

Adenocarcinoma of the esophagus and gastric cardia

The incidence of adenocarcinoma of the distal esophagus and gastric cardia has been increasing rapidly over the past two decades in the United States and Western Europe.¹⁶² Among white men, adenocarcinoma of the distal esophagus has increased >350% since the mid-1970s.¹⁶³ Current or past cigarette smoking may be one of the contributing factors.^{163, 164} However, one of the most consistent observations has been a positive association between risk and BMI and/or abdominal obesity.^{165–168} As the prevalence of obesity has increased in the United States, a parallel trend is observed in the incidence of adenocarcinoma of the esophagus and gastric cardia.¹⁶⁹ The mechanism remains under investigation; however, it has been speculated that obesity may predispose to gastroesophageal reflux disease. Other nutritional factors that have been investigated relative to the increased adenocarcinoma risk include dietary patterns characterized as rich in animal sources of fat, low in fiber, and low in fruits and vegetables.^{170, 171} Additional efforts are needed to clarify the risk factors in addition to obesity that are responsible for the dramatic increases in the incidence of adenocarcinoma of the esophagus and to devise

effective intervention strategies.

Stomach cancer

Gastric cancer is the fourth most common cancer worldwide.³⁹ The incidence varies dramatically among countries and is highest in parts of Asia (e.g., Japan) and South America. A dramatic decrease in the incidence of stomach cancer in many affluent nations has been documented over the past century. In the United States, the current rate is among the lowest in the world, whereas, in 1930, gastric cancer was the most frequently diagnosed malignancy in Americans. In recent years, investigators have identified a divergent incidence pattern for cancers of the gastric cardia and distal stomach, which suggests different etiologies. Adenocarcinoma of the cardia is typically grouped etiologically with those arising from the metaplastic distal esophagus, which show a similar histology and may share risk factors. Convincing evidence for specific foods and nutrients is lacking. However, several variables under study are considered to be likely related, including: (1) the protective role of diets rich in fruit and vegetables^{172, 173}; (2) the protective effects of modern food processing and storage, thereby reducing spoilage; (3) the increased risk due to high exposure to foods with salt curing, pickling, and nitrates for preservation¹⁷⁴; (4) the role of *Helicobacter pylori* infection and interactions with dietary factors^{175–177}; (5) identification of natural carcinogens or precursors, such as nitrates, found in foods¹⁷⁸; (6) the production of carcinogens during food storage and preparation; and (7) the synthesis of carcinogens from dietary precursors, such as nitrates, in the acid environment of the stomach.^{1, 164, 175, 176}

Liver cancer

Primary hepatocellular carcinoma is less common in the United States and Northern Europe. In contrast, it is one of the most frequent types of cancer in the developing nations of sub-Saharan Africa and Asia and is now ranked as the sixth most common cancer worldwide.¹ Hepatitis B and C infections appear to be the major etiologic factors in many high-risk areas, where the carrier state imparts an increased risk of ~200-fold.¹⁷⁹ Contamination of foods with carcinogenic fungal products, such as certain aflatoxins, also likely contribute to risk in some populations.¹ Aflatoxins are found in geographic areas where food processing and storage are not optimal. Groups with high aflatoxin exposure often have high rates of hepatitis B infection, parasitic infections, and nutritional deficiencies, which may interact to determine risk. In low-risk nations, obesity, overweight, the syndrome of nonalcoholic steatohepatitis (NASH), and the consumption of alcohol are relevant dietary factors in the pathogenesis of liver cancer.^{1, 59, 72, 180, 181} The data also suggest that risk factors may act in an additive or synergistic manner.¹⁸² It has been hypothesized that liver cancer primarily occurs in those whose cumulative experiences with alcohol, viral hepatitis, and toxin exposure lead to cirrhosis. Increasingly, coffee intake is associated with a decreased risk, and there is limited evidence that consumption of fish and regular physical activity may also reduce the risk of liver cancer.^{183–186}

Pancreatic cancer

Pancreatic cancer is frequently detected at an advanced stage and, thus, is highly lethal. Cigarette smoking has been firmly established as one etiologic factor.^{24, 187} The risk of smoking at least a pack per day is approximately fourfold, compared with that of nonsmokers.¹ There is limited evidence that diets rich in red and processed meats, alcohol, fructose-containing foods, and saturated fat may increase pancreatic-cancer risk.¹⁸⁸ Body fatness and excess energy intake are positively associated with pancreatic-cancer risk,^{1, 188, 189} and are consistently supported by studies in animal models.¹⁹⁰

Endometrial cancer

In general, endometrial cancer shows an international distribution similar to that of other cancers of affluence, such as breast, colon, and prostate cancers. Evidence for association between endometrial cancer and excess energy intake, lack of physical activity, obesity, and high glycemic load continues to accumulate.^{1, 18, 20, 97, 108, 187} Coffee consumption has emerged as a protective factor in the development of endometrial cancer, with several studies suggesting a 7–8% reduction in risk for each cup consumed on a daily basis.^{20, 191} A role for fruits and vegetables in decreasing the risk of endometrial cancer is suggested by some studies.^{1, 192} At the present time, the most appropriate guidance is to avoid obesity through reduced energy consumption and regular physical exercise coupled with a dietary pattern rich in fruits, vegetables, and grains.

Ovarian cancer

There is considerable international and geographic variation in the incidence and mortality rates of ovarian cancer. The disease is more common in nations exhibiting Western culture, especially among the higher socioeconomic groups.^{1, 187} At present, no conclusive role for dietary components in the pathogenesis of ovarian cancer has been established although there is increasing evidence that body fatness enhances risk and limited evidence that lactation may decrease risk.²¹ Additional studies are needed, particularly in conjunction with known risk factors of low parity and specific inherited genetic abnormalities.¹

Bladder cancer

Bladder cancer is more frequent in industrialized nations, especially among smokers and those in urban areas and of lower socioeconomic status.^{1, 59, 143, 193, 194} The majority of epidemiologic and case–control studies support the hypothesis that the frequent consumption of fruits and vegetables will reduce risk.^{1, 143, 193, 195} A diet rich in cruciferous vegetables, such as broccoli, but not other classes of fruits and vegetables, has been associated with a reduced bladder cancer risk in both smokers and nonsmokers.¹⁹⁵ The role of fluid intake in bladder cancer risk has frequently been proposed.^{1, 196} The prospective evaluation of fluid intake found a significant inverse association between total daily fluid intake and bladder-cancer risk, with no evidence for a benefit or risk from specific sources of fluid.¹⁹⁶ Several recent studies have reported that diets rich in red and processed meats may be an important contributor to bladder cancer.^{197–199} Laboratory studies have found that the high doses of non-nutritive sweeteners, such as cyclamates and saccharine, may be weak initiators or promoters of bladder carcinogenesis in rodents, but their contribution to human cancer is likely to be exceptionally small.¹

Current research

Specific foods, nutrients, and dietary components frequently associated with cancer prevention

Many people at risk of cancer focus their attention upon specific foods or nutrients in part because of the extensive marketing of products and publicity generated by the popular press. This tendency is facilitated by the news media when science reporters publicize results of single studies or preliminary findings, often confusing readers with contradictory and conflicting results. The following section briefly summarizes data regarding selected food components or nutrients and might assist the medical practitioner

in responding to specific inquiries from individuals.

Vitamins

Vitamin A

Vitamin A is essential for the normal growth and development of epithelial tissues. Vitamin A deficiency is common in many parts of the developing world, but is extremely rare in Americans. Vitamin A is provided in the diet as retinol and its esters, primarily from milk and organ meats, and as β -carotene and a few other provitamin A carotenoids in yellow and leafy green vegetables. A protective effect of consuming foods rich in vitamin A has been hypothesized for several types of cancer.^{1, 5, 143} However, there is no clear evidence that vitamin A supplementation will decrease the risk of cancer in populations or individuals consuming a healthy diet. Although many studies in laboratory models indicate that vitamin A deficiency increases the susceptibility of tissues to chemical carcinogenesis, these observations do not support the concept that a lower risk will be observed by excessive supplementation in persons with adequate vitamin A status. The use of vitamin A and synthetic retinoids as pharmacologic agents in chemoprevention trials to determine their efficacy in specific high-risk populations is an important area of translational research.²⁰⁰

Vitamin D

Vitamin D is a hormone-like nutrient obtained through the diet, and it is endogenously produced with exposure to sunlight. Evidence has accumulated that suggests an important role of vitamin D in several cancer subtypes including colon, prostate, breast, among others, though clear dose–response relationships and a benefit beyond the recommended daily allowances remains uncertain.^{1, 119} Recent studies indicate that a vitamin D deficiency may be much more common than previously recognized and may contribute to cancer risk.²⁰¹ Cancer cells derived from many human tumors express the receptor for 1,25-dihydroxy vitamin D₃ and respond to this agent *in vitro*, but the pathophysiologic significance in human cancer remains to be determined, particularly, beyond dosages considered adequate to correct risk of deficiency.^{5, 202}

Vitamin E

Vitamin E is a family of eight compounds that are collectively referred to as *tocopherols*. Vegetable oil, eggs, and whole grains are the major sources of dietary vitamin E. The antioxidant and free-radical scavenger properties of vitamin E suggest a possible role in the inhibition of carcinogenesis.^{202, 203} However, few rodent, epidemiologic, or intervention studies provide strong evidence to support the consumption of vitamin E supplements, particularly beyond the requirement, to prevent cancer.^{1, 204}

Vitamin C

Vitamin C, which includes ascorbic acid and dehydroascorbic acid, functions as a water-soluble antioxidant and a component of several enzymatic reactions in intermediary metabolism. Citrus fruits, leafy vegetables, tomatoes, and potatoes are rich sources of vitamin C. Despite a large volume of publications, very little evidence supports a critical role of dietary vitamin C in the etiology of most human cancers, although several studies suggest that diets rich in foods containing vitamin C may be cancer protective.⁵ Supplement studies, although few in number, have failed to show a reduced risk of cancer.²⁰⁵ Some provocative evidence concerns the ability of vitamin C to inhibit the formation of carcinogenic nitrosamines, which ultimately may reduce the incidence of cancers that are thought to be

associated with nitrosamines, such as gastric cancer.²⁰⁶ At present, there is no evidence to suggest that consumption of vitamin C supplements at levels higher than the typical amount achieved in a well-balanced diet containing ample fresh fruits and vegetables is useful for the prevention or treatment of human cancer.^{1, 5}

Folate

Folate is an essential, water-soluble B vitamin required for the normal metabolism of amino acids, methyl groups, and nucleotides. It is found in many vegetables, fruits, beans, and whole grains, and folic acid is also found in fortified grain products in the United States.²⁰⁷ Folate plays a role in the methylation of DNA, which may be critical for the normal regulation of gene expression and tissue differentiation. Epidemiologic and laboratory studies are beginning to accumulate evidence suggesting that insufficient folate may relate to the risk of several malignancies, particularly colon and breast cancers.²⁰⁸ Cancer risk may also be higher among persons who consume alcohol regularly with a low-folate diet.^{5, 16, 111, 209} However, caution should be advised, as folate is critical for DNA metabolism and cell proliferation, and the potential for high folate to enhance cancer progression has been raised.^{84, 210}

Minerals

Calcium

Calcium is hypothesized to reduce the risk of colon cancer but enhance the risk of prostate cancer.^{1, 5} For example, several prospective cohort studies have found that those who develop colon cancer had a significantly lower intake of calcium and vitamin D.^{1, 5, 211} Calcium supplementation of 1.2 g/day reduced the proliferative rate of colonic cells in patients who are considered to be at an increased risk of colon cancer.^{47, 212} Several clinical trials to determine the effects of calcium supplementation on polyp formation are currently ongoing with initial reports suggesting a modest benefit. Conversely, calcium from dietary sources and from supplements has been demonstrated in several prospective studies to be associated with an increased risk of prostate cancer,^{118, 121, 213} particularly cancers with more aggressive characteristics. At this time, it is appropriate to target calcium intake at RDA levels from a variety of food sources. The RDA is currently 1000 mg/day for those aged 19–50 years and 1200 mg/day for people older than 50 years of age.

Selenium

Selenium is a mineral required in the diet at very small concentrations with an RDA of 55 µg/day for both men and women. Grains, cereals, seafood, and meat are good sources of selenium. Selenium is an essential constituent of glutathione peroxidase, and it participates in the destruction of hydrogen peroxide and organic hydroperoxides, using reducing equivalents from glutathione. Selenium, thus, participates in cellular and tissue defense against oxidative damage. A major obstacle for epidemiologic studies is that estimates of dietary selenium intake are unreliable, especially in the developed nations where foods are extensively processed and shipped for long distances, because the selenium content of food is very sensitive to soil concentrations. An inverse association between the selenium levels in forage crops from different geographic areas or tissue selenium and mortality rates from certain cancers has been suggested.^{1, 5, 113} A landmark human intervention trial reported that selenium supplements might reduce the risk of lung, colon, and prostate cancers.¹¹³ However, larger randomized controlled trials are required to confirm and expand upon these findings. Overall, individuals choosing to consume a selenium supplement should be advised to consume the requirement of 55 µg/day and not more than 200 µg/day because there

is a narrow margin between safe and potentially toxic dosages.^{1, 5}

Foods and food components

Soy products

People living in countries such as Japan and China, where soy foods are regularly consumed, have a much lower risk of cancers of the breast, colon, and prostate than do people living in the United States where soy foods are not commonly consumed. However, many other variables in addition to soy undoubtedly contribute to the geographic variations. Soy foods contain several components, including soy protein, isoflavones, lignans, and saponins, which have been investigated for their anticancer effects in laboratory models.^{214, 215} Although many studies are currently underway, there is no convincing evidence demonstrating that the use of soy supplements, soy extracts, pure soy concentrates, or other soy components currently marketed will significantly impact human cancer risk. Some concerns have been raised about the risks and benefits of soy consumption relative to breast or endometrial cancer. Several soy isoflavones have a chemical structure similar to estrogen and may bind to the estrogen receptor and act as weak estrogen. It is plausible that high amounts of phytoestrogens may actually increase cell proliferation, although this remains controversial. At this time, it is probably best for women at high risk of breast cancer to avoid concentrated isoflavone supplements, but it is unlikely that moderate amounts of soy foods, as part of a plant-based diet, will increase cancer risk.^{37, 216–220}

β-Carotene

Foods rich in β-carotene, including many fruits and vegetables, are associated with a lower risk of cancer. However, recent intervention trials with pharmacologic doses of β-carotene clearly question the hypothesis that the benefits of a plant-based diet can be produced through β-carotene supplements. Two large intervention studies of β-carotene, utilizing doses beyond that achieved from dietary sources, demonstrated a higher risk of lung cancer in smokers.^{146, 221} Although β-carotene is a potential antioxidant and source of vitamin A, supplements should be discouraged for cancer prevention, and diets rich in carotenoids should be encouraged.

Lycopene

The bright red color of tomato products is caused by the nonprovitamin carotenoid lycopene. Interest in lycopene has emerged, because many studies demonstrate that the consumption of tomato products is associated with a lower risk of several cancers, particularly prostate cancer.^{129, 130, 133} The recent WCRF/AICR Continuous Update Project report concluded that the relationship between lycopene and prostate cancer is too limited to draw a conclusion.^{1, 22} However, at the present time, it is sensible to consume tomatoes and tomato products as one component of a carotenoid-rich dietary pattern based on fruit and vegetable intake.

Omega-3 fatty acids, fish oil, and olive oil

Diets rich in total fat have a high caloric density and may contribute to excess energy intake and obesity. Thus, most healthy dietary patterns are slightly lower in total fat than the current American pattern. However, differing types of lipids also may have varying impacts upon cancer. Fish is a rich source of omega-3 fatty acids that can influence cell biology through a number of mechanisms, including modulation in the production of bioactive lipids such as prostaglandins and leukotrienes. Animal models suggest some inhibition of specific cancers, such as prostate and breast.²²² Olive oil has generated interest

because of its lack of association with cancers in studies, where total lipids, saturated fats, and other measures of lipid intake demonstrate positive associations. Like other lipids, olive oil contributes to caloric intake and risk of obesity but can be used in certain recipes to replace other types of lipid that may have a greater association with cancer and cardiovascular disease. Overall, definitive data regarding lipid sources or fatty-acid profiles and human cancer risk do not exist; it is yet under study, and specific recommendations are not possible at this time.^{1, 5}

Organic and natural foods

Government regulators will continue to evaluate information and provide updated standards and recommendations to consumers regarding expectations when the term “organic” is used in food labeling. In general, the term refers to foods grown without the use of synthesized pesticides or herbicides, and it has been expanded to include non-genetically manipulated foods. At the present time, there are very few studies suggesting that consuming organic foods will substantially lower cancer risk when compared to the same foods produced by standard farming practices.^{1, 5} One notable prospective study evaluating intake of organic foods and cancer risk in over 600,000 women followed for 9.3 years found that consumption of organic foods was not associated with total cancer incidence or cancer subtype incidence, with the exception of non-Hodgkin lymphoma.²²³

Pesticides, herbicides, and environmental contaminants in food

Residues of pesticides and herbicides are found in low concentrations in fruits and vegetables. Overall, studies have not clearly defined cancer risks associated with exposure to the modern agents at low concentrations, and the preponderance of data supports the recommendation that fruits and vegetables should be consumed at greater concentrations. Additional concerns relate to the accumulation of some environmental toxins in meats, including fish, but without definitive evidence of a cancer risk. Certainly, exposures to high concentrations of these compounds through industrial and agricultural exposures are associated with toxicity and raise concerns about cancer risk. Most importantly, regulatory agencies must continue to monitor agents and ensure safety at expected exposure levels in the food supply.^{1, 5}

Artificial sweeteners (aspartame and saccharin)

Artificial sweeteners are the basis of many low-calorie foods currently marketed. No links between aspartame and human cancer have been identified. Saccharin has been shown to slightly enhance the risk of bladder cancer in rodent studies when provided concentrations that would greatly exceed that consumed by humans. Human epidemiologic studies have not identified saccharin or aspartame consumption as a risk factor for human cancer.^{1, 5}

Table 4 Public health guidelines for cancer survivorship

	American Cancer Society ³⁷	National Comprehensive Cancer Network ²²⁴
Body weight	Achieve and maintain a healthy weight (BMI between 18.5 and 25 kg/m ²). After cancer treatment, weight gain or loss should be managed with a combination of diet, physical activity, and behavioral strategies	Maintain a healthy weight. Weight gain and being overweight during cancer treatment and survivorship may increase risk of recurrence and lower odds for survival
Physical	Engage in regular physical activity. Avoid	Engage in at least 30 min of moderate-

activity	inactivity and return to normal daily activities as soon as possible following diagnosis. Aim to exercise at least 150 min/wk. Include strength training at least 2 days/wk	intensity activity on 5 days/wk or more, or at least 20 min of vigorous-intensity activity on 3 days or more. In addition, perform strength training at least 2 days/wk
Plant-based diet	Achieve a dietary pattern that is high in vegetables, fruits, and whole grains	Aim for a variety of foods. Create a balanced plate that is one-half cooked or raw vegetables, one-fourth lean protein (chicken, fish, lean meat, or dairy), and one-fourth whole grains
Vegetable and fruit	Few studies exist that evaluate fruit, vegetables, and cancer recurrence or survival. Consistent with the <i>2010 Dietary Guidelines for Americans</i> , cancer survivors should consume at least 2–3 cups of vegetables and 1.5–2 cups of fruits each day for health benefits	Eat a minimum of five servings of fruits and vegetables per day. Use plant-based seasonings, such as herbs and spices
Breads, grains, and cereals	Choose whole grains instead of refined grain products. Eat plenty of high-fiber foods	Choose whole grains. Opt for high-fiber breads and cereals. Avoid refined foods and those high in sugar
Animal products	Limit intake of processed and red meats. Avoid cooking these and other high-fat sources of protein at high temperatures	Choose lean protein such as fish, poultry, and tofu. Limit red meat and processed meats Eat fatty fish at least twice a week. Choose low-fat dairy products. Select skim milk, low fat yogurt, and reduced fat cheeses
Dietary fat	Limit the intake of foods and beverages high in fat and with added sugar to promote healthy weight control	Eat fatty fish, such as salmon, sardines, and canned tuna, at least twice a week. Walnuts, canola oil, and flaxseeds are additional sources of heart healthy omega-3 fats
Processed foods and refined sugar	Limit the intake of foods and beverages high in fat and with added sugar to promote healthy weight control	Avoid refined foods and those high in sugar
Salt and sodium		
Alcohol	Alcoholic drinks (up to one or two drinks per day for women and men, respectively) can lower the risk of heart disease, but higher levels may increase the risk of specific cancers. It is important for the health care provider to tailor advice on alcohol consumption to the individual survivor	Limit alcohol consumption. Alcohol has been linked to cancer risk. Men should have no more than two drinks per day and women no more than one drink per day
Supplements	Before supplements are prescribed or taken,	A healthy dietary pattern, not supplements, is

all attempts should be made to obtain needed nutrients through dietary sources. Supplements should be considered only if a nutrient deficiency is biochemically or clinically demonstrated

the ideal strategy for adequate vitamin and mineral intake. There is no evidence that dietary supplements alone provide the same anticancer benefits as a healthy dietary pattern. Some high-dose supplements may actually increase cancer risk

Sugar

Highly refined simple sugars provide calories but without the nutrients associated with whole foods. Diets containing large amounts of simple sugars are frequently nutrient-poor and might also contribute to promoting obesity and hormonal changes that could potentially increase cancer risk. However, sugars *per se* are not carcinogens, and a diet with a modest amount of sweets should not be a concern in the context of a healthy dietary pattern.^{1, 5}

Tea

Clinical investigations of green and black teas are currently underway to determine whether these products may have anticancer properties in humans to support data derived from laboratory studies. Thus far, tea has not been shown to lower the risk of any human cancer, but important studies are underway.^{1, 5}

Survivorship: diet and nutritional guidance during and following cancer treatment

Although the focus of this chapter is diet and nutrition in the etiology and prevention of cancer, we briefly introduce the emerging field of diet and nutrition during cancer survivorship. “Survivorship” is now accepted as beginning at the time of cancer diagnosis and continuing throughout the life of the individual. Diet and nutrition may have a role in several components of cancer survivorship, including (1) enhancing the benefits of treatment and reducing the frequency or severity of acute treatment-related toxicities; (2) promoting recovery during the immediate post-treatment phase; (3) supporting of patients suffering from cancer cachexia and during terminal phases of incurable or advanced cancers; and (4) promoting long-term survivorship by reducing the chance of recurrent disease, secondary prevention of cancer, and reducing the frequency and severity of late complications of therapy and enhancing overall health and longevity. At current rates, >1.2 million Americans are diagnosed with cancer each year, and >10 million are categorized as survivors. The need for scientifically based recommendations is now acute and has not kept pace with the desire of patients or survivors to obtain information on diet and nutrition. The ACS recently published a review of the field, summarizing the state of nutrition and physical activity research and providing guidelines for communicating with survivors ([Table 4](#)).³⁷

Diet and nutrition represents, for many cancer patients, an opportunity to counteract the profound sense of loss of control that accompanies cancer treatment. Quality of life is improved when patients feel that they are active participants in the course of their care. Unfortunately, scientific evidence to help a patient choose optimal diet and nutritional information is insufficient in most areas. Cancer survivors are faced with a bewildering array of sources of dietary information, ranging from well-intended family and friends to alternative healthcare providers and those marketing products or selling publications touting dietary approaches. Coupled with the limited training and knowledge of nutrition by many health-care providers, including physicians and nurses, a survivor is frequently confused or easily misled. Although definitive and detailed guidelines are not possible at the present, the following provides a framework for

communicating with patients and directing future survivorship research.

Active treatment phase

Cancer treatment often includes surgery, radiation, chemotherapy, or biologic treatments, as well as combinations of approaches as multimodality interventions are established for a greater number of clinical scenarios. The key to guiding a patient undergoing therapy is to individualize the nutritional support. The care team should monitor individual needs through assessment of body weight, lean body mass, and the presence of eating or digestive impairments. Treatments for some cancers may compromise nutritional status as a result of impairment of food intake, digestion, absorption, and metabolism of nutrients. For example, loss of appetite, nausea, vomiting, altered taste and smell perception, constipation, and diarrhea may transiently occur. Individually tailored interventions to nutritionally support a patient during these periods will enhance quality of life. In some patients, maintaining adequate energy intake is an obstacle, and specific commercially prepared and tested nutritional products can easily be incorporated into a diet plan. Early referrals of patients at high risk for nutritional complications to a RD can prevent the development of more severe malnutrition that may limit the ability of the medical team to provide the optimal treatment intensity.³⁷

The use of nutritional supplements during cancer therapy is controversial, and few studies have been conducted to provide detailed guidance. For example, vitamin supplements with high doses of antioxidants (vitamins C or E, selenium, etc.) during chemotherapy or radiation therapy are considered by some clinicians to potentially reduce the efficacy of treatments that may depend on oxidative stress in the cancer cell as the mechanism of action. However, others suggest that antioxidant supplements may provide a benefit to patients by limiting damage to normal tissues, such as bone marrow. In general, it is judicious for clinicians to advise patients undergoing chemotherapy or radiation therapy to limit antioxidants to levels that do not exceed the RDAs and avoid other products that contain herbals or extracts enriched in antioxidant components. Folic acid is one nutrient where large dosages exceeding the RDA could influence the outcome of chemotherapy with agents such as methotrexate or 5-fluorouracil (5-FU) that target metabolic pathways involving folate. Daily supplements containing folate above the RDA should be discouraged for these patients.³⁷

Recovery following treatment

The days and weeks following completion of intensive treatment are points in the cancer care continuum where many patients explore dietary and nutritional interventions to enhance survivorship. During this period, the frequency of contact with health-care providers lessens, and the patient is concerned about the efficacy of treatment and recovery from therapy. Diet and physical activity should be a component of the treatment plan with the goal of restoring muscle mass and functional status. Health-care providers must continue to question patients regarding supplements and alternative medical treatments and provide counseling as needed. Continuing individualized nutritional evaluation will identify those with more serious long-term nutritional complications of therapy, such as dysphagia, malabsorption, and bowel changes common in those treated for cancers of the oral pharynx, esophagus, stomach, pancreas, bowel, and others. A focus on energy balance and ensuring adequate intake of essential nutrients is critical. For example, gastric surgery or resection of the terminal ileum may lead to a vitamin B12 deficiency unless parenteral administration is initiated.³⁷ Consultation with a RD can provide each individual with a risk assessment and personalized counseling.

Advanced cancer

In general, progressive cancer is associated with a loss of appetite, and, if a patient does not succumb quickly to a complication of the disease or co-morbid condition, progressive weight loss and other features of malnutrition will become evident. Unfortunately, many families and caretakers have the impression that reversal of the nutritional deficits will significantly prolong life. In reality, the failure to control the growth of the cancer, rather than malnutrition, is the critical issue. Frequently, the patient and caregivers experience conflict based on loss of appetite and food consumption. The medical team should be alert in order to identify conflicts centering on food, help establish understanding, and provide guidance to families. In the setting of advanced disease, dietary and nutritional interventions can contribute to a sense of well-being and quality of life. Dietitians and the medical team can assist the patient in altering food choices and eating patterns and help maintain nutritional status in the setting of advanced disease often complicated by pain-control issues and the resulting constipation caused by narcotic analgesics. Some medications can be coupled with limited physical activity to enhance appetite and improve bowel function. In some cases, additional nutritional support may be indicated.³⁷

Prevention of cancer recurrences and long-term complication of therapy

The patient who achieves a complete remission from cancer is concerned about the reappearance of the primary cancer. Additionally, survivors of certain cancers are at greater risk of second primaries. Indeed, survivors of oral or lung cancer may experience a ~10% chance of a second tobacco-related primary cancer yearly. Many cancer survivors are also at risk for cancers of other sites, which are often related to treatment; for instance, patients cured of testis cancer via treatment with etoposide-based chemotherapy are at a higher risk for secondary leukemia, and survivors of adolescent lymphoma treated with mediastinal radiation have a higher risk of secondary breast cancer. Very little research has been undertaken to establish optimal dietary patterns to prevent recurrent disease or second primaries at the same or different sites. In general, most experts will focus on the dietary recommendations summarized at the beginning of this chapter and by various groups for the prevention of cancer.^{1, 5, 37}

As the population of cancer survivors expands and physicians continue to monitor them over longer periods, long-term complications of treatments that are potential targets of dietary interventions are becoming apparent. For example, premature menopause in women treated with chemotherapy for breast cancer may contribute to accelerated osteoporosis²²⁵ that may require alterations in dietary calcium and physical activity. Mediastinal radiation in young adults and children may contribute to premature coronary atherosclerosis. Medical caregivers should emphasize early interventions with dietary and exercise patterns that will maintain healthy blood cholesterol and triglyceride profiles. Although very little research concerning diet and nutrition has been accumulated to provide clear guidance to cancer survivors thus far, we anticipate that future efforts in this area will expand rapidly as a result of patient demands and the response of the National Institutes of Health through their support of survivorship research.

Chapter 37

Chemoprevention of cancer

William N. William, Jr. MD ■ Waun Ki Hong, MD ■ Scott M. Lippman, MD

Overview

The field of cancer chemoprevention is underpinned by two phenomena of neoplasia: field carcinogenesis and multistep carcinogenesis. Accurate cancer risk models are critical to chemoprevention and may accelerate drug development in this setting. The Food and Drug Administration has approved several chemoprevention strategies. This chapter describes completed chemoprevention clinical trials focused on the four major cancer sites in the Western world (lung, colon and rectum, prostate, and breast), as well as site-agnostic chemoprevention studies. The contributions of vaccines to cancer prevention are also discussed.

Biology of chemoprevention

The field of cancer chemoprevention is underpinned by two phenomena of neoplasia: (1) field carcinogenesis, which is the multifocal development of intraepithelial neoplasia (IEN, or precancer) or the clonal spread of one or more IENs, and (2) multistep carcinogenesis, which is driven by genetic instability and accumulates progressive genetic and epigenetic changes.^{1–4} These processes spur evasion of apoptosis, strong replicative potential, and sustained angiogenesis leading to IEN and cancer development. Multistep carcinogenesis allows chemopreventive interventions at step(s) of neoplasia that precede invasive cancer. Drugs developed for cancer therapy can be examined for cancer chemoprevention because of important commonalities—including genetic and epigenetic abnormalities, loss of cellular control, and certain phenotypic characteristics—between cancer and multistep IEN.⁵ Field carcinogenesis makes approaches such as systemic agents attractive for controlling the neoplastic results of diffuse exposure to carcinogens throughout an epithelial field. The FDA has approved several treatments for IEN.

Cancer risk modeling

Accurate cancer risk models are critical to chemoprevention. Models based on clinical/demographic factors have been developed for breast cancer risk (Gail model) and lung cancer risk (Spitz model), and established identifiers of increased risk include precursor clinical/histologic lesions.^{6, 7} These risk models and lesions are useful on a population-wide basis but are less helpful in identifying individual or personalized risk. Recent work showed that clinical lung cancer risk models integrating genomics (somatic gene-expression arrays and host DNA-repair capacity) and metabolomics assessed risk more accurately than did the clinical models alone.^{8–10} Barrett's esophagus is a well-established but modest predictor of absolute esophageal cancer risk, whereas a striking model incorporating certain loss of heterozygosity (LOH) and DNA-content profiles with Barrett's distinguished between populations with a high (79% in 6 years) and low (0% in over 6 years) esophageal cancer risk.¹¹ In oral leukoplakia, LOH at

specific loci in chromosomes 3p and/or 9p confers a substantially increased risk of oral cancer (vs oral leukoplakia without such LOH)^{12–14} especially in patients with a previously treated oral cancer,¹⁵ and this marker was used as a selection criterion in the first and only personalized, molecularly based, randomized oral cancer chemoprevention trial completed till date—the Erlotinib Prevention of Oral Cancer study.^{16, 17} A high cancer risk is associated with a specific cyclin D1 genotype (adenine/guanine single-nucleotide polymorphism at position 870 of exon 4 of the cyclin D1 gene)¹⁸ in patients with dysplastic oral and/or laryngeal premalignant lesions. Recent work has shown that high cyclin D1 protein expression plus the high-risk cyclin D1 genotype further increased the cancer risk of laryngeal dysplasia patients.¹⁹ As such, selection of high-risk individuals for chemoprevention based on cancer risk modeling is considered a key factor to increase the therapeutic index of any given intervention, leading to successful drug development in this area.

Chemoprevention trials

This section describes completed chemoprevention clinical trials focused on the four major cancer sites in the Western world (lung, colon and rectum, prostate, and breast), as well as site-agnostic chemoprevention studies. The contributions of vaccines to cancer prevention are also discussed.

The lung

Premalignancy

Clinical and translational chemoprevention trials, including five negative randomized trials of retinoids in smokers with metaplasia, have had little to no effect in reversing lung premalignancy.²⁰ Despite the general negative results, encouraging phase IIb data have emerged from studies of 9-*cis*-retinoic acid modulation of RAR- β and Ki-6,^{21, 22} myo-inositol modulation of the PI3 kinase gene-expression pathway,²³ budesonide modulation of computed tomography-detected peripheral nodules,²⁴ and anethole dithiolthione²⁵ and iloprost²⁶ modulation of bronchial dysplasia.

Prevention of primary lung cancer

The *National Cancer Institute*-sponsored Alpha-Tocopherol, Beta-Carotene (ATBC) Cancer Prevention Study was a phase III trial of α -tocopherol and β -carotene to prevent primary lung cancer. The ATBC study involved 29,133 male smokers between 50 and 69 years of age who had smoked an average of one pack of cigarettes a day for approximately 36 years.²⁷ This trial's 2×2 factorial design called for α -tocopherol (50 mg/day) and β -carotene (20 mg/day) to be given in a randomized, double-blind, placebo-controlled fashion. The factorial design allowed the study scientists to assess the individual effects of each agent. Significant increases in lung cancer incidence (18% increase, $p = 0.01$) and total mortality (8%, $p = 0.02$) occurred in the β -carotene-treated subjects after 6.1 years' median follow-up. α -Tocopherol had no significant impact on the lung cancer mortality rate, and there was no evidence of an interaction between α -tocopherol and β -carotene.²⁸

The Beta-Carotene and Retinol Efficacy Trial (CARET) tested the combination of β -carotene (30 mg/day) plus retinyl palmitate (25,000 IU/day) in 17,000 smokers and asbestos workers.²⁹ It confirmed the major finding of the ATBC study with its primary finding that the β -carotene combination increased lung cancer risk in this high-risk population. There was no evidence from either the ATBC study or the CARET that β -carotene increased lung cancer risk in nonsmokers, or former or moderate (<1 pack a day) smokers.

SPT prevention

Two large-scale phase III retinoid trials have been completed in the setting of second primary tumor (SPT) prevention: one in Europe (investigating retinyl palmitate and/or *N*-acetyl-L-cysteine)³¹ and the other in the United States (investigating low-dose 13cRA).³² Neither demonstrated a reduction in SPT in the population overall. Selenium also failed to prevent SPTs compared with placebo in a RCT of 1151 patients with resected stage I nonsmall cell lung cancers.³³

Colon and rectum

Colorectal trial designs have primarily employed the intermediate end points of adenomatous polyp development and response and hyperproliferation markers.

Sulindac and celecoxib can effectively treat (but not prevent) adenomas in individuals with familial adenomatous polyposis (FAP).^{34, 35} High-dose celecoxib (800 mg/day) reduced large-bowel polyposis by 28% and duodenal polyposis, which is difficult to resect, by 14% (vs placebo).³⁶ These studies led to the interim FDA approval of celecoxib as an adjunct to endoscopic and surgical treatment of FAP patients. However, the labeled indication for polyp management in FAP patients was withdrawn due to challenges in conducting confirmatory trials in this high-risk setting. Calcium (1200 mg/day) reduced the risk of sporadic adenomas by 15% overall³⁷ and even more in later-stage disease (vs placebo). The CAPP-1 and CAPP-2 trials examined aspirin (600 mg q.d.) in subjects with the hereditary colorectal cancer (CRC) syndromes of FAP and Lynch syndrome, respectively. CAPP-1 identified a nonsignificant reduction (23%) in polyp count and a trend toward reduced largest polyp size within the aspirin-treated group, after a median of 17 months of intervention. CAPP-2 found a significant reduction in risk of CRC (59%) only in subjects completing at least 2 years of intervention after a mean of 55.7 months of follow-up.^{38, 39}

Four RCTs have tested the efficacy of aspirin in preventing sporadic adenomas, showing significant reductions in recurrent adenomas among patients treated for 1 or more years.^{40–43} There was no protective effect of aspirin on CRC risk in men and women in the Physician's Health Study and Women's Health Study (WHS). However, after an overall follow-up time of 18 years, recent results from the WHS indicate a significantly reduced risk for CRC in healthy women.⁴⁴ Recent pooled analyses of the British Doctors Aspirin Trial and the UK Transient Ischaemic Attack Aspirin Trial found that aspirin was associated with a significant 26% reduction in CRC risk. The effect was greatest with at least 5 years treatment and did not appear for at least 10 years.⁴⁵ The latter results are consistent with a recent, very large cohort study involving over 47,000 men from the Health Professionals Follow-up Study, which found a significant dose- and duration-related reduction in CRC risk.⁴⁶

Three RCTs assessed coxibs (vs placebo) in preventing sporadic adenomas in patients with a prior history of colorectal polyps. The Adenomatous Polyp Prevention on Vioxx (APPROVe) trial tested rofecoxib, and various doses of celecoxib were tested in the APC and Prevention of Colorectal Sporadic Adenomatous Polyps (PreSAP) trials. Interim cardiovascular event rates were unexpectedly higher in APPROVe and APC but not PreSAP.^{47–49} The relevant data and safety monitoring committees stopped all three RCTs early because of these safety issues, despite significant activity against colorectal adenomas, and rofecoxib was withdrawn from the world market by the manufacturer. In APPROVe (2587 randomized subjects), rofecoxib reduced adenomas by 24%.⁵⁰ In the APC (2035 randomized patients), adenoma rates were significantly different at 37.5% (celecoxib, 400 mg twice daily), 43% (celecoxib, 200 mg twice daily), and 60% (placebo) ($p < 0.001$)⁵¹; serious cardiovascular adverse event rates significantly increased in a dose-dependent manner. The PreSAP trial with 1561 randomized patients

found incidences of adenomas of 33.6% (celecoxib, 400 mg once daily) and 49.3% (placebo) ($p < 0.001$).⁴⁷ The risk of cardiovascular events did not increase in the PreSAP trial. In a recent extension analysis of APC patients, it appeared that the serious cardiovascular event rate wore off 2 years after stopping the drug and that a repression of adenomas persisted (albeit diminished), particularly for advanced adenomas. Results of a recent pooled analysis of the major celecoxib placebo-controlled trials (double-blind and planned follow-up of at least 3 years in nonarthritis disease settings) suggested that there was no increase in serious cardiovascular events at any studied dose (up to 400 mg b.i.d.) in people with a low-baseline cardiovascular risk (about 15–20% of people on these trials). These results strongly suggest that low-baseline cardiovascular risk can improve risk-benefit and help in selecting patients for future COX-2-specific NSAID (nonsteroidal anti-inflammatory drug) trials.⁵²

Trials of vitamins and diet (low-fat, high fruits and vegetables and fiber) for reducing colorectal adenoma risk have had largely negative results.^{53, 54} Calcium reduced adenoma risk by a modest statistically significant 19%,³⁷ which persisted in long-term follow-up.⁵⁵ Two RCTs of folate showed no reduction in adenoma risk with a 0.5- or 1-mg/day dose; a subset analysis of one study suggested that folate (1 mg/day) may even increase the risk of advanced or multiple adenomas.^{43, 56}

Preclinical studies of low doses of DFMO and sulindac supported an RCT of combined oral DFMO (500 mg) and sulindac (150 mg; vs placebo) for 36 months in 375 patients with a history of resected (≥ 3 mm) adenomas [stratified by use of low-dose aspirin (81 mg) at baseline and clinical adenoma site].⁵⁷ Colorectal adenoma recurrence rates were as follows: one or more adenomas—41.1% placebo versus 12.3% (combination; relative risk (RR) 0.30; 95% confidence interval (CI), 0.18–0.49; $p < 0.001$); one or more advanced adenomas—8.5% (placebo) versus 0.7% (combination; RR 0.085; 95% CI, 0.011–0.65; $p < 0.001$); multiple adenomas—13.2% (placebo) versus 0.7% (combination; RR 0.055; 95% CI, 0.0074–0.41; $p < 0.001$). Combination chemoprevention has been long believed to have great potential for enhancing the activity and reducing the toxicity of active single agents, a belief that is reinforced by the landmark advance of this combination trial.

The breast

Based on highly significant positive results of the Breast Cancer Prevention Trial (BCPT), the selective estrogen-receptor modulator (SERM) tamoxifen became the first chemopreventive agent to earn FDA approval. Conducted by the National Surgical Adjuvant Breast and Bowel Project (NSABP), the BCPT compared tamoxifen with placebo in preventing breast cancer in 13,388 women at high-risk of this disease.⁵⁸ The major high-risk eligibility criteria were age >60 years and history of lobular carcinoma *in situ* (LCIS), or women from 35 to 59 years old with 5-year breast cancer risk of 1.66% based on the Gail model. The actual overall average, 5-year baseline, breast cancer risk was 3.2%. At a median follow-up of 55 months, primary invasive breast cancer findings for the tamoxifen and placebo groups were 89 versus 175, respectively, for a 49% relative reduction ($p < 0.00001$). The relative breast cancer risk reduction was similar for all age and risk groups and was limited to ER (estrogen-receptor)-positive tumors. Tamoxifen nonsignificantly reduced overall and breast cancer mortality. Beneficial secondary findings included 19% fewer fractures in the tamoxifen group. Secondary adverse findings associated with tamoxifen were increased endometrial cancers, vascular events, and cataracts.

Although the BCPT successfully completed testing its primary hypothesis, it also raised several key unresolved issues, such as effects on mortality, optimal tamoxifen duration, generalizability of results, and the issue of prevention versus treatment. The FDA subsequently approved tamoxifen for breast cancer risk reduction in high-risk women. The FDA recommendation is 20 mg/day for 5 years for high-risk women

and warns of tamoxifen-associated risks. The FDA also approved tamoxifen for reducing the incidence of contralateral breast cancers, based on consistent secondary adjuvant data.⁵⁹

The NSABP B-24 study tested 5 years of tamoxifen (20 mg/day) versus placebo after resection and radiation in 1804 patients with ductal carcinoma *in situ* (DCIS).⁶⁰ At a median follow-up of 74 months, 5-year incidences of all breast cancer events (invasive and noninvasive) were 8.2% and 13.4% in the tamoxifen and placebo groups, respectively, representing a 43% relative risk reduction ($p = 0.0009$). The cumulative incidence at 5 years of all invasive breast cancer events in the tamoxifen group was 4.1% versus 7.2% in the placebo group ($p = 0.004$). The FDA approved tamoxifen for risk reduction in the setting of locally treated (resection and radiation) breast DCIS.

The International Breast Cancer Intervention Study (IBIS-I) randomized 7410 women and showed a 32% reduction in breast cancer risk with tamoxifen.⁶⁰ The positive results in this trial and the BCPT (the two stronger RCTs in this setting) were limited to ER-positive cancers. A report of the long-term follow-up of IBIS-I suggests that the beneficial tamoxifen effects on breast cancer risk reduction persist for at least 10 years, but most side effects resolve after the 5-year treatment period, including all serious adverse events (e.g., thrombotic events and endometrial cancer).⁶¹ These long-term findings have important implications for the risk/benefit profile of tamoxifen for prevention.

The Study of Tamoxifen and Raloxifene (STAR) tested the SERM raloxifene against its fellow SERM tamoxifen for better efficacy and lesser toxicity in breast cancer prevention.⁶² A total of 19,747 postmenopausal women with an increased risk of breast cancer were randomized to tamoxifen (20 mg/day) or raloxifene (60 mg/day) for 5 years. On long-term follow-up, raloxifene had slightly higher rates of invasive breast cancer (RR 1.24; 95% CI, 1.05–1.47), but produced fewer cases of uterine cancer than tamoxifen (RR 0.55; 95% CI, 0.36–0.83). Furthermore, the risks of thromboembolic events and cataracts were statistically significantly lower with raloxifene than with tamoxifen. Tamoxifen and raloxifene had similar effects in reducing noninvasive breast cancer.⁶³ Raloxifene was approved by the FDA for invasive breast cancer risk reduction in postmenopausal women at a high such risk or with osteoporosis.

Following these seminal trials, the chemopreventive effect of third-generation SERMs was investigated. The Postmenopausal Evaluation and Risk-Reduction with Lasofoxifene Trial studied the effects of lasofoxifene in postmenopausal women with low bone mineral density (BMD),^{64, 65} showing a 79% reduction of invasive breast cancer and an 83% reduction in ER-positive breast cancer. A similar phase III prevention trial, known as the Generations Trial, reported a 56% decrease in invasive breast cancers in postmenopausal women with low BMD treated with arzoxifene.^{66, 67} These trials found that both lasofoxifene and arzoxifene reduce the risk of nonvertebral and vertebral fractures; however, these third-generation SERMs, like raloxifene and tamoxifen, still increase the risk of venous thromboembolic events.

A recent meta-analysis that included all nine of the large-scale phase III SERM prevention trials⁶⁸ found that both overall and ER-positive breast cancer incidence is decreased by SERMs, and that DCIS incidence is decreased by all SERMs analyzed except raloxifene.

Based largely on results of the Anastrozole, Tamoxifen Alone or in Combination (ATAC) trial,⁶⁹ there has been great interest in aromatase inhibitors for breast cancer prevention in postmenopausal women. The Mammary Prevention 3 trial randomized 4560 postmenopausal high-risk women to receive 25 mg of exemestane or placebo for 5 years. There was a 65% reduction in the annual incidence of invasive breast cancer in favor of exemestane (hazard ratio (HR) 0.35; 95% CI, 0.18–0.70). There were no differences

between the groups in bone fractures, cardiovascular events, or other cancers.⁷⁰ The IBIS-II trial evaluated anastrozole 1 mg daily versus placebo for 5 years in 3864 high-risk postmenopausal women and also demonstrated a reduction in the incidence in invasive breast cancer in favor of the aromatase inhibitor (HR 0.47; 95% CI, 0.32–0.68). Anastrozole also reduced the incidence of skin, gynecologic, gastrointestinal, and other cancers. More aches and pains, joint stiffness, vasomotor symptoms, dry eyes, and hypertension were seen in the anastrozole group, but there was no statistical significant difference in the incidence of fractures between the arms.⁷¹ To date, no agent has proven efficacy in the prevention of ER-negative breast cancer, although a number of drugs are under investigation.

The prostate

Prostate carcinogenesis is an androgen-driven process, and a large-scale RCT, the Prostate Cancer Prevention Trial (PCPT), tested finasteride (5 mg/day), which inhibits 5- α -reductase from converting testosterone into the more potent androgen dihydrotestosterone, versus placebo for 7 years in 18,882 men 55 years of age or older who had normal digital rectal exam (DRE) and prostate-specific antigen (PSA) level. Finasteride not only reduced the 7-year prostate cancer prevalence by 24.8%⁷² but also appeared to increase high-grade disease—6.4% (finasteride) versus 5.1% (placebo). Finasteride also reduced the risk of high-grade prostatic IEN.⁷³ PCPT analyses also indicated a reduction in benign prostatic hypertrophy symptoms and an increase in sexual side effects, although a recent detailed analysis found that the effect of finasteride on sexual functioning was minimal.⁷⁴ Secondary PCPT findings indicated a high risk of prostate cancer, including high-grade disease, among men with normal PSA levels⁷⁵ and differences in PSA screening performance in men taking or not taking finasteride.^{76, 77} The adverse high-grade disease finding has sharply limited public interest in finasteride for prostate cancer prevention, and another major concern is that intensive PSA/DRE screening and early detection of prostate cancer in the PCPT could mean that finasteride may have prevented clinically “insignificant” more than “significant” prostate cancer. Several analyses, however, challenge these concerns.^{77–83} A recent long-term (18-year) follow-up report attempted to address the significance of the high-grade finding (e.g., finasteride-driven artifact vs new finasteride-induced high-grade cancers) and found no significant between-group difference in the rates of overall survival or survival after the diagnosis of prostate cancer.⁸⁴

The Reduction by Dutasteride of Prostate Cancer Events study compared dutasteride 0.5 mg/day versus placebo in 8231 men 50–75 years of age, with a PSA level between 2.5 and 10 ng/mL and a negative prostate biopsy within 6 months. Participants underwent ultrasound-guided biopsies at years 2 and 4 of treatment. There was a 22.8% relative risk reduction in prostate cancer favoring dutasteride (95% CI, 15.2–29.8; $p < 0.001$). There were 29 and 19 cancers with Gleason scores of 8–10 in the dutasteride and placebo groups, respectively ($p = 0.15$) over years 1 through 4; however, during years 3 and 4, there were 12 tumors with Gleason scores of 8–10 in the dutasteride group, and only 1 in the placebo group ($p = 0.003$). Acute urinary retention was less frequent, but the composite end point of cardiac failure as well as erectile dysfunction and loss of libido was more common in the dutasteride group.⁸⁵

Another very large RCT, the Selenium and Vitamin E Cancer Prevention Trial (SELECT), recently discontinued supplements and reported results demonstrating that selenium or vitamin E, alone or in combination, did not prevent prostate cancer at the doses and formulations used in a heterogeneous population of 35,533 relatively healthy men. A harmful trend for increased risk of prostate cancer in the vitamin E arm ($p = 0.06$; RR 1.13; 99% CI, 0.195–1.35)⁸⁶ became statistically significant on further follow-up.⁸⁷ A recent follow-on analysis of SELECT investigated whether selenium or vitamin E might benefit men with low-baseline selenium. Contrary to this hypothesis, there was no evidence of benefit of

the intervention in the low-baseline selenium group; in fact, vitamin E supplementation actually increased the risk of total prostate cancer by 63% in men with low-baseline toenail selenium, and this effect was even stronger for high grade.⁸⁸

Vaccines

The proof of principle of vaccinating against infection-related cancer was provided in Taiwan, where vaccinating children against hepatitis B has dramatically reduced the incidence and the mortality of liver cancer.⁸⁹

HPV infection is an established major risk factor for cervical cancer, and molecular targeting through immunization against infections related to neoplasia is a very successful way to prevent early steps of host cell damage that otherwise can lead to cancer. The landmark advances of cancer chemoprevention are the relatively recent RCTs of HPV vaccines to prevent HPV infection in girls and young women and subsequent FDA approval of HPV vaccination in this setting.

The placebo-controlled (phase III) trial, Females United to Unilaterally Reduce Endo/Ectocervical Disease (FUTURE) I, evaluated the role of quadrivalent vaccine against HPV types 6, 11, 16, and 18 in preventing anogenital diseases in women aged 16–24 years. The co-primary composite end points were the incidence of genital warts, vulvar or vaginal IEN, or cancer and the incidence of cervical IEN, adenocarcinoma *in situ*, or cancer associated with HPV types 6, 11, 16, or 18 in a per-protocol susceptible population of women without virologic evidence of HPV infection. The vaccine efficacy was 100% for each of the co-primary end points.⁹⁰ Similarly, the FUTURE II study found that the quadrivalent vaccine reduced the risk of the primary composite end point [cervical IEN (grades 2 and 3), adenocarcinoma *in situ*, or cancer-related to HPV types 16 or 18] by 98% in women between ages 15 and 26 years with no virologic evidence of HPV types 16 or 18.⁹¹ Another phase III trial tested a bivalent (HPV types 16 and 18) vaccine in 18,644 girls and women aged 15–25 years. The primary end point, grade 2 cervical IEN associated with HPV types 16 or 18, was reduced by 90% in women with no evidence of prior HPV infection.⁹² In a community-based, randomized, control trial in young women aged 18–25 years, the bivalent vaccine has been demonstrated to have high efficacy against HPV types 16 or 18 persistent infection and partial cross-protection against HPV types 31, 33, and 45.⁹³

In males, the quadrivalent HPV vaccine has also been shown to reduce HPV infections and development of related external genital lesions,⁹⁴ as well as anal IEN.⁹⁵ Oral HPV infections are also reduced by HPV vaccination in women (bivalent vaccine), but it is unknown whether this will eventually translate into prevention of HPV-related head and neck squamous cell carcinomas.⁹⁶ HPV vaccines have not been shown to accelerate HPV clearance and so are unlikely to prevent cancer in already infected patients.⁹⁷

Overall cancer

Two important large US trials have tested the ability of β -carotene to reduce overall cancer incidence. The Physicians' Health Study (PHS) was a 12-year test of β -carotene effects on overall cancer incidence.⁹⁸ β -Carotene produced no significant differences in overall incidence of cancer (including lung cancer). Only 11% of this population were current smokers. Similar β -carotene results of the Women's Health Study were reported.⁹⁹ Recently, the results of the PHS II were reported. This large-scale ($N = 14,641$ men), randomized, placebo-controlled study demonstrated that daily low-dose multivitamin led to a statistically significant reduction in the incidence of total cancer compared with placebo (17.0 and 18.3 events, respectively, per 1000 person-years; HR 0.92, 95% CI, 0.86–0.998; $p = 0.04$), primarily in individuals with a prior cancer history. There were no reductions in the incidence of site-specific

cancers.¹⁰⁰ The clinical significance of this modest effect is yet to be determined.

Conclusions

Clinical cancer chemoprevention has matured with the FDA approvals of several agents to prevent cancer or to treat or prevent IEN, most recently raloxifene is used for preventing invasive breast cancer in high-risk women and HPV vaccine is used for anogenital cancer prevention. The current list of FDA-approved agents for cancer prevention includes diclofenac, Photofrin [in conjunction with photodynamic therapy (PDT)], tamoxifen, hepatitis B vaccine, bacillus Calmette–Guerin, valrubicin, masoprocol, 5-FU, aminolevulinic acid (with PDT), and HPV vaccine. Personalized approaches to identify patients most likely to benefit and least likely to be harmed by particular interventions are evolving from continued study of aspirin and celecoxib in colorectal neoplasia. One of the most promising current directions of cancer chemoprevention is combined agents. The concept that combinations can increase the ratio of benefit (activity) to risk (toxicity) for effective single agents received strong support from the stunning colorectal adenoma results of the DFMO-sulindac trial discussed earlier. Based on this trial, chemopreventive combinations may be at the threshold of becoming a standard clinical reality, and other active combinations should be moved into clinical trials.¹⁰¹

Summary

Cancer chemoprevention is beginning to add impressive data to the long list of advances resulting from cancer therapy. There have been several exciting developments in clinical chemoprevention, including, for example, the US Food and Drug Administration (FDA) approval of tamoxifen for reducing the risk of preinvasive and invasive breast cancer in the late 1990s, followed by subsequent FDA approvals of raloxifene for reducing the risk of invasive breast cancer and of human papillomavirus (HPV) vaccine for reducing cervical neoplasia risk. More recently, aromatase inhibitors have been shown to prevent breast cancers in postmenopausal women, with a favorable side effect profile. A randomized controlled trial (RCT) of combined sulindac and difluoromethylornithine (DFMO) achieved an extraordinary 70% reduction in colorectal adenomas (>90% in advanced adenomas) highlighting the chemoprevention focus on combined agents and signaling, perhaps the near realization of this approach in standard clinical practice.

Chapter 38

Cancer screening and early detection

Otis W. Brawley, MD, MACP

Overview

Cancer screening is an intervention to find cancer at an early stage. The primary goal of screening is to reduce the mortality from the disease being screened for. Secondary is to successfully treat the disease with the least morbidity. In order for screening to be effective, the disease must have a phase in its natural history in which the disease is localized and therapeutic interventions can successfully stop disease progression. The natural history of some cancers is such that screening is not effective. One can best assess a disease as screenable and a screening intervention as useful through a prospective randomized in which people at risk for the cancer are enrolled and randomized to the screening intervention, which is administered on a regular basis or not to get the screening intervention. People who are diagnosed with the disease on both arms should have access to adequate treatment. Over time, the death rate from those who were to be screened is compared to those who were not to be screened. Of note, assessment should be by intention to screen. A successful screening test reduces the death rate. Assessment through a prospective randomized trial is important as some screening tests have been associated with an increase in overall and 5-year survival rate without a decrease in mortality or risk of death. Indeed, the benefit and risk of a screening test is important in determining whether a screening test should be recommended or used.

Cancer screening is a means of early detection of malignancy in an asymptomatic individual at risk for a disease. A positive test indicates that disease may be present and additional “diagnostic” testing is necessary to confirm the presence and extent of disease. In a symptomatic person, the same test is often considered “diagnostic” rather than screening.¹

The purpose of screening is not simply to find disease, but to reduce the incidence of advanced disease, and find disease at a point in its natural history where treatment will prevent death. In clinical study, prevention of death is demonstrated by reduction in cancer mortality rates.² Some screening tests decrease morbidity associated with treatment and/or improve quality of life. Some screening efforts now focus on identifying and treating precursor lesions to prevent malignancy.

Key criteria for screening

Cancer screening is most effective and efficient if performed for diseases with high prevalence and significant population impact. The *sojourn time* is the period in which an occult tumor can be detected by screening before metastasis or the onset of symptoms.² For successful screening, the sojourn time should be sufficiently long to allow periodic screening to detect cancer in the target population before disease has spread; treatment of disease should have greater benefit when given before compared to after symptom onset; and the screening test should meet acceptable levels of accuracy and cost.¹

Evaluation of early detection programs

Evaluation of a screening test should assess whether the test finds cancer, truly increases survival time, and whether subjects have a lower risk of dying from the disease as a result of screening. Evaluations of screening tests outside the context of a rigorous research design are subject to many biases that can invalidate the conclusions drawn.

Potential biases in the evaluation of screening

Lead-time bias: The time from an occult condition being detected by screening and the moment that condition would have become known through development of symptoms is known as the *lead time*. There is always a bias toward better survival in a screened group because screening moves the point of diagnosis earlier. True lead time bias occurs when earlier detection only advances the time of a patient's diagnosis, without prolonging life ([Figure 1](#)). Because of the effect of lead-time bias, an increase in survival or improved 5-year survival rates cannot be used alone to assess a screening test.

Length bias is the bias toward detection of less-threatening cancers ([Figure 2](#)). Cancers that grow more slowly and have a long sojourn time are more likely to be detected in screening. Faster growing, more aggressive, cancers with a short sojourn time are more apt to escape detection and be diagnosed due to symptoms in between scheduled screens. A cohort of cancer patients with screen-detected tumors will have a higher proportion of slow growing tumors compared to a population diagnosed without screening, and thus will appear to have better survival.

Overdiagnosis is the concept that some tumors fulfill all histologic criteria of malignancy, but are not destined to cause death and would not have become known to the patient without screening ([Figure 3](#)).³ Overdiagnosis is an extreme example of length bias. There are two kinds of overdiagnosis. First is the disease that histologically is indistinguishable from precancer or cancer but has no biological propensity to progress.⁴ This is common among screen-detected premalignant lesions of the uterine cervix and cancers of the prostate and thyroid.⁵ Second are tumors that can be lethal, but not in the specific patient because she/he would have died from another cause during the sojourn time.⁴ A persistently higher incidence rate within a population can be due to lead-time or the introduction of unscreened cohorts into a screening program and overdiagnosis.

Figure 1 The natural history of cancer. In this figure, $t_2 - t_0$ is the duration of the preclinical screen-detectable period, known as the “sojourn time”; $t_2 - t_1$ is the amount of time by which the diagnosis is advanced by screening, known as the “lead time.” Under the assumption of an exponential distribution of sojourn time, the expected lead time of an individual screen-detected case is equal to the mean of the distribution of the sojourn time.

Figure 2 Lead-time bias. In this figure, Dx is the time of diagnosis. Note that the screen-detected cases and the cases diagnosed with symptoms each die at the same time, but the survival time looks greater in the screen-detected case because of lead-time bias.

Figure 3 Length bias. In this figure, the horizontal lines represent the sojourn times of individual tumors detected in a screening program. The two screening examinations detect six out of eight long sojourn time tumors, but only two out of six short sojourn time tumors.

Selection bias is the concept that individuals who participate in screening may differ from those who do not, that is, they may be more health conscious, more likely to control risk factors, more disease aware, more adherent to treatment, and generally live healthier lives.⁶ Selection bias can give the appearance of better screening outcomes than expected and may even limit the generalizability of results of studies designed to overcome the influence of selection bias. For example, current and former smokers who entered the National Lung Screening Trial (NLST) had substantially less emphysema, cardiac disease, and diabetes compared to a representative sample of Americans.⁶

A unique form of selection bias can occur in a randomized trial in which subjects in the intervention arm are consented, while those in the control arm are not aware they are being followed in the study. Less-healthy individuals in the intervention arm may refuse participation, while those in the control arm cannot.⁷

Characteristics of a screening test

Sensitivity and Specificity: Sensitivity or the positive rate is the probability of a positive result when applied to a person who truly has the disease. Specificity or the true negative rate is the probability of a negative result in a person who does not have the disease ([Table 1](#)). Both high sensitivity and high specificity are desirable in a screening test. Unfortunately, they tend to be negatively correlated. While tests with high sensitivity succeed at detecting most occult disease, a test with low specificity will lead to many false positives and additional workup.

Table 1 Measures of screening performance

	Disease	Status
Screening test results	Yes	No
Positive	<i>a</i>	<i>b</i>
Negative	<i>c</i>	<i>d</i>

Sensitivity = $a/(a + c)$; specificity = $d/(b + d)$; positive predictive value (PPV) = $a/(a + b)$; negative predictive value (NPV) = $c/(c + d)$.

Positive and negative predictive values: The positive predictive value (PPV) is the probability that a

subject with a positive screening result actually has the disease ([Table 1](#)). The negative predictive value (NPV) is the probability that a subject who screens negative is truly free of disease and provides some quantification of the reassurance value of a negative test. It is arguably more important to have a high NPV, as this will mean that few disease subjects are missed and potentially have delayed diagnosis and treatment.

Efficacy versus effectiveness: Screening studies usually assess the *efficacy* of an intervention, that is, whether the test saves lives among the population enrolled in the trial. An additional question is the *effectiveness* of the intervention when it is widely used. A few large clinical trials come close to assessing effectiveness, although these studies may be influenced by healthy volunteer effects due to the consent process.¹ Ultimately, the effectiveness of a screening intervention should be assessed through program evaluation in “real-world” situations rather than experimental studies, in order to consider factors such as provider experience, improvements in screening technology over time, acceptability to the population, and cost effectiveness.

Research designs to evaluate a screening intervention

Descriptive studies are the easiest screening studies to perform and often provide the first evidence that screening may contribute to disease control. These are uncontrolled observations based on the experience of physicians, clinics, or cancer registries. Descriptive studies can yield useful information, but provide the weakest evidence owing to inherent biases and cannot establish efficacy because of the absence of a control group.

Case–control studies are typically retrospective studies comparing a group of patients (cases) who have an outcome of interest (disease, death, interval cancer, etc.) with a group of patients (controls) who do not, in order to examine factors that may have contributed to the outcome.⁸ Cases and controls are matched for key characteristics, such as age, gender, and socioeconomic status. Case–control studies are generally inexpensive and provide evidence more quickly than prospective studies.⁸ These studies are challenging owing to the need to avoid biases, and results can be easily confounded by uncontrolled factors.

Prospective randomized clinical trials (RCTs) are the most rigorous assessment of screening, in that they typically compare disease-specific mortality in a group randomized to receive a screening invitation with a group that receives usual care. The distorting effects of self-selection and other biases are minimized through randomization. The mortality endpoint is not subject to the effects of lead-time, length bias, or overdiagnosis. RCTs should be analyzed by intention-to-treat (ITT), meaning end results are based on comparisons between invited and uninvited groups rather than screened and unscreened groups. Analysis that includes only those who are screened introduces bias.

The large sample size required, the expense, and the long duration has limited the number of prospective RCTs conducted. Some have argued that all-cause mortality is preferred to disease-specific mortality as the primary endpoint, as it avoids potential biases in allocation of cause of death and avoids failure to measure other causes of death that may be an outcome of diagnostic and treatment interventions. The greater size and cost of an RCT measuring all-cause mortality makes them highly impractical.⁹

A number of medical and professional organizations review the scientific literature and develop screening recommendations or guidelines.⁵ The US Preventive Services Task Force (USPSTF) is known for using a very conservative process designed to minimize the influence of conflicts of interest, financial, intellectual, and emotional.¹⁰ These recommendations are available at www.uspreventiveservicestaskforce.org. The American Cancer Society (ACS) also publishes guidelines

([Table 2](#)). A number of medical specialty societies publish guidelines or screening recommendations for specific their disease.

Table 2 American Cancer Society screening guidelines for the early detection of cancer in average-risk asymptomatic people

Cancer site population test or procedure frequency			
Breast	Women, ages 40–44	Mammography	All women should become familiar with the potential benefits, limitations, and harms associated with breast cancer screening. Women should have the opportunity to begin annual mammographic screening between the ages of 40 and 44 years
	Women, ages 45–54	Mammography	Women with an average risk of breast cancer should undergo annual screening mammography starting at age 45 years
	Women, ages 55+	Mammography	Women who are 55 years and older should be screened every 2 years but may choose to continue annual screening
Mammography			
Cervix	Women, ages 21–65	Pap test & HPV DNA test	Cervical cancer screening should begin at age 21. For women ages 21–29, screening should be done every 3 years with conventional or liquid-based Pap tests. For women ages 30–65, screening should be done every 5 years with both the HPV test and the Pap test (preferred), or every 3 years with the Pap test alone (acceptable). Women ages 65+ who have had ≥3 consecutive negative Pap tests or ≥2 consecutive negative HPV and Pap tests within the past 10 years, with the most recent test occurring within 5 years, and women who have had a total hysterectomy should stop cervical cancer screening. Women should not be screened annually by any method at any age
Colorectal	Men and women, ages 50+	Fecal occult blood test (FOBT) with at least 50% test sensitivity for cancer, or fecal immunochemical test (FIT) with at least 50% test sensitivity for cancer, or	Annual, starting at age 50. Testing at home with adherence to manufacturer's recommendation for collection techniques and number of samples is recommended. FOBT with the single stool sample collected on the clinician's fingertip during a digital rectal examination is not recommended. Guaiac-based toilet bowl FOBT tests also are not recommended. In comparison with guaiac-based tests for the detection of occult blood, immunochemical tests are more patient-friendly, and are likely to be equal or better in sensitivity and specificity. There is no justification for repeating FOBT in response to an initial positive finding
		Stool DNA test, or	Every 3 years, starting at age 50
		Flexible sigmoidoscopy	Every 5 years, starting at age 50. FSIG can be performed alone, or consideration can be given to combining FSIG

		(FSIG), <i>or</i>	performed every 5 years with a highly sensitive gFOBT or FIT performed annually
		Double-contrast barium enema (DCBE), <i>or</i>	Every 5 years, starting at age 50
		Colonoscopy	Every 10 years, starting at age 50
		CT colonography	Every 5 years, starting at age 50
<i>Endometrial</i>	Women, at menopause		At the time of menopause, women at average risk should be informed about risks and symptoms of endometrial cancer and strongly encouraged to report any unexpected bleeding or spotting to their physicians
<i>Lung</i>	Current or former smokers aged 55–74 in good health with at least a 30 pack-year history	Low-dose helical CT (LDCT)	Clinicians with access to high-volume, high-quality lung cancer screening and treatment centers should initiate a discussion about lung cancer screening with apparently healthy patients aged 55–74 who have at least a 30 pack-year smoking history, and who currently smoke or have quit within the past 15 years. A process of informed and shared decision making with a clinician related to the potential benefits, limitations, and harms associated with screening for lung cancer with LDCT should occur before any decision is made to initiate lung cancer screening. Smoking cessation counseling remains a high priority for clinical attention in discussions with current smokers, who should be informed of their continuing risk of lung cancer. Screening should not be viewed as an alternative to smoking cessation
<i>Prostate</i>	Men, ages 50+	Digital rectal examination (DRE) and prostate-specific antigen test (PSA)	Men who have at least a 10-year life expectancy should have an opportunity to make an informed decision with their health care provider about whether to be screened for prostate cancer, after receiving information about the potential benefits, risks, and uncertainties associated with prostate cancer screening. Prostate cancer screening should not occur without an informed decision-making process
<i>Cancer-related checkup</i>	Men and women, ages 20+		On the occasion of a periodic health examination, the cancer-related checkup should include examination for cancers of the thyroid, testicles, ovaries, lymph nodes, oral cavity, and skin, as well as health counseling about tobacco, sun exposure, diet and nutrition, risk factors, sexual practices, and environmental and occupational exposures

Organized versus opportunistic screening: Screening can be offered in a regimented program in which subjects are tracked for compliance with screening recommendations and quality of screening is measured through systematic audit. This is how screening is done in many European countries. In the United States, most screening is opportunistic, with limited tracking of compliance or quality. Some American mammography facilities do meet high world-class standards. In the United States and Europe, there are

very few broad standards for screening in other diseases.

Breast cancer screening

Among women worldwide, breast cancer is the most commonly diagnosed cancer and the leading cause of cancer death. In the United States, the median age at diagnosis is 61, and the median age of death is 68.¹¹

Screening methods for breast cancer

Mammography is an X-ray examination of the breasts that produces high-quality craniocaudal (CC) and mediolateral oblique (MLO) images of each breast with minimum X-ray dose. Evidence suggests that digital imaging allows for more accurate interpretation, improved diagnosis in women with dense breasts, and equivalence to traditional film mammography for postmenopausal women.¹²

The rate of abnormal interpretations is higher for first screening (5–10%) than for later mammograms. Most abnormalities are resolved through additional imaging with other mammographic views or by ultrasonography. Abnormalities that cannot be resolved are biopsied with ultrasonographic or radiographically directed fine needle aspiration, core needle biopsy, or surgical excision.

Nine RCTs of breast cancer screening have been published to date ([Table 3](#)). The trials vary in the age range of women enrolled, the screening tests used [mammography alone or with clinical breast examination (CBE)], the screening intervals, and even the years of follow-up. All RCTs were started and most completed before the modern era of adjuvant chemotherapy, and several before the advent of hormonal therapy. Screening and diagnostic equipment have also improved.¹³ Experts try to take these limitations and flaws into account by considering nonrandomized studies and mathematical models.^{14, 15} There is consensus that a well-run screening program has the potential to reduce risk of breast cancer-specific death.⁸

Table 3 Breast cancer screening randomized trials

Study	Randomization	Sample size	Intervention	Follow up	Finding
Health Insurance Plan, United States 1963 ^a	Individual	60,565–60,857	MMG and CBE for 3 years	18 years	RR 0.77 (0.61–0.97)
Malmo, Sweden 1976 ^{b,c}	Individual	42,283	Two-view MMG every 18–24 months × 5	12 years	RR 0.81 (95% CI, 0.62–1.07)
Ostergotland (County E of Two-County Trial) Sweden 1977 ^{d,e}	Geographic cluster	38,405–39,034 study 37,145–37,936 control	Three single-view MMG Every 2 years women-50 Every 33 months women 50+	12 years	RR 0.82 (95% CI, 0.64–1.05) Ostergotland
Kopparberg	Geographic	38,562–	Three single-view MMG	12	RR 0.68

(County W of Two-County Trial) Sweden 1977 ^{d,e}	cluster	39,051 intervention 18,478–18,846 control	Every 2 years women-50 Every 33 months women 50+	years	(95% CI, 0.52–0.89)
Edinburgh, United Kingdom ^f	Cluster by physician practice	23,266 study 21,904 control	Initially, two-view MMG and CBE Then annual CBE with single-view MMG years 3, 5, and 7	10 years	RR 0.84 (95% CI, 0.63–1.12)
NBSS-1, Canada 1980 ^g	Individual	25,214 study (100% screened after entry CBE) 25,216 control	Annual two-view MMG and CBE for 4–5 years	13 years	RR 0.97 (95% CI, 0.74–1.27)
NBSS-2, Canada 1980 ^h	Individual	19,711 study (100% screened after entry CBE) 19,694 control	Annual two-view MMG and CBE	11–16 years (mean 13 years)	RR 1.02 (95% CI, 0.78–1.33)
Stockholm, Sweden 1981 ⁱ	Cluster by birth date	Declined from 40,318 to 38,525 intervention group Rose from 19,943 to 20,978 control group	Single view MMG every 28 months × 2	8 years	RR 0.80 (95% CI, 0.53–1.22)
Gothenberg, Sweden 1982 ^j	Complex	21,650 invited 29,961 control	Initial two-view MMG. Then single-view MMG every 18 months × 4. Single read first three rounds, then double-read	12–14 years	RR 0.79 (95% CI, 0.58–1.08)
AGE Trial ^h	Individuals	160,921 (53,884 invited; 106,956 not	Invited group aged 48 and younger offered annual screening by MMG (double-view first screen, then single mediolateral oblique view thereafter);	10.7 years	RR 0.83 (95% CI, 0.66–1.04)

		invited)	68% accepted screening on the first screen an 69% and 70% were reinvited (81% attended at least one screen).

There has been tremendous debate about whether screening of normal risk women should begin at age 40 or 50.¹³ The dispute is based largely on the lack of clear evidence from RCTs that mammography screening for women aged 40–49 years is effective. Some studies show a statistically significant advantage to screening women in their forties and others do not.¹⁶ The most recent RCT is the AGE Study, in which some patients may have received modern adjuvant therapy.¹⁷ In all, 53,884 women aged 39–41 years were invited to screening. The control group was unaware of their participation and received “usual medical care.” With 10.7 years of follow-up, there was a statistically nonsignificant 17% lower relative risk of breast cancer death in the screening versus control group (RR = 0.83, 0.66–1.04).¹⁷

The USPSTF meta-analysis of large RCTs ([Table 4](#)), including AGE, concluded a 15% relative risk reduction in mortality (RR = 0.85, 95% CI, 0.75–0.96) for women aged 40–49 invited to 2–9 rounds of screening after 11–20 years of follow-up.¹⁸ This translates into 1904 women being invited to screening to prevent or delay one breast cancer death.¹⁹ More than half of these women are estimated to have a false-positive scan during the 10 years of screening. Changing the screening interval to every 2 years marginally decreases the number of lives saved while nearly halving the false positive rate.²⁰

Table 4 Pooled RRs for breast cancer mortality from mammography screening trials for all ages

Age (years)	Trials included, <i>n</i>	RR for breast cancer mortality (95% CrI)	NNI to prevent 1 breast cancer death (95% CrI)
39–49	8 ^a	0.85 (0.75–0.96)	1904 (929–6378)
50–59	6 ^b	0.86 (0.75–0.99)	1339 (322–7455)
60–69	2 ^c	0.68 (0.54–0.87)	377 (230–1050)
70–74	1 ^d	1.12 (0.73–1.72)	Not available

CrI, credible interval; NNI, number needed to invite to screening; RR, relative risk.

Source: Taken from **The Breast Cancer Evidence Review: An Update for the U.S. Preventive Services Task Force.** Heidi D. Nelson, MD, MPH; Kari Tyne, MD; Arpana Naik, MD; Christina Bougatsos, BS; Benjamin K. Chan, MS; and Linda Humphrey, MD, MPH. www.uspreventiveservicestaskforce.org/Page/SupportingDoc/breast-cancer-screening/final-evidence-summary9.

The higher prevalence of mammographic density among women in their forties compared to their fifties complicates interpretation of mammogram in the younger group. Studies show that the accuracy, sensitivity, and specificity of a given mammogram vary by radiologist, but in general improve with increasing patient age.^{21, 22} Among women screened regularly, interval cancers are more prevalent in women aged 40–49 years.²³

CBE and breast self-examination (BSE): A competent CBE involves physical palpation of the breast by a trained healthcare provider in small segments, from the nipple to the periphery of the breast, including the axilla.²⁴ In some settings (especially in developing countries), this may be the only method of breast cancer screening available.¹⁸

No RCT has adequately evaluated CBE as a single screening modality. A small proportion of palpable masses are not seen on mammography, leading to screening guidelines that include routine CBE, ideally just before mammography. Some data suggest that CBE contributes very little in a setting of high adherence with regularly scheduled high-quality mammography.¹⁸

BSE has appeal as a screening test because it is simple, convenient, and noninvasive. The “monthly BSE”

was once widely advocated.²⁵ However, two prospective RCTs have reported a lack of evidence of efficacy and even some evidence of harm, although both studies have some methodological issues.^{26, 27} Monthly BSE promotion distracts from the importance of mammography, can provide false reassurance, can heighten anxiety about breast cancer, and create false positives. Today, no professional organization in the United States or Europe encourages monthly BSE, instead advocating “breast awareness” and consulting a healthcare provider if a possible abnormality is found.^{25, 28}

Evaluation of the effectiveness of screening

While the RCTs of breast cancer screening suggest a benefit, estimating the effectiveness of routine screening programs in the community is not straightforward. The United States has had a 35% decline in age-adjusted mortality from 1989 to 2011. Mathematical modeling estimates that screening and improvements in breast cancer therapy, especially hormonal therapy, are each responsible for about half of the mortality decline.²⁹

The harms of breast cancer screening

Every screening test has some associated harms. Slightly more than half of women screened in a 10-year period will have a false positive requiring at least additional imaging.^{30, 31} Surveys show about a quarter of these women still suffered distress and anxiety 3 months after cancer was ruled out.³² False negatives lead to a false sense of security. Overdiagnosis estimates in breast cancer screening range from 0% to 54% of cancers diagnosed with the aid of mammography, with most estimates suggesting overdiagnosis is 10–30%.^{14, 33}

Mammography screening has also caused a dramatic rise in the diagnosis of ductal carcinoma *in situ* (DCIS). Previously a rare, incidental finding after mastectomy, there are now >70,000 cases diagnosed annually in the US. A study which has yet to show that early detection and treatment of DCIS reduces mortality. It is believed that most DCIS lesions do not progress to invasive cancer,^{15, 34} and there is increasing interest in its overtreatment.³⁵ Renaming DCIS has been suggested to remove the word carcinoma.³⁶ In the future, genomic medicine may allow us to distinguish the tumors (in situ and true cancer) that need aggressive therapy from those that should be observed.

New technologies

Digital breast tomosynthesis (DBT) and 3D mammography are newer technologies that appear to offer increased sensitivity and a reduction in recall rates.³⁷

Magnetic resonance imaging (MRI) is more sensitive but less specific than mammography in detecting breast cancer.³⁸ Initial MRI is associated with a very high number of false positive results, which is reduced with subsequent studies. MRI has found a niche in screening women with significant breast density and women who may be at elevated risk due to mutations in breast cancer susceptibility genes.

Ultrasound imaging has been used for many years as a diagnostic. The limitations of mammography in screening the dense breast have led to ongoing interest in using ultrasound for primary screening or as an adjunct to mammography.^{39, 40}

In 2003, the American College of Radiology Imaging Network (ACRIN) initiated a multicenter trial in women at increased risk for breast cancer due to family history and significant breast density.^{41, 42} The breast cancer detection rate was increased by 4.2 cancers per 1000 women screened with mammography

and ultrasound versus mammography alone (11.8 vs 7.6 per 1000). However, the false-positive and negative biopsy rates were also very high. While a significant improvement was seen in the diagnostic yield of small, node-negative cancers in this higher-risk population, it is unclear that it will save additional lives and questions remain about the potential for screening ultrasound.⁴⁰ Routine ultrasound screening is not advocated at this time.

An interesting technology that is gaining use is 3D automated breast ultrasound. It offers more standardized imaging compared to conventional ultrasound and can be performed by a technologist instead of a radiologist. It is still used as a diagnostic, but there is interest in using it as an initial screening test with mammography and CBE.

Screening recommendations

As of 2015, the ACS guideline recommends that all women become familiar with the potential benefits, limitations, and harms associated with breast cancer screening. Women with an average risk of breast cancer should undergo regular screening mammography starting at age 45 years. Women who are aged 45–54 years should be screened annually. Women who are 55 years and older should be screened every 2 years but may choose to continue annual screening. Women should have the opportunity to begin annual screening between the ages of 40 and 44 years. Women should continue screening as long as their overall health is good and they have a life expectancy of 10 years or more. Beginning in 2015, the ACS does not recommend clinical breast examination for breast cancer screening among women at any age with an average risk of breast cancer. The ACS guideline applies to women who have access to mammographic screening.

The 2009 USPSTF recommendation is women aged 50–75 years have a mammogram every 1–2 years.⁴³ USPSTF did not recommend CBE, citing the lack of study to show it beneficial. The Task Force recommends against “routine” mammographic screening for women aged 40–49 years, instead advising this decision be made following physician–patient discussion including individual risks and concerns.

As of December 2014, the USPSTF, the American College of Physicians, and the Canadian Task Force on the Periodic Health Examination recommend routine screening beginning at age 50.⁴⁴ An advisory committee on cancer prevention in the European Union recommends that screening be offered to women aged 50–69 years in an organized screening program.⁴⁵

On the basis of the accumulation of data, but no RCTs, the ACS now recommends that women at very high risk of breast cancer begin annual mammography and MRI at age 30, or perhaps earlier if she and her physician believe it is prudent.³⁸ It is impossible to perform a prospective RCT in this population. High risk is defined as having a known mutation of *BRCA1* or *BRCA2*, 20–25% or greater lifetime risk based on family history, a high-risk genetic syndrome, such as Li-Fraumeni syndrome or Cowden disease, or having received high-dose mantle radiation to the chest.²²

Colorectal cancer

Worldwide, colorectal cancer is the third most commonly diagnosed cancer in men and the second in women and accounts for 8% of all deaths. In the United States, colorectal cancer is the third most commonly diagnosed cancer and the third leading cause of cancer death among men and women. While most cases are diagnosed among individuals aged 60–80 years, there is increasing concern about colorectal cancer in those aged 40–50 years.¹¹

The goal of colorectal screening is both the detection of early-stage adenocarcinomas and the detection and removal of adenomatous polyps, given the significant evidence that adenomatous polyps are precancerous lesions. Colorectal polyps are common in adults over age 50. One-half to two-thirds of all colorectal polyps are adenomatous, which can progress to cancer, although the majority never will. It is estimated that it takes 10 years for an adenomatous polyp <1 cm to become an invasive lesion.⁴⁶ Other polyps, including incidental hyperplastic polyps and mucosal tags, are not significant in the development of colorectal cancer.⁴⁷

Screening methods for colorectal cancer

Evidence suggests that a number of tests, applied in a program of regular surveillance, have the potential to reduce deaths from colorectal cancer. They include:

1.

Fecal occult blood tests (FOBTs) aim to discover occult blood in stool, which is often caused by polyps (especially >2 cm). Common FOBTs include *guaiac-based tests (gFOBTs)* and *fecal immunochemical tests (FITs)*.

The gFOBT detects blood in the stool through the pseudoperoxidase activity of heme. This test requires diet modification, as it can react positively with red meat, cruciferous vegetables, and some fruits. Rehydration of gFOBT not only improves sensitivity but also increases the false-positive rate.⁴⁸ The gFOBT can be done in the physician office but it is preferred that patients collect the specimen at home for processing in a laboratory. Any positive stool blood test requires follow-up diagnostic colonoscopy.

Limitations of gFOBT have led to a decrease in usage but some high-sensitivity tests are still available. The gFOBT performed with stool collected during a digital rectal examination (DRE) is not recommended.

The FIT reacts to human globin. FIT is not reactive to diet as gFOBT is, and will not react to digested human blood from upper gastrointestinal bleeding. The fecal hemoglobin threshold can be set to balance sensitivity and specificity based on individual risk or programmatic requirements. FITs are usually processed in a laboratory. Sensitivity declines with delay in sample processing. Even a 5-day delay is significant.⁴⁹

In 1000 ambulatory patients (with and without symptoms of colorectal cancer), the sensitivity for cancer with three FIT samples with a hemoglobin threshold of 75 ng/mL was 94.1%, and specificity was 87.5%. In a screening study with one FIT evaluation of stool followed by colonoscopy, FIT had higher sensitivity for detection of advanced neoplasms in patients taking low dose aspirin compared to those not taking aspirin. There was a minor decrease in specificity.⁵⁰

In a systematic review of gFOBT and FIT, there was no clear evidence for superiority of either test.⁵¹ Bleeding from cancers or large polyps may be intermittent. Generally, FIT requires two tests over a week or so and gFOBT requires three. In practice, FIT is replacing gFOBT.

2. Stool DNA (sDNA) testing detects relatively well-defined DNA markers associated with colorectal neoplasia in cells exfoliated by colorectal polyps and malignancies into the colonic lumen. Available sDNA tests focus on >21 separate point mutations in the K-RAS oncogene, a probe for BAT-26 (a marker of microsatellite instability), and a marker of DNA integrity analysis (DIA) to achieve high sensitivity.⁵² As with stool blood testing, any positive stool blood or DNA test must be followed up

with colonoscopy to rule out the presence of polyps or cancer.

3. Flexible sigmoidoscopy (FSIG) with a 60 cm scope is a relatively simple procedure, requires minimal preparation, and allows for examination of about half of the average colon.⁵³ Generally, the test is performed without sedation. The presence of polyps in the distal bowel signals an elevated risk for polyps or cancer in the proximal bowel. If FSIG is positive, the patient is referred for colonoscopy.

Quality indicators for FSIG have been published and emphasize appropriate training, satisfactory examination rates to >40 cm, expected adenoma detection rates based on age and gender, and ability to biopsy suspected adenomas.

4.

Barium enema is an X-ray examination of the bowel that derives contrast from barium (single-contrast study) or the combination of barium and instilled air (double-contrast barium enema study, DCBE). DCBE is more sensitive than single-contrast study for both malignancies and polyps. If the patient has a positive test, the next step is a colonoscopy.⁵⁴

Evidence for the efficacy of DCBE is largely indirect, based on its performance in detecting small malignant lesions and polyps and on the known benefits of early detection and polypectomy for reducing mortality. The proportion of examinations in which adenomatous polyps identified by colonoscopy were also detected by DCBE was significantly influenced by lesion size. Among all currently recommended screening tests, barium enema is the least utilized.

5.

Colonoscopy has a unique advantage among colorectal cancer screening tests in that direct visualization of the entire bowel is possible, with >90% of examinations terminating at the cecum, and clinically significant adenomas can be identified and removed during the examination.^{24, 55} Colonoscopy is done in an outpatient setting predominantly. While conscious sedation is standard, some patients receive general anesthesia. Proper bowel preparation is critical to ensure that the bowel is clean.

The examination is more complicated than sigmoidoscopy with higher risk of complications due mostly to sedation, biopsy, or polypectomy. Blood loss can be seen with polyps of any size but is more common when removing large polyps or polyps in the proximal colon. Risk of bowel perforation increases with age and is higher in individuals with diverticular disease. Perforation occurs in about 1 in 500 Medicare beneficiaries and 1 in 1000 patients overall.

In 1256 adults rescreened about 5 years after a negative colonoscopy, no cancers were detected, but 201 (16%) adults had one or more adenomas, of which 16 were advanced.⁵⁶ The findings support the conclusion that the 5-year risk of colorectal cancer is extremely low among those with a normal colonoscopy.

In a study of 35,000 asymptomatic patients in Manitoba who had undergone negative colonoscopy and were followed for 10 years, reductions in the expected colorectal cancer incidence of 45% at 5 years and 72% at 10 years were observed.⁵⁷ These findings suggest some detection failures during the initial apparently normal colonoscopy.

The long duration of reduced risk of colorectal cancer after colonoscopy depends on quality of the examination and complete removal of polyps. Quality assurance recommendations emphasize training and experience, proper risk assessment and documentation, complete examination to the

cecum with adequate mucosal visualization and bowel preparation, ability to detect and remove polyps safely, documentation of polypoid lesions and removal, timely and appropriate management of adverse events, appropriate follow-up of histopathology findings, appropriate recommendation for surveillance or repeat screening based on published guidelines, and continuous assessment and evaluation of performance, with corrective action when necessary.

6. CT colonography or virtual colonoscopy is an imaging procedure that computationally combines multiple helical CT scans to create two- or three-dimensional images of the colon interior. These images can be rotated for different views and even combined for a complete, “virtual” view.⁵⁴

Evaluations of CT colonography have typically involved CT examination followed by optical colonoscopy, with the colonoscopist blinded to the CT results. Although early results with 2D imaging were disappointing, recent back-to-back evaluations of CT colonography using faster scanners, updated 3D luminal displays, and oral stool tagging with digital subtraction have demonstrated sensitivities for large adenomas equivalent to colonoscopy. Using these advances, one study of back-to-back CT and optical colonoscopy in asymptomatic adults reported 94% sensitivity for large adenomas, with per-patient sensitivity for adenomas ≥ 6 mm of 89%.⁵⁸

In a collaborative ACRIN/NCI trial,⁵⁹ CT colonography detected 90% of patients with large (≥ 10 mm) adenomas and cancers, with 86% specificity and 84% per-polyp sensitivity. Thirty large lesions were detected by CT colonography that were not detected by optical colonoscopy. Five of 18 lesions ≥ 10 mm were confirmed by colonoscopy as true positives. Although the sensitivity of CT colonography is lower for lesions ≤ 6 mm, generally, these lesions are regarded as clinically insignificant. For lesions of ≥ 1 cm in size, CT colonography has performance very similar to optical colonoscopy.⁵⁸

CT colonography requires the same full bowel preparation and restricted diet as optical colonoscopy, and as an “imaging-only” evaluation, patients with polyps ≥ 6 mm in size must be referred to therapeutic colonoscopy and polypectomy.⁵⁹

Colorectal screening trials

The initial evidence that colorectal screening saves lives was based on studies showing that gFOBT found lesions at earlier stages than cases diagnosed with symptoms. This led to prospective trials in Europe and the United States evaluating the efficacy of FOBT. In the Minnesota trial, 46,551 asymptomatic participants aged 50–80 years were randomized to invitation to annual screening, biennial screening, or usual care.⁶⁰ Participants with positive gFOBT received colonoscopy. The 13-year cumulative mortality was 5.33, 8.33, and 8.83 per 1000 in the annual screening, biennial screening, and usual care (control) groups, respectively. After 18 years of follow-up, both annual and biennial gFOBT were associated with a statistically significant reduction in deaths and with a 20% and 18% reduction in cancer incidence, respectively.⁴⁸ Cancer prevention was attributed to detection and removal of adenomatous polyps. Similar results with gFOBT every 2 years have been observed in two other trials.⁶¹

Sigmoidoscopy. In the early 1990s, two case–control studies evaluating the efficacy of screening sigmoidoscopy reported a 70% or more reduction in risk of colorectal cancer death.^{62, 63} Five sigmoidoscopy screening RCTs have reported incidence and mortality results. In meta-analysis, there was a 28% relative risk reduction in colorectal cancer mortality (RR = 0.72, 95% CI, 0.65–0.80). Incidence was reduced by 18% (RR = 0.82, 95% CI, 0.73–0.91). Left-sided cancer was reduced by 33% (RR = 0.67, 95% CI, 0.59–0.76).^{64, 65}

Combined stool blood testing and FSIG every 5 years is superior to FOBT or FSIG alone. FOBT provides some surveillance in the proximal colon (outside the reach of FSIG), and FSIG has higher sensitivity and specificity than FOBT in the distal colon. In an RCT in asymptomatic individuals aged ≥ 40 years, there were fewer colorectal cancer deaths in patients receiving annual FOBT and sigmoidoscopy than in those receiving sigmoidoscopy alone (0.36 vs 0.63 per 1000; $P = 0.53$) after 5–11 years of follow-up.⁶⁴ On the basis of modeling, USPSTF concluded that combining FSIG every 5 years with high-sensitivity FOBT every 3 years is approximately equivalent in terms of life years gained to colonoscopy every 10 years.⁶⁵

Table 5 Guidelines for screening and surveillance for early detection of colorectal polyps and cancer for individuals at greater than average risk

Risk category and description	Recommendation	Age to begin	Screening interval and recommendation
<i>Moderate risk</i>			
People with single, small (<1 cm) adenomatous polyps	Colonoscopy	At the initial polyp diagnosis	TCE within 3 years after initial polyp removal; if normal, follow recommendations for average-risk individuals
People with large (≥1 cm) or multiple adenomatous polyps of any size	Colonoscopy	At time of initial polyp diagnosis	TCE within 3 years after initial polyp removal; if normal TCE every 5 years
Personal history of curative-intent resection of colorectal cancer	TCE ^a	Within 1 year after resection	If normal, TCE in 3 years; If second TCE is normal, TCE in 5 years
Colorectal cancer or adenomatous polyps, in first-degree relative younger than age 60 or in two or more first-degree relatives of any ages	TCE ^a	40 years, or 10 years before the youngest case in the family, whichever is earlier	Every 5 years
Colorectal cancer in other relatives (not first degree)	Follow recommendations for age-risk individuals	—	—
<i>High risk</i>			
Family history of FAP	Early surveillance with endoscopy, counseling to consider genetic testing, and referral for specialty care	Puberty	If genetic test is positive or polyposis is confirmed, consider colectomy; otherwise, continue endoscopy every 1–2 years
Family history of HNPCC	Colonoscopy and counseling to consider genetic testing	21 years	If untested, or if genetic test is positive, colonoscopy every 2 years until age 40; after age 40, colonoscopy every year
Inflammatory bowel disease	Colonoscopy with biopsies for dysplasia	8 years after the start of pancolitis; 12–15 years after the start of left-sided colitis	Colonoscopy every 1–2 years

Abbreviations: FAP, familial adenomatous polyposis; HNPCC, hereditary nonpolyposis colorectal cancer; TCE, total colon examination.

^a TCE includes either colonoscopy, DCBE, or CT colonography. CT colonography or DCBE should be added to the colonoscopy examination in those instances when the entire colon cannot be visualized by colonoscopy.

Colonoscopy. No prospective RCTs with mortality endpoints have been conducted to evaluate whether colonoscopy screening prevents colorectal cancer death. That more than 40% of those receiving annual FOBT in the Minnesota trial ultimately received at least one colonoscopy is perhaps the strongest evidence of efficacy. In addition, several case–control studies suggest that screening with colonoscopy and polypectomy has significant impact on colorectal cancer incidence and by extension, mortality.^{66, 67}

Screening recommendations

As given in [Table 2](#), the ACS recommendations for average-risk individuals include seven options for regular surveillance for colorectal cancer beginning at age 50,^{68, 69} including annual high-sensitivity FOBT (gFOBT or FIT); sDNA (interval unknown); FSIG every 5 years, annual high-sensitivity gFOBT or FIT and FSIG every 5 years after initial screening with both tests; total colonic examination with DCBE every 5 years; or total colonic examination with colonoscopy every 10 years. In reality, most adults who undergo screening have stool testing with gFOBT or FIT or colonoscopy. In clinics where endoscopists are experienced and perform complete examination on well-prepared patients with scope insertion >40 cm, a 10-year interval between screening FSIG may be justified. Annual DRE is no longer recommended, owing to low sensitivity, but DRE should be done before FSIG or colonoscopy. While there is strong consensus among US organizations about the value of colorectal cancer screening in adults ≥50 years of age, the USPSTF states that, currently, there is insufficient evidence to recommend for or against CT colonography or sDNA.

Guidelines for higher-risk individuals recommend earlier onset of surveillance and more thorough examinations of the colon ([Table 5](#)). Higher-risk individuals include those with family history of adenomatous polyps or colorectal cancer, FAP, or hereditary nonpolyposis colorectal cancer (HNPCC), or a history of inflamma.⁷⁰

Cervical cancer

Cervical cancer is the third most commonly diagnosed cancer in women and fourth leading cause of cancer death worldwide,¹¹ and is still the leading cause of cancer death among women in some areas of Africa and Asia. A dramatic decline in mortality due to improvements in both treatment and early detection has occurred, particularly in the United States and western Europe, where the mortality rate in 1980 was >70% lower than in 1930.⁷¹

The improvement in early detection was due to the Pap test or smear, developed by Dr. George Papanicolaou in the 1920s. In many western countries, it gained widespread adoption in the late 1940s to 1950s.⁷² The Pap test diagnoses early cancers and precursor lesions [dysplasia or cervical intraepithelial neoplasia (CIN)], for which a variety of treatment options are available. The diagnosis of treatable precursor lesions is considerably more common than the diagnosis of invasive disease, and screening has caused a drop in cervical cancer incidence far more dramatic than the decline in mortality.⁷³

Screening and diagnostic methods

In many respects, the Pap test is extremely low tech.⁶⁹ It involves the collection of exfoliating epithelial cells from the cervical squamocolumnar junction or transformation zone. Both the ectocervix and endocervix are sampled. Two samples are applied to one side of a glass slide and quickly fixed to

prevent air-drying. The slide is stained and examined under a microscope by a cytotechnologist. Although simple to conduct, its accuracy is highly dependent on obtaining a high-quality specimen, good slide preparation, expert microscopic examination, and interpretation.⁶⁹

Table 6 Bethesda System 2001

Specimen type	Indicate conventional smear (Pap smear) versus liquid-based versus other
Specimen adequacy	
Satisfactory for evaluation	Describe presence or absence of endocervical/transformation zone component and any other quality indicators, for example, partially obscuring blood and inflammation
Unsatisfactory for evaluation	Specimen rejected/not processed (specify reason), or specimen processed and examined, but unsatisfactory for evaluation of epithelial abnormality because of (specify reason)
General categorization (optional)	Negative for intraepithelial lesion or malignancy Epithelial cell abnormality: see interpretation/result (specify “squamous” or “glandular” as appropriate)
	Other: see interpretation/result (e.g., endometrial cells in a woman >40 years of age)
Automated review	If case examined by automated device, specify device and result
Ancillary testing	Provide a brief description of the test methods and report the result so that it is easily understood by the clinician
Interpretation/result negative for intraepithelial lesion or malignancy	When there is no cellular evidence of neoplasia, state this in the general categorization above and/or in the interpretation/result section of the report, whether or not there are organisms or other non-neoplastic findings)
Organisms	<i>Trichomonas vaginalis</i>
	Fungal organisms morphologically consistent with <i>Candida</i> spp.
	Shift in flora suggestive of bacterial vaginosis
	Bacteria morphologically consistent with <i>Actinomyces</i> spp.
	Cellular changes consistent with herpes simplex virus
Other non-neoplastic findings	Reactive cellular changes associated with inflammation (includes typical repair) radiation intrauterine contraceptive device (IUD)
(Optional to report; list not inclusive)	Glandular cells status post hysterectomy Atrophy
Other	Endometrial cells (in a woman ≥ 40 years of age) (specify if “negative for squamous intraepithelial lesion”)
Epithelial cell abnormalities	
Squamous cell	Atypical squamous cells of undetermined significance (ASC-US) cannot exclude HSIL (ASC-H)
	Low grade squamous intraepithelial lesion (LSIL) encompassing: HPV/mild dysplasia/CIN 1

	High grade squamous intraepithelial lesion (HSIL) encompassing: moderate and severe dysplasia, CIS/CIN 2 and CIN 3 with features suspicious for invasion (if invasion is suspected)
	Squamous cell carcinoma
Glandular cell	Atypical
	Endocervical cells (NOS or specify in comments)
	Endometrial cells (NOS or specify in comments)
	Glandular cells (NOS or specify in comments)
	Endocervical cells, favor neoplastic
	Glandular cells, favor neoplastic
	Endocervical adenocarcinoma <i>in situ</i>
	Adenocarcinoma
	Endocervical
	Endometrial
	Extrauterine
	Not otherwise specified
Other malignant neoplasms	Specify
Educational notes and suggestions (optional)	Suggestions should be concise and consistent with clinical follow-up guidelines published by professional organizations (references to relevant publications may be included)

The Pap smear has a significant error rate. Sampling error is estimated to account for about two-thirds of false-negative tests and errors in interpretation for the remaining third. Pap smear screening is estimated to have specificity of 98% and sensitivity of 51%.⁷⁴ The NCI's Bethesda System ([Table 6](#)), released in 1988, provides “... a uniform format for cytopathology reports. It is intended to communicate clinically relevant information using standardized terminology.”⁷⁵

Clinical studies of efficacy

Screening with the Pap smear is comparatively inexpensive and is widely accepted, although no RCTs of its efficacy have been conducted. Perhaps the most widely cited evidence for its effect on mortality is the long-term decline in cervical cancer death rate in the United States coincident with the introduction of the Pap smear.²⁵ Death rates had begun to decline before widespread use of the test, owing to factors such as an increase in the hysterectomy rate and improved treatment of cervical cancer. However, the decline in incidence and mortality was so significant that improvements in treatment could not account for all of it. Furthermore, from the 1950s to 1970s, cervical cancer mortality remained comparatively unchanged in Norway, a late adapter to cervical screening, whereas it dropped by more than 70% in Iceland, an early adapter.⁷¹ Numerous case–control studies also show a benefit from cervical cancer screening. The majority of American women diagnosed with cervical cancer today have no history of cervical screening in the 5 years before diagnosis; compelling evidence that screening reduces incidence.^{76, 77}

Precursor lesions usually take years to progress to cancer such that it is safe to screen normal risk women

every 3 years.⁷⁸ Overdiagnosis and overtreatment is a significant concern as observational studies show that untreated lesions such as atypical squamous cells of undetermined significance (ASCUS) often regress.⁷⁹ Strategies of triage, observation, and repeat testing are being used to avoid overtreatment.⁸⁰

New technologies

Liquid-based cytology uses specimen collection techniques similar to the conventional Pap smear. It is equally dependent on collecting an adequate sample, but the sample is suspended in a fixative solution, dispersed, filtered, and distributed on a glass slide to achieve a monolayer of cells. Computer-aided diagnosis of liquid-based cytology is common, and abnormal smears are reviewed by a cytotechnologist.⁸¹

Accuracy is increased because there are fewer artifacts (blood, mucus, etc.) and because cells are not overlapping. Studies have shown liquid-based cytology to have higher sensitivity in populations with lower prevalence of cytologic abnormalities.⁸¹ Reviews applying rigorous evidence-based criteria found no significant advantage in sensitivity or specificity for liquid-based over conventional Pap testing. The number of inadequate specimens is considerably reduced, however, with liquid-based cytology.

There is a strong association between persistent infection with certain subtypes of human papilloma virus (HPV) and cervical cancer.⁸² The ability to test for HPV DNA or HPV RNA has allowed for better diagnosis of cervical dysplasia. Increasingly, HPV testing is used as a cotest to triage women with abnormal cytologic tests [ASCUS and atypical glandular cells of undetermined significance (AGUS)]. There is also movement toward HPV screening tests replacing the Pap smear in women aged ≥ 30 years.⁸³ A prospective randomized trial in India demonstrated that HPV testing detects high grade cervical dysplasia and early cervical cancer and treatment leads to a decrease in mortality.⁸⁴ The US Food and Drug Administration (FDA) has approved an HPV DNA test that can be used alone for primary screening. This screen is not used among women in their 20s because an active and transient HPV infection is common among women under 30. HPV testing may represent a lower resource-intensive strategy for screening.⁸⁵

Screening recommendations

In 2012, the ACS, the American Society for Colposcopy and Cervical Pathology (ASCCP), and the American Society for Clinical Pathology (ASCP) issued joint guidelines for cervical cancer screening based on a systematic and collaborative review of evidence among 25 professional organizations.⁸⁶ Similar recommendations were released in 2012 by the USPSTF.⁸⁵ While these new recommendations still endorse more aggressive screening than in many European countries, they specify a more rational, cost-effective approach than earlier guidelines. However, many American clinicians are hesitant to embrace less frequent cervical cancer screening, despite good evidence that overscreening is wasteful of resources and contributes to potential harms.⁷⁸

The screening guidelines specifically recommend:

- Women under age 21 years should not be screened regardless of their age of sexual initiation.
- Women aged 21–29 years should receive cytology screening (conventional smears or liquid-based cytology) every 3 years. HPV testing should not be used for women in this age group (but can be used as a reflex test for women diagnosed with ASCUS). For women aged 30–65 years, the preferred approach is to be screened every 5 years with the combination of HPV testing and cytology (co-testing). It is also acceptable for women to continue to be screened every 3 years with cytology alone.

- Women should discontinue screening after age 65 if they have had 3 consecutive negative cytology tests or 2 consecutive negative co-tests within the previous 10-year period, with the most recent test occurring within the last 5 years.
- Women at any age should NOT be screened annually by any screening method.

These recommendations were developed for women at average risk and do not apply to women with a history of cervical cancer; who were exposed to diethylstilbestrol while *in utero*; and who are immunocompromised due to medical therapy, or infected with the human immunodeficiency virus (HIV). Women who have had their cervix removed should not be screened, unless they have a history of CIN2 or a more severe cervical disease. Women with a history of CIN2 or more severe diagnosis should follow screening recommendations for women aged 30–65 for at least 20 years after definitive treatment, even if screening extends beyond age 65 years. Recommended screening practices should not change based on HPV vaccination status.

Prostate cancer

Worldwide, prostate cancer is the second most common cancer diagnosed and the sixth most common cause of cancer death among men.¹¹ Incidence and mortality rates vary considerably. Among American males, prostate cancer is the most commonly diagnosed nonskin cancer, and the second leading cause of cancer death. Mortality rates are higher in men of African ancestry, in Caucasian men in the Americas, and in Scandinavia. Rates are lowest in Asia.

A subset of prostate cancers is aggressive and poses a significant risk of death. Unfortunately, they often do not produce symptoms until locally advanced or metastatic. Prostate cancer among older men is more often slow growing or indolent. Efforts to distinguish clinically significant versus nonsignificant localized prostate cancer have included pathologic grading and genomic testing.⁸⁷

Screening and diagnostic methods

DRE aims to find hard nodular areas that sometimes indicate the presence of prostate cancer. There are three principal limitations of DRE: the test is highly operator-dependent, the majority of palpable cancers are not early cancers, and many clinically important cancers are located in regions of the prostate inaccessible to palpation. DRE is often recommended as a screening component because it can detect prostate cancers missed by other tests; may predict high-grade disease; is a low-cost procedure; and can detect other abnormalities such as benign prostatic hyperplasia. Even with the above, in the early phases of the European Randomized Study of Prostate Cancer, DRE appeared to have limited value as a stand-alone test even though between one-quarter and one-third of all prostate cancers were detected by DRE in the normal PSA range (<4.0 ng/mL).⁸⁸

Prostate-specific antigen (PSA) is a glycoprotein secreted by the epithelial component of the prostate. Progression of prostate cancer is correlated with a rise in serum PSA. Serum PSA measurement was first used to monitor metastatic disease in the early 1980s. By 1992, it gained high patient acceptance and became a widely used screening test in the United States. Unfortunately, its operating characteristics were determined far later.⁸⁹ Today, we know that serum PSA can be elevated in a variety of conditions besides cancer, such as benign prostatic hyperplasia, inflammation, and following trauma to the gland. PSA screening both finds and misses a lot of cancer. Whether PSA screening results in a decline in mortality rate is one of the most pressing questions in cancer medicine today.⁹⁰

Accumulating evidence supports the efficacy (vs effectiveness) of PSA testing, alone or in combination with DRE, in finding localized disease.^{88, 91} Approximately, one in four men aged ≥ 50 years with PSA >4 ng/dL has cancer after prostate biopsy. Reducing the cutoff makes the test more sensitive but reduces specificity.

The Prostate Cancer Prevention Trial (PCPT) randomized more than 19,000 men aged ≥ 55 years with initial PSA of 3.0 ng/mL to finasteride or placebo.⁹² Subjects were screened every year for 7 years (eight total screens) with serum PSA and DRE, and 14% were diagnosed with prostate cancer. Among men with normal PSAs and DREs, an additional 14% were diagnosed with prostate cancer based on end of study biopsy.⁹² The fact that more than 25% of men completing PCPT were diagnosed with prostate cancer suggests some overdiagnosis. PCPT also showed that a PSA cutoff of 4 ng/mL as an upper limit of normal or a 1 ng/mL increase in 1 year missed essentially as much cancer as it found. There is no natural cut point for PSA screening. Indeed, there were men diagnosed with prostate cancer with serum PSA <0.6 ng/mL.⁸⁹

Transrectal ultrasonography (TRUS) uses a small rectal probe placed against the prostate to image the entire gland. Unfortunately, cancer within the prostate has no unique and reliably assessed ultrasonic signature. TRUS as a sole screening modality has poor sensitivity and specificity. It can be used to accurately measure gland dimensions and volume and to direct prostate needle biopsies.

Endorectal MRI is not used in screening but has an evolving role in diagnostic evaluation of the prostate and following men with confirmed disease.⁹³

Clinical trials of prostate cancer treatment

In a study started before the PSA era, 767 men with localized prostate cancer were followed expectantly. A small proportion died of prostate cancer, suggesting significant overdiagnosis. After 20 years of follow-up, 4–7%, 6–11%, and 18–30% of men with Gleason 2–4, 5, and 6 disease, respectively, had died of prostate cancer.⁸⁷ This raises the question whether treatment of localized or locally advanced prostate cancer is beneficial or saves lives. Prospective RCTs published in the late 1990s were the first to demonstrate a positive treatment effect for men with locally advanced disease. These studies demonstrated an advantage to radiation and hormonal therapy over radiation therapy alone.^{94, 95}

In 2002, the Scandinavian Prostate Cancer Group-4 study (SPCG-4) was the first to show that treatment of localized disease saved lives. They randomized 695 men with clinically localized prostate cancer to radical prostatectomy or watchful waiting, with hormonal therapy if symptoms dictated. At median follow-up of 12.8 years, 14.6% of the prostatectomy group had died versus 20.7% of the watchful waiting group (RR = 0.75, $P = 0.007$). The number needed to treat to prevent one death was 15. Less than 15% of participants had PSA-detected disease.⁹⁶ One would predict that the NNT in a screened population would be much higher.

The Prostate Intervention Versus Observation Trial (PIVOT) randomized 731 men with PSA screen-detected disease to radical prostatectomy or watchful waiting.⁹⁷ At median follow-up of 12 years, prostatectomy was associated with a statistically insignificant 2.9% absolute and 2.6% prostate cancer-specific reduction in mortality. Subgroup analyses suggested a small, but statistically significant, mortality benefit for men diagnosed with PSA >10 ng/mL and for those with intermediate- and high-risk disease.⁹⁷

Taken together, the SPCG-4 and PIVOT studies suggest that our therapeutic interventions save lives in a minority of those diagnosed, and that a substantial proportion of men diagnosed with prostate cancer are overdiagnosed and do not need treatment. Substantial efforts are being made to identify these patients.

The effects of prostate cancer screening

Prostate cancer screening rates increased dramatically after FDA approval of PSA for following diagnosed disease in 1989. The FDA has since approved PSA for diagnosis of suspected disease but not for screening. The simplicity of a blood test enabled mass PSA screening at health fairs and community events and American prostate cancer incidence rates went up.

Prostate cancer mortality rates were rising for 20 years before the approval of PSA testing. Rates peaked in 1993, and since, the United States has experienced a 40% decline in age-adjusted prostate cancer death rates.⁹⁸ How much of the decline is due to screening is unknown. Etzioni and Feuer⁹⁹ argued that declining mortality within the first decade of widespread PSA testing is unlikely to be entirely due to PSA testing, given the long natural history of prostate cancer. Prostate cancer mortality rates have declined in 21 countries.¹⁰⁰ Screening is common in the United States and very few other countries.

Possible explanations for the decline in prostate cancer mortality seen in all countries are (1) a shift in the tendency to classify prostate cancer as the underlying cause of death and (2) significant improvements in prostate cancer treatment at all stages.¹⁰¹ Supporting the first theory, the World Health Organization (WHO) algorithm for adjudicating cause of death was changed as mortality rates began to rise in the late 1970s and reverted back to the older algorithm in 1991 about the time when prostate cancer mortality began declining.¹⁰² Supporting the second theory is the fact that prostate cancer is overwhelmingly a disease of older men. Even a 2- to 3-month increase in median survival due to more effective treatment could cause a decline in prostate cancer mortality as competing causes of death become more significant. Others have speculated that aggressive use of newer hormonal therapies may have increased cardiovascular deaths and thereby prevented prostate deaths.¹⁰³ All three could contribute to the decline in prostate cancer death rates in the United States in addition to the possibility that screening could have a positive effect.

Epidemiological studies show a significant decrease in the incidence of distant disease at diagnosis by the year 2000. On the basis of the assumption that screening results in a shift from distant to local/regional disease, modeling efforts within the NCI's Cancer Intervention Surveillance Modeling Network (CISNET) estimate 45–70% of the observed prostate cancer mortality decline in the United States could plausibly be attributed to screening-induced stage shifts.⁹⁹

Ultimately, the strongest assessment of screening efficacy requires long-term large prospective RCTs with a mortality endpoint. Five studies have been reported, all of which are judged to have some limitations. The two trials considered of higher quality are the multicenter US NCI Prostate, Lung, Colorectal, and Ovarian trial (PLCO) and the multicenter European Randomized Study of Prostate Cancer (ERSPC).^{88, 91}

The PLCO was initiated in 1992.⁹¹ Nearly 77,000 men aged 55–74 years were randomized to annual PSA testing for 6 years or usual care. At 13 years of follow-up, a statistically insignificant increase in prostate cancer mortality was observed among men randomized to annual screening (RR = 1.09, 95% CI, 0.87–1.36).⁹¹ A limitation of this trial was the high rate of PSA testing in the control arm, which reduced statistical power. Rather than screening versus no screening, PLCO is best viewed as comparing routine to opportunistic screening.

The ERSPC was initiated in 1991,⁸⁸ with seven countries eventually reporting results. Prostate cancer-specific mortality was not reduced by screening in the initial analysis of 182,160 men, aged 50–74 years, but significantly decreased in a subset of men aged 55–69 years. A 21% relative reduction of prostate cancer death (RR = 0.79, 95% CI, 0.68–0.91) was observed after median follow-up of 11 years and maintained at 13 years. The number of men needed to be diagnosed and treated to prevent one prostate

cancer death was 37 after 11 years and 27 after 13 years.^{104–106}

Applying the ERPC findings to an American population would suggest that for every 200 men diagnosed through screening, about 8 lives would be saved after 13 years; about 1 in 200 men treated with radical prostatectomy dies as a result of surgery. The remaining 191 men would experience the negative effects of diagnosis and treatment but their prostate cancer destiny would not be changed. In comparison, after 13 years, 32 men would have died of prostate cancer. It is unknown how many of the 159 remaining would die of prostate cancer in the future.

The ERSPC trial would have been negative if not for the Swedish component. Screening was very effective in Sweden, marginally effective in the Netherlands, and showed a statistically insignificant trend toward benefit in four countries. The Finnish component of ERSPC was the largest and did not show benefit at 12 years.¹⁰⁷ Screening may have been more effective in Sweden because of the higher risk of prostate cancer death or because the randomization scheme in Sweden might have created a “healthy volunteer” selection bias among those in the screening arm that is not seen in the control group. Those who were screened were consented, while those in the control arm did not know they were in a clinical trial.¹⁰¹

Screening recommendations

A number of professional organizations in the United States, Europe, and Canada have issued prostate cancer screening guidelines. All acknowledge legitimate concerns regarding the risk–benefit ratio of screening. There is general agreement that screening should be done only in the context of fully informed consent with a decision between a man and his physician.^{108–110} All recommend against mass screening in public places. The investigators of ERSPC also concluded that data do not support widespread screening.¹⁰⁶

The ACS 2010 guidelines state that the balance of benefits and harms related to prostate cancer early detection are uncertain and the existing evidence is insufficient to support a recommendation for or against routine PSA screening.¹⁰⁹ The ACS calls for discussion and shared decision making within the physician–patient relationship.

The USPSTF 2012 guideline recommends against the *routine* use of PSA screening on the basis of its conclusion that there is moderate certainty that the harms of PSA testing outweigh the benefits.¹⁰ The task force acknowledged that some men will continue to request screening and some physicians will continue to offer it. Similar to the ACS and AUA, they state that screening under such circumstances should respect an informed patient's preferences.¹⁰

In 2013, the AUA conducted a systematic review of over 300 studies and updated its guideline.¹¹⁰ It concluded that the greatest benefit of screening appears to be in men aged 55–69 years although “the quality of evidence for benefits associated with screening was moderate, whereas the quality of the evidence for harm was high.” The AUA places primacy on shared decision making versus physician judgments about the balance of benefits and harms at the population level even for men aged 55–69 years.¹¹¹ The committee recommends screening every 2 years instead of every year. They recommend *against* screening men <40 years of age, average-risk men aged 40–54 years, most men >70 years of age, and men with a life expectancy of <10–15 years. They recommend that screening decisions be individualized for higher risk men aged 40–54 years and men >70 years of age in excellent health.

The author believes that men should be informed of the potential benefits of screening and the documented harms associated with screening, especially the risk of overdiagnosis. Observation is appropriate for

many. The decision to screen should include a commitment not to rush into aggressive therapy, if diagnosed.

Lung cancer

Worldwide, as in the United States, lung cancer is the most commonly diagnosed nonskin cancer and the leading cause of cancer death in men and second leading cause of cancer death in women.^{11, 19}

Screening and diagnostic methods

Chest X-ray screening was first advocated in the early 1950s, and by 1960, several lung cancer screening campaigns began. The Mayo Lung Project (MLP), initiated in 1971, enrolled more than 9200 male smokers and randomized them to chest X-ray and sputum cytology every 4 months or every year, for 6 years. Follow-up continues to this day.^{112, 113} After 13 and 20 years of follow-up, the intensively screened arm had an increased number of lung cancers diagnosed and a significant increase in disease-specific survival.^{113, 114} Lung-cancer mortality was not reduced, demonstrating that screening can increase survival rates without decreasing mortality. An estimated 18% of cancers diagnosed in the intensive group were judged to be overdiagnosis of cancer in one study.¹¹⁵ Three other large, randomized studies of chest X-ray and sputum cytology using different screening schedules confirmed the findings of the MLP.^{116, 117}

These chest X-ray studies had important limitations, that is, they did not randomize to an unscreened control group, and they used 1960s to 1970s X-ray and treatment technology. Whether lung cancer screening was effective was readdressed in the US PLCO.¹¹⁸ Participants were randomized to annual posteroanterior view chest radiograph for 4 years or usual care (without screening). With a median of 12 years of follow-up, PLCO found no mortality advantage to chest X-ray screening.¹¹⁹

Spiral computed tomography (CT) is more sensitive than chest X-ray in detecting small lung nodules. Low-dose computed tomography (LDCT) uses an average 1.5 mSv of radiation to perform a lung scan in 15 s. This led to the launch of the NLST in 2002.¹²⁰ Approximately 53,000 persons at high risk for lung cancer were randomized to three annual LDCT scans or single-view postero-anterior chest X-rays. With median follow-up of 6.5 years, there was a 20% relative reduction in lung cancer mortality (95% CI, 6.8–26.7; $P = 0.004$) compared to the chest X-ray arm.¹²⁰ This corresponds to lung cancer death rates of 247 and 309 per 100,000 person-years, respectively. There was a 6.7% decrease in death from any cause in the LDCT group (95% CI, 1.2–13.6; $P = 0.02$), a rare finding in a prospective RCT. Screening prevented the greatest number of lung cancer deaths among participants who were at highest risk and very few deaths among those at lowest risk. These findings provide empirical support for risk-based screening.¹²¹

LDCT screening is clearly promising but has limitations. In NLST, 96.4% of positive findings were false.¹²⁰ Positive results require additional diagnostic procedures, mostly conventional CT scans, but in some cases, needle biopsy, bronchoscopy, mediastinoscopy, or thoracotomy, which are associated with anxiety, expense, and complications (e.g., pneumo- or hemothorax after lung biopsy). The NLST reported 16 deaths within 60 days of an invasive diagnostic procedure; whether the procedure was causative is unknown. Of these participants, 6 did not have cancer. There is increasing interest in evaluation algorithms to decrease the number of invasive diagnostic procedures.^{122, 123}

Other harms from screening include the theoretical potential for radiation-induced cancers resulting from LDCT and overdiagnosis. Overdiagnosis was estimated to be 18.5% (95% CI, 5.4–30.6%) in NLST.¹²⁴ Interestingly, this is very similar to the MLP.¹¹² Overdiagnosis is impossible to prove in the living, but in

one autopsy study, one-sixth of all lung cancers found had not been diagnosed before death.¹²⁵ Some believe that NLST needs longer follow-up to make an accurate overdiagnosis estimate.

Screening recommendations

The ACS, the American College of Chest Physicians (ACCP), and the American Society of Clinical Oncology (ASCO) recommend that clinicians discuss lung cancer screening with patients who would have qualified for the NLST: aged 55–74 years, ≥ 30 pack-year smoking history, currently smoke or have quit within the past 15 years, relatively good health.

This discussion should include the benefits, uncertainties, and harms associated with LDCT screening for lung cancer. Adults who choose to be screened should enter an organized screening program at an institution with expertise in LDCT and access to a multidisciplinary team skilled in the evaluation, diagnosis, and treatment of abnormal lung lesions. If a high-quality program is not available, the risks of harm associated with screening may be greater than the benefits.^{70, 126} Recommendations state an annual LDCT should be performed as long as subjects would benefit from treatment if diagnosed. All screening guidelines also stress that current smokers should be offered help with smoking cessation.

Testicular cancer

Testicular cancer is relatively uncommon¹¹ and its treatment is often successful. Over 70% of patients with metastatic disease have prolonged complete remissions.

Screening and diagnostic methods

Most diagnoses are made through the patient or physician recognizing an abnormality in the scrotum. Suspicious masses are evaluated further through ultrasonography and biopsy.

While self-palpation of the testes is simple, available data suggest that it is of low specificity and predictive value, and would be done infrequently if advocated.¹²⁷ Self-examinations result in false alarms that burden the healthcare system and can be costly. A useful intervention may be health education to encourage men to seek medical care if they notice a lump or nodule or any change in the size, shape, or consistency of the testes. Patient delay after becoming aware of a testicular abnormality is clearly associated with poorer survival.

Screening recommendations

No organization recommends routine screening for testicular cancer in average-risk men. The American Academy of Family Physicians recommends palpation of testicles for men aged 13–39 years at higher risk due to a history of cryptorchidism, orchiopexy, or testicular atrophy.¹²⁷

Hepatocellular cancer

Hepatocellular cancer (HCC) is the fourth most common cancer worldwide.¹²⁸ Age-standardized incidence rates are 40-fold higher in China compared to North America. Rates are rising in the United States.¹¹

Chronic hepatitis B and C are major risk factors. Other risk factors include alcoholic cirrhosis, hemochromatosis, alpha-L-antitrypsin deficiency, glycogen storage disease, porphyria cutanea tarda,

tyrosinemia, and Wilson disease.¹²⁸ In parts of Africa, the high incidence of HCC may be related to ingestion of aflatoxin-contaminated foods.

Currently, four types of tumor markers are being used or studied as screening tests: oncofetal antigens and glycoprotein antigens, enzymes and isoenzymes, genes, and cytokines.¹²⁹ Serum AFP, a fetal-specific glycoprotein antigen, is the most widely used. In high-risk populations, sensitivity of 39–97%, specificity of 76–95%, and PPV of 9–32% have been reported. AFP is not specific for HCC. It rises due to hepatitis, pregnancy, and germ cell tumors.¹²⁸

Ultrasound and CT imaging have been studied as adjuncts to AFP.¹³⁰ These tests have limited sensitivity and specificity. A prospective randomized study in China using AFP and US found HCC mortality was lower in the screened group [83.2 vs 131.5 per 100,000 with a mortality rate ratio of 0.63 (95% CI: 0.41–0.98)]. The results from this study have differed in various publications and it is unclear that this was an intention to screen analysis.^{131, 132}

Screening recommendations

Screening is not advocated among the general population and its benefit among those with HCC risk factors is questioned.

Endometrial cancer

Endometrial cancer is the most commonly diagnosed gynecologic malignancy among women in the United States and western Europe¹¹ where approximately one in four endometrial cancers is advanced at the time of diagnosis.

Screening and diagnostic methods

The efficacy of screening for endometrial cancer has never been evaluated in a prospective RCT. Occasionally, the Pap test identifies endometrial abnormalities, but it is insensitive and should not be used for endometrial cancer screening. Endometrial biopsy is the gold standard screening test. More recently, interest in transvaginal ultrasound (TVU) screening has increased.¹³³ Two well-designed studies of endometrial screening with TVU and biopsy have reported disappointing results and significant harms, including some cases of uterine perforation.

Screening recommendations

At this time, no organization recommends routine screening for endometrial cancer in average-risk women. The ACS recommends women be informed of the risk and symptoms of endometrial cancer at the time of menopause and strongly encouraged to report unexpected bleeding or spotting to their physician.¹³⁴

The ACS recommends a risk-based approach for women at high risk for endometrial cancer.⁶⁹ High risk includes women known to carry HNPCC-associated mutations (Lynch syndrome), women likely to be a mutation carrier based on relatives known to be mutation carriers, and women from families appearing to have an autosomal dominant predisposition to colon cancer in the absence of genetic testing results.²⁶⁹ Women known or suspected to have Lynch syndrome should be offered endometrial screening annually beginning at age 35 following discussion of benefits, risks, and limitations of testing.⁸⁴

Ovarian cancer

Ovarian cancer has the highest mortality rate of all gynecologic cancers and accounts for 6% of all cancer deaths among women in the United States.¹¹ Recent science shows that many so-called ovarian cancers actually are primary fallopian tube cancers. A few start as primary abdominal wall tumors. Most women are diagnosed with “ovarian cancer” after symptoms develop, and only 19% have disease truly localized to the ovary.¹⁹

Screening and diagnostic methods

Pelvic examination has low sensitivity and specificity for the detection of ovarian cancer and thus cannot be recommended alone as a screening method. However, recent studies suggest that a more favorable diagnosis may be possible if early symptoms are evaluated.

CA-125 is the most extensively studied ovarian cancer serum marker. It is a tumor-associated antigen, mainly used for surveillance after surgical removal of an epithelial ovarian cancer. The currently available assay, CA-125 II, utilizes both OC125 and MC11 antibodies.¹³⁵ CA-125 levels >30–35 U/mL are considered abnormal. Although CA-125 is elevated in the majority of advanced ovarian cancers, only half of early ovarian cancers yield a positive test. Moreover, CA-125 levels can be elevated in noncancerous diseases of the ovaries¹³⁶ and influenced by the presence of other cancers, a history of hormone use, and current smoking.

Ultrasonography: Abdominal ultrasonography has been used in ovarian cancer screening with poor results, owing to low specificity.¹³⁷ TVU is capable of detecting small masses but is poor at indicating malignancy. Color Doppler ultrasonography was believed to hold promise for differentiating benign from malignant masses, but studies have not shown that it improves diagnostic accuracy. Current data are insufficient to support TVU or other imaging modalities as stand-alone screening tools in average-risk asymptomatic women.¹³⁸

Combination CA-125 and ultrasound: Nonrandomized cohort studies and pilot RCTs in average- and high-risk women have shown the limited sensitivity of CA-125 or ultrasound (abdominal or transvaginal) alone at an acceptable level of specificity and the poor predictive value of a positive test. High specificity is especially important because laparoscopy and/or laparotomy is required to rule out the presence of ovarian cancer when screening is positive. Multimodal approaches that combine CA-125, ROC CA-125 algorithms, and imaging have been evaluated in prospective RCTs. The PLCO is a prospective RCT. It recruited 78,237 women aged 55–74. A total of 39,115 were randomized to ovarian cancer screening with baseline CA-125 and TVU tests, followed by three additional annual rounds of TVU and five of CA-125. There were 2.1 versus 2.6 ovarian cancer deaths per 10,000 women-years in the screened versus control group (RR = 1.18, 95% CI, 0.82–1.71).

Several studies targeting women at high risk for ovarian cancer are also underway.¹³⁸ The United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS)^{139, 140} randomized 200,000 average risk, postmenopausal women aged 50–74 years to usual care ($n = 100,000$); annual multimodal screening with serum CA-125 followed by CA-125 and ultrasound ($n = 50,000$); or annual ultrasound screening with repeat ultrasound in 6–8 weeks ($n = 50,000$) for 7 years. The primary endpoint is ovarian cancer mortality screening using multiple modalities reduced overall average mortality by 20% (RR = 0.80, 95% CI, 0.60–0.98).

Serum proteomic pattern recognition algorithms are being developed to identify a key subset of peptides

that discriminate ovarian cancer cases from control subjects. The potential for either a stand-alone or adjunctive proteomic test for ovarian cancer screening is regarded as promising but remains unrealized.

Screening recommendations

No major guideline-making organization recommends ovarian cancer screening in average-risk women, and the USPSTF specifically recommends against it.¹⁴¹ In 1994, a NIH Consensus Panel concluded that a comprehensive family history should be taken from all women, and women with two or more first-degree relatives with a history of ovarian cancer should be offered counseling by a gynecologic oncologist (or other qualified specialist) as these women have a 3% chance of being positive for an ovarian cancer hereditary syndrome.¹⁴² Women with known hereditary ovarian cancer syndrome, such as mutations on *BRCA1* and *BRCA2*, including breast-ovarian cancer syndrome, site-specific ovarian cancer syndrome, and HNPCC, should receive annual recto-vaginal pelvic examinations, CA-125 determinations, and TVU until childbearing is completed or at least until age 35, at which time prophylactic bilateral oophorectomy is recommended. Women with these hereditary syndromes are estimated to represent only 0.05% of the female population and have a 40% estimated lifetime risk of ovarian cancer.

Melanoma and nonmelanoma skin cancer

Skin cancers, together, are the most common cancers diagnosed worldwide and in the United States. They account for nearly half of all malignancies.¹¹ The most common are basal cell and squamous cell skin cancer, which are referred to as nonmelanoma skin cancer (NMSC). NMSC is highly curable, although significant morbidity can result from delayed diagnosis and treatment. Melanoma, however, is a significant cause of cancer death. In the United States, melanoma accounts for 2% of all skin cancer cases but the vast majority of skin cancer deaths.

Screening and diagnostic methods

Interest in screening for melanoma has increased in recent years because mortality rates are increasing. Screening involves a visual skin examination, by a clinician or self-examination. A 2- to 3-min total examination of the skin is preferable because skin cancers often occur at anatomic sites that are not directly exposed to sunlight. Skin examinations by a healthcare provider are uncommon in the United States but are more common among dermatologists than primary care physicians. Basal cell skin cancer may appear as a flat growth or a small, raised pink or red translucent shiny area that may bleed following a minor injury. Squamous cell skin cancer may appear as a growing lump, often with a rough surface, or as a flat, reddish patch that grows slowly. Signs of melanoma include changes over time in size, shape, or color of a mole or other skin lesion. This is summarized as an ABCD algorithm that emphasizes asymmetry [A] of the lesion, uneven borders [B], changes in color [C], and changes in diameter [D]. A Cochrane Review endorsed the addition of an “E” category—“evolving”—to emphasize the importance of change over time in the lesion. However, it appears most dermatologists rely on the overall pattern of appearance (ugly duckling sign) versus a stepwise assessment of features.

Case-control studies have suggested that increased awareness of melanoma and its symptoms leads to earlier presentation and thinner lesions at presentation.¹⁴³ High-risk patients routinely screened by dermatologists have thinner lesions at diagnosis than among historical or population-based controls.

The American Academy of Dermatology program of skin cancer screening has examined >600,000 people of various risk categories since 1985.¹⁴⁴ In addition to detecting >35,000 NMSCs, melanomas diagnosed

by screening were more likely than historical controls to be <1.5 mm. Skin cancer screening may be more effective if targeted to high-risk persons such as Caucasian patients aged >20 years with atypical mole syndrome or congenital melanocytic nevi, patients with specific phenotypic traits, or patients with a history of NMSC.¹⁴⁴

No RCT has assessed whether skin cancer screening decreases mortality. Some large observational studies suggest its efficacy. A Scottish campaign to promote melanoma awareness and early presentation appears to be associated with a decline in mortality. The Skin Cancer Research to Provide Evidence for Effectiveness of Screening (SCREEN) Project launched an intensive screening program among 360,000 participants in one area of Germany.^{145, 146} Although there were many false positives, melanoma incidence was raised by 16% in men and 38% in women in a 2-year period of time and returned to baseline after conclusion of the intervention period. Five years after the end of the intervention period, melanoma death rates were half that of the rest of Germany.^{147, 148} A community-based, randomized population trial of self-examination versus clinician skin examination is underway in Australia, with a primary outcome of melanoma mortality after 15 years of follow-up.^{69, 149}

Screening recommendations

The ACS recommends skin examination during periodic preventive health examinations.⁶⁹ The American College of Preventive Medicine recommends periodic total cutaneous examinations for high-risk populations, including those with Caucasian race, fair complexion, presence of pigmented lesions (dysplastic or atypical nevus), several large nondysplastic nevi, many small nevi, moderate freckling, or familial dysplastic nevus syndrome.

The USPSTF recommends people, especially high-risk individuals, be alert to skin abnormalities.¹⁴⁹ The Taskforce concluded that evidence was insufficient to recommend for or against routine screening using total-body skin examination for the early detection of cutaneous melanoma, basal cell cancer, or squamous cell skin cancer.

Oral cancer

Oral cancer is more common in men than in women.¹¹ Approximately one-third of oral cancers are diagnosed at a localized stage.¹⁵⁰

Screening and diagnostic methods

Oral cancer is generally accessible to physical examination by the patient and healthcare providers, especially the dentist. Screening can be made more efficient by inspecting high-risk sites where 90% of squamous cell cancers arise: floor of mouth, ventrolateral aspect of the tongue, and soft-palate complex. Leukoplakia and erythroplastic lesions are the earliest and most serious signs of squamous cell carcinoma.¹⁵¹ Although new technological approaches to screening are being evaluated, such as toluidine blue, brush cytology, tissue reflectance, and autofluorescence, none has been shown to be reliably superior to conventional oral examination.

Using a cluster-RCT design, high-risk men and women aged ≥ 35 years in Kerala, India were randomized to three rounds of oral visual inspection by trained health workers at 3-year intervals.¹⁵² There were 21% fewer oral cancer deaths in the 96,517 participants in the intervention group compared with the control group (RR = 0.79, 95% CI, 0.51–1.22), which rose to 34% fewer among tobacco and alcohol users.

While some have advocated oral cavity inspection as part of every physical examination in dental and physician offices, the absence of a general recommendation results in this occurring infrequently. Ironically, those at highest risk for oral cancer (smokers and heavy alcohol drinkers) are less likely to see a physician or dentist than those at lower risk. Common symptoms leading to diagnostic evaluation include sores on the lip or mouth, oral bleeding, persistent white or red patches in the mouth or on the gums, oral swelling and/or pain, sore throat, and difficulty swallowing.

Conclusion

In the near term, the greatest potential for reducing deaths from cancer is through early detection and appropriate treatment. Complete benefit of early detection strategies remains unfulfilled globally due to limitations in access, insufficient resources, uneven quality, and lack of organized systems. Screening opportunistically rather than systematically is inefficient at both the individual and population level. A comprehensive system of early detection and intervention can lead potentially to high levels of participation, provide the readiness to implement any new early detection technology that could improve disease control, and ensure that all program elements are highly competent, interrelated, and interdependent. A systematic approach has the potential not only to increase quality but also to reduce the volume of small errors that contribute to incremental erosion of efficiency, as well as the volume of gross failures that result in death when mortality is avoidable. While many practical barriers must be overcome to establish true population-based screening programs, a system of organized screening holds the greatest potential to realize the benefits of reducing the incidence rate of advanced cancers and, subsequently, avoiding premature mortality.

Clinical Disciplines

Chapter 39

Nexgen pathology: predicting clinical course and targeting disease causation

Carlos Cordon-Cardo, MD, PhD ■ Adolfo Firpo-Betancourt, MD, MPA

Overview

Pathology is a bridging discipline involving basic and clinical biomedical sciences. This context includes both descriptive and mechanistic approaches, with the goals of understanding the anatomical changes and underlying molecular events involved in disease-related processes. Neoplastic disorders are a focal point for the further development of this chapter. The two main objectives of pathology are to define disease causation [from “Pathos” (Greek) “Disease”] and categorize disease states to render clinical diagnostic services. A modern academic Department of Pathology encompasses education activities, including teaching students, training residents and fellows, and mentoring faculty; and hospital-based clinical services usually under three divisions, comprising anatomic pathology (surgical pathology, cytology, and autopsy services); clinical pathology (embodying a variety of laboratory services from blood bank and coagulation to chemistry and microbiology, among others); and molecular pathology (commonly housing somatic genetics, cytogenomics, and flow cytometry). During the past two decades, we have witnessed the transition from descriptive analysis of tissue histology and analyte variables that categorized patients and broad disease stages to more objective and quantitative multidimensional studies aimed at defining individual patient signatures. More traditional population and cohort-based classifications are turning into patient-specific profiles that optimize treatment efficacy and outcome: from diagnostic and prognostic approaches that group patients into disease categories to the development of a more precise, predictive, and individualized patient assessment (Table 1). Such an integrated care model drives selection of evidence-based treatment protocols to optimize clinical outcome, engendering a cost-effective and personalized healthcare. Disease classification and assistance in selection of therapy is the focus of this “patient-centric” pathology approach, expanding into monitoring of therapy (such as assessing therapeutic index and mutational load through tumor genotypes) and managing high-risk patients through early diagnosis of their disease condition ([Figure 1](#)). The ultimate goals are to move from treating symptomatology to treating disease causation once origin of the disease is better understood and to move from a fee-for-service to population-based accountable healthcare management.

From anatomic and clinical pathology to molecular and predictive integrated diagnostics

The origins and the academic establishment of pathology can be traced to the sixteenth to seventeenth centuries in Italy, where physicians systematically performed autopsies to further elucidate diseases suffered by their patients. It is in the writings of Benivieni (1443–1502) and Morgagni (1682–1771) that we find the first clinicopathological correlations, based on meticulous autopsy studies. This descriptive,

gross anatomic approach was supplanted by the French and English “tissue pathology” schools, represented by Bichat (1771–1802) and eventually by the German school of “cellular pathology,” led by Muller (1801–1858) and Virchow (1821–1902).¹ The cell was defined as the unit of life and the target for most diseases, being further expressed by histopathological alterations in the tissue of origin ([Figure 2](#)).² Biochemical, immunological, and genetic discoveries brought scientific knowledge into clinical medicine, and a new armamentarium of technologies during the mid-to-late 1900s. An upsurge of innovative approaches, from DNA amplification and mutation-identification platforms to automated clinical chemistry appeared in the late twentieth century. Molecular pathology evolved from these investigations, integrating histology with immunohistochemical (IHC) and genetic technologies to render phenotype/genotype correlations, thus establishing individualized patient assessment ([Figure 3](#)).^{3, 4}

Table 1 Evolution of pathology from diagnostic to integrated predictive platforms

	Classical pathology	Molecular and systems pathology
Diagnosis and staging	Descriptive analysis of clinical variables, tissue histology, and biomarkers to categorize patients into broad disease stages; no predictive value to inform treatment selection	Objective, quantitative multidimensional analysis of clinical variables, tissue morphometrics, and molecular tumor signatures to define individual patient tumor phenotype and genotype
Prognostic evaluation	Traditional population and cohort-based classification used to deduce disease progression and likelihood of treatment response; nonspecific	Patient-specific characteristics and molecular tumor profiles are used to predict drug sensitivity and radiation response, thus optimizing treatment efficacy and outcome
Treatment selection	Group management approach that stratifies patients into disease categories, assigning therapies on predetermined population-based protocols instead of being patient specific	Personalized and integrated care model drives selection of evidence-based treatment protocol to optimize clinical outcome; patient-tailored treatments improve survival and quality of life
	<i>Diagnostic and prognostic approach that “groups” patients into disease categories</i>	<i>Precise, predictive, and cost effective; individualized patient management</i>

Early diagnosis

- Management of high-risk patients for primary tumors
- Early metastasis detection

Discovery

- New mutations
- Potential targets
- Innovative methods

Diagnosis

Development

- Test validation
- QC/QA
- Disease classification

Clinical service

- Germ line testing (e.g., BRCA1)
- Somatic genetic testing (e.g., EGFR mutations)

Monitoring therapy

- Assessing therapeutic index and reaching effective targeting (e.g., exosome analysis)
- Mutational load and tumor genotypes

Figure 1 Integrated approach to disease management: translating data into knowledge.

(a)

(b)

Figure 2 (a, b) Cellular profiling. The microscope became the innovative device that allowed Dr. Rudolf Virchow (1821–1902) to describe the cell as the unit of life and main target of disease. Disease classification based on histogenesis was developed. Hematoxylin and eosin (H&E) of bladder cancer histological sections; upper microphotograph illustrating a papillary noninvasive transitional cell carcinoma; lower microphotograph illustrating a transitional cell carcinoma *in situ* of the urinary bladder.

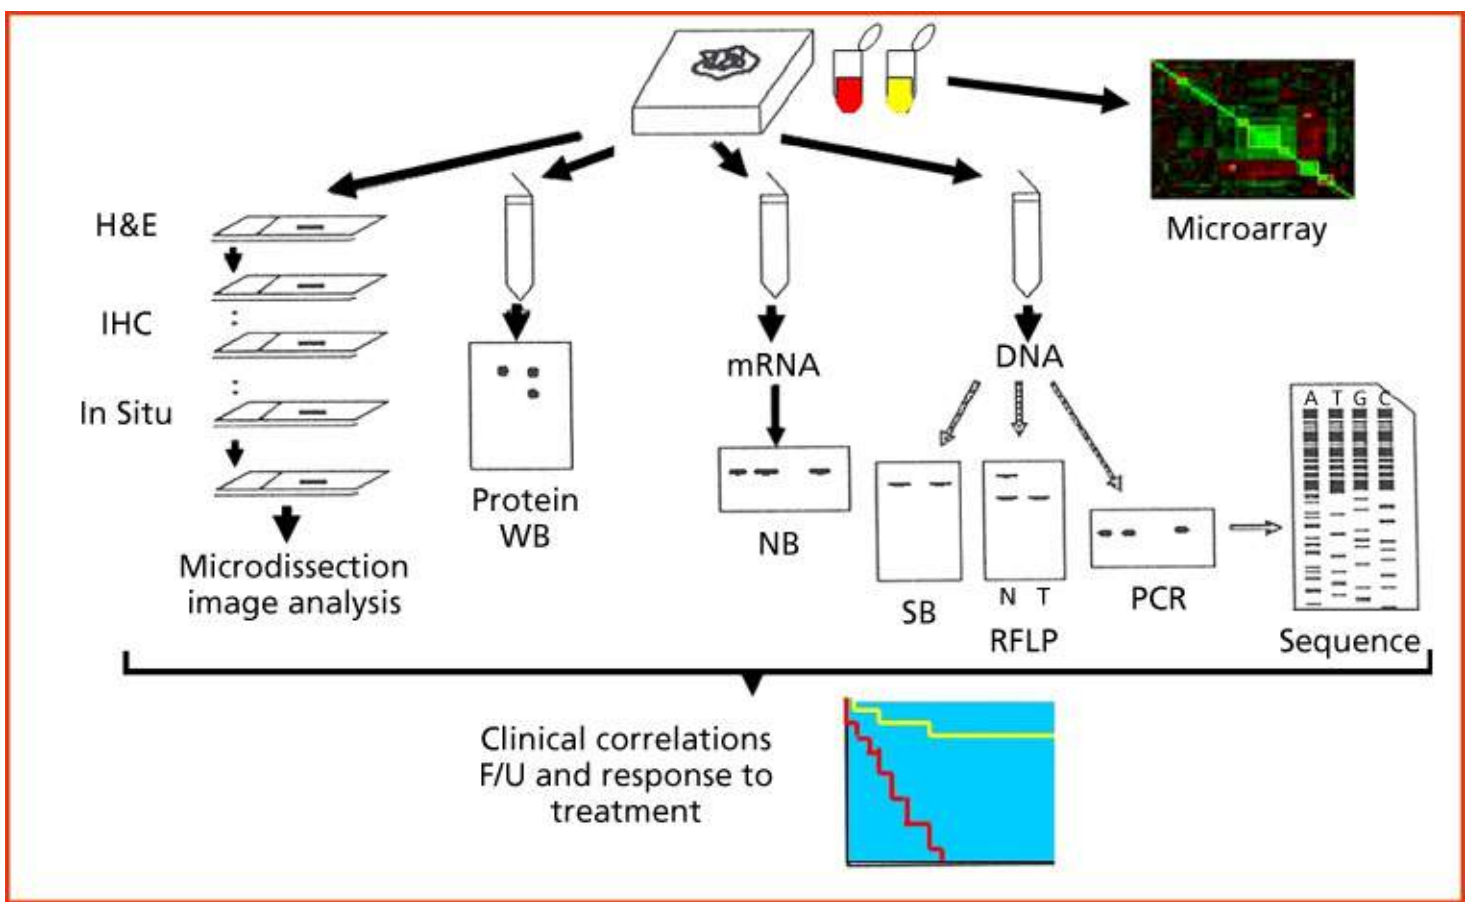

Figure 3 Molecular pathology. Integration of histological, immunochemical, and genetic approaches defines the nature of molecular profiling. Phenotype and genotype are integrated using low- and high-throughput technologies, including histology, protein studies, and nucleic acid analyses. The use of microarray technologies allows the interrogation of multiple analytes on a single assay. H&E: hematoxylin and eosin stain; IHC: immunohistochemistry; WB: western blot; NB: northern blot; SB: southern blot; PCR: polymerase chain reaction; RFLP: restriction fragment length polymorphism; F/U: follow-up.

The role of the pathologist has changed over the years. Traditionally, the main task of the pathologist was the evaluation of patients through morphologic analyses of human tissues and analysis of certain chemicals and biomolecules in body fluids. The diagnosis of cancer involves the analysis of tissue samples and body fluids for features that correlate with malignant transformation and tumor progression. Tissue specimens, cells, and fluids (e.g., blood, urine, and effusions) are obtained through several procedures, including surgical biopsy, endoscopic biopsy, core or aspirational needle biopsy, venipuncture, spinal tap, scraping of tissue surfaces, and collection of exfoliative cells from urine or sputum. The acquired tissue or cell specimens are subjected to a series of analytic modalities for diagnostic purposes. Light microscopy, assessing morphological features of the procured specimens, was utilized almost as the sole approach for many years and remains the standard diagnostic method to which all novel methods need to be compared. The use of enzyme histochemistry and electron microscopy expanded the primary microanatomical evaluation to include biochemical and subcellular structural features. More recently, cytogenetics, analysis of DNA content, molecular genetic assays, and IHC studies have been added as valuable adjuncts to light microscopy in cancer diagnosis, expanding to an in-depth genotype–phenotype characterization. These methods, particularly IHC, have enhanced significantly our ability to define the lines of differentiation of human tumors. The inclusion of these technologies with more recent high throughput, such as next generation DNA sequencing platforms and RNA expression arrays among others, constitutes the basis for molecular pathology, and has added valuable information to

the current classification schemes.⁵ The main goal now is to integrate the data that emanate from this multidimensional arsenal of technologies and translate it into knowledge and to manage such knowledge in order to better manage our patients and community of individuals at high risk for developing certain diseases.

Molecular pathology

Molecular pathology studies the origins and pathogenesis of disease at the biochemical, immunological, and genetic levels. Cancer is a clonal disease driven primarily by genetic mutations and epigenetic derangements.^{6, 7} This means that any given tumor originates in a single cell (clonality) that has been primed by specific molecular triggers (tumorigenesis). Such a cell accepts genetic manipulation, does not activate pathways of cell death or immune surveillance, and progresses toward invasion and metastatic spread, the ultimate malignant phenotype. Even though several tumors have their origin in viral infections (oncoviruses) in which certain viral proteins (oncoproteins) enhance proliferation and abolish apoptotic responses, such as the case of certain human papilloma virus subtypes, most cancers can be defined as diseases driven by either inherited or somatic mutations. In this regard, pathology differs from medical genetics, in which the main objective is to determine the abnormalities associated with inherited disorders carried as germ-line mutations. Molecular pathology of cancer aims to identify and understand the aberrations involved in the development and progression of neoplastic diseases. Clinically relevant objectives include (1) establishing a definitive diagnosis and classification of tumors, based on the recognition of complex profiles (fingerprints) or unique molecular alterations that occur in specific tumor types; (2) providing early detection of tumor cells using sensitive molecular techniques, thus anticipating therapeutic intervention; (3) rendering prognostic information of clinical relevance, through the assessment of molecular predictors of outcome; and (4) assisting in the selection of individualized treatment regimens, thereby gaining specificity and avoiding unnecessary drug toxicity. Companion diagnostic tools are designed to guide targeted clinical trials and personalized oncological treatments. The clinical services rendered also include the analysis of minimal residual disease and evidence of early relapse usually driven by new resistant clones of cancer cells. Protocols based on molecular markers have been proven to increase the chances for cure by opting for the right management approach and improve the quality of life of patients with cancer.

Molecular pathology also serves as a bridge between clinical and basic biomedical sciences. The translational aspects of research in molecular pathology are bidirectional, involving both the active transfer of relevant observations that are the result of the analysis of primary tumors and clinicopathological correlations to basic laboratory studies and the effective transfer of laboratory findings into clinical analyses and protocols. Molecular pathology thus facilitates the transfer of biological discoveries into diagnostic, prognostic, and therapeutic applications.

The use of molecular techniques has led to remarkable progress in our understanding of cell growth, differentiation, maintenance of genomic integrity, and programmed cell death, these being key pathways in tumor development and progression.³⁻⁵ Certain biological markers, such as alterations of TP53 tumor suppressor gene, correlate with tumor behavior when detected in specific tumor types.⁸ Similarly, prospective clinical analyses utilizing well-characterized cohorts of patients and properly selected normal and tumor paired samples are needed to better delineate the role of mutations occurring in these genes, as they impact on patients affected with cancer. Discrepancies of reported results aimed at the identification of gene mutations and altered patterns of gene expression in primary tumors can be explained by the use of different probes and methods. Critical caveats include the presence of viable

tumor, the extent of necrosis, normal-to-tumor cell ratio, and the stage and grade of the lesion being studied. Distinct methods are often available to detect a given marker, differing in specificity, sensitivity, speed, and cost, as well as appropriateness for particular clinical situations. The application of the full spectrum of molecular methods to evaluate tissue specimens and the potential availability of therapeutic agents aimed at specific molecular targets have led to changes in the established patterns of tissue procurement, processing, and tissue banking. Protocols should be implemented and constantly updated to guarantee that samples are handled in a way that will allow optimal application of molecular testing. In daily practice, this means that part of a specimen should be set aside prospectively for advanced diagnostics whenever possible. Adding predictive assays to our diagnostic and prognostic tools will enhance our ability to design effective treatment regimens.

Bladder cancer as a model of molecular pathology classification

Bladder cancer is the fifth most commonly diagnosed noncutaneous solid malignancy and the second most frequently diagnosed genitourinary tumor after prostate cancer.^{9–11} Prevalence of bladder cancer is 6 times higher in developed compared to developing countries. As it is characterized by frequent recurrences, bladder cancer represents one of the most costly malignancies to health care systems owing to the requirement for intensive surveillance with cystoscopies and urinary cytologies, as well as frequent tumor resections under anesthesia.^{9–11} Clinically, most patients with bladder cancer present with dysuria and hematuria.¹² After cystoscopy and biopsy evaluation, two distinct superficial (noninvasive) type lesions have been described: low-grade neoplasms, which are always papillary (Ta low-grade urothelial carcinomas), and high-grade carcinoma *in situ* (Tis or CIS) lesions. CIS is a flat high-grade tumor that progresses to invasive bladder cancer in 60–80% of cases within 5 years, representing the cause of death in 40% of these patients.^{13–15} These two clinicopathological entities define a novel model for tumor initiation and progression of bladder cancer based on molecular genetic studies.^{16–22} Two distinct genetic pathways characterize the evolution of early-stage bladder neoplasms, as well as later bladder cancer progression.^{23, 24} Superficial papillary bladder tumors are characterized by gain-of-function mutations affecting oncogenes H-RAS, FGFR3, and/or PI3K, and deletions of the long arm of chromosome 9 (9q). CIS lesions are characterized by loss-of-function mutations affecting tumor suppressor genes p53, RB, and/or PTEN.^{25–40} These mutations are the main genetic precursors of invasive bladder cancer. On the basis of these data, a model for bladder tumor progression has been proposed in which two separate genetic pathways characterize the evolution of early bladder neoplasms ([Figure 4](#)).

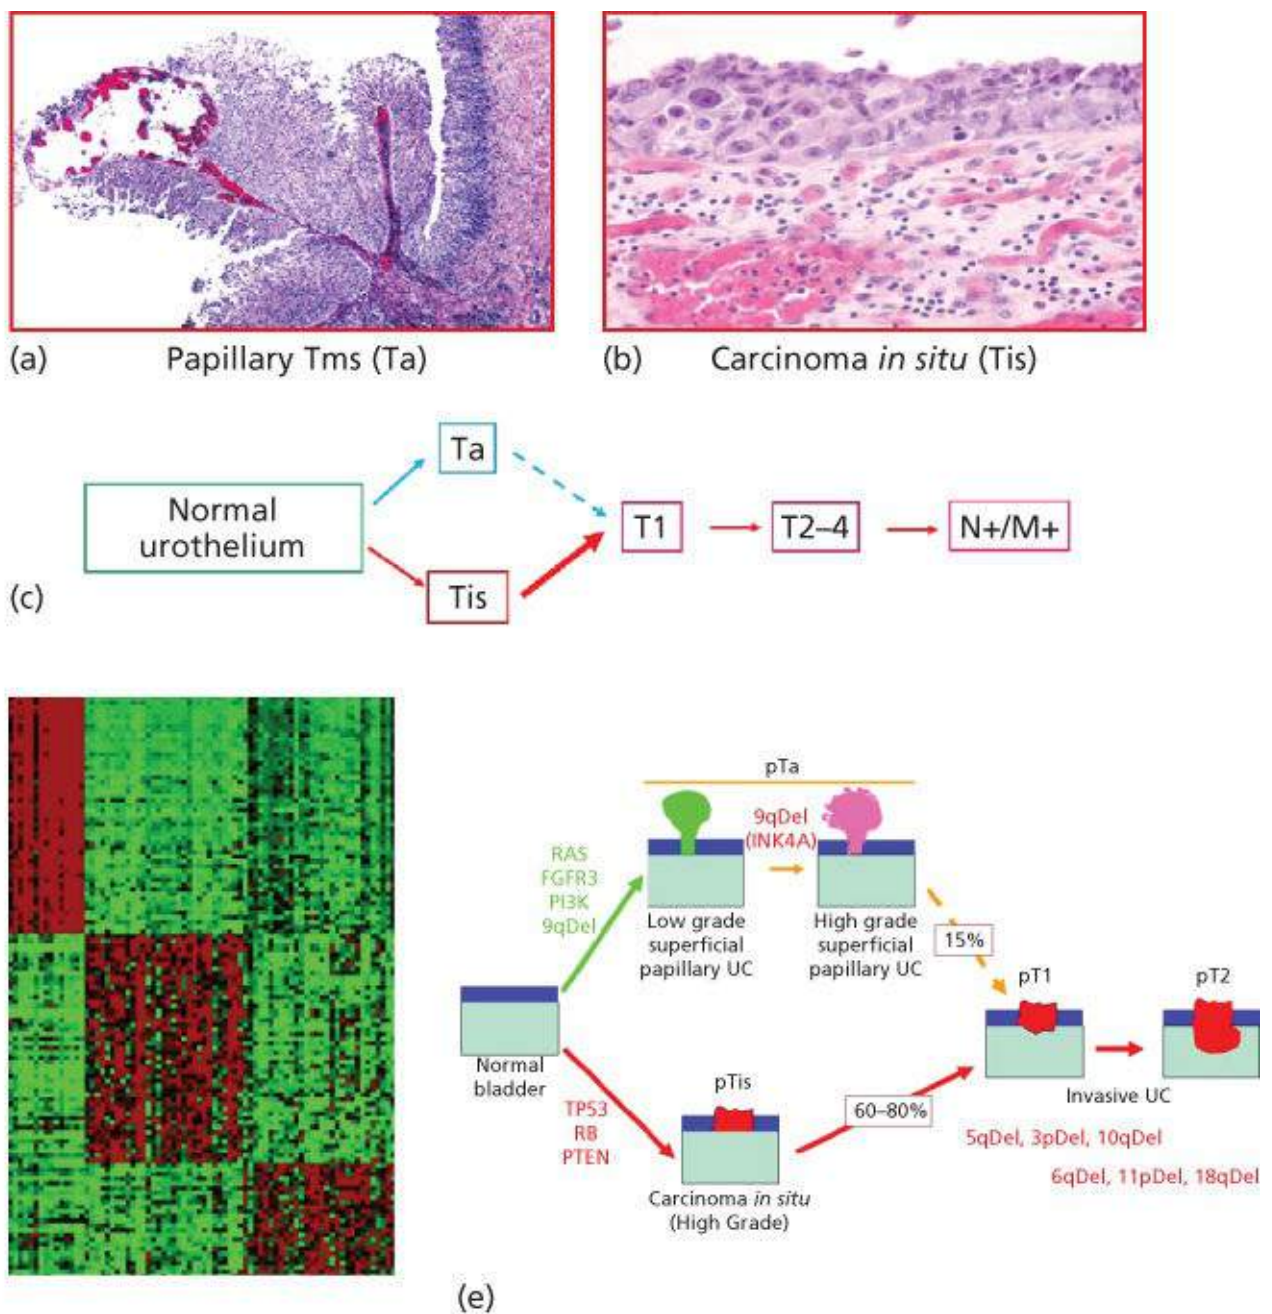

Figure 4 (a–e) A molecular approach to disease classification: bladder cancer as a model. Bladder tumors present as initial clinical entities as either papillary noninvasive (Ta) tumors that tend to recur but not to progress to invasion, or noninvasive dysplastic carcinoma *in situ* (Tis) lesions that tend to invade and progress to a clinical aggressive disease and, ultimately, metastasis spread. Multiple technologies, including expression profiling, reveal also a two-stage molecular classification, namely superficial and invasive bladder cancer. Superficial papillary bladder tumors are characterized by mutations affecting oncogenes (e.g., H-RAS, FGFR3, and PI3K), and/or chromosome 9 (9q) deletions; while carcinoma *in situ* tumors are characterized by mutations affecting tumor suppressor genes (e.g., p53, RB, and PTEN).

Systems pathology and predictive oncology

Most diagnostic platforms are based on unidimensional tools, extracting morphological or biomarker information based usually on a particular technology. Systems pathology represents a novel, comprehensive approach to personalized medicine. “Systems pathology” can be defined as the platform that integrates clinical variables, histological and cellular features, as well as molecular profiles through the application of novel technologies in the areas of image analysis, pattern recognition, and quantitative

biomarker multiplexing ([Figure 5](#)).^{41–46} Such approach, from formalin-fixed paraffin-embedded tissue sections stained by hematoxylin–eosin and through antibody/probe-fluorescence-labeled analytes, enables conduction of cell-level quantitative imaging studies. Tumor phenotypes, including analysis of signaling pathways, can be evaluated in the context of dynamic histological studies using the patient's own clinical data and tissue specimens to construct a baseline characterization defining a clinical risk state.^{42, 44} The data generated can be transformed into actionable clinical options for decision-making tools produced by machine learning and artificial intelligence. Highly accurate algorithms of predictive nature for patient management can be generated to improve outcomes. After the computations are complete, the end result often renders a user-friendly report providing an individualized prediction for the patient's probability of experiencing a specific outcome over time. For example, in the case of prostate cancer, this can include predictions of the time to disease recurrence and of clinical failure after radical prostatectomy.^{45, 46} The systems pathology approach can be further illustrated using prostate cancer as a model. The diagnosis and staging of prostate cancer has become increasingly problematic in recent years. As a result of widespread screening, the incidence of late-stage disease has declined dramatically. Furthermore, earlier diagnoses have led to a compression of clinical assessments, whereby approximately 85% of diagnosed patients are categorized as low or intermediate risk, categories where current risk stratification tools (e.g., Gleason score) are less well correlated with outcomes.^{47–51} Given the current homogeneity in initial clinical impression, traditional diagnostics have left physicians without a reliable method of determining who will go on to develop life-threatening disease and who has indolent disease that will not exhibit symptoms or limit longevity. Part of the stratification problem rests with the limitations of the currently available tests. Prostate-specific antigen (PSA) is neither a very sensitive nor a very specific indicator for the presence of prostate cancer. PSA is also not very good at predicting clinically significant disease for the majority of patients. With earlier detection, significant problems arise surrounding the current Gleason grading systems that are subjective and lack reproducibility, specifically for diagnosing dominant high-grade Gleason 4 disease. Multiple prognostic features can be discordant when reviewed as a group. For example, a patient can have a high PSA but a “low-risk” Gleason score (e.g., six or less). In addition, a large subjective component exists in defining surgical margin status. There is a significant clinical need to incorporate additional quantitative, objective measures that are derived from the analysis of an individual patient's tissue specimen to provide a personalized prediction of risk ([Figure 6](#)).

Algorithm-based platform for the accurate diagnosis and better management of cancer patients. founded on tests of higher precision that render more efficient patient care.

Figure 5 Systems pathology. A novel diagnostic and predictive oncology platform integrating phenotype and genotype using artificial intelligence and algorithms.

Figure 6 (a–d) An integrated system approach for outcome prediction: prostate cancer as a model. Digital conversion of hematoxylin and eosin stain tissue sections (a) into morphometric images that allows quantification of microanatomical features (e.g., number of glands) (b). Protein multiplexing using antibodies to clinical relevant biomarkers (e.g., androgen receptor or AR, proliferation index by Ki67 analysis) (c) allows quantitation of biological markers and stratification of patients in clinically significant groups, such as prostate cancer patients with low versus high AR levels.

The first version of a precision pathology platform was aimed at risk evaluation after surgical removal of the prostate gland affected by prostatic carcinoma.^{45, 46, 52} This “Post-Prostatectomy” assay uses prostatectomy tissue to predict which patients are likely to have either disease progression, which reflects on the aggressive nature of the disease, or biochemical recurrence (through PSA detection and rising PSA) within 5 years after surgery. Such an assay assists physicians to properly assess the risk of disease progression postradical prostatectomy by identifying a baseline objective phenotype that can be used to guide potential future treatment. The assay was developed using a cohort of 758 patients from Memorial Sloan-Kettering Cancer Center, New York. The predictive models in this assay outperformed independent clinical factors and other common postsurgical risk factors such as positive surgical margins, extracapsular extension, as well as integrative nomograms in predicting patient progression postsurgery.

The postoperative assay added significant biometric information to standard of care features with improved risk stratification accuracy [hazard ratio (HR) 11.4, concordance index (CI) 0.84, $P < 0.0001$]. After radical prostatectomy, the postprostatectomy assay yields a personalized risk assessment report that (1) provides more information on the risk of serious disease progression for patients experiencing a biochemical recurrence; (2) predicts serious disease progression and PSA recurrence at the time of surgery; and (3) supports objective decision making on the appropriate use of adjuvant therapy.^{45, 46, 52}

Following the prostatectomy model, a second development centered on an assay for prostate needle biopsies for newly diagnosed patients.⁵³ The test is based on biopsy tissue at diagnosis to predict disease progression. In addition, the assay also provides for the recognition of a favorable pathologic stage (potentially indolent disease). It helps physicians to properly assess disease severity for newly diagnosed men and make more-informed treatment decisions. The test was developed on 1027 patients from an international multi-institutional cohort of leading institutions. The predictive models in this assay outperform independent clinical factors and other integrative tools, such as nomograms, in predicting patient risk at the time of diagnosis. The first version of the biopsy test added important biometric data to standard of care features with significant risk stratification accuracy (HR 3.47, CI 0.73, $P < 0.001$). This test allows the treating physician to apply appropriate treatment paradigms to individual patients. At diagnosis, the biopsy test provides physicians with objective, actionable information that adds significantly to the clinical information currently used to assess risk. In this context, it can assist the urologist in (1) predicting disease progression after definitive treatment (e.g., prostatectomy); (2) making objective, informed treatment decisions; (3) identifying high-risk patients presenting as lower risk; (4) re-classifying clinically ambiguous intermediate-risk patients as either high or low risk; (5) helping to alleviate some of the anxiety of the unknown for patients. For patients who proceed to radiotherapy, the initial biopsy sample and associated Gleason score will be the only “tissue view” of their disease. There will never be the opportunity to evaluate the resected prostate. The assay provides an additional and unique window on the status of the prostate and associated tumor. Of note, exploratory validation of the assay in a small cohort treated by radiotherapy yielded strong results. In addition, low-risk patients considering active surveillance/watchful waiting can use the biopsy results to determine if they should avoid this conservative regimen and instead proceed with treatment. Of particular significance are the promising results of the assay in a preliminary active surveillance population. Briefly, a well-characterized cohort ($n = 181$) of men enrolled in an active surveillance program was studied using the Needle Biopsy assay and found that the integrated analytics successfully predicted time to treatment (e.g., exit from active surveillance) with a CI of 0.65 and HR of 3.6 ($P < 0.0001$).

As a corollary of the above-referred studies and developments, pharmacoeconomic analyses were performed revealing that the post-prostatectomy test had a cost-effectiveness ratio of US\$2100/QALY (quality-adjusted life years) compared with clinical practice. Similarly, an initial cost-effectiveness analysis of the Biopsy Test in the clinically important intermediate risk population yielded a cost savings of US\$2300. A refined analysis based on 233 prostate cancer patients of 23 nationwide urologists yielded cost savings of US\$1889 in the crucial combined intermediate and high-risk patient population.^{54–56}

From treating symptomatology to treating disease causation

Cellular homeostasis develops and is maintained by the coordinated balance of four critical programs: proliferation (cell-cycle division), differentiation, senescence, and cell death (apoptosis).^{4, 7} Tissue renewal has been postulated to be regulated by a balance of these programs guided by a tissue-specific stem cell compartment.^{57–62} Many characteristic properties have been attributed to stem cells. There are

two cardinal features: (1) stem cells are capable of self-renewal, producing new stem cells through cell division and (2) stem cells are multipotent progenitors that can give rise to differentiated transient amplifying cells through asymmetrical cell division. Of course, these cells also display an undifferentiated phenotype ([Figure 7](#)).

[Figure 7](#) Characteristics of stem cells versus differentiated cells. Essential characteristics of stem cells include an undifferentiated phenotype, asymmetrical cell division, and self-renewal capacity. Differentiated cells divide through symmetrical division, also known as mitosis. The originating cell after completion of asymmetrical cell division or self-renewal persists and continues its physiological functions; while the originating cell in mitosis disappears through nuclear division and cytokinesis producing two identical daughter cells.

Cancer is a term used to define a group of diseases characterized by unregulated cell proliferation, aberrant differentiation, and defective apoptosis. Two major hypotheses regarding tumor initiation have been postulated: the “stochastic model” which predicts that every neoplastic cell can generate an entirely new tumor; and the “cancer stem cell (CSC) model” which proposes that tumor cells exist in a hierarchical state and that only a few stem cells possess tumor-initiating potential ([Figure 8](#)).^{58–62} Regarding the latter model, all neoplastic diseases may have in common an initial transforming event that is manifold in nature (e.g., viral infection, chemical carcinogens, and spontaneous mutation) that impacts this unique somatic tissue cell, the so-called adult stem cell. These transforming events are believed to generate a CSC that is responsible for tumor initiation and the hierarchical organization of cancer. Supporting this hypothesis is the fact that cancer is a clonal disease, meaning that it develops as the progeny evolves from a single cell.

Figure 8 Cancer stem cell model of tumorigenesis and tumor progression. It is our working hypothesis that neoplastic transformation initiates in a somatic tissue stem cell capable of sustaining genetic manipulation, based on down-regulated apoptotic programs and an HLA-negative phenotype that favors escaping immune surveillance. This transformed cancer stem cell undergoes self-renewal as well as asymmetrical cell division, producing differentiated clones that rapidly expand, creating heterogeneous populations of differentiated tumor cells.

The CSC hypothesis posits that in addition to CSC, tumors comprise a small population of transit amplifying clonogens and large sets of differentiated malignant cells (Figure 9).⁶² CSCs, like their normal stem cell counterparts, are characterized by a specific set of properties that include an undifferentiated phenotype capable of displaying asymmetrical cell division, resulting in self-renewal and production of differentiated clonogens, thus contributing to tumor heterogeneity. In addition, CSCs have been postulated to be refractory to most standard chemotherapy treatments, although such treatments frequently result in eradication of the fastest dividing cells, an early tumor response, but not in CSC depletion.⁶² Such a model could explain why standard human cancer chemotherapy frequently results in initial tumor shrinkage, although most cancers eventually recur owing to regeneration by surviving CSCs.

1 Transition

2 Selection

3 Stemness

Figure 9 Cancer stem cell and chemotherapy resistance. Different models have been postulated to address chemoresistance. The transition model proposes that a state transition develops whereby sensitive tumor changes into a resistant clonogenic neoplasm. The selection model follows a Darwinian hypothesis and proposes that heterogeneous subpopulations exist in the primary, untreated tumor and that while sensitive clones die, resistant clones survive and expand. The stemness model proposes that cancer stem cells represent a small subpopulation of the tumor and that such cancer stem cells are nonresponsive to most conventional agents, and while sensitive cells die, the cancer stem cell compartment expands through self-renewal and new resistant clones to the agent are generated through asymmetrical cell division.

It is important to define and differentiate “resistance” versus “nonresponse” phenotypes. Resistance in the context of chemotherapeutic resistance is an acquired phenomenon after overcoming the sensitivity state. However, nonresponse is a *de novo* phenomenon that does not imply a preceding responder phenotype. CSC expresses high levels of export pumps of the multidrug resistance protein (MRP), including the multidrug resistance 1 (MDR1) or P-glycoprotein. In addition, the mechanism by which asymmetrical division proceeds is not well defined, but there is documented *in vitro* evidence that asymmetrical division occurs even in the presence of certain conventional mitotic inhibitors, such as taxanes. Taken together, these mechanisms can confer a nonresponding phenotype to CSC enabling survival despite exposure to certain chemotherapeutic agents. These viable CSC then produce resistant clones that eventually preclude successful treatment (Figure 9). Our laboratory first reported such a CSC subpopulation using prostate cancer as a model system.⁶³ Our study also revealed the contribution of such CSCs to chemotherapy resistance. These therapy-resistant CSCs exhibit an undifferentiated phenotype characterized by loss of epithelial differentiation markers (e.g., cytokeratins¹⁸), lack of HLA class I expression in the cell membrane, and activation of developmental pathways, programmed by Notch and Hedgehog genes.^{63, 64} Importantly, the experimental models developed by our laboratory enabled us to isolate and identify for the first time CSCs in clinical prostate cancer tissues and to elucidate a novel therapeutic strategy where inhibition of Notch and Hedgehog signaling pathways abrogates tumor relapse after conventional therapy using patient-derived tumor xenografts in an immunodeficient murine model. More recently, through the interrogation of public patient-derived data sets with the gene expression profiles of chemotherapy-resistant CSC models, we found that the transcription factor GATA2 regulates an IGF2-driven polykinase program that contributes to chemotherapy resistance and tumorigenicity in

lethal prostate cancer.⁶⁵ Notably, in this study, we generated for the first time patient-derived xenografts from circulating tumor cells that facilitated the preclinical validation of a promising new treatment combination (docetaxel or cabazitaxel plus a dual IGF1R/INSR inhibitor) for prostate cancer. The initial prostate cancer translational model has been extended to other cancers, including breast and colon carcinomas, as well as gliomas and sarcomas.

The fact that these CSC generically exhibit a negative histocompatibility signature is consistent with our previous report that single cells and clusters of human tumor cells that lacked HLA class I expression, correlated with aggressive behavior locally and metastatic capacity.⁶⁴ Furthermore, an HLA-negative phenotype is also shared by embryonic stem cells. Human preimplantation embryos are reported to be HLA class I and class II negative. This phenomenon precludes rejection because of expression of paternal antigens, until a blood-tissue barrier develops, which in this situation is generated in part by the placenta. In the context of CSCs, such a histocompatibility negative phenotype has major clinical implications, as it can explain host mutation permissiveness, as well as tumor spread and metastatogenic capabilities, as CSC could escape immune surveillance. Furthermore, it may be linked to some clinical failures observed in the innovative immunotherapeutic targeting of cancer, as when using activated T lymphocytes for which the presence of MHC expression on the target cells is critical.

In sum, we have been able to identify and characterize a newly defined prostate CSC in human cancer cell lines and tissue samples. Moreover, we have been able to isolate this population of cells using HLA class I surface marker and demonstrated its tumor initiating capacity. Further, we show that similar CSC populations are present in human breast, colon, lung, and bladder carcinomas, as well as in human sarcomas and glioblastomas, a fact that gives further universality to the findings. The discovery of this human CSC has important clinical implications in diagnostic and predictive laboratory assays, as well as for development of novel therapeutic strategies targeting both the CSC and the differentiated clones ([Figure 10](#)).

Figure 10 A working model for targeting symptomatology and causation. This model postulates that in order to eradicate cancer two different subpopulations need to be targeted: the differentiated tumor clones and the cancer stem cells. This figure illustrates distinct approaches to combine anticancer stem cell (anti-CSC) therapies with those targeting differentiated cancer clones, including epigenetic agents that could turn an undifferentiated clone into a differentiated clone, as well as novel agents and targeting the microenvironment.

Chapter 40

Molecular diagnostics in cancer

Roshni D. Kalachand, MBBCh, MD ■ Bryan T. Hennessy, MD ■ Robert C. Bast Jr. MD ■ Gordon B. Mills, MD, PhD

Overview

Molecular diagnostics refers to the use of molecular alterations that are associated with cancers to facilitate detection, diagnosis, monitoring, and/or treatment. Molecular biomarkers have often been studied in cancer tissue but potentially can be assayed in readily available patient samples (saliva, sputum, blood, urine, and feces), thereby minimizing the need for invasive biopsies. Traditional blood biomarkers—CEA (carcinoembryonic antigen), PSA (prostate specific antigen), hCG (human chorionic gonadotropin), AFP (alpha-fetoprotein), CA125 and CA15-3—have been used to monitor response to treatment and to detect disease recurrence. Their clinical utility often depends on the availability of effective treatment for residual or recurrent disease. Early detection requires biomarkers with high sensitivity to detect preclinical and ideally premetastatic disease, as well as high specificity to permit efficient, cost-effective screening. Two-stage strategies are often most promising where rising biomarkers trigger imaging or results of imaging are combined with biomarkers to improve positive predictive value. Cancer-specific genomic aberrations have been identified which guide therapy and predict outcomes in subgroups of patients. Trastuzumab has dramatically altered the outcomes of patients with *HER2* amplified breast cancers, as have EGFR (epidermal growth factor receptor) inhibitors in the treatment of metastatic *EGFR* mutation positive non-small-cell lung cancer. As single driver gene aberrations frequently are not sufficient to predict therapeutic responses, gene signatures and multimarker panels incorporating DNA, RNA, and/or protein aberrations are being evaluated as potential effective biomarkers. A panel of multiple biomarkers (OncoType Dx) has proven useful in predicting the need for chemotherapy in addition to hormonal therapy in hormone receptor-positive breast cancer. As targeted therapies are becoming a reality, so is the predictable emergence of resistance to these therapies, often occurring through gene amplification, secondary mutations, or reactivation of signaling mechanisms downstream from the targeted molecular aberration. The search for molecular biomarkers, the so-called companion diagnostics, predictive of first-line therapy resistance and second-line therapy response, is now inherent to targeted drug development. However, these emerging integrative technologies have yet to benefit the majority of patients with cancer. Interpretation of the extensive number of aberrations identified by high-throughput technologies, availability of adequate high-quality tissue, cost, and clinical validation remain significant challenges to developing and implementing effective biomarkers. Strategic use of bioinformatics, international collaboration, development of prospectively collected clinically annotated biobanks containing fresh frozen tissue, and clinical validation in large prospective data sets key to bringing useful molecular biomarkers into clinical practice.

Introduction

Molecular diagnostics involves the use of molecular biomarkers (Box 1) to detect, diagnose, or monitor cancer, as well as to estimate patient prognosis or to predict therapeutic interventions likely to benefit the patient. Ultimately, the development of molecular diagnostics is expected to facilitate the individualization of cancer treatment with the goal of maximizing treatment benefit for individual cancer patients, while minimizing toxicity. Important progress has already been made in developing and applying molecular diagnostics to clinical management. This chapter provides an overview of the current status of molecular diagnostics for cancer. It will also review potential approaches to the integration of biomarker-driven approaches into the future development of individualized cancer therapies, as well as new techniques and likely problems and hurdles that will need to be addressed and overcome.

Box 1 Cancer biomarkers

A cancer biomarker includes any characteristic of tumor cells, stroma, normal tissues, or body fluids that aid in detecting, diagnosing, monitoring, defining prognosis, or predicting response or toxicity from treatment. Thus biomarkers include alterations in DNA, RNA, protein, carbohydrate, lipid, or metabolites as well as biophysical characteristics of tumor cells, the tumor microenvironment, or the host genome and response. Pathologic examination and imaging techniques have provided conventional tumor histologic and staging information that have guided patient management to date. However, these approaches do not consider the full inter- and intratumoral heterogeneity of cancers at the molecular level. Individualization of screening, prevention, and treatment should be substantially improved by considering the profile of multiple molecular biomarkers across different platforms.

Molecular biomarkers for screening and early detection of cancer

Early detection implies the diagnosis of cancer at its earliest stage of development. It is essential that early diagnosis occur at a stage of tumor development where cure can be achieved with currently available therapy. Screening strategies generally require high sensitivity and specificity. Early detection could be facilitated by identifying individuals at high risk for developing specific cancers, decreasing the hurdle of specificity by assessing higher risk individuals.^{1–4} Screening is a term used for approaches that facilitate detection of tumors at an early curable stage. Effective cancer screening strategies must be cost effective, acceptable to patients and associated with limited morbidity from both the intervention and from false positive results. As screening of the entire population is seldom practicable, guidelines for patient risk assessment are often necessary to appropriately target approaches to prevent and diagnose cancer early. As our understanding of cancer's molecular heterogeneity advances, novel criteria can be added to the conventional criteria that describe an ideal screening biomarker (Box 2). Thus, as most cancer treatments are effective in only a minority of cancer patients, future useful screening biomarkers could also guide appropriate therapies in individual patients.

Box 2 An optimal screening test

Five critical terms describe the criteria for a screening test: *sensitivity*, *specificity*, *selectivity*, and *positive* and *negative predictive values*. Sensitivity is the fraction of cases of the disease that are detected by the test (number of true positives/number of true positives plus false negatives).

Specificity is the fraction of cases without cancer that are detected as negative by the test (number of true negatives/number of true negatives plus false positives). Selectivity represents the ability of a screening test to differentiate between different types of cancer. When a test result is a continuous variable, sensitivity and specificity are inversely related and a cutoff for the presence of disease is placed in an arbitrary manner that indicates the clinical consequences of an incorrect result. In most effective screening approaches, a two-stage strategy has proved optimal with a primary diagnostic test followed by a secondary test that optimizes sensitivity and/or specificity beyond that achievable with only a primary test alone (e.g., colposcopy following Pap smear). This approach can help control the consequences of false positive results, invasive approaches, and cost. The prevalence of the disease in a population also affects screening test performance: in low-prevalence settings, even very good tests have poor positive predictive values (the proportion of patients with positive test results who are correctly diagnosed, that is, number of true positives/number of true positives plus false positives). Hence, knowing the prevalence of the disease is a critical prerequisite to interpreting screening test results. Screening for relatively uncommon cancers (e.g., ovarian and pancreatic) requires much greater specificity than screening for more common cancers (e.g., breast or prostate).

Emerging radiologic and endoscopic techniques afford increasingly more sensitive noninvasive procedures for early detection of small tumors. Despite some controversy, low-dose computed tomography appears to detect early lung cancer and decrease lung cancer-related mortality in people at high risk from cigarette smoking, in contrast to routine chest films.⁵ Similarly, the addition of annual bilateral breast magnetic resonance imaging to annual mammography as an early breast cancer detection strategy for *BRCA1/2* gene mutation carriers could decrease the use of bilateral prophylactic mastectomies to reduce the risk of breast cancer in these patients.^{6, 7} In colon cancer, the ability of colonoscopy to visualize small lesions throughout the entire colon has made this the screening method of choice over double contrast barium enemas. Nonetheless, such tools depend on a tumor's anatomical features for detection, whereas molecular markers could identify cancer at an early and perhaps premalignant stage, before anatomical detection. Moreover, biomarkers can be detected in bodily fluids (urine, feces, and blood), avoiding potential patient discomfort from endoscopy preparation as well as potentially harmful ionizing radiation from radiologic imaging.

Screening is generally applied to those populations where there is conclusive evidence of an associated survival benefit and, to assure cost effectiveness, where the cancer is a common cause of mortality. As an example, although controversial, most regulatory agencies in the United States recommend annual mammography for women aged 40 years and older.⁸ Alternatively, risk assessment can be used to stratify select patients to screening or, if the risk is high enough, prevention. This way, the exposure of large numbers of individuals to false positive screening tests and unnecessary biopsies is avoided while maintaining a high cancer detection rate in at-risk patients. Currently, risk assessment is based largely on patient-specific factors, including age, family history, and social factors (e.g., tobacco use), as is the case in lung cancer screening. However, some molecular markers, such as mutations in cancer predisposition genes (e.g., *BRCA1*, *BRCA2*, and *p53*), have demonstrated utility in the identification of at-risk populations.

Molecular biomarkers in current clinical practice for screening, prevention and early detection

Prostate cancer

Prostate-specific antigen (PSA) is normally present in the blood at very low levels ranging between 0 and 4.0 ng/mL. Increased PSA levels can be associated with an underlying prostate cancer. Serum PSA measurement for prostate cancer screening is controversial, despite widespread use.⁹ Up to 15% of prostate cancers can occur in the absence of an elevated PSA. PSA levels can be elevated due to prostate infection, irritation, benign prostatic hypertrophy, or recent ejaculation. Thus, PSA is not an adequately sensitive or specific marker for prostate cancer screening. PSA screening can lead to a high rate of unnecessary biopsies, over-diagnosis and overtreatment, resulting in morbidity. Both prostatectomy and radiotherapy can be associated with impotence and incontinence. Patients diagnosed with less aggressive (Gleason score < 7) prostate cancer can survive decades with their cancer, often dying from comorbid diseases. PSA screening in men over the age of 50 years can confer up to a 20% decrease in prostate-cancer-specific mortality, although this may or may not translate into a decrease in overall mortality, judging from large multicenter trials.^{10, 11} In the past, PSA screening has been recommended for men older than 50 years with an expected life expectancy of 10 years or more, following discussion with the patient about screening-associated risks.¹² The United States Preventive Health Task Force now recommends against using PSA for screening.¹³ The American Urological Association (AUA) has more nuanced age-dependent guidelines.¹⁴ The AUA recommends against PSA screening for men under age 40. Between age 40 and 54, PSA screening is recommended only for African-American men or men with a positive family history conferring increased risk. For men ages 55–69, the benefits of preventing prostate cancer mortality in one man for every 1000 men screened over a decade must be weighed against the known harms associated with screening and treatment. PSA screening is not recommended for men over 70 years.

Most PSA in the blood is bound to serum proteins. A small amount is not, and is called free PSA, an isoform of which, [-2]proPSA, is highly associated with prostate cancer. The combination of PSA, free PSA, and [-2]proPSA in a single score, the Prostate Health Index (PHI), shows increased sensitivity over PSA screening alone in men with PSA levels between 4 and 10 ng/mL but has not been widely adopted as a prostate cancer screening tool.¹⁵

Ovarian cancer

The relatively low prevalence of ovarian cancer—1 : 2500 in the United States—means that strategies for early ovarian cancer detection must have relatively high sensitivity (>75%) for preclinical disease and an extremely high specificity (99.6%) to attain a positive predictive value of at least 10%, that is, 10 operations for each case of ovarian cancer detected. Serum CA125 has received the most attention but lacks the sensitivity or specificity to function as a stand-alone screening test. Two-stage screening strategies promise to be more effective, where increasing levels of serum biomarkers over time prompt transvaginal sonography (TVS) to detect lesions that require laparotomy. With annual determination of CA125 in women at average risk for ovarian cancer, a computer algorithm has been developed to determine deviations from each woman's own baseline. If CA125 increases significantly, TVS is performed and if imaging is abnormal, laparotomy is undertaken. If the CA125 is unchanged, a woman returns in 1 year and if CA125 is mildly elevated, biomarker levels are obtained in 3 months. On the basis of this strategy, a study of more than 5000 healthy postmenopausal women coordinated by MD Anderson, performed 18 operations to detect 2 borderline and 10 invasive cancers with 75% in stage I or II.¹⁶ No more than three operations were required to detect each cancer. A much larger randomized trial involving 200,000 in the United Kingdom is powered to test the impact of this strategy on survival and mortality. Data from the first 2 years of accrual suggest that a two-stage strategy could increase the fraction of disease detected in early stage.¹⁷ Using deviations from each woman's baseline, rather than a single cutoff

for CA125 alone, doubled the number of ovarian cancer cases detected.¹⁸ Outcome of the study will be reported in the near future and could change practice, if positive. As only 80% of ovarian cancers express CA125, other markers will be required for early detection of all ovarian cancers. The development of technologies that measure multiple serum markers simultaneously, linked to the creation of statistical methods that enhance sensitivity without sacrificing specificity, hold great promise.

Cervical cancer

The establishment of national cervical cancer screening programs involving the detection and treatment of the premalignant stage of cervical intra-epithelial neoplasia (CIN) through cervical Pap smear cytology has reduced incidence and mortality from cervical cancer by 80%. Isolated Pap smears have false negative rates of 20–40%, which are partly overcome by regular screening (every 3 years). The human papilloma virus (HPV), in particular strains 16 and 18, is critical to cervical carcinogenesis. Testing for HPV DNA in cervical smears increases the cervical cancer detection by 30% over cytology-based screening and could lengthen the screening interval to 5 years.¹⁹ Incorporation of HPV-based screening into guidelines is being considered. Importantly, however, the Pap smear and HPV DNA function as primary screens that are followed by visual and pathologic evaluation through colposcopy as a secondary screen.

Individuals at elevated risk

Specific guidelines exist for patients with strong family histories of cancer, particularly for carriers of genomic biomarkers of high cancer risk. When the cancer risk associated with the specific (usually hereditary) biomarker is high enough, recommendations focus on prevention rather than early detection. As prevention strategies generally impact quality of life to a greater degree than does screening, the identification of inherited mutations associated with a very high cancer risk necessitates patient education and careful shared decision making. Furthermore, hereditary biomarkers testing has significant implications for family members. Prophylactic surgery and chemoprevention are particularly effective risk reduction techniques that are reserved for people at highest risk. Prophylactic oophorectomy and/or mastectomy has the greatest protective effect for *BRCA1/BRCA2* mutation carriers, reducing the risk of ovarian cancer and breast cancer by more than 90%.^{20, 21} However, some patients prefer mammography, MRI, or other screening approaches to delay surgical intervention either for personal preference or to allow childbearing. There are many factors (e.g., ethics and cost) to consider in discussing options for early detection and prevention with very high-risk patients, and this area of medicine is a rapidly evolving specialty.^{22–24}

Breast and ovarian cancer

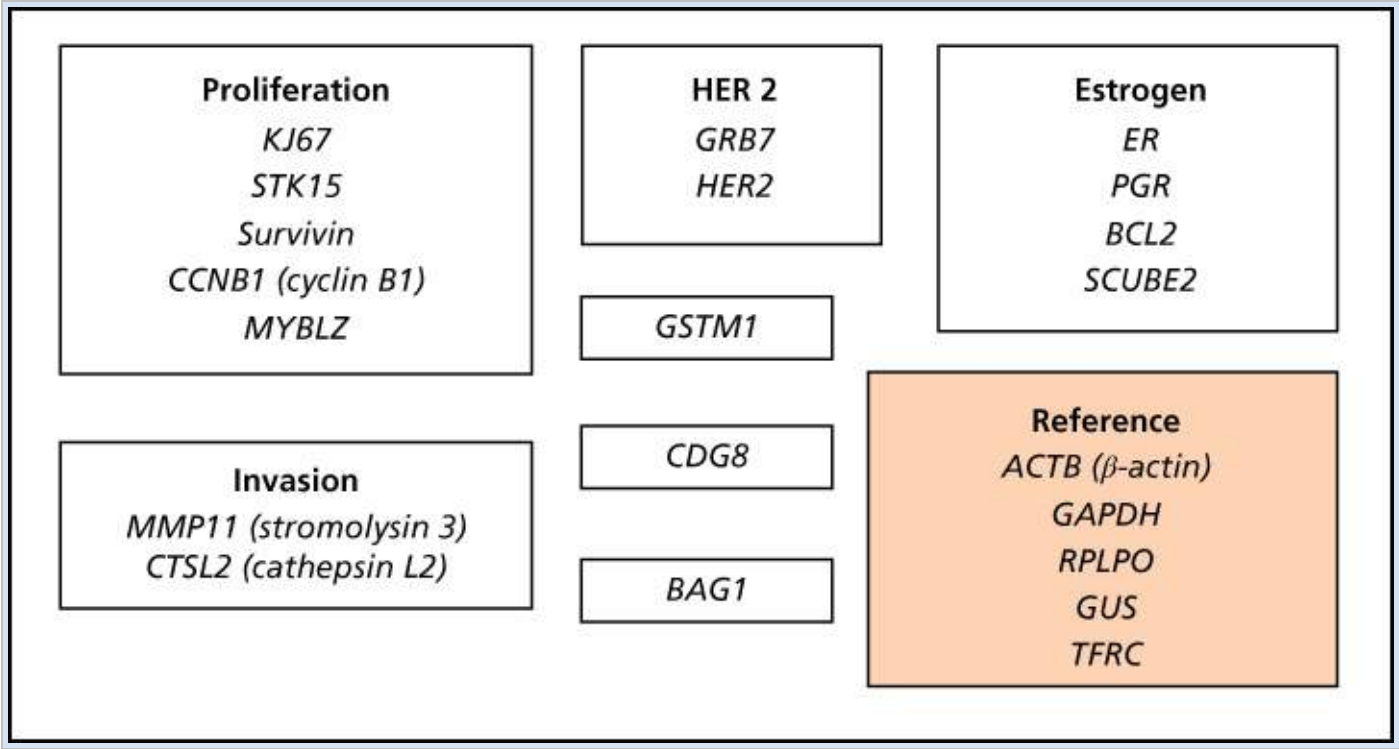

In families with a significant history of breast and/or ovarian cancer, key cancer risk biomarkers (usually hereditary mutations) can now be identified in a minority of cases, using clinical prediction models (e.g., BRCAPRO model).²⁵ Such models can be useful in guiding specific molecular tests that further stratify risk and guide subsequent screening or prevention. Inherited mutations in *BRCA1* and *BRCA2* account for 5–10% and 10–15% of all breast cancers and ovarian cancers, respectively.^{26, 27} Furthermore, approximately 15% of patients with triple negative breast cancers or with high-grade serous ovarian cancer will carry deleterious germ line mutations in *BRCA1/2* in the absence of a significant family history. Moreover, *BRCA1/2* mutations guide therapy in ovarian cancer, as outlined in the following section. Approximately 12% of women at high-risk do not carry *BRCA1/2* mutations and are estimated to have another cancer predisposing genomic alteration,²⁸ suggesting a need for improved testing approaches

that identify additional risk biomarkers. Less well-studied breast cancer susceptibility genes include *CHEK2*, *ATM*, *RAD51C*, *BRIP1*, *PALB2*, *NBS1*, *LKB1*, *PTEN*, *p53*, *XRCC1*, and *STK11*, but these are not commonly assessed due to the rarity of inherited mutations.^{29–32} Recently, these genes have been integrated into multiplex sequencing assays, both providing more information and greater challenges in patient decision making for genes associated with a lower frequency of cancer development.

Colon cancer

Familial adenomatous polyposis (FAP) and hereditary nonpolyposis colon cancer (HNPCC) predispose to early-onset familial/hereditary colon cancer. They are characterized by germ line mutations in the adenomatous polyposis coli (*APC*) and DNA mismatch repair genes, respectively. In HNPCC, routine tumor molecular screening using antibodies to mismatch repair proteins has superseded clinical risk models to guide screening (e.g., revised Bethesda guidelines). Tumor molecular screening, however, results in excessive genetic testing for HNPCC, as 10–15% of cases represent sporadic disease.³³ Combining the clinical risk prediction models with tumor molecular screening, or testing the tumor for molecular markers of sporadic disease (*MLH1* promoter methylation and/or *BRAF* V600E gene mutation) could improve screening for HNPCC while maintaining high detection rates.³⁴ Management guidelines entail surgical cancer prevention (colectomy) with FAP and intensive colonoscopic screening with HNPCC.

Table 1 The panel of 21 genes in *Oncotype Dx* and their subdivision based on function

In a recent study, fecal hemoglobin detection was combined with fecal DNA tests for mutant K-Ras, aberrant *NDRG4* and *BMP3* methylation and B-actin.³⁵ When compared to a standard fecal immunohistochemical test (FIT) in 9989 evaluable participants at average risk, the composite Cologuard® test demonstrated greater sensitivity for detecting colorectal cancer (92.3% vs 73.8%, *P* = 0.002), greater sensitivity for detecting advanced precancerous lesions (42.4% vs 23.8%, *P* < 0.001), a higher rate of detection of high-grade dysplastic polyps (69.2% vs 46.2%, *P* = 0.004), and greater detection of serrated sessile polyps measuring 1 cm or more (42.4% and 5.1%, *P* < 0.001). Specificity, however, was somewhat lower with DNA testing than with FIT (86.6% vs 94.9%). On the basis of these results, the test was approved in 2014 by the United States FDA for individuals greater than 50 years of

age.

Future approaches to early detection and screening

While current approaches to early detection have impacted mortality from certain forms of malignancy such as cervical cancer, low sensitivity, unnecessary use of invasive diagnostic procedures due to false positives, and overdiagnosis/treatment remain significant issues. Moreover, many tumor types, such as ovarian and pancreatic cancer, do not benefit from these approaches. Patients continue to present with advanced disease and thus have poor outcomes. Elevation of circulating tumor biomarkers may require a substantial tumor volume. Autoantibodies could be evoked by small volumes of cancer at an earlier interval. Novel molecular screening techniques, including circulating DNA, RNA, and exosomes, have the potential to complement current protein-based screening markers and revolutionize early cancer detection, while facilitating accurate risk assessment and individual treatment planning.

Current molecular biomarkers for predicting outcomes and therapy responsiveness

Although molecular biomarkers that predict outcomes in cancer patients are useful, greater clinical utility lies in biomarkers that predict benefit from specific cancer therapies. There is considerable overlap between both types, as those biomarkers that predict benefit for particular patients from specific cancer therapies will predict improved outcomes.

Breast cancer

Hormone receptors (HR)

Hormone receptors (HR)-positive breast cancer comprises approximately 70% of all breast cancers and is marked by the expression of estrogen receptor (ER) alpha and/or progesterone receptor (PR). The HR biomarkers identify breast tumors that are sensitive to growth inhibition by antihormonal treatments, including ER partial agonists/antagonists (e.g., tamoxifen), ER downregulators (e.g., fulvestrant), and aromatase inhibitors (e.g., letrozole).^{36, 37} In clinical practice, HR protein expression is assessed routinely in all breast cancers using immunohistochemistry. Despite 5 years of adjuvant antihormonal therapy, however, a significant fraction of women with early stage HR-positive breast cancer relapse, and the majority of women with metastatic HR-positive breast cancer, develop resistance to antihormonal manipulation. Thus, in the United States, over 25,000 women with HR-positive breast tumors die each year, more annual deaths than are caused by all other types of breast cancer combined.

Multiparameter gene expression profiles

Our ability to predict the likelihood of cure for patients with HR-positive breast cancer after treatment with antihormonal drugs has improved dramatically. *Oncotype Dx* ([Table 1](#)), based on the expression of 21 genes, predicts the benefit for individual node-negative HR-positive breast tumor patients from adjuvant tamoxifen and selects patients for cytotoxic chemotherapy based on features associated with tamoxifen resistance.³⁸ However, despite this approach's clinical utility, this and similar assays such as PAM50 and Mammoprint do not increase our understanding of antihormone resistance mechanisms in HR-positive breast cancer beyond the known roles of tumor grade, HER2, and HR levels.^{36, 38, 39} The phosphatidylinositol-3-kinase (PI3K)/AKT/mTOR and mitogen-activated protein kinase (MAPK) pathways are major mediators of the effects of membrane receptor tyrosine kinases (RTKs) such as HER2

and mediate resistance to antihormonal therapies.⁴⁰ The mTOR inhibitor everolimus improves progression-free survival for approximately 60% of women with HR-positive breast cancers resistant to antihormonal therapies.⁴¹ A predictive molecular biomarker of response to this drug is lacking however.

HER2

The oncogene encoding *HER2* is amplified and the protein overexpressed in 15–20% of invasive breast cancers. *HER2* overexpression dictates an aggressive breast tumor phenotype and poor prognosis.⁴² Combining trastuzumab (Herceptin), a recombinant humanized monoclonal antibody targeting *HER2*, with cytotoxic chemotherapy to treat patients with metastatic and early stage *HER2* oncogene-amplified breast cancer, has resulted in increased response rates and improved survival.⁴³ Thus, *HER2* is a biomarker for breast tumor responsiveness to trastuzumab and other *HER2*-targeted therapies (e.g., pertuzumab, lapatinib, and TDM1).⁴⁴ More recently, *HER2* has been validated also as a biomarker predictive of response to trastuzumab-based chemotherapy in 15–20% of advanced gastric cancer patients with *HER2*-driven oncogenesis.⁴⁵

A significant fraction of *HER2*-amplified breast and gastric cancers do not respond initially to trastuzumab or acquire resistance to trastuzumab. This could be mediated by a cleaved form of *HER2* that does not bind trastuzumab (p95-*HER2*), by upregulation of other membrane RTKs such as IGF1R or MET or by upregulation of the PI3K/AKT pathway.^{46–49} The latter can occur through inactivating mutations of PTEN (a negative PI3K/AKT regulator), PTEN loss, or by PIK3CA mutations, the oncogene that encodes the p110 α subunit of PI3K.⁵⁰ Indeed, PI3K pathway activation and mutations in PIK3CA and PTEN are negative prognostic markers in *HER2*-positive breast cancers treated with anti-*HER2* targeted therapies.⁵¹

A panel of the American Society of Clinical Oncology (ASCO) thus recommended that *HER2* status should be determined for all invasive breast cancers.⁵² This panel has proposed a testing algorithm that relies on accurate, reproducible assay performance, including newly available types of bright-field *in situ* hybridization (ISH), and has specified elements to reliably reduce assay variation (e.g., specimen handling, assay exclusion, and reporting criteria). This emphasizes the need for quality control and validation approaches for all predictive markers, both in terms of reliability and clinical utility.

Ovarian cancer: BRCA1/2

Approximately 20% of high-grade serous ovarian cancers have an underlying inherited or somatic *BRCA1/2* mutation, rendering them deficient in homologous recombination, a pathway essential for repairing double-stranded DNA breaks.⁵³ These tumors rely on alternative DNA repair mechanisms such as base excision repair, to which the PARP enzyme is key. Inhibitors of PARP exploit vulnerability of *BRCA1/2*-mutated ovarian cancers to DNA damage. In a randomized phase II trial, the PARP inhibitor olaparib increased progression-free survival by 82% as compared to placebo when used as maintenance therapy in platinum-sensitive recurrent *BRCA1/2*-mutated ovarian tumors.⁵⁴ Olaparib has now been approved for use with this indication, with approvals for other PARP inhibitors and other uses expected imminently. Resistance mechanisms include function-restoring *BRCA1/2* mutations, loss of 53BP1 (a protein involved in an alternative DNA repair mechanism), and upregulation of the PI3K/AKT/mTOR pathway.⁵⁵ The combination of olaparib and BKM120, a PI3K inhibitor, has shown activity in early clinical studies of high-grade serous ovarian and triple negative breast cancer.⁵⁶

Lung cancer

Epidermal growth factor receptor

The reversible EGFR (epidermal growth factor receptor) tyrosine kinase inhibitors (TKIs) gefitinib and erlotinib and irreversible pan-HER TKI afatinib and dacomitinib provide effective therapies in approximately 10–30% of patients with non-small-cell lung cancer, whose tumors harbor activating EGFR mutations, the common ones being located on exon 19 and 21.^{57–60} Female nonsmokers of Asian origin with adenocarcinoma represent the typical phenotype, although EGFR mutations are also observed in men and former smokers. While first line treatment with dacomitinib in EGFR-mutant lung cancers has been associated with an impressive progression-free survival (18.2 months), and afatinib shows greatest efficacy in exon 19 mutations, the benefit of one TKI over another has yet to be established.

Multiple acquired resistance mechanisms to EGFR inhibitors, including secondary mutation in *EGFR* (T790M) and MET amplification,⁶¹ limit the efficacy of EGFR-targeted therapy. New EGFR TKIs have shown promise in treating or preventing resistance in phase I/II studies and are being evaluated in larger clinical trials,⁶² with the hope that they will translate into effective therapies for patients with lung cancer.

ALK and ROS-1

Two targetable chromosomal gene rearrangements leading to oncogenic gene fusions guide novel therapies in advanced adenocarcinoma of the lung.^{63, 64} ALK (anaplastic lymphoma kinase) and ROS-1 gene translocations are present in 4–6% and 1–2% of advanced lung adenocarcinomas, respectively, rendering them markedly sensitive to the ALK, ROS-1, and MET inhibitor, crizotinib. The short period between the identification of these targets and crizotinib's approval engenders excitement for an evolution away from the prolonged time period traditionally required for drug discovery and implementation. Crizotinib is associated with response rates of over 70% and a median progression-free survival of 11 and 19 months for ALK and ROS-1 rearranged tumors, respectively. Gene overexpression, bypass mechanisms, and secondary mutations commonly cause acquired resistance, though unlike EGFR-mutated non-small-cell lung cancer, multiple mutation types are observed in a single tumor at disease progression. Strategies to overcome acquired resistance involving second-generation ALK inhibitors such as ceritinib show promise in early clinical trials.⁶⁵

On the basis of these results, routine molecular testing is recommended for EGFR and ALK in all advanced stage lung adenocarcinomas (or lung tumors with an adenocarcinoma component), regardless of clinical characteristics. Tumors that do not contain an adenocarcinoma component perhaps due to a sampling error but are suspected as such due to clinical characteristics (young, never smoker) may also be tested.⁶⁶

Colon cancer

Microsatellite instability

Current guidelines recommend adjuvant 5-fluorouracil-based chemotherapy in stage II colon cancer in “high-risk” patients, defined by the presence of high-grade tumors with lymphovascular space invasion, evidence of tumor perforation, and/or less than 12 nodes extracted at surgery. Approximately 11% of stage II colon cancers have a deficiency in mismatch DNA repair, manifested as microsatellite instability.⁶⁷ Such tumors have good outcomes in the absence of adjuvant chemotherapy. Therefore, guidelines advise routine immunohistochemical testing of stage II colon cancers for mismatch repair proteins, the absence of which obviates the need for adjuvant chemotherapy.

KRAS, BRAF, and NRAS

KRAS is a proto-oncogene downstream of EGFR that initiates signaling through the Ras-Raf-MAPK pathway. Approximately 60% of metastatic colorectal cancers have the favorable wild type *KRAS* profile, predicting sensitivity to the anti-EGFR monoclonal antibodies, cetuximab and panitumumab. *KRAS* mutations, found mainly at codons 12 and 13 of exon 2, predict resistance to these therapies, as do the rarer *NRAS* mutations.^{68–71} Downstream *BRAF* mutations occur in about 5–9% of cases and correlate with poor prognosis, although their reported lack of benefit from EGFR inhibitors remains uncertain.

Gastrointestinal stromal tumors (GIST): KIT and PDGFRA

GIST (gastrointestinal stromal tumor) is associated with primary activating mutations in the *KIT* (80% of GISTs) or platelet-derived growth factor receptor A (*PDGFRA*; 5–10% of *GISTs*) genes that result in constitutive RTK activation.⁷² Imatinib (Gleevec), which inhibits both *KIT* and *PDGFRA*, results in clinical benefit in approximately 85% of patients with unresectable or metastatic disease, with a median progression-free survival of 20–24 months, although patients with exon 11 mutations fare better than exon 9 mutations. In the latter case, a higher dose of imatinib confers a greater benefit. The mechanisms of acquired resistance to imatinib are heterogeneous, involving mostly the emergence of secondary mutations in *KIT* exons 13, 14, or 17. In patients with imatinib-resistant *GIST*, novel kinase inhibitors, such as sunitinib, nilotinib, dasatinib, and regorafenib, can inhibit the mutant protein's function and restore antitumor activity.

Melanoma

BRAF

About half of all melanomas carry the *BRAF* V600E gene mutation, leading to constitutive downstream activation of the MAPK pathway engendering sensitivity to *BRAF* inhibitors (e.g., vemurafenib and dabrafenib).^{73, 74} Clinically, the duration of response to these drugs is short, with progression occurring at a median of 6–7 months. Novel approaches to overcome resistance resulting from compensatory overactivation of the MAPK pathway involve the upfront combination of *BRAF* and MEK inhibitors (such as trametinib), which increases the efficacy and decreases the toxicity of therapy.⁷⁵

NRAS

MEK inhibitors will likely play a significant role in treating *NRAS*-mutated melanoma, which involves approximately 15–20% of all melanomas and dictates a particularly aggressive biology. Interestingly, MEK inhibitors may demonstrate activity in combination with immune therapies.⁷⁶

KIT

A small number (3%) of *BRAF/NRAS*-negative melanomas carry *KIT* proto-oncogene mutations, particularly in mucosal and acral melanomas. Targeted therapies with imatinib or sunitinib are viable therapeutic options that can provide durable responses, with evidence of nilotinib activity at progression post imatinib therapy.^{77, 78}

Chronic myeloid leukemia (CML)

***Bcr-Abl* translocation**

Most chronic myeloid leukemia (CML) cases are driven by constitutive activation of the Abl kinase as a result of the breakpoint cluster region (Bcr) to the Abl kinase translocation (Philadelphia chromosome). Imatinib targeted therapy, which inhibits the kinase activity of Abl, has markedly improved the outlook for patients with CML. However, imatinib resistance can emerge despite initial benefit. Furthermore, efficacy of imatinib is limited in advanced “blast-crisis” CML.⁷⁹ Resistance is due predominantly to novel mutations in the Abl kinase domain, interfering with drug binding. Thus, new Abl kinase inhibitors (AKIs) were developed, among which nilotinib, dasatinib, and bosutinib gained regulatory approval. Unfortunately, all available AKIs exhibit inactivity to certain kinase domain mutations, the cross-resistant *Bcr-Abl* (T315I) mutant being the most common. The third-generation AKI ponatinib demonstrates clinical benefit in *Bcr-Abl* (T315I) mutant CML and some other multidrug-resistant mutations. However, cardiovascular toxicity concerns, potentially related to the choice of a high-drug dose during clinical development, precluded regulatory approval. Trials investigating dose-optimized ponatinib are underway.⁸⁰

Lymphoma

CD20 and other biomarkers

Biomarker-targeted therapeutics have impacted significantly the treatment of non-Hodgkin lymphoma (NHL).^{81, 82} The development of the chimeric anti-CD20 antibody rituximab heralded a new era in NHL treatment approaches. Rituximab is now standard monotherapy for front-line treatment of follicular lymphoma and is used in conjunction with chemotherapy for other CD20-positive B-cell lymphomas. The subsequent development and approval of radio-immunoconjugates of rituximab (⁹⁰Y-ibritumomab tiuxetan and ¹³¹I-tositumomab) has improved outcomes further.

Clinical evaluation of antibodies has been based largely on knowledge of antigen expression on the lymphoma cells' surface, leading to the development of antibodies against CD22 (e.g., unconjugated epratuzumab), CD80 (galiximab), CD52 (alemtuzumab), CD2 (siplizumab), CD40 (SGN-40), and CD30.⁸³ The anti-CD30 antibody brentuximab has been conjugated with a drug, vedotin, to target cytotoxic drug delivery to CD30-positive Hodgkin's or anaplastic large cell lymphoma, producing significant clinical benefit with acceptable toxicity. It was approved for use recently in relapsed Hodgkin's lymphoma following autologous stem cell transplant and relapsed anaplastic large cell lymphoma. Currently, it is being investigated for use upfront with chemotherapy.

Oropharyngeal cancer (OPC)

Human papilloma virus

The epidemiology of oropharyngeal cancer (OPC) has changed over the last two decades with studies reporting the presence of HPV p16 subtype in 60–70% of all OPC in western countries. Molecular tumor testing is easily done using p16 immunohistochemistry, which has a high concordance with HPV FISH. Retrospective analyses of large clinical trials demonstrate superior response rates and survival with chemoradiotherapy in HPV-related OPCs, as compared to HPV-negative OPCs.⁸⁴ Therefore, HPV is an important stratification tool for future therapeutic investigations in OPCs and may dictate a different therapeutic approach. Suggestions that HPV-associated OPCs may benefit from less intensive chemoradiotherapy require further evaluation.

Molecular biomarkers for monitoring of cancer

A number of circulating biomarkers are used for monitoring of cancer response to therapy and/or for the early detection of recurrent disease in cancer patients.

Alpha-fetoprotein (AFP) and human chorionic gonadotropin (hCG)

Many germ cell tumors [most male testicular cancers, gestational trophoblastic disease (choriocarcinoma), and rare ovarian cancers] produce circulating tumor markers [AFP (alpha-fetoprotein), hCG (human chorionic gonadotropin), lactate dehydrogenase (LDH)].⁶⁷ These biomarkers are useful in diagnosing, staging, monitoring therapeutic response, and detecting early tumor recurrence. As recurrent germ cell tumors can be cured with cytotoxic chemotherapy, particularly when the recurrence is detected early, increasing tumor marker levels during patient follow-up are an indication for initiating salvage therapy, despite absence of evident disease. The markers' half-lives must be considered when evaluating therapeutic responses.

AFP is a glycoprotein normally produced by the fetal yolk sac, liver, and gastrointestinal tract but not by normal adult tissues. It is re-expressed in germ cell tumors, including yolk sac tumors and embryonal carcinomas. hCG is a glycoprotein produced by syncytiotrophoblastic cells consisting of two subunits, α and β . The α -subunit is common to three pituitary trophic hormones: FSH, LH, and TSH; the β -subunit makes hCG enzymatically and immunologically distinct. Assays measure only the β subunit (β -hCG). In males, it is highly specific for testicular cancer, in particular choriocarcinoma cells and 5–10% of pure seminomas. LDH reflects “tumor burden,” growth rate, and cellular proliferation and has independent prognostic significance. LDH is increased in about 80% of advanced seminomas and about 60% of advanced nonseminomatous germ cell tumors. The LDH isoenzyme 1 seems to be more specific and sensitive for germ cell tumors than isoenzymes 2–5.⁸⁵

CA125

CA125 is a mucinous transmembrane glycoprotein product of the MUC16 gene that ranges up to 5 mD. CA125 is best known as an ovarian cancer marker, though elevations in endometrial, fallopian tube, lung, breast, and gastrointestinal cancers, as well as relatively benign conditions including endometriosis, are observed. CA125, when used alone on a single occasion, is not sensitive or specific enough for ovarian cancer screening.⁸⁶ Moreover, 20% of ovarian cancers do not produce elevated CA125 levels. However, serum CA125 is very useful for following treatment response, for predicting post-therapy prognosis, and for detecting recurrence in women with ovarian cancer. During first-line platinum-based ovarian cancer chemotherapy, CA125 levels should be followed regularly (e.g., every 3 weeks). The CA125 level at nadir, 3-month normalization of CA125 and CA125 half-life are strong predictors of progression-free and overall survival times.^{87–89} The failure of serum CA125 normalization after initial treatment with surgery and platinum-based chemotherapy is a particularly ominous indication of poor prognosis in women with ovarian cancer.

In women in clinical remission following previously treated ovarian cancer, the National Comprehensive Cancer Network (NCCN) (www.nccn.org) recommends evaluation of serum CA125 level at each follow-up visit if the CA125 level was elevated at the initial diagnosis. After a documented CA125 elevation, the median time to clinical disease relapse is over 4 months, although increases within the normal range can produce much longer lead times. One large, randomized study in the United Kingdom concluded a lack of overall survival benefit when women with recurrent disease were treated at the time of CA125 elevation, although only 25% of women on the control and experimental arms were treated promptly with optimal combination chemotherapy.⁹⁰ At a minimum, earlier recurrence detection with CA125 provides time to receive known and novel agents, given the relatively short interval between symptomatic

recurrence and death. With such controversy, however, using CA125 to monitor recurrence should be discussed with each patient.

CA15-3 and CA27.29

CA15-3 and CA 27.29 are well-characterized assays that detect circulating MUC1 antigen in peripheral blood.⁹¹ Several studies support the prognostic relevance of this circulating marker in early stage breast cancer though monitoring MUC1-based serum markers has demonstrated utility in making treatment decisions.^{92, 93} ASCO regards available data as insufficient to recommend using CA15-3 or CA 27.29 for breast cancer screening, diagnosis, staging, or for monitoring patients for recurrence, as conclusive evidence that early detection of recurrence improves survival is lacking.⁹¹ Although present data cannot recommend the use of CA15-3 or CA 27.29 alone for monitoring treatment response, rising CA15-3 or CA27.29 may be used to indicate treatment failure in the absence of readily measurable disease. However, caution should be used when interpreting a rising CA27.29 or CA15-3 level during the first 4–6 weeks of a new therapy, as spurious early rises may occur. These recommendations apply also when monitoring metastatic colon cancer with CEA (carcinoembryonic antigen).

CA19-9

Carbohydrate antigen 19-9 is elevated primarily in the serum of patients with gastrointestinal tract carcinomas. The greatest utility of serum CA19-9 is in monitoring treatment response in pancreatic cancer. For patients with locally advanced or metastatic pancreatic cancer undergoing active therapy, ASCO recommends measurement of serum CA19-9 levels every 1–3 months.⁹⁴ Serial CA19-9 elevations suggest progressive disease in the face of treatment, but confirmatory studies (e.g., CT scanning) should be sought before a therapy change is initiated.

Carcinoembryonic antigen (CEA)

CEA is a cell adhesion glycoprotein.⁹⁵ It is produced during fetal development and is not usually present in healthy adults' blood, although levels are raised in heavy smokers. Serum CEA may be elevated in patients with colorectal, gastric, pancreatic, lung, breast, and medullary thyroid carcinomas. ASCO has developed clinical practice guidelines to monitor serum CEA levels in patients with colorectal cancer, in whom serum CEA should be ordered preoperatively, if it would assist in staging and surgical planning. Postoperative CEA levels should be performed every 3 months, for patients with stages II and III colorectal cancer, for at least 3 years if the patient is a potential candidate for surgery (e.g., liver resection) or chemotherapy for metastatic disease. CEA is also the marker of choice for monitoring systemic therapy response in metastatic colorectal cancer.

Prostate specific antigen

Measuring serum PSA is important in men with an established diagnosis of prostate cancer. The rate of PSA rise can predict prostate cancer prognosis. Men with prostate cancer whose PSA level increased by more than 2.0 ng/mL during the year before the diagnosis of prostate cancer have a higher risk of death from prostate cancer after radical prostatectomy. PSA level along with clinical stage and Gleason tumor grade are components of most nomograms and predictive models used for prostate cancer risk assessment.⁹⁶ Further, serum PSA provides an indicator of disease response to treatment.

For prostate cancer patients treated initially with curative intent, serum PSA level should be assessed every 6–12 months for 5 years and annually thereafter. A rising PSA level indicates biochemical failure and often precedes a clinically detectable recurrence by several years. As biochemical failure may

represent an isolated local recurrence, identifying those patients is important as they may be candidates for salvage therapy.

Novel molecular biomarkers and platforms for their detection

Malignant tumors are characterized by multiple molecular anomalies responsible for the behavior of individual cancers. The driving aberrations can be in the germ line genome or may occur in a somatic or acquired manner in the cancer genome and/or proteome. Novel cancer biomarkers may be detectable not only in the tumor or its microenvironment but also in the circulation, either as circulating tumor cells (CTCs) or as circulating nucleotides, proteins, or metabolites.

Novel high-throughput molecular technologies that comprehensively characterize the cancer genome and proteome are creating many new possibilities for the identification of biomarkers and, in particular, the development of multimarker (e.g., multigene) panels that integrate information across many markers. Many of the earlier high-throughput approaches such as gene methylation analysis, gene microarrays, comparative genomic hybridization, mass spectrometry/spectroscopy, and bead-based analysis methods are being replaced by next generation sequencing. Gene expression profiles have been explored extensively to identify good and poor prognosis subsets of various human tumors.⁹⁷ Currently, the ability of methylation analysis to detect early cancer cell DNA methylation aberrations is being investigated. The high-throughput reverse phase protein lysate array (RPPA) proteomic technology allows concurrent analysis of the expression and activation of multiple specific kinases and other proteins.^{98–102} This platform is particularly suited to investigate kinase signaling in cancer and the molecular effects of novel agents (e.g., TKIs) during treatment and in high-risk tissue during chemoprevention ([Figure 1](#)). Emerging mass spectrometry approaches such as MRM (multiple reaction monitoring) and SWATH could provide additional information on candidate genes when high-quality antibodies are not available, and mass spectrometry is particularly useful for biomarker discovery. Together, genomic and proteomic platforms provide information that can be incorporated to develop meta-signatures reflecting global DNA, RNA, and protein abnormalities. These may be capable of outperforming data derived from a single technology examining only one of these platforms.¹⁰³ For example, proteomic studies can augment genomic panels by providing information on posttranslational modifications and on proteins' relative levels and activation. As such, data sets, systems for effective data management, integrated analysis of pathways, and “meta-analysis” are critical components of successful development of molecular markers.^{104–106}

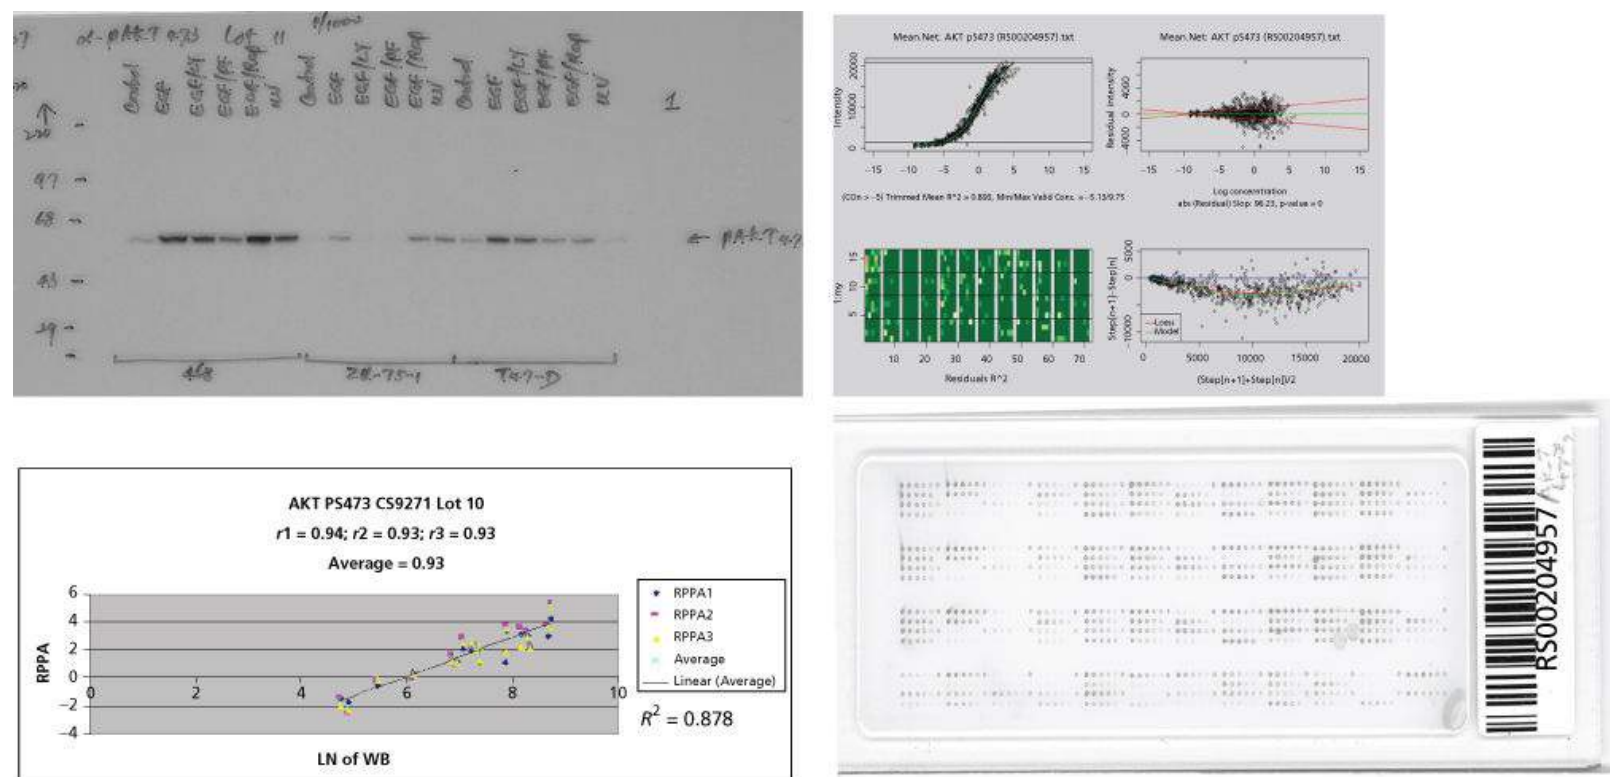

Figure 1 Validation of antibodies for reverse phase protein lysate arrays (RPPAs). Protein lysates from cell lines have been serially diluted on a nitrocellulose-coated slide followed by probing with monospecific antibodies to phosphorylated Akt and signal detection and amplification. Serial dilution curves are used for quantification purposes. Comparisons to western blotting are demonstrated with an r value of 0.878. Quantification and quality control of staining are represented in the upper right panel.

Novel germ line biomarkers

The germ line genome likely contains an underexplored trove of novel cancer risk biomarkers as well as biomarkers for toxicity and efficacy of specific anticancer treatments. For example, germ line polymorphisms have been associated with toxicity and efficacy of the *EGFR* inhibitor erlotinib in lung cancer.¹⁰⁷ Recent large-scale studies of the germ line genome have also begun to uncover a large set of cancer susceptibility markers, many with low penetrance, thereby improving our ability to predict high cancer risk as well as response to therapy utilizing novel germ line biomarkers.^{108–110}

Tissue-specific biomarkers of high risk and for early detection of cancer

Early malignant change may be an indicator of high cancer risk in specific tissues. With availability of less invasive ways to obtain cells likely to be at risk of or to harbor early neoplastic change in tissue at risk of cancer (e.g., in sputum, bronchial washings, blood, feces, urine, or nipple aspirate), the study of tissue markers for screening of carcinogenesis risk and of early malignant transformation becomes more feasible. To date, the cost, invasiveness, lack of large prospective outcome validation studies, and absence of standardized guidelines has confined most of these potentially useful approaches to small clinical studies.

Although screening to detect lung cancer at an early stage using routine cytological examination of sputum did not decrease cancer-specific mortality, the application of molecular detection methods to sputum and bronchial washings is now being studied in an attempt to detect molecular changes associated with premalignant and early malignant bronchial epithelial cells.¹¹¹ For example, FISH with locus-specific probes to chromosomal regions 5p15, 7p12 (*EGFR*), 8q24 (*C-Myc*), and the centromere of chromosome 6

may improve significantly the sensitivity for detection of malignancy in sputum and bronchial washing specimens.¹¹²

Cancer-specific biomarkers

As discussed earlier, progress has been made in identifying single biomarkers and multimarker panels (e.g., *Oncotype Dx*) to predict responses and overcome resistance to targeted therapy. However, progress in this regard has been more limited in other cancer types. Emerging basket clinical trials may address this deficiency in part. Basket trials are based on the observation that common molecular aberrations occur across different cancer types. These trials evaluate the role of targeted therapies against specific molecular aberration(s), regardless of cancer type, within the same trial.¹¹³

In the future, pharmacodynamic biomarkers of early drug activity must also be defined in preclinical tumor models and then confirmed in patient samples to assure that patients are receiving a biologically relevant dose of the drug. In this regard, optimal target inhibition by the drug in the tumor may be a more important endpoint than maximum tolerated dose of the drug. However, whether optimal drug activity is dependent on maximal target inhibition, area under the curve, or trough values is not known for most drugs. Precepts derived from Systems Biology such as sensitivity analysis may provide guidelines regarding the optimal inhibition pattern required. This approach may optimize drug efficacy, decrease toxicity, in particular off-target toxicity, and facilitate early identification of nonresponders for triage to alternative therapies. For example, perifosine-induced inhibition of AKT in the tumor correlates remarkably well with tumor growth inhibition using multiple dosing schedules of perifosine. Furthermore, the integrated assessment of the activation status of multiple PI3K/AKT pathway members in the tumor soon after initiation of therapies, using proteomics assays such as RPPA, may prove superior to single markers for prediction of tumor response to PI3K pathway inhibitors.

Serum and urine biomarkers

Novel serum biomarkers have potential utility in cancer screening, in prediction of tumor responsiveness to specific therapies, and in monitoring tumor responses to therapy. As discussed earlier, while conventional serum cancer biomarkers are used routinely for cancer monitoring, their application to screening is limited by suboptimal sensitivity and specificity.^{114–116} Specificity can be improved by monitoring increases in individual marker levels over time, but marker panels will almost certainly be required to increase sensitivity for screening. The conventional concept concerning the screening utility of serum biomarkers is that their detection should trigger clinical assessment by imaging and biopsy or increased surveillance if appropriate. Alternatively, novel serum markers might be used following screening by other means to increase the specificity of the latter approach. Thus, a novel biomarker may allow definition of an equivocal mammographic lesion as appropriate for serial monitoring or immediate biopsy.

Mass spectrometry-based unbiased approaches to identify novel serum biomarkers from the proteome or metabolome present in blood or urine have the potential to identify biomarker panels that could identify tumors from an early stage of development. Ovarian cancer has been the subject of several such studies because of diagnosis in advanced stages, poor patient outcomes, and the absence of a well-established screening method. Two general approaches have been utilized: identification of distinctive signatures and discovery of discrete markers that might be assembled into panels. However, none of the mass spectrometry-based approaches have validated in large prospectively based sample sets.¹¹⁷

In the urine, the sensitivity of FISH or of cytokeratin (e.g., keratin 19, 20) detection using IHC or reverse

transcriptase (RT)-polymerase chain reaction (PCR) may be higher than that of conventional cytology for bladder and urothelial cancer screening.¹¹⁸ A commercial kit (UroVysion) containing hybridization probes for chromosomes 3, 7, 9p21, and 17 is used for FISH analysis of urine. The sensitivity and specificity associated with this analysis were 60% and 82.6%, respectively, for detection of bladder cancer. In contrast, the sensitivity and specificity associated with urine cytology were 24.1% and 90.5%, respectively. Thus, a FISH assay for chromosomes 3, 7, 9, and 17 may have a higher sensitivity than cytology and a similar specificity for the detection of urothelial cancers. [Table 2](#) summarizes the various approaches that have been investigated as potential tools to facilitate bladder cancer screening.¹¹⁹

Table 2 Sensitivity, specificity, and positive predictive value of urine cytology, bladder tumor antigen (BTA) immunoassay, nuclear matrix protein-22 (NMP22) detection, ImmunoCyt, and urine FISH for early detection of bladder cancer

	Sensitivity (%)	Specificity (%)	PPV (%)
PSA	72	93	25
Urine cytology	48–73	48–100	48–69
BTA	53	77	63
NMP22	71	66	21
ImmunoCyt	78–81	74–100	26
FISH	69–71	78–95	68

Note: Serum prostate-specific antigen (PSA) in prostate cancer screening is shown only as a point of reference. ImmunoCyt is currently approved by the US Food and Drug Administration for the monitoring of recurrent bladder cancer. ImmunoCyt uses a cocktail of three monoclonal antibodies to detect bladder cancer cells in the urine. One antibody is directed against a high-molecular-weight form of glycosylated carcinoembryonic antigen, 19A211. The other two antibodies, LDQ10 and M344, are directed against mucins that are specific for bladder cancer and are labeled with fluorescein.

Circulating tumor cells

CTCs have potential utility in cancer screening, target identification, response prediction, and in monitoring response to treatment. Indeed, the predictive and prognostic utility of CTCs and, more recently, circulating tumor DNA have already been demonstrated in metastatic breast cancer.^{120, 121} Initial studies of the utility of CTCs in breast cancer screening are proceeding.¹²² In ovarian cancer, peripheral blood CTC-specific *p53* sequences are detectable in some FIGO stage III/IV ovarian cancer patients, suggesting that this approach may be useful as a building block toward early detection.¹²³

The use of CTCs to study molecular biomarkers is limited currently to gene expression signatures because of the need for substrate amplification. However, CTCs have the potential to replace invasive tumor biopsies with “liquid” biopsies and facilitate early access to the tumor genome and proteome for molecular biomarkers predictive of therapy response and resistance, as demonstrated in lung and prostate cancers.^{124, 125} A major challenge is the difficulty in harvesting CTCs and exploring molecular markers in a limited number of cells. Methods of CTCs enrichment are being explored and include the enhanced density gradient system.¹²⁶ Currently, we are investigating novel methods of DNA and protein extraction to allow detection of mutations and protein expression/activation changes in CTCs, the latter utilizing RPPA.^{127, 128}

Circulating nucleotides

DNA, RNA, microRNA, and proteins are released from tumor cells and can be found in the circulation. Circulating biomarkers have the potential to reflect processes occurring across all tumor sites in the body that cannot be detected by analysis of the primary tumor and/or metastatic sites. Thus, there is great excitement in the potential for “liquid” biopsies to provide information not accessible from tumor biopsies. Moreover, they would obviate the need for tumor biopsy and, in particular, repeat tumor biopsies to determine tumor response and molecular evolution following therapy. Tumors can release large amounts of nucleotides into the circulation with up to 20% of circulating DNA being derived from a patient tumor. Thus, any aberration such as mutation, rearrangement, increased copy number, increased microRNA, or RNA level could be detected in the circulation, as is the case with *KRAS* and *p53* mutations. However, the amount of DNA in the circulation and the ability to detect tumor-related aberrations varies markedly across tumor types. Nevertheless, commercial tests based on circulating DNA are becoming available.

Challenges in validation of novel molecular biomarkers

The novel unbiased technologies being used to profile the cancer genome or proteome to define new biomarker panels are susceptible to challenges in reproducibility that can be attributed to the simultaneous assay of many gene or protein markers with a limited number of cancer specimens. The large number of potential biomarker combinations introduces a significant likelihood that uncovered associations are simply the result of chance. A rigorous train, test, and validation approach to novel biomarker studies is critical to impact patient management meaningfully. Most studies presenting novel biomarker panels have not impacted patient management to date, either because they did not contend with this multiple parameter problem or because they did not adopt sufficiently robust statistical approaches to validation. The importance of bioinformatic and biostatistical support for the development of novel molecular diagnostics cannot be overemphasized.

Rigorous validation of molecular marker panels in large numbers of well-documented cases is required to test their clinical utility before adoption for routine use in patient management. The applicability of several preliminary panels is still being validated.^{129, 130} A major hindrance to designing novel molecular studies for biomarker discovery and validation is the frequent lack of availability of adequately preserved and annotated tissue or blood samples in large numbers to correlate with outcome using emerging technologies. In particular, novel high-throughput approaches are often limited in their utility to fresh frozen specimens (paraffin-embedded samples are more plentiful). Thus, a popular model for biomarker development involves discovery using novel high-throughput profiling technologies (e.g., transcriptional profiling) in frozen tissue, followed by validation using moderate-throughput technologies (e.g., RT-PCR) applied to paraffin-embedded tissue. The specific tissue type in which a molecular marker will be validated for clinical use is critical to define.^{131, 132} Novel comprehensive approaches to biomarker discovery using proteome- or genome-wide expression profiling have now redefined ways tumor banks collect and store tumor samples, with a major emphasis placed on fresh frozen specimens.^{133, 134}

Presently, it is not possible to apply all available investigative technologies to every person, or even every patient at high risk for the development of cancer. Putting cost issues aside, one challenge is to obtain adequate material from biopsy, cellular or serum specimens. Indeed, several hundred nanograms are required for comprehensive analysis of genomic DNA or RNA, but the amount of DNA and RNA available from a fine needle aspirate is in picograms. Furthermore, biopsies frequently have relatively low tumor content, thereby complicating analysis. In the case of CTCs and circulating nucleotides, the DNA and RNA yield can be even smaller. Amplification by PCR can increase mRNA yield, but PCR-

generated errors are not uncommon. Approaches to contend with low amounts of protein are minimal. As noted earlier, MRM and other mass spectrometry approaches may complement antibody-based approaches. Currently, we are exploring “barcoding” antibodies with DNA sequences to allow use of amplification approaches that have been applied to DNA detection. These major difficulties need to be addressed to facilitate the routine application of novel molecular technologies to cancer diagnostics.

Recommendations

The effective discovery of novel cancer biomarkers requires the integration of multiple critical factors, including collaborative studies, availability of appropriate human tissue sample sets, standardized reagents and technologies for analyzing, identifying and quantitating candidate biomarkers in tissue and fluid, mouse models of disease, integrated bioinformatics platforms, and implementation of automation, all of which were key to achieving the Human Genome Project, for example. Standard operating procedures (SOPs) regarding tumor specimen biobanking, specimen processing and quality control, validation, performance, and interpretation of analytical assays should be developed at a national or, ideally, international level, to allay concerns regarding potentially unreliable study results and permit accurate pooling and comparison of cross-study results. The American Association for Cancer Research (AACR), the Food and Drug Administration (FDA), the National Cancer Institute (NCI) Cancer Biomarker Collaborative, and the European Group on Tumour Markers have defined these key procedures for effective biomarker development. These strategies can be facilitated by the creation of national biospecimen repositories such as the Cancer Human Biobank, which retrieves highly clinically annotated tumor specimens across centers in the United States and processes them according to SOPs before being made available for analysis.

As biomarker discovery programs characterize tissues using high-throughput genomic, transcriptional and proteomic approaches, the development of adequate and centralized computational infrastructure is critical to allow storage, utilization, and integration of the vast and heterogeneous data derived from novel “omics” technologies. Such a computational resource should be easily accessible to all investigators, protect confidentiality, and avoid duplication of efforts. These resources should facilitate data mining, retrieval, and automated analysis, thus facilitating data integration across molecular platforms and between data sets, and the association of specific aberrations with clinical endpoints. Currency should be maintained as novel “omics” technologies are introduced and upgraded. Access should foster novel biostatistical approaches that further our ability to select clinically useful cancer biomarkers. Approaches are being implemented to facilitate sample and data sharing across the community, given that the amount of data available far exceeds the ability of any group to adequately mine and interpret it. The Biospecimen and Biorepositories Research Branch of the NCI provides effective tools and resources to establish high-quality biobanking. A significant number of online data repositories, such as The Cancer Genome Atlas Portal and The Clinical Proteomic Tumor Analysis Consortium, are now publicly available, thereby facilitating the interrogation of biomarkers by different research groups.

The selection of novel biomarkers from data derived using novel high-throughput technologies needs careful consideration, to discern chance associations from true biological relationships. False biomarker discovery can result from selection bias, overfitting, inpatient correlation, multiplicity, multiple clinical endpoints, and inpatient correlation, which must be eliminated from research designs using accurate statistical methods and study designs including sample sizes that enable markers meeting prespecified performance characteristics for well-defined clinical applications to be identified. New biomarkers should be validated before potential introduction into clinical management by measuring the biomarker's impact on costs and carefully chosen clinical outcomes in a prospective, randomized study.¹³⁵

However, study costs and regulatory and healthcare market constraints often make such clinical trials impractical. Improved study designs involving retrospective samples, such as the ProBE method, have been developed as alternatives. Alternatively, retrospective analysis of archived prospectively collected samples, or pooled analyses of published and unpublished cohorts with a systematic review can also provide a high level of evidence, as long as specific requirements ensuring high quality within these study designs are met. Moreover, researchers and policymakers turn to simulation modeling to predict the effects of new biomarkers on outcomes. The latter approach can optimize sensitivity, specificity, and cost in addition to identifying leverage points where more definitive biomarkers may be needed. This approach has already been used to assess the cost effectiveness of flexible sigmoidoscopy for colorectal cancer screening.

A Committee on Developing Biomarker-Based Tools for Cancer Screening, Diagnosis, and Treatment of the Institute of Medicine of the National Academies has produced a formal set of recommendations for development of biomarker-based tools for cancer (Box 3).

Box 3 Summary of recommendations to develop biomarker-based tools for cancer

Methods, tools, and resources needed to discover and develop biomarkers

1. Federal agencies should develop an organized, comprehensive approach to biomarker discovery and foster development of novel technologies.
2. Industry and other funders should establish international consortia to generate and share precompetitive biomarker data.
3. Funders should place a major emphasis on developing pathway biomarkers to broaden applicability.
4. Funders should sponsor demonstration projects to develop biomarkers that can predict efficacy and safety in patients for drugs already on the market.
5. Government agencies and other funders should sustain support for high-quality biorepositories of prospectively collected samples.
6. Biomarkers should be developed and validated with high negative predictive value for prediction of response to targeted therapies, particularly those with high cost.

Guidelines, standards, oversight, and incentives needed for biomarker development

7. Government agencies and other stakeholders should develop a transparent process to create well-defined consensus standards and guidelines for biomarker development, qualification, validation, and use.
8. The FDA and industry should work together to facilitate the codevelopment and approval of diagnostic-therapeutic combinations.
9. The FDA should clearly delineate and standardize its oversight of biomarker tests used in clinical decision making.
10. The Centers for Medicare and Medicaid Services should develop a specialty area for molecular diagnostics under the CLIA.

Methods and processes needed for clinical evaluation and adoption

11. The Centers for Medicare & Medicaid Services should revise and modernize its coding and pricing system for diagnostic tests.

12. The Centers for Medicare and Medicaid Services, as well as other payors, should develop criteria for conditional coverage of new biomarker tests.

As a component of conditional coverage, procedures for high-quality population-based assessments of efficacy and cost effectiveness of biomarker tests should be established.

Conclusion

In summary, significant progress has been made in the development of molecular diagnostics in certain forms of cancer such as breast cancer. Recent molecular studies have revealed the biologic heterogeneity and complexity of cancer and this necessitates the application of more global studies of the cancer genome and proteome to identify novel biomarkers that facilitate further advances in the understanding, treatment and early detection of cancer. Indeed, the application of high-throughput technologies is already advancing significantly the ability to predict responsiveness to specific cancer treatments. Improving understanding of the molecular heterogeneity of cancer along with rapid improvements in molecular technologies that can profile this heterogeneity has revealed possibilities for the development of molecular diagnostics in cancer. Eventually, these approaches will not only advance our ability to diagnose cancer at an early stage but will also allow simultaneous profiling of molecular targets that will facilitate individualization of patient care. Achievement of these goals necessitates overcoming many challenges that presently preclude successful application of both traditional and novel molecular technologies to cancer diagnostics. As high-throughput technologies acquire an increasing foothold in the development of novel molecular cancer diagnostics, the establishment of robust collaborations and bioinformatics approaches to high-throughput data storage, integration, analysis and validation will be critical.

Chapter 41

Principles of imaging

Lawrence H. Schwartz, MD

Overview

Imaging is an indispensable component of clinical oncology. Computed tomography (CT) is usually more informative than plain X-rays. Metabolic imaging with ^{18}F -fluorodeoxyglucose is best combined with anatomical verification by CT. Evolving studies of function linking magnetic resonance to CT imaging is another advance for precision assessment. Targeting specific molecules with labeled agents is an evolving sector. Invasive procedures performed under radiologic imaging have substantially displaced open surgery, with benefits to patients in comfort, time and costs.

Imaging plays a major and fundamental role in every aspect of oncology. Radiological studies provide invaluable information about tumor detection, characterization, staging, and therapeutic response monitoring. Increasingly, imaging in oncology is being used both as a prognostic biomarker and as a predictive biomarker, either alone or in combination with other tissue and serum biomarkers. Screening examinations such as mammography, low-dose CT for lung cancer, and virtual colonoscopy are other examples of the use of imaging in oncology. Finally, image-guided intervention has evolved significantly over the past few years and has tremendous potential for minimizing the invasiveness of many cancer therapies.

Cross-sectional imaging studies, including computed tomography (CT) and positron emission tomography (PET) scans using ionizing radiation as well as nonionizing magnetic resonance (MR) imaging, are the mainstay of care in the oncology patient and typically complement more traditional radiographs. While conventional radiological studies such as plain diagnostic X-ray examination films are easy to perform, deliver a low-dose of radiation, and are relatively inexpensive, their utility in the care of cancer patients is limited.

The type and frequency of radiological evaluation of the cancer patient depend on the tumor, the stage of the disease, and the specific clinical indication for the scan. There is a wide spectrum of indications that include screening, workup of the symptomatic patient, further evaluation of an abnormality found on another imaging study, assessing response or progression of a patient's disease after a therapy or intervention, and evaluating complications of therapy. Before every radiology study is ordered, it is imperative to understand the clinical scenario, what information is needed, whether the test can provide the necessary evidence, and, importantly, what can and will be done with the results to change the treatment of the patient and potentially the patient's outcome.

Integration of imaging with other diagnostic tools, including genomic and proteomic assays, is enabling complementary information to be obtained for the cancer patient. However, there is growing need for these imaging studies to provide more information than simple anatomic visualization and localization of tumors. Contemporary oncology requires that imaging studies visualize basic molecular events that would increase our understanding of malignancies and eventually influence clinical practice.

The growth of a molecular imaging began in the early 1990s, with the use of PET imaging and the glucose

analog probe, [^{18}F]-2-fluoro-2-deoxy-D-glucose (FDG). Over the past several years, FDG-PET imaging has become one of the most important tools to evaluate cancer patients for characterization of primary tumors and their metastases as well as for monitoring treatment response to cancer therapy. PET images are less detailed anatomically and create the potential for fusion of morphologic, detailed anatomic information from a CT scan with a PET scan. Hybrid, dual PET/CT scanners as well as PET/MRI provide combination imaging, which is of higher diagnostic value than separate PET, CT, or MRI scans in many cancers and clinical indications. As a move toward molecular imaging continues, the development of new targets, techniques, and tumor-specific imaging probes should provide more accurate diagnostic information. The use of PET imaging and other molecular imaging techniques has increased along with MRI to evaluate cell metabolism, cell proliferation, hypoxia, apoptosis, receptor expression, gene expression, angiogenesis, and signal transduction. In the future, molecular imaging may be able to address many current unresolved diagnostic issues in oncology. Although the technology is undergoing dramatic expansion, the radiologic community has a responsibility to study new molecular imaging techniques carefully to determine if they are truly useful and cost effective. The ability to create ever more spectacular images does not necessarily improve patient management and outcomes.

Hypothesis-driven, evidence-based studies are essential if noninvasive anatomic and molecular imaging is to have an impact on patient care. Because imaging is a fundamental part of diagnostic evaluation, understanding the utility of particular tests will guide a more efficient patient evaluation. This section's collection of chapters provides an overview of imaging principles, with a focus on the cancer patient. Imaging plays a central role in clinical management, and the information presented here provides general guidelines for using radiologic studies in everyday clinical practice.

Chapter 42

Interventional radiology for the cancer patient

Judy U. Ahrar, MD ■ Michael J. Wallace, MD ■ Rony Avritscher, MD

Overview

In the past decades, there has been a substantial expansion in the use of image-guided procedures for diagnosing and treating various types of cancer. Percutaneous biopsy is usually the first step in obtaining a definitive diagnosis and aids in the development of the treatment plan. Patients with primary or metastatic disease involving the liver are candidates for a wide range of image-guided interventions such as hepatic arterial embolization procedures, liver tumor ablation, and portal vein embolization. Cancer patients also benefit from a variety of palliative image-guided interventions, such as vena cava filter placement, biliary drainage and stent placement, and renal artery embolization, to name a few. Interventional radiology offers a multitude of minimally invasive procedures that are a key component in the management of cancer patients.

In the past decades, there has been a substantial expansion in the use of image-guided procedures for diagnosing and treating various types of cancer. There are several reasons for this increased use. Advances in cancer diagnosis and novel medical and surgical therapies have led to increased survival in this patient population. Owing to the prevalence of imaging, more patients now present with primary or metastatic disease confined to an organ and, consequently, are more likely to benefit from locoregional therapies than from systemic treatment. Thus, a neoplasm can be defined using standard imaging modalities, and then minimally invasive percutaneous techniques can be used to establish the diagnosis and provide locoregional or palliative therapies to treat the cancer patient. Recent improvements in catheter/device technology, embolic agents and chemotherapy drugs, and delivery systems are associated with improved patient outcome and have sparked renewed interest in these approaches. In this chapter, we discuss hepatic vascular interventions, genitourinary interventions, thoracic interventions, several forms of palliative therapeutic procedures, and some additional image-guided procedures (vena cava filter placement, biopsy, and intratumoral gene therapy).

Hepatic vascular interventions

The liver has long occupied center stage in interventional oncology, the practice of interventional radiology specific to the oncology patient. Hepatic interventions for diagnosis and treatment are popular for a number of reasons, among them being that this organ is a common site of metastatic disease and can be accessed easily percutaneously. However, the key feature that makes liver tumors particularly amenable to catheter-delivered therapies stems from the unique nature of their blood supply. Hepatic tumors derive most of their blood supply from the hepatic artery, whereas normal hepatic parenchyma derives most of its supply from the portal venous system. This unique arrangement allows the interventional oncologist to treat hepatic lesions while sparing the surrounding normal liver.

Arterial infusion therapy

The goal of arterial infusion is to achieve better tumor response by delivering chemotherapeutic agents directly into the artery that supplies the neoplasm. The rationale behind arterial infusion therapy is based on the first-pass effect, which occurs when a drug is given directly into the tissue that metabolizes it. The first-pass effect, compared with systemic administration, can lead to a several-fold increase in the drug concentration within the affected organ and, at the same time, a reduction in systemic concentration. Therefore, regional drug delivery is seen as a method of overcoming the limitations of the maximum-tolerated dose.¹

Arterial infusion therapy has been used primarily for the treatment of metastatic colorectal cancer confined to the liver. A meta-analysis by Mocellin et al.² summarized the results of 10 randomized controlled trials that compared hepatic arterial infusion (HAI) with systemic chemotherapy. Although the study revealed better tumor response to fluoropyrimidine-based HAI than systemic fluoropyrimidine therapy, tumor response rates for modern systemic chemotherapy regimens using a combination of fluorouracil with oxaliplatin or irinotecan were similar or superior to those for HAI. Moreover, the meta-analysis showed no survival benefit associated with fluoropyrimidine-based HAI therapy. Further studies of the use of HAI for the delivery of novel anticancer agents will be instrumental in determining the role of this approach in future locoregional cancer therapy.

Arterial embolization

The aim of transcatheter hepatic arterial embolization is to completely or partially occlude the arterial supply to the tumor. The rationale is that such occlusion will cause tumor ischemia, which in turn will lead to growth arrest and necrosis. After hepatic arterial embolization, collateral hepatic circulation comes into play immediately. This collateral circulation should be traced and occluded if it supplies the neoplasm. The more central the occlusion, the more abundant is the collateral flow. Therefore, to maximize ischemia, the most effective embolization should result in distal terminal vessel occlusion. Peripheral (segmental and subsegmental) vascular embolization is best accomplished with coaxial catheters and small particles.

Many different embolic agents have been used with success for hepatic embolization. The most common agents include absorbable gelatin sponge particles and powder, polyvinyl alcohol foam granules, fibrin glue, *n*-butyl cyanoacrylate, ethiodized oil, microspheres, and absolute alcohol. Gelatin sponge segments or stainless steel coils are used for central occlusion and not often used for tumor embolotherapy.

The most common complication after hepatic arterial embolization is postembolization syndrome. This syndrome consists of fever, nausea, fatigue, and elevated white blood cell count and liver function tests. These symptoms are usually self-limited. Complications resulting from nontarget embolization include cholecystitis, pancreatitis, and gastrointestinal ulcers. Hepatic embolization may also lead to liver necrosis, hepatic abscess, and liver failure. Failure to recognize intrahepatic arteriovenous shunts during embolization may cause embolic material to reach the pulmonary circulation, which can in turn lead to respiratory failure. The complications of hepatic embolization in 284 patients who underwent 410 embolizations over a 10-year period were analyzed by Hemingway and Allison.³ Minor complications occurred in 16% of patients, serious complications in 6.6%, and death in 2%.

Arterial chemoembolization

Arterial chemoembolization consists of intra-arterial delivery of a combination of chemotherapy drugs and an embolic agent into a liver tumor. The rationale behind chemoembolization is based on the theory that tumor ischemia caused by embolization of the dominant arterial supply has a synergistic effect with

the chemotherapeutic drugs. This technique has been the mainstay of interventional radiology since it was introduced by Yamada in 1977.⁴ The introduction of iodized oil, an iodinated ester derived from poppy-seed oil, advanced this technique significantly. Iodized oil is well suited for chemoembolization because of its preferential tumor uptake by hepatocellular carcinoma (HCC) and certain hepatic metastases; it acts simultaneously as an embolic agent and a vehicle for the chemotherapeutic agent.^{5, 6} These findings are explained partially by the concept of enhanced permeability and retention suggested by Maeda et al.⁷ Newly formed tumor vessels are more permeable. This increased permeability coupled with a lack of lymphatics in the neoplasm results in retention of molecules of higher molecular weight within the tumor interstitium for a more prolonged period. This retention may explain, in part, the accumulation of iodized oil or the increase in concentration of polymer conjugates of chemotherapeutic agents in neoplasms.

There are many different chemoembolization protocols. The most commonly used chemotherapy agent is doxorubicin, which is combined with cisplatin and mitomycin C. Subsequently, these chemotherapeutic agents are mixed with iodized oil and infused slowly into the hepatic artery branch that feeds the tumor. Drug-eluting beads, which are microspheres loaded with chemotherapy agents (doxorubicin and irinotecan), have recently come into common use for chemoembolization. Additional embolization with gelatin sponge or particles can be performed to enhance tumor ischemia. The proximal arterial supply to the tumor should be preserved because increased response is observed with repeated procedures.

Transcatheter arterial chemoembolization has been used to treat unresectable HCC, cholangiocarcinomas, and hepatic metastases and has been used in conjunction with liver resection or tumor ablation or as a bridge to liver transplant. Two randomized clinical trials^{8, 9} showed a survival advantage when chemoembolization was performed in selected HCC patients. Recent advances in chemotherapy agents and embolic material suggest future potential for this technique. Incorporation of antiangiogenic agents into the mixture to be delivered to the tumor is being investigated.^{10, 11} Moreover, advances in technology now allow intraprocedural acquisition of cross-sectional images using C-arm cone-beam computed tomography ([Figure 1](#)). This technique enables more selective embolization as multiplanar and three-dimensional images are used to understand the arterial anatomy and assess completeness of embolization.¹²

Figure 1 Transcatheter arterial chemoembolization performed in a 71-year-old man with unresectable hepatocellular carcinoma. (a) Contrast-enhanced CT scan obtained before chemoembolization shows a large, solitary, hypervascular mass in segment IV of the liver (arrow). (b) Anteroposterior digital subtraction angiography (DSA) of the abdomen shows a replaced right hepatic artery arising from the proximal superior mesenteric artery (arrowhead). This vessel supplies the hypervascular tumor in the left liver (arrows). (c) C-arm cone-beam CT images obtained during the procedure show tip of 3-French catheter in the distal replaced right hepatic artery (arrowhead) confirming origin of vascular supply to the hepatocellular carcinoma (arrows). (d) C-arm cone-beam CT images obtained after chemoembolization demonstrate retention of iodized oil throughout the lesion.

Hepatic intra-arterial brachytherapy

Radioembolization with yttrium-90 (^{90}Y) microspheres is a technique in which particles incorporating the isotope ^{90}Y are infused through a catheter directly into the hepatic arteries. Yttrium-90 is a beta emitter with a short half-life. The concept is similar to chemoembolization in that the injected particles are distributed selectively into the tumor arterial bed. This distribution is possible because the arterial blood flow within the tumor is several times greater than the flow in the surrounding liver parenchyma. Consequently, a much higher amount of radiation can be delivered to the lesion than with external-beam radiation, and at the same time, the potential for radiation-induced hepatitis is reduced.

TheraSphere beads (MDS Nordion, Ottawa, Canada) are FDA approved for neoadjuvant treatment of unresectable HCC in patients with portal vein thrombosis or as a bridge to transplantation. SIR-Spheres (Sirtex Medical, Lane Cove, Australia) with concomitant use of floxuridine is approved for the treatment of colorectal cancer metastatic to the liver. Knowledge of the vascular anatomic variants in the celiac axis

and superior mesenteric artery is critical to administering this therapy safely to avoid nontarget embolization of the radioactive microspheres, which can have devastating consequences. Multiple studies have demonstrated the safety of radioembolization with yttrium-90 for the treatment of unresectable HCC and metastatic colorectal cancer.^{13–15}

Local tissue ablation

Image-guided tumor ablation of focal hepatic malignancies can be accomplished using chemical agents or thermal energy. Chemical ablation options include direct intratumoral percutaneous ethanol injection (PEI) and ablation using hot water or saline, acetic acid, or chemotherapeutic agents that induce tumor cell death. Thermal ablation options include high-energy radiofrequency (RF), interstitial laser photocoagulation, microwave, cryotherapy, and high-intensity focused ultrasound that causes coagulation necrosis. These procedures can be performed under imaging guidance by interventional radiologists or surgeons in the operating suite.

Ethanol is the most commonly used agent for chemical tumor ablation worldwide.¹⁶ Once ethanol is injected into the tumor, it causes cytoplasmic dehydration, denaturation of cellular proteins, and small-vessel thrombosis.¹⁷ PEI is well established for the treatment of HCC, but it is much less successful in the treatment of hepatic metastases; in metastases, thermal ablation methods are more promising. This distinction appears to stem from the way in which ethanol disseminates within the different tumors. The distribution of ethanol tends to be uniform in soft lesions surrounded by hardened cirrhotic liver parenchyma, as is the case in HCC. However, when the surrounding parenchyma is softer than the tumor, as is often the case with metastases, ethanol distribution is less uniform and the treatment is less effective. Ebara et al.¹⁸ reported on 20 years of experience with PEI for HCC lesions ≤ 3 cm in a total of 270 patients. The local recurrence rate at 3 years was 10%, with overall 3- and 5-year survival rates of 81% and 60%, respectively.

Livraghi et al.¹⁹ studied RF ablation versus PEI in the treatment of small HCCs (≤ 3 cm in diameter). Complete necrosis was achieved in 47 of 52 tumors (90%) in an average of 1.2 sessions per tumor with RF ablation and 48 of 60 tumors (80%) in an average of 4.8 sessions per tumor with PEI. One major complication (hemothorax) and four minor complications (bleeding, hemobilia, pleural effusion, and cholecystitis) occurred with RF ablation, although there was none with PEI. Lencioni et al.²⁰ reported treatment of HCC with either RF ablation or PEI in a randomized series of 102 patients with hepatic cirrhosis. Although there was no overall difference in 1- and 2-year survival, there was a significant difference in 1- and 2-year local recurrence-free survival (98% for RF ablation vs 83% for PEI at 1 year and 96% vs 62% at 2 years). The study was limited to patients with either a single HCC ≤ 5 cm in diameter or a maximum of three HCCs ≤ 3 cm in diameter. However, up to 25% of the lesions in Ebara and colleagues' study¹⁸ of PEI could not have been treated by RF ablation because of anatomic considerations, which emphasizes that there is still a role for PEI in small tumors despite results that overall favor RF ablation. Thermal ablation for hepatic metastases from colorectal cancer has also been reported to improve survival. Median survival time after thermal ablation was increased to 39 months from 21 to 25 months in a study reported by Gillams and Lees.²¹

Portal vein embolization

Successful resection of the liver depends on the function of the residual hepatic parenchyma. When the portal vein is occluded, hepatocyte growth factors (hepatopoietin A, insulin, and glucagon) are shunted into the liver segments supplied by nonembolized vessels.²² The result is atrophy of the segments supplied

by the occluded vessels and hypertrophy of the other areas of the liver. Thus, portal vein embolization (PVE) is used preoperatively to induce liver hypertrophy in potential surgical candidates with anticipated marginal future liver remnant (FLR) volumes ([Figure 2](#)).

Figure 2 Transhepatic ipsilateral right portal vein embolization (PVE) extended to segment IV using Tris-acryl particles and coils performed in a 52-year-old man with rectal cancer metastatic to the liver. (a) CT scan obtained before PVE shows marginal future liver remnant (FLR) [FLR-to-TELV (total estimated liver volume) ratio = 17%] (arrows). (b) Anteroposterior DSA portogram shows a 6-French vascular sheath in a right portal vein branch (arrowheads) and a 5-French flush catheter within the main portal vein (arrow). (c) Final DSA portogram shows occlusion of the portal vein branches to segments IV through VIII with continued patency of the vein supplying the left lateral liver. (d) CT scan obtained 1 month after right PVE extended to segment IV shows substantial FLR hypertrophy (FLR-to-TELV ratio = 27%) (arrows). The degree of hypertrophy is 10%.

PVE is performed if the FLR is estimated to be <20% of the estimated total liver volume (TLV) in patients without underlying liver disease, <30% of TLV in patients with underlying severe liver injury, and <40% of TLV in patients with cirrhosis.²³ For embolizations performed before extended right hepatectomy, modification of the preoperative embolization to include segment IV may optimize liver hypertrophy. The range of reported mean absolute FLR increase for PVE in general was 46–70%, depending on the particle type used for embolization. PVE results in hepatocyte apoptosis, so the postembolization syndrome associated with transarterial embolization and necrosis does not occur. Madoff et al.²⁴ reported on 44 patients who underwent PVE before major liver surgery. None of the patients developed liver failure after the resection.

Fibrin glue, gelatin sponge, thrombin, particles, coils, and absolute ethanol all have been used for PVE. In

the United States, a combination of particles and embolization coils is the most common embolic agent.

Retrospective studies and meta-analysis suggest improved surgical outcomes after PVE.^{23, 25} For this reason, PVE before a major hepatectomy is now considered the standard of care in many comprehensive hepatobiliary centers worldwide.

Considerations in hepatocellular carcinoma

HCC is the fifth most prevalent type of cancer and the third most common cause of cancer death in the world.²⁶ This disease is common worldwide because of its strong association with underlying liver cirrhosis and hepatitis. Surgical removal of the tumor is the only potentially curative treatment. However, curative resection is possible only in 20–30% of patients.²⁷ Recurrence rates after surgical resection are high because of dissemination of primary disease, undetected hepatic micrometastases, or metachronous lesions. Five-year survival after partial hepatic resection is approximately 50%.²⁸ For patients with cirrhosis and unresectable disease, liver transplantation can potentially cure both the underlying liver disease and the tumor. Intra-arterial therapies (embolization, chemoembolization, and radioembolization) and ablative techniques are viable alternatives in patients who are not candidates for partial hepatectomy or transplantation. Systemic chemotherapy for HCC has been disappointing because of the low response rates. In recent times, sorafenib, a multikinase inhibitor with antiangiogenic, proapoptotic, and Raf kinase-inhibitory activity, has been shown to be well tolerated; it is the first agent to demonstrate a statistically significant improvement in overall survival for patients with advanced HCC.²⁹

Local etiologic factors have to be evaluated when considering locoregional therapy because HCC in western countries is often different from the typical HCC treated by interventional radiologists in Japan and the far east.³⁰ Nodular HCC is seen in fewer than 25% of western patients but is seen in approximately 75% of patients in Japan. For patients with early to intermediate disease, ablative techniques are appealing, as the damage to the surrounding liver parenchyma is minimized, allowing for repeated treatments and serving as a bridge to transplantation. The current literature supports the use of percutaneous RF ablation in patients with HCC and either a single lesion <5 cm in diameter or up to three lesions <3 cm in diameter if partial hepatic resection or transplantation is not available.³¹

Chemoembolization is currently used for noncurative therapy for nonsurgical patients with large or multifocal HCC that has not spread extrahepatically. Two randomized studies have reported more favorable results for chemoembolization than for bland embolization, conservative therapy, or both. Llovet et al.⁹ reported survival rates of 75% and 50% at 1 and 2 years, respectively, for 37 patients assigned to embolization alone, 82% and 63% for 40 patients assigned to chemoembolization, and 63% and 27% for 35 patients assigned to conservative treatment. The study was stopped early because of the proven survival benefit. Another study by Lo et al.⁸ demonstrated a benefit in survival for patients with unresectable HCC treated with chemoembolization (iodized oil, cisplatin, and gelfoam) compared with a control group treated with symptomatic therapy only. Survival in the chemoembolization group was 57% at 1 year, 31% at 2 years, and 26% at 3 years, compared with 32%, 11%, and 3%, respectively, in the control group. Radioembolization with yttrium-90 is FDA approved for neoadjuvant treatment of unresectable HCC in patients with portal vein thrombosis or as a bridge to transplantation, but randomized studies are needed to establish a wider role.

Considerations in hepatic metastases

Colorectal metastases

The liver is often the first and only site of metastasis from colon cancer. Many of these patients will die of their liver disease, thus local control can affect patient outcome positively. Although surgical resection is the first line of treatment for liver metastases, the majority of patients are not surgical candidates because of extent of disease or presence of medical comorbidities. Novel systemic chemotherapy agents are now available, which have been shown to effect significant improvement in patient survival.³² In addition, local tissue ablation can be offered to patients who are not surgical candidates because of the presence of medical comorbidities or to patients with bilobar disease that can be treated with a combination of ablation and surgery. Recent series of patients with up to five lesions, each measuring ≤ 5 cm, showed 5-year survival ranges of 24–44%.^{33, 34} PVE may also be employed to increase the number of patients who can be converted into surgical candidates.²³ Palliative treatment can be offered in the form of arterial infusion therapy and radioembolization. The role of novel chemotherapy agents combined with arterial infusion is being investigated as an alternative viable palliative therapy. Radioembolization with SIR-Spheres (resin microspheres) and concomitant use of floxuridine are approved for the treatment of colorectal cancer metastatic to the liver.

Neuroendocrine metastases

Hepatic artery embolization or chemoembolization is indicated for patients with multiple nonresectable, hormonally active tumors. The goal of treatment is to reduce tumor bulk and hormone secretion. The 5-year postembolization survival range is 50–60%, with symptomatic and biochemical response ranges of 40–80% and 50–60%, respectively.³⁵ Moertel et al.³⁶ reported their 10-year experience in 111 patients with neuroendocrine hepatic metastases, usually hypervascular, who received vascular occlusion therapy by a variety of methods. As many as 71 patients received subsequent alternating chemotherapy regimens (dacarbazine combined with doxorubicin, alternating with streptozotocin combined with 5-fluorouracil). Response rates of 60% with vascular occlusion alone and 80% with sequential therapy of vascular occlusion and chemotherapy were observed. Median survival times of 37 and 49 months were experienced in patients with islet cell carcinoma and carcinoid hepatic metastases, respectively. For the symptomatic treatment of hormonally active liver metastases, the use of repeated embolizations is preferred.

The best results for metastatic disease of the liver treated with hepatic artery embolization have been observed in patients with neuroendocrine tumors metastatic to the liver. Sequential and periodic embolization is required for effective palliation. Gupta et al.³⁷ have reported on 81 patients with carcinoid syndrome who were treated with either bland embolization or chemoembolization. Imaging was available for evaluation of a response in 69 patients. Partial response occurred in 67% of the patients, stable disease in 16%, and progression of tumor in 8.7%. The median response duration was 17 months in those patients with a partial response. A reduction of tumor-related symptoms occurred in 63%, with a median progression-free survival of 19 months and a median overall survival time of 31 months. In a subsequent study by Gupta et al.,³⁸ these 69 patients with carcinoid tumors were compared with 54 patients who had islet cell tumors with metastases to the liver. Patients with carcinoid tumors had a higher response rate and a longer progression-free survival than did patients with islet cell tumors (67% vs 35% and 23 months vs 16 months). Although chemoembolization, compared with bland embolization, did not prove to be beneficial for survival in patients with carcinoid tumors, it did result in improved overall survival and improved response (32 months vs 18 months and 50% vs 25%) in patients treated for islet cell tumors.

RF ablation can be used to palliate symptoms associated with metastatic neuroendocrine tumors. In a series by Berber et al.,³⁹ RF ablation provided complete symptomatic relief in 63% of 222 patients and partial relief in 95%. Radioembolization is another minimally invasive alternative to palliating a large burden of hepatic metastases from neuroendocrine tumors.

Other hepatic metastases

Other types of hepatic metastases are usually not as well suited for locoregional therapy as the tumor is likely widespread by the time of liver involvement. However, occasionally, certain types of hepatic metastases are amenable to local treatment because of the indolent nature of the primary disease. Such hepatic metastases that can sometimes be treated by chemoembolization include ocular melanoma, leiomyosarcoma, breast carcinoma, and renal cell carcinoma. In a group of 30 patients with metastatic ocular melanoma, chemoembolization with cisplatin produced a response rate of 46% and a median survival period of 11 months.⁴⁰ The longest survival was 5 years from the initial chemoembolization. In the past, such patients lived for 2–6 months after presentation with hepatic metastases. Additional studies have been reported using HAI of carboplatin-based chemotherapy and fotemustine, with response rates of 38% and 40%, respectively.⁴⁰ Hepatic artery immunoembolization has also been reported with variable responses. A group of 14 patients with leiomyosarcoma metastatic to the liver were treated with chemoembolization every 4 weeks with cisplatin and polyvinyl alcohol foam granules 150–250 μm in size, followed by vinblastine infusion.⁴¹ The response rate was 70%, and responses lasted 4–19 months (median, 9 months). This rate compared well with the response rate of 15% obtained after systemic therapy with ifosfamide with doxorubicin. Of note, these are not common tumors and most are treated on protocol studies. At MD Anderson, our approach to chemoembolization of hepatic metastases is similar to our approach to HCC; that is, a hypervascular tumor is more likely to benefit from the treatment than a hypovascular tumor. The goal of treatment, whether it is to provide symptomatic relief or to prolong survival, must be weighed against the risk of complications.

Genitourinary interventions

Renal arterial embolization

Renal artery embolization for renal cell carcinoma may be performed preoperatively to decrease operative blood loss in patients with extensive local disease. A study by Zielinski et al.⁴² showed a survival benefit to preoperative embolization, although previous studies have not demonstrated this advantage. Embolization of renal carcinoma can be performed for palliative relief of symptoms in patients with extensive local tumor or as a cytoreductive measure when patients are not candidates for surgery.⁴³ Renal artery embolization has been used in the management of congestive heart failure caused by arteriovenous shunting through the renal carcinoma and for hypertension, hypercalcemia, polycythemia, and hemorrhage caused by the renal neoplasm. Selective segmental embolization is especially necessary and effective in patients with impaired renal function or solitary kidney.

Renal ablation

Thermal ablation plays an increasingly important role in the management of renal cell carcinoma. Although nephrectomy remains the gold standard for treatment of renal cell carcinoma, RF ablation is increasingly a viable alternative ([Figure 3](#)). RF ablation for the treatment of renal tumors is minimally invasive with a low morbidity rate.⁴⁴ Patients who are candidates for renal RF ablation include those

with high surgical risk secondary to medical comorbidities; patients with a solitary kidney or multifocal disease, who are not candidates for nephron-sparing surgery; and patients who do not wish to undergo surgery. Patients with hereditary syndromes, such as von Hippel–Lindau disease, are at high risk for multiple renal neoplasms over their lifetimes. These patients may be treated repeatedly with RF ablation, in an effort to preserve normal renal parenchyma adjacent to the tumors.

Figure 3 Percutaneous radiofrequency (RF) ablation performed in a 62-year-old man with biopsy-proven renal cell carcinoma. (a) Contrast-enhanced CT image obtained before RF ablation shows an enhancing mass in the left kidney (arrowhead). (b) CT image obtained with patient in prone position at RF ablation shows single needle electrode in tumor (arrow). (c) Contrast-enhanced CT image obtained after RF ablation shows no residual enhancement in the treated kidney (arrowheads).

Gervais et al.^{45, 46} demonstrated that tumor size and location are related directly to ablation effectiveness. Exophytic lesions can be ablated more effectively because of surrounding fat, the presence of which makes lesions easier to target and provides heat insulation during ablation. Complete necrosis was achieved in 90% of tumors measuring <4.0 cm. Larger or central tumors may not be amenable to complete ablation and may require multiple ablations or, in some cases, multiple treatment sessions. This owes in part to the proximity of medullary tumors to the renal hilar vessels resulting in an increased heat-sink effect, which affects ablation efficacy by lowering intralesional temperatures. A medullary tumor location also increases the risk of procedure-related complications. The most common complication of renal RF ablation is hemorrhage. This complication was observed in 5% of the patients in the series of 100 lesions treated by Gervais et al.^{45, 46} Hemorrhage can occur into the collecting system requiring stent placement for ureteral obstruction, or it can be confined to the subcapsular space.

Ahrar et al.⁴⁴ described their experience with 29 patients with 30 renal tumors who underwent percutaneous RF ablation. The lesions had a mean largest diameter of 3.5 ± 0.24 cm. The primary tumor was completely ablated in 96% of patients. Mean and median follow-up intervals were 10 and 7 months, respectively. Major complications were observed in 12% of the patients, including gross hematuria and urinary obstruction in three patients. All hemorrhagic complications were treated successfully. One patient had persistent weakness of the anterior abdominal wall. None of the patients in the study showed significant degradation of renal function after treatment.

Thoracic interventions

Lung ablation

Thermal ablation can be used to treat primary and metastatic lung cancers. Lung ablation is optimal for

patients with early lung cancer, where complete ablation with curative intent can be attempted. In patients with large tumor burden, ablation may provide palliation of tumor-related symptoms.⁴⁷ Lung ablation is offered primarily to patients with lung cancer who are not operative candidates as well as to patients with pulmonary metastases.

Simon et al.⁴⁸ reported a series of 153 patients with 189 primary or metastatic inoperable lung cancers treated with percutaneous pulmonary RF ablation. The overall 1-, 2-, 3-, 4-, and 5-year survival rates, respectively, for stage I non-small-cell lung cancer were 78%, 57%, 36%, 27%, and 27%; rates for colorectal pulmonary metastasis were 87%, 78%, 57%, 57%, and 57%. The incidence of pneumothorax was 28.4%. Postablation pneumothorax may be treated conservatively if the patient remains asymptomatic. In the patients with symptoms or progressively enlarging pneumothorax, placement of a chest drain is necessary. In the series by Simon et al.,⁴⁸ procedure-related 30-day mortality rate was 2.6%.

Pleural effusion is also a common complication after lung ablation. In their series of 60 patients, de Baere et al.⁴⁹ reported a minor pleural effusion in 9% of patients immediately after treatment and on 60% of CT scans obtained 24–48 h after treatment. Postprocedure hemoptysis was observed in 10% of the patients. The hemoptysis started 1–9 days after the ablation and lasted 2–13 days. These complications did not require any treatment.

Lung chemoembolization

Lung chemoembolization can be used for the treatment of a multitude of lung tumors. The purpose of lung chemoembolization is to deliver chemotherapeutic agents to the tumor while blocking its blood supply. This is accomplished by simultaneously injecting embolic material and the chemotherapy into the pulmonary artery branches that supply the tumor. The embolization increases the chemotherapy dwell time within the lesion by slowing agent washout.

In 2005, Vogl et al.⁵⁰ examined transpulmonary chemoembolization with mitomycin C combined with iodized oil as an option for treatment of unresectable lung metastases in 23 patients. This study demonstrated that transpulmonary chemoembolization was feasible and well tolerated. No major complications were observed; 35% of patients had a partial response, 26% had stable tumor size, and 39% showed progression of disease.

Palliative therapy

Percutaneous biliary drainage

Pancreatic carcinoma, cholangiocarcinoma, and ampullary carcinoma are the primary neoplasms that produce intrinsic biliary obstruction, whereas lymphadenopathy, HCC, and hepatic metastasis can produce extrinsic compression. Nonsurgical palliation of malignant biliary obstruction may be accomplished either endoscopically or percutaneously. The percutaneous methods include drainage by insertion of external or internal–external percutaneous biliary catheters.

The aims of palliative therapy are to provide relief of jaundice and pruritus as well as associated cholangitis and, most important, to prepare patients for anticancer therapy. Neither the endoscopic nor the percutaneous approach has an advantage with regard to influencing survival, and the choice of technique is often a team decision based on the available local expertise.

Internal drainage via endoscopy is preferable because of the inconvenience of an external catheter and the

potential for pain at the tube entry site, bile leakage around the catheter, and sepsis from skin organisms. The percutaneous approach has the advantage of allowing prompt access to the biliary tree. Regardless of the approach, partial or complete jaundice relief can be achieved in 73–100% of treated patients.⁵¹

Percutaneous biliary stenting

Speer et al.⁵² described 70 patients with malignant biliary obstruction who were randomized to undergo percutaneous versus endoscopic biliary stent placement. The success rate in relieving jaundice was 81% for endoscopically placed stents compared with 61% for the percutaneously placed stents. The complication rate was 19% versus 67%, in favor of the endoscopic approach. In addition, the 30-day mortality rate in the two groups was 15% for endoscopic stents versus 33% for the percutaneous method.

Cholangitis, hemorrhage, and bile leakage are the most common complications of stent placement. The incidence of cholangitis is lower in patients treated with a metallic stent than in patients treated with a plastic stent.⁵³ Plastic stents are also more prone to migration and remain patent on average for only 3–4 months.⁵³ Self-expanding metallic stents have longer patency but are more expensive. Metallic stents may be dislodged by balloon dilation immediately after deployment, but the incidence of spontaneous migration over the long term is negligible. These uncovered metallic stents cannot be removed. Despite advances in stent technology, occlusion secondary to tumor ingrowth or overgrowth remains a complex issue.

Musculoskeletal ablation

The majority of patients with breast, prostate, and lung cancer show evidence of bone metastases at the time of death. These lesions are often accompanied by pain and occasional fractures, which can dramatically decrease the quality of life of this patient population.⁵⁴ External-beam radiation therapy is the gold standard for localized pain secondary to osseous metastases. The majority of the patients will experience symptomatic relief after radiation therapy. However, in a substantial minority of patients, radiation therapy provides suboptimal response and durability of relief.⁵⁵

Patients are candidates for ablative therapy of painful metastases when a patient reports moderate or severe musculoskeletal pain, the patient's pain is focal in nature and correlates with abnormality evident with radiological imaging, and the painful metastatic lesion is accessible to percutaneous treatment.⁵⁶

Lesions that are amenable to ablative therapy are typically osteolytic or mixed osteolytic and osteoblastic in nature or otherwise composed of soft tissue. RF ablation and cryoablation are safe and effective treatments for the palliation of painful metastatic lesions that are refractory to standard therapies. Importantly, the quality of life for these patients is improved with this therapy. Goetz et al.⁵⁷ reported on 43 patients with painful bone metastases treated with RF ablation. As many as 95% of the patients experienced symptomatic relief that was considered clinically significant with decrease of opioid usage. A single ablative treatment is effective in most patients and appears to provide a long duration of pain relief.

Miscellaneous

Vena cava filter placement

Cancer patients experience an increased incidence of thrombosis and pulmonary embolism (PE). The percutaneous placement of a vena cava filter is the optimal therapeutic approach for patients with PE,

who have a contraindication to anticoagulant therapy or who develop recurrent emboli despite adequate anticoagulant administration. There are numerous filters currently in use, including devices that are retrievable and MRI compatible.

Wallace et al.⁵⁸ reported on the experience of vena cava filter placement in 308 patients with venous thromboembolic disease in the setting of malignancy. Median survival times were 145 and 207 days for 267 patients with solid tumors and 41 patients with liquid tumors, respectively. Patients with metastatic or disseminated disease were 3.7 times as likely to die as those with local disease, and patients with deep venous thrombosis and a history of hemorrhage were twice as likely to die as those with deep venous thrombosis and no history of hemorrhage. Major complications included pulmonary emboli, new caval thrombus, retroperitoneal hemorrhage, and incorrect filter deployment.

Prophylactic placement of retrievable IVC filters in the perioperative period has also become common practice. The current indications are for patients who have a history of thromboembolic disease and must come off therapy for planned surgery or patients who will be at high risk for developing clots in the immediate postoperative period. Once patients are eligible for systemic anticoagulation therapy, then IVC filter retrieval should be scheduled.

Stent placement for venous stenosis

Vena caval syndrome is most frequently the result of intrinsic or extrinsic malignant disease.⁵⁹ In this syndrome, neoplasms, by their extension and localization or by causing mediastinal, retroperitoneal, and pelvic lymphadenopathy, create stenosis and obstruction by extrinsic compression of the vena cava. The complications of radiation therapy and chemotherapy for this syndrome include mediastinal fibrosis and thrombophlebitis.⁵⁹

Superior vena cava syndrome symptoms have been grouped into four classes: (1) central nervous system symptoms, including headache, blurred vision, and cognitive dysfunction; (2) laryngopharyngeal edema, producing dyspnea and hoarseness; (3) nasal or facial edema; and (4) other signs of venous congestion and dilatation.⁶⁰ In addition to the stenosis or obstruction, there is frequently thrombosis complicating the mediastinal compression or intraluminal invasion by the tumor. Parish et al.⁶¹ reported an average survival time of 7 months after the diagnosis of malignant superior vena cava obstruction. Vascular stents can effectively palliate symptoms of malignant vena cava stenosis in 68–80% of patients.⁵⁹

Biopsy

Percutaneous biopsy has been traditionally a cost-effective modality to diagnose the patient with cancer. Almost all tissues, including the myocardium, are accessible to percutaneous biopsy. Various needles (11–25 gauge) as well as biopsy forceps are efficient in obtaining representative specimens. Biopsy guns are available to automate the procedure. However, a negative biopsy result does not exclude the possibility of malignancy; it may represent merely an error in sampling. Most biopsies of lesions in adults are scheduled electively on an outpatient basis.

Guidance by CT is usually adequate for biopsy of the lung or mediastinum.⁶² The reported accuracy of percutaneous transthoracic needle biopsy in patients with lung cancer and pulmonary metastases is 90–98%,⁶³ whereas the diagnostic yield for local pulmonary infection in immunocompromised patients is 73%.⁶⁴ Serious complications of lung and mediastinal biopsies include systemic air embolization, hemorrhage, pericardial tamponade, seeding of malignant cells into the needle track, and empyema. The incidence of pneumothorax, when using CT guidance, is approximately 22–45%.^{65, 66} In a study described

by Cox et al.,⁶⁷ when biopsies were done under CT guidance, smaller lesions (<2 cm) and the presence of emphysema correlated strongly with the occurrence of pneumothorax.

Abdominal biopsies guided by ultrasonography, CT, and MRI yielded adequate diagnostic material for cytologic analysis in 84–95% of patients. When a 20- to 23-gauge needle is used, biopsies of the liver, pancreas, kidney, adrenal gland, spleen, and ovary, among other organs, are performed with a sensitivity of 86%, a specificity of 98%, and an accuracy of 90%. The overall complication rate in a study of 63,180 biopsies was 0.16%. Seeding of malignant cells along the needle track occurred in 0.05% of patients.^{68–70}

The diagnostic accuracy of percutaneous skeletal biopsy is on average 80%. The overall diagnostic accuracy of 78% was reported in a series of 178 patients with primary skeletal tumors who underwent percutaneous needle biopsy.⁷¹ The procedure was more accurate for malignant neoplasms (83%) than benign tumors (64%).

Transjugular intrahepatic portosystemic shunt placement

The formation of a transjugular intrahepatic portosystemic shunt (TIPS), by placing a metallic stent between the hepatic and portal venous systems, is an accepted means of decreasing certain sequelae associated with portal hypertension. Indications include gastrointestinal variceal bleeding, ascites, portal gastropathy, hepatic hydrothorax, and Budd–Chiari syndrome. Cancer patients with hepatic disease may be candidates for this procedure. Wallace et al.⁷² have described 38 patients with malignancy and hepatic disease treated with TIPS placement. Technical success was achieved in 97% of patients. Recurrent variceal hemorrhage occurred in only 1 of 19 patients (5%), and ascites or hydrothorax resolved or significantly improved in 9 of 12 patients (75%). Intimal hyperplasia and occlusion of the TIPS stent is the most feared postprocedural complication. The 1-year patency rate for TIPS is reported at 25–66%.⁷³ Development of covered stents to prevent stenosis has shown dramatic promise, with two studies demonstrating identical 1-year primary patency of 84%.^{74, 75}

Chapter 43

Principles of surgical oncology

Mark Bloomston, MD, FACS ■ Kenneth K. Tanabe, MD, FACS ■ Raphael E. Pollock, MD, PhD ■ FACS and Donald L. Morton, MD, FACS (deceased)

Overview

The discipline of surgical oncology describes a surgical super specialty to which a board certification process is now attached in the United States. A cognitive as well as technical surgical focus, the surgical oncologist is an oncology specialist who uses surgery as his or her mainstay therapeutic modality in treating tumor problems. As such, the surgical oncologist has a thorough grounding in the natural history of solid malignancy, extensive experience in tumor biopsy and staging approaches, the knowledge needed to orchestrate a multidisciplinary solid tumor treatment program, and the commitment, via vigorous personal participation, in the many relevant research opportunities by which we will advance comprehensive care of the cancer patient.

In spite of significant advances in various systemic approaches to the care of the cancer patient, surgical therapy remains the mainstay of treatment for most solid malignancies and plays a role in various components of the cancer care continuum, from prevention to diagnosis, curative therapy, survival prolongation, and palliation. To be maximally effective, the cancer surgeon must function as a member of the oncology team and is frequently the first oncology specialist that a patient will consult. The cancer surgeon is commonly charged with the responsibility to establish a tissue diagnosis for a suspicious lesion; this may require either an operative procedure or an image-directed or other biopsy approach. The cancer surgeon will usually bear the responsibility for communicating the biopsy findings to the patient, completing the procedures needed to stage the cancer, and initiating subsequent interaction between the patient and other members of the multimodality oncology team. Because of these responsibilities, it is most often the cancer surgeon who initially explains to the patient the sequence and rationale of the various treatment components that will be used to manage the specific malignancy. To be maximally effective, the cancer surgeon must therefore be aware of the different therapeutic options, the natural history of a given malignancy, and how these factors will be integrated into a well-conceived and appropriate multimodality treatment algorithm. It is also usually the surgical oncologist's responsibility to provide initial information about prognosis and to make decisions about follow-up care and surveillance to detect tumor recurrence. In these aspects, the surgical oncologist is unlike almost any other surgical specialist in that the commitment to a given patient is for both the acute and the long-term components of the patient's disease process.

Over the years, the practice of surgical oncology has come full circle. Originally, surgeons attempted to treat cancer conservatively by removing only the gross lesion. Unfortunately, this led to extremely high rates of local recurrence and subsequent patient mortality. In the late nineteenth century, surgeons began to undertake radical en bloc resections and amputations to treat patients with malignant disease. These techniques yielded improved results, but the procedures were often mutilating. With the advent of other complementary and effective treatment modalities, notably radiation therapy in the 1920s and chemotherapy after the 1940s, the orientation of surgical resection is once again becoming conservative

with a focus on organ preservation and restoring the comorbid state when possible.

Adjuvant chemotherapy, alone or in combination with radiation therapy, has improved disease free survival and prolonged quality of life for patients who have been rendered free of gross disease by surgery but who still have a high likelihood of recurrence as a consequence of microscopic residual metastases. Randomized clinical trials have demonstrated the benefit of adjuvant chemotherapy in a variety of tumors, including breast cancer, colorectal cancer, pancreatic cancer, osteosarcoma, testicular cancer, ovarian cancer, and certain lung cancers.

Surgery is most effective in the treatment of apparently locoregionally confined primary disease. The principles of surgical resection include en bloc resection of the primary tumor that attempts to encompass gross and microscopic tumor in all contiguous and adjacent anatomic locations. For some tumor types, concomitant resection of regional lymph nodes comprises an important component of the initial surgical management. In many cases, when disease is diagnosed and removed at an early stage, resection is the single therapeutic modality, often associated with a high rate of long-term success. Intuitively, it appears logical that surgery should have little role in disease management once a neoplasm has spread from the primary location to a distant site. However, surgical therapy is being applied with increasing frequency for metastatic disease as well. Prolonged survival can be seen in selected patients following resection of various metastatic sites, including in the liver, lung, or brain. In particular, complete resection of hepatic colorectal metastases results in 5-year survival rates in excess of 50% in most contemporary series. As more active systemic cytotoxic and targeted therapies are prolonging survival in patients with various tumor types, resection or ablation of residual metastatic sites are being utilized with increasing frequency.

Surgery operates by zero-order kinetics, in which 100% of excised cells are destroyed. In contrast, chemotherapy and radiation therapy operate by first-order kinetics, where only a fraction of tumor cells are killed by each treatment. It is for this reason that these therapies can be considered complementary. Surgical resection reduces the tumor burden, which hopefully increases the efficacy of nonsurgical adjuvant therapies intended to eliminate microscopic residual disease, thereby decreasing the risk of recurrence and prolonging survival.

During the past several decades, a significant reduction has been seen in the morbidity and mortality associated with many complex cancer operations. These results, in part, can be attributed to improvements in surgical technique, patient selection, and regionalization to high-volume centers. For example, both perioperative risk and long-term survival after pancreaticoduodenectomy have been shown to be strongly influenced by hospital volume.¹ In addition, trends toward more limited cancer resections are being seen with comparable or improved oncologic outcome. Specifically, breast-conserving surgery has become an alternative to mastectomy in patients with breast carcinoma, limb salvage is often possible in patients with bone and soft-tissue sarcomas, and sphincter function and sexual potency can frequently be preserved for patients with rectal cancer. Because surgery is increasingly combined with other treatment modalities, it is essential that most patients with solid neoplasms have their treatment planned by a multidisciplinary team, which includes radiation and medical oncologists as well as surgical oncologists. To retain a primary role in the management of the cancer patient, the successful surgical oncologist must be able to coordinate and integrate the efforts of the entire oncologic team while maintaining a patient-centered focus on dignity and quality of life.

Table 1 Landmark advances in surgical oncology

Year	Event	Surgeon
1775	Etiologic basis of cancer	Percival Pott

1809	Elective oophorectomy	Ephraim McDowell
1829	Metastatic process	Joseph Recamier
1846	Ether as anesthesia	John Collins Warren
1867	Carbolic acid as antisepsis	Joseph Lister
1873	Laryngectomy	Albert Theodore Billroth
1878	Resection of rectal tumor	Richard von Volkman
1880	Esophagectomy	Albert Theodore Billroth
1881	Gastrectomy	Albert Theodore Billroth
1890	Radical mastectomy	William Stewart Halsted
1896	Oophorectomy for breast cancer	G.T. Beatson
1904	Radical prostatectomy	Hugh H. Young
1906	Radical hysterectomy	Ernest Wertheim
1908	Abdominoperineal resection	W. Ernest Miles
1909	Thyroid surgery (Nobel Prize)	Theodore Emil Kocher
1910	Craniotomy	Harvey Cushing
1912	Cordotomy for the treatment of pain	E. Martin
1913	Thoracic esophagectomy	Franz Torek
1927	Resection of pulmonary metastases	George Divis
1933	Pneumonectomy	Evarts Graham
1935	Pancreaticoduodenectomy	Allen O. Whipple
1945	Adrenalectomy for prostate cancer	Charles B. Huggins
1957	Isolated limb perfusion	Oliver Creech
1958	Organization of National Adjuvant Breast and Bowel Project (NSABP) to conduct prospective randomized trials	Bernard Fisher
1965	Hormonal therapy of cancer	Charles Huggins
1971	Free tissue transfer with microvascular anastomosis	Harry Buncke

The history of surgical oncology

Oncology (from the Greek words onkos, meaning mass or tumor, and logos, meaning study) is the study of

neoplastic diseases. Early authors suggested that certain families, races, and working classes were predisposed to neoplastic transformations. In 1862, Edwin Smith, an American Egyptologist, discovered the apparently earliest recordings of the surgical treatment of cancer.² Written in Egypt circa 1600 BC, this treatise was based on teachings possibly dating back to 3000 BC. The Egyptian author advised surgeons to contend with tumors that might be cured by surgery but not to treat those lesions that might be fatal.

Hippocrates (460–375 BC) was the first to describe the clinical symptoms associated with cancer. He advised against treating terminal patients, who would enjoy a better quality of life without surgical intervention.³ He also coined the terms carcinoma (crab legs tumor) and sarcoma (fleshy mass). In the second century ad, Galen published his classification of tumors, describing cancer as a systemic disease caused by an excess of black bile.⁴ Galen cautioned that as a systemic disease, cancer was not amenable to cure by surgery, which was often promptly followed by patient death. This strong admonition against surgery for cancer persisted for more than 1500 years until eighteenth-century pathologists discovered that cancer often grew locally before spreading to other anatomic sites. Before the advent of safe general anesthetics, surgery was used primarily to manage trauma or severe infectious problems such as abscess drainage. In that era, cancer surgery consisted primarily of amputation or cauterization of surface tumors of the trunk or extremities. Patients were usually unwilling to submit to the pain of tumor surgery, when there was little likelihood of improved survival.

During the eighteenth and nineteenth centuries, advances in anatomic pathology led to an increase in autopsies, which in turn resulted in a better understanding of human anatomy and physiology. The early work of Morgagni, Le Dran, and Da Salva established that there was an initial period of local tumor growth before distant dissemination. This led to the understanding that not all tumors spread systemically and that certain malignancies cause death solely by local invasive growth. Percival Pott (1714–1788) was the first to describe a specific etiologic factor associated with cancer development. In 1775, Pott demonstrated a high incidence of cancer of the scrotum in chimney sweeps who had reached puberty and recommended wide local resection for cure. In 1829, the French Surgeon Joseph Recamier (1774–1852) first described the complicated process of tumor dissemination. The first recorded elective tumor resection was performed in 1809 by Ephraim McDowell, an American surgeon. He successfully removed a 22-pound ovarian tumor from a patient, who subsequently survived 30 years. McDowell's work, which included 12 more ovarian resections, stimulated greater interest in elective surgery for cancer patients.

Surgeons were initially hindered by the extreme discomfort that patients experienced during surgical procedures as well as the lack of agents that could reduce the incidence of infection. Crawford Long (1815–1878) was the first to use ether for general anesthesia in 1842, but it was the reported work of John Collins Warren (1778–1856) and William T.G. Morton (1819–1868) that brought the potential of anesthesia to public attention. The surgical procedure in Warren's first published account of ether anesthesia (1846) was the elective removal of a tongue carcinoma for which submaxillary gland resection and partial glossectomy were performed. Warren was also responsible for the first American-authored textbook of tumor surgery, *Surgical Observations on Tumors*, published in 1838. Joseph Lister (1827–1912) was the first to report the successful use of antisepsis during elective surgery. In 1867, Lister applied Pasteur's concept that bacteria caused infection, when he introduced the use of carbolic acid as an antiseptic agent in conjunction with heat sterilization of surgical instruments. Lister is also credited with the introduction of absorbable ligatures as well as the placement of drainage tubes to control secretions and dead space in surgical wounds.

Even with the advent of antisepsis and general anesthesia, surgical oncology in the second half of the nineteenth and early twentieth centuries was still associated with high mortality rates. Cancer was rarely

diagnosed in the early stages; consequently, few patients were considered candidates for curative surgery. Those surgeons who did attempt surgical excision of malignant lesions were hindered by rudimentary anesthesia, which was also independently associated with high patient mortality. Antibiotics were not yet available, and surgical instruments were crude. The importance of the microscope to evaluate frozen tissues for surgical margins was not yet appreciated, and surgeons had great faith in their own unaided gross visual assessment of the tumor perimeter. However, several important developments in this era led to rapid advancements in surgical oncology. Emphasizing meticulous surgical technique, gentle tissue handling, and applications of Listerian principles, pioneers such as Albert Theodore Billroth (first gastrectomy, laryngectomy, and esophagectomy), William Stewart Halsted (en bloc resection, radical mastectomy), and many other more contemporary surgeons defined and advanced the boundaries of surgical oncology ([Table 1](#)).³

Ongoing innovations to advance effective surgical primary tumor control have improved surgical outcomes and quality of life. Advances in microvascular surgery now permit the free transfer of complex autologous tissues, such as free jejunal grafts to reconstitute the upper aerodigestive system or osteomyocutaneous flaps to reconstruct extremities and other mobile body parts such as the jaw. Automatic stapling devices as well as laparoscopic/robotic instrumentation coupled with high-resolution optics have remarkably advanced minimally invasive cancer surgery resulting in less-morbid procedures that require significantly less patient discomfort and recuperation time ([Figure 1](#)). The rapid deployment of robotic technologies is changing traditional surgical interventional approaches. Among the potential advantages, robotic surgery is performed as a direct extension of the operator's prehensile hand replete with multiplanar articulating robotic “wrists,” thereby avoiding the crossed rigid armature impediments of laparoscopic surgical maneuvers. Optoelectronic visualization systems incorporated into robotic display enables the appearance of three-dimensional surgical fields with supra-normal visual acuity. Gating the displayed images coupled with the ability to scale up or down discrete surgical actions (e.g., suture placement and cannulation) enables damping out of tremor effects while facilitating operations performed on moving anatomic structures, especially on the microscopic level. Robotic procedures can be performed over great distances between the robot and console display systems, which will facilitate telesurgical applications in the future. The development of molecular radiologic probes for imaging tumor cellular components possessing more ominous genetic character portends a future in which interventional onco-radiologists and minimally invasive surgical oncologists will work together in the operating room to laser capture micro-dissect these less favorable tumor subsections, perhaps in conjunction with intraoperative navigation systems and various visual interfaces such as direct retinal display systems.

Figure 1 Robotic enucleation of insulinoma in the body of the pancreas.

Improvements in preoperative optimization of comorbid disease and advances in perioperative critical

care have made it possible to safely undertake increasingly complicated surgical procedures. A more sophisticated awareness of the patterns of tumor spread has also resulted in increasing opportunities for less-invasive surgical approaches. One example is the use of lymphatic mapping and sentinel node biopsy instead of formal lymphadenectomy in early-stage melanoma and breast carcinoma. In other cases, this better understanding of recurrence risk has led to more, not less, extensive surgical resections. An example of this includes the selected use of total hepatectomy and orthotopic liver transplantation for early-stage hepatocellular carcinoma.

Surgical oncology in the modern era

Surgical oncologists are surgeons who devote most of their time to the study and treatment of malignant neoplastic disease. They must possess the necessary knowledge, skills, and clinical experience to perform both the standard and extraordinary surgical procedures required for patients with cancer. Surgical oncologists must be able to diagnose tumors accurately and differentiate aggressive neoplastic lesions from benign reactive processes. In addition, surgical oncologists should have a firm understanding of radiation oncology, medical oncology, and diagnostic and interventional radiology. They must also be capable of organizing interdisciplinary studies of cancer. Surgical oncologists should also be trained in pathology because they will be called on to excise appropriate tumor samples for pathologists and make decisions about adequacy of surgical margins. Surgical oncologists should have a shared role with medical oncologists as the “primary care physicians” of cancer treatment. Almost all cancer patients will initially be managed by one of these two specialists, who will bear the ultimate responsibility for coordinating appropriate multimodality care for the individual patient.

Given the complexity of contemporary multidisciplinary approaches to the cancer patient, cancer centers have developed facilities to provide the needed planning expertise, clinical care, patient support services, and access points to clinical trials. Comprehensive cancer centers are often affiliated with academic medical institutions and offer the complete spectrum of oncology therapies, clinical trials, rehabilitation, and social services as well as basic and translational research programs to move new knowledge from the laboratory bench to the patient bedside. In this contemporary understanding of the continuum of care of the cancer patient, the role of the surgical oncologist is taking on an ever-increasing importance.

Surgical oncology is more of a cognitive than a technical surgical specialty. With the exception of a small cluster of index operations, such as pancreaticoduodenectomy, limb salvage, retroperitoneal sarcoma surgery, isolated limb perfusion, and complex liver resection, most of the surgical procedures that are performed by surgical oncologists are similar to those performed by surgeons who are not oncologically trained. What frequently differentiates these two types of surgeons is not mere knowledge about *how* to do a specific operation but an awareness of how and *when* to do that operation; that is, the cognitive knowledge of contemporary multimodality cancer care. A broad knowledge of cancer in its presenting and recurring forms as well as an awareness of the mechanisms driving tumor proliferation and dissemination is an integral part of the special cognitive database of the surgical oncologist.

As cancer management continues to march forward in the age of genomics, proteomics, and metabolomics, there is an ever-increasing need to study human tumor tissue. At a minimum, the surgical oncologist can contribute to cancer science by helping to secure access to these precious tissues. In reality, the surgical oncologist can do much more than passively provide tumor tissue access. An unparalleled understanding of the pathophysiology of solid tumors coupled with intimate knowledge of anatomy and the workflow in the operating room and pathology department places the cancer surgeon in

the central role of organizing, maintaining, optimizing, and overseeing effective tissue procurement and tumor banking; thus making the surgical oncologist a vital member of a translational science team. In addition, the cancer surgeon, working with pathologists and researchers, has the opportunity to provide meaningful clinical information, which can be used to annotate archival tissue repositories and aid in the creation of tissue microarrays. These are valuable tools whose utility can range from explorative, hypothesis-generating retrospective studies to confirmation of specific laboratory findings.

As part of the larger surgical community, the surgical oncologist is a critical conduit for the dissemination of cancer information to colleagues in general surgery and other surgical specialties. This individual makes academic presentations at large surgical meetings, directs hospital-based tumor boards, and consults on behalf of individual cancer patients. Because of their leading role in the initial diagnosis of cancer, it is not surprising that surgical oncologists are also frequently in leadership roles in cancer prevention and screening programs. Nationally based multimodality clinical trial groups also depend on surgical oncology expertise in helping with trial design; establishing the criteria of surgical quality control; educating trial participants regarding standards of surgical care (including indications for procedures); assuring safe acquisition of research grade tumor and autologous normal tissues for correlative studies, and assisting in accurate data collection, analysis, and presentation of trial results.

Multidisciplinary management

Multidisciplinary management of solid tumors requires surgeons to play a key role in decisions concerning sequencing of treatment modalities. For example, a patient with rectal cancer and resectable liver metastases may ultimately be treated with a liver resection, rectal resection, rectal radiation therapy, and systemic chemotherapy. Traditionally, the sequence for these treatments was preoperative chemoradiation therapy, followed by rectal resection (e.g., abdominoperineal resection or low anterior resection), subsequent liver resection, and then adjuvant chemotherapy—an aggressive approach but one that produces long-term survival in a subset of patients. However, in recognition that the greatest risk for mortality in these patients comes from systemic relapse, there is a more recent trend toward starting with chemotherapy, rather than leaving it to the end. Another benefit of this approach is that the nature of response to neoadjuvant treatment serves as an important prognostic marker. Moreover, tumor shrinkage may lead to a less difficult liver resection or rectal resection. While liver and bowel operations were rarely performed simultaneously, these are now more commonly performed together based on data showing safety of this approach in select patients. More often, in cases in which the two operations are performed separately, liver resection is now often performed first. The basis for this approach is that while preoperative chemotherapy rarely has any adverse impact on colon or rectal operations, accumulation of chemotherapy treatments is known to increase the risk of chemotherapy-induced liver pathology leading to complications from liver surgery. Use of short course adjuvant radiation therapy such as 25 Gy in five fractions followed by surgery 1 week later rather than the traditional 5-week course of radiation shortens the time required for trimodality treatment and reduces the length of time off of chemotherapy. Fundamental principles that influence the sequence of multimodality treatment apply to most other solid tumors as well, and are requisite knowledge for surgical oncologists.

Pediatric oncologists pioneered the use of combined modality therapy (radiation in combination with chemotherapy and surgery) as effective management of childhood neoplasms. Control of localized retinoblastoma in children has been dramatically increased using multimodality therapy. The cure rate for patients with Wilms tumor is 75% and if surgical therapy is followed by chemotherapy and, in some cases, radiation, by an increase of 40% over operation alone. Embryonal rhabdomyosarcoma responds best to combinations of radiation, chemotherapy, and operation. Until recently, the effectiveness of

multimodality therapy was only occasionally demonstrable for adult neoplasms. A striking example is the approach to skeletal and soft-tissue sarcomas. Surgical therapy, the accepted method for local management of most skeletal and soft-tissue sarcomas of the extremities, is associated with frequent treatment failure if used alone. In the past, approximately 50% of patients with soft-tissue sarcomas and 80% of those with bone sarcomas eventually succumbed to distant metastases, even after amputation of the extremity bearing the primary tumor. Consequently, multimodality treatment regimens were developed to improve these results. Preoperative chemotherapy with intra-arterial doxorubicin followed by radiation resulted in extensive tumor cell necrosis in as many as 75% of patients.⁴ The effectiveness of this preoperative therapy permitted local resection of the sarcoma and salvage of a viable functional extremity. Local recurrence rates were as low as with amputation, and long-term results were functionally and psychologically superior. In addition, there was no decrease in overall or disease-free survival rates. Multimodality therapy is also effective for other solid malignancies, including colorectal cancer. Specifically, clinical trials have demonstrated improved efficacy and higher sphincter-preservation rates with the use of neoadjuvant chemoradiation therapy for stage II or III rectal cancer. Multimodality therapy has also been demonstrated to improve resectability rates and long-term survival in patients with hepatic colorectal metastases.⁵

Unlike surgery and radiation therapy, systemic therapies, such as chemotherapy, immunotherapy, and hormonal therapy, are treatments that can kill tumor cells that have already metastasized to distant sites. These systemic modalities have a greater chance of cure in patients with minimal (or even subclinical) tumor burden as compared with those patients with clinically evident disease. Consequently, surgery and radiation therapy may be useful in decreasing a given patient's tumor burden thereby maximizing the impact of subsequent systemic approaches. Whether the goals of therapy should be cure or palliation depends on the stage of a specific cancer. If the cancer is localized without evidence of spread, it may be possible to eradicate the cancer and cure the patient. When the cancer has spread beyond the possibility of cure, the goal is to control symptoms and maintain maximum activity and quality of life for as long as possible. Patients are generally judged incurable if they have distant metastases or evidence of extensive local infiltration of critical structures adjacent to tumor. However, some patients are potentially curable even though they have distant metastases. Specifically, patients with solitary hepatic or pulmonary metastases may still be curable by resection, and patients with disseminated germ cell or gastrointestinal stromal tumor may still be cured using systemic therapy alone. Histologic proof of distant metastases should be obtained before the patient is deemed incurable. Occasionally, an exploratory operation may be necessary to determine the histology of ambiguous lesions in the lungs or liver. In rare situations, the clinical situation may point so overwhelmingly to distant metastases that the patient may be considered incurable without biopsy. For each anatomic site, there are certain local criteria that place the patient unequivocally in an incurable status, whereas other anatomic constraints may imply a poor prognosis but are not an absolute indication of incurability per se. In equivocal situations where extensive studies fail to demonstrate metastatic or incurable local extension, the patient deserves the benefit of the doubt and should be treated for cure.

The selection of therapeutic modalities depends not only on the type and extent of cancer but also on the patient's general condition and the presence of any comorbid conditions. For example, surgery may be contraindicated in a patient who has significant emphysema or liver failure. A patient with preexisting diabetes will be much more susceptible to the toxic effects of hormonal therapy with corticosteroids. Renal disease may increase the toxicity of some of the chemotherapeutic agents, such as cisplatin or ifosfamide. Extensive staging procedures may indicate that a tumor is localized to a primary site and/or regional lymph nodes and hence potentially curable by locoregional therapy. However, approximately 60% of localized malignant tumors ultimately recur, suggesting that many such patients must have had

subclinical metastases at the time of initial diagnosis. The probability of cure may be improved if systemic approaches are coupled with local treatment. Chemotherapeutic drugs must be given when the number of tumor cells is low enough to permit their destruction at doses that can be tolerated by the patient. The opportunity for cure is most likely during the early stage of disease or immediately after surgery when the tumor burden has been minimized. Adjuvant chemotherapy has remarkably improved surgical results in some malignancies, primarily because of cytotoxic effects on clinically undetectable malignant cells outside the operative field. Neoadjuvant chemotherapy that is initiated before local and regional treatments also can affect micro-metastatic distant disease while significantly cytoreducing the primary tumor.

Classically, surgical extirpation has been first in the sequence of therapies for resectable solid malignancies, but increasing evidence suggests that it may be more effective when used later in the treatment plan, particularly in more advanced tumors. Chemotherapy and radiation therapy both work by first-order kinetics. However, because of tumor cell heterogeneity, it can be anticipated that resistant clones of viable neoplastic cells may persist in the primary tumor after these therapies. Such clonal heterogeneity is more likely in large tumors that are both poorly perfused by chemotherapeutic agents and are also relatively hypoxic and therefore resistant to radiation therapy. Because surgery works by zero-order kinetics, it effectively removes the local residual primary tumor cells that are resistant to these other modalities.

From a practical management standpoint, the use of chemotherapy before surgical therapy can provide useful prognostic information regarding response to therapy. Presence of response to neoadjuvant therapy can aid in the planning of additional postoperative adjuvant chemotherapy. In addition, earlier administration of systemic therapy addresses the potential occult micro-metastatic disease. In some cases, preoperative therapy (or “conversion” therapy) can be used to downsize a tumor from an unresectable to resectable status ([Figure 2](#)).

Figure 2 Previously unresectable (involvement of all three hepatic veins) intrahepatic cholangiocarcinoma downstaged using neoadjuvant gemcitabine and cisplatin.

Components of surgical management in the care of the cancer patient

Surgical prevention

As the role of genetic mutations that pre-dispose to subsequent cancer development expands, one can anticipate that prophylactic surgery will be extended to encompass some of these conditions. In such cases, it is imperative that the surgical oncologist become intimately knowledgeable about the indications, limitations, and ethical considerations regarding genetic counseling, if only because it will be the responsibility of the surgeon to alert other family members at risk and arrange for appropriate testing. The

above emerging indications are being added to an already established role for prophylactic surgery in the prevention of predisposing malignancies, including ulcerative colitis with dysplasia, familial adenomatous polyposis, multiple endocrine neoplasia syndromes, and hereditary breast cancer. Assessing the risk–benefit ratio of prophylactic surgery is critical but frequently inexact. The future advent of inexpensive and reliable genetic screening technologies, coupled with emerging insights derived from the new field of molecular epidemiology, should bring more definitive understanding of prophylactic surgery benefits in populations at risk.

Biopsy and diagnosis

The diagnosis of solid tumors depends on locating and performing a biopsy of the lesion. The findings from biopsy specimens will be used to determine the histology and/or grade of a tumor, which is a prerequisite for planning definitive therapy. Significant therapeutic errors have been made when biopsy confirmation of malignancy was not obtained before treatment. Even when biopsy reports from another hospital are available, the slides of the previous biopsy must be obtained and reviewed before the institution of therapy. This is essential because all too often an erroneous interpretation may have been made in the initial pathology assessment.

Surgeons play a key role in the initial diagnosis for many solid tumors, including the decision on whether and how to biopsy a mass. In the case of a clinically suspicious breast mass combined with an abnormal mammogram, core biopsy rather than excisional biopsy is often appropriate as a strategy to limit the number of surgical procedures and allow for multidisciplinary planning and possibly neoadjuvant therapy. Conversely, in a patient with chronic viral hepatitis, and an arterially enhancing mass with imaging features suggestive of a resectable hepatocellular carcinoma, needle biopsy is typically not indicated if resection represents the most appropriate treatment pathway. Proper approaches to biopsy of a cutaneous pigmented lesion for possible melanoma requires understanding of the importance of proper intraoperative tissue manipulations to avoid compromising tumor thickness measurements by leaving a positive deep margin and understanding the difficulty in clinically following an atypical nevus that has only been partially biopsied; complete excisional biopsy is appropriate in most circumstances. The strategy for biopsy of masses suspicious for soft tissue sarcomas involves thoughtful planning to obtain sufficient tissue for histologic study, minimize disruption and potential seeding of tissue planes and allow for needle biopsy tracks to be placed within fields used for adjuvant or neoadjuvant radiation therapy. The strategy for biopsy of very small lesions causing obstruction of the common bile duct typically integrates understanding of the relatively high likelihood of false-negative results and the observation that the most curable lesions are the smallest and most difficult from which to attain a true-positive result. Resection is commonly performed in such circumstances even in the absence of a positive biopsy. And because diagnosis of distant metastases will often change overall management, surgeons commonly decide on how to achieve a tissue diagnosis at distant sites with minimal morbidity and high sensitivity. Fundamental principles that influence approaches to biopsy are requisite knowledge for surgical oncologists.

Biopsy is easiest when the tumor is near the surface or involves an orifice that can be examined with appropriate visualizing instruments, such as the bronchoscope, colonoscope, or cystoscope. Carcinomas of the breast, tongue, or rectum can be seen or palpated and a portion can be excised for definitive diagnosis. In contrast, deep-seated lesions may grow to quite a large size before causing symptoms. Ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) are all useful techniques for localizing such lesions at the time of invasive biopsy. However, although image-directed needle biopsy may be useful in some patients, exploratory surgery is occasionally required to obtain a

definitive biopsy that establishes the exact histologic diagnosis. In some cases, tissue samples larger than that which is obtained by percutaneous biopsy may be required for tumor characterization, such as lymphoma, necessitating surgical biopsy. Fortunately, such procedures can now be frequently performed on an outpatient basis using minimally invasive technology such as laparoscopic surgical approaches.

Three methods are commonly used to biopsy suspicious lesions: needle biopsy (fine needle aspiration (FNA) or core), open incisional, or excisional biopsy. Regardless of the method used, the pathologic interpretation of the tumor mass will be valid only if a representative section of tumor is obtained. The surgical oncologist must be aware that a sampling error can occur with needle and incisional biopsies where only small portions of the total tumor mass are submitted for pathologic examination. It is the surgeon's task to provide adequate tissue for diagnosis. Orientation of the specimen, as may be necessary, is also the responsibility of the surgeon. It is axiomatic that adequate tissue can provide the basis for diagnosis by an adequate pathologist, whereas inadequate tissue will be insufficient for diagnosis by an adequate or inadequate pathologist.

FNA is a cytologic technique in which cells are aspirated from a tumor using a needle and syringe. The technique can be performed using image-directed guidance and is particularly helpful in the diagnosis of relatively inaccessible lesions such as deep visceral tumors. Because the aspirate consists of disaggregated cells rather than intact tissue, diagnosis of malignancy usually depends on detection of abnormal intracellular features, such as nuclear pleomorphism; thus, the margin of error is higher than with other biopsy techniques. In addition, because of the lack of intact tumor architecture, FNA cannot distinguish invasive from noninvasive malignancy. Negative results do not rule out malignancy. Depending on the clinical context, such as distinguishing carcinoma *in situ* from an infiltrating malignancy, other types of biopsy may be more appropriate.

Core biopsy is the simplest method of histologic (as opposed to cytologic) diagnosis and may be useful for biopsy of subcutaneous masses and muscular masses as well as some internal organs, such as liver, kidney, and pancreas. The added benefit is that this method is inexpensive and causes minimal disturbance of the surrounding tissue. Cutting-core biopsies are performed with a large-bore needle such as the Vim Silverman or Tru-Cut appliance. This technique retrieves a small piece of intact tumor tissue, which allows the pathologist to study the invasive relationship between cancer cells and the surrounding microenvironment. The danger of implanting tumor cells in a needle track during biopsy is extremely small. This risk can be avoided altogether if the needle track is positioned so that it can be excised en bloc at the time of the definitive surgical procedure. Needle biopsy may be less appropriate if the specimen is small, which increases the likelihood of the needle missing the lesion or the biopsy not being representative of the entire tumor. Consequently, a needle biopsy report that is negative for malignant disease should be viewed with skepticism if it is inconsistent with the clinical presentation and should be followed by incisional or excisional biopsy.

Incisional biopsy for pathologic examination involves removal of a small portion of the tumor mass. It is best performed in circumstances where the incisional wound can be totally excised in continuity with the definitive surgical resection in the event that any tumor cells are spilled at the time of biopsy. Incisional biopsy is indicated for deeper subcutaneous or intramuscular tumor masses when initial needle biopsy fails to establish a diagnosis. An incisional biopsy is also appropriate when a tumor is so large that complete local excision would violate wide tissue planes and impair a subsequent wide local resection for curative purposes. If possible, an incisional biopsy should retrieve a deep section of tumor as well as a margin of normal tissue. Incisional biopsies suffer from the same disadvantages as needle biopsies in that the removed portion may not be representative of the entire tumor. Consequently, a negative biopsy does not preclude the possibility of cancer in the residual mass.

Excisional biopsy completely removes the mass of interest. It is used for small, discrete masses that are generally <3 cm in diameter, where complete removal will not interfere with a subsequent wider excision that may be required for definitive local control. Excisional biopsy allows the pathologist to examine the entire lesion. However, this method is contraindicated in large tumor masses because the biopsy procedure could scatter tumor cells throughout a large surgical field that would need to be widely and totally encompassed by the ultimate surgical resection. For this reason, excisional biopsy is usually contraindicated for skeletal and soft tissue masses when the diagnosis of sarcoma is being entertained. The excisional method is also used for polypoid lesions of the colon, for thyroid and breast nodules, lymph nodes, for small skin lesions, and when the pathologist cannot make a definitive diagnosis from tissue removed by incisional biopsy. An unbiopsied mass is also surgically removed when the suspicious character of the lesion, the need for its removal (whatever the diagnosis), and the nonmutilating nature of the operation render such an approach feasible. Examples of such procedures include subtotal thyroidectomy for thyroid nodules after an inconclusive FNA and a right hemicolectomy for a cecal mass that might be either inflammatory or neoplastic. In the latter instance, colonoscopic biopsy is informative only if positive for neoplasm. Surgeons should always mark the excisional biopsy margins with sutures or metal clips so that if removal is incomplete and further excision is needed the positive margin can be accurately identified *in situ*.

Orientation of biopsy incisions is also extremely important. Ill-conceived incisions can unnecessarily open up additional tissue planes, necessitating subsequent wider radiotherapy fields or more extensive ultimate surgical resections. For example, tumors of the extremities are best biopsied using incisions that run parallel to the long axis of that limb. This facilitates a definitive en bloc resection that encompasses the biopsy track ([Figure 3](#)). Biopsy incisions should be closed using meticulous hemostasis because a hematoma can lead to dissemination of tumor cells with contamination of tissue planes. Instruments, gloves, gowns, and drapes should be discarded and replaced with unused substitutes if the definitive surgical resection immediately follows the biopsy procedure.

Figure 3 Appropriate and inappropriate biopsy incisions. (a) A patient with a cruciate-shaped biopsy scar overlying the patellar tendon that contained a synovial sarcoma. Note the erythema in this infected incision. This ill-conceived biopsy scar would have required a wide-field soft tissue and osseous composite resection to encompass all of the violated tissue planes. Unfortunately, tumor was *intruded* into the joint space at the time of this biopsy, and this patient ultimately required an above-knee amputation to treat this small, otherwise limb-salvageable sarcoma. (b) An appropriately oriented incisional biopsy scar in the lower extremity. Note the alignment of the scar parallel with the long axis of the extremity and the meticulous placement of small biopsy wound sutures. The entire scar could be excised at surgery (blue ellipse) with minimal concomitant normal tissue sacrifice.

Lymph nodes should be carefully selected for biopsy. Axillary nodes may be preferable to groin nodes if both are enlarged because of a decreased likelihood of postoperative infection. Other caveats are also noteworthy. For example, lymph node specimens preserved in formaldehyde cannot be analyzed for cytogenetics or flow cytometric immunophenotyping. The laboratory work-up for lymphoma usually requires unfixed sterile tissue. Cervical lymph nodes should not be biopsied until a careful search for a primary tumor has been made using nasopharyngoscopy, esophagoscopy, and bronchoscopy because enlargement of the upper cervical nodes by metastases is usually caused by laryngeal, oropharyngeal, and nasopharyngeal primary neoplasms. In contrast, supraclavicular nodes are more frequently enlarged as a result of metastases from primary tumors of the thoracic or abdominal cavities or breast.

The tumor specimen may be prepared for pathologic examination by either frozen or permanent sections. Frozen sections are made at the time of biopsy, and pathologic diagnosis can typically be obtained within 10 min. Frozen sections are used when the diagnosis is required to assess resectability at the time of major surgery or to check tumor margins intraoperatively. Frozen-section biopsy-proven carcinomatosis may mandate abandoning a procedure with a curative intent in favor of a palliative approach. Occasionally, mediastinoscopy, laparoscopy (peritoneoscopy), thoracoscopy, exploratory thoracotomy, or even laparotomy is necessary to obtain adequate representative tissue samples for microscopic examination to confirm diagnosis or tumor stage.

Staging

Tumor staging is a system used to describe the anatomic extent of a specific malignant process in an individual patient. Staging systems cluster relevant prognostic factors about the primary tumor, such as size, grade, and location, as well as information about dissemination to regional sites, such as lymph nodes or distant metastatic sites. Accurately staging a cancer is essential in designing an appropriate therapeutic program and advising on prognosis. Without accurate staging, it is impossible to meaningfully

compare the results of therapies administered in different centers. New forms of therapy can be appropriately evaluated only by comparing the impact of current therapy of neoplasms of equivalent stage. The recognized importance of staging has led to a variety of international and national attempts to standardize the staging of the patient with cancer. To date, no single system has been universally accepted. The American Joint Committee on Cancer (AJCC) has recommended a staging system ranging from stage I (small, localized malignancy) to stage IV (distant metastatic spread).⁶ Both the AJCC and the Union Internationale Contre Cancer (International Union Against Cancer, UICC) have adopted a shared TNM system that defines a cancer in terms of the primary tumor (T), the presence or absence of nodal metastases (N), and the presence or absence of distant metastases (M). Increasing numerals after the T, such as T1, T2, T3, or T4, indicate lesions of increasing size or depth of penetration that are usually associated with a poorer prognosis. The absence of nodal metastasis is designated as N0, the presence of nodal metastasis is N1, and for more extensive nodal involvement, additional numbers may be used. Finally, distant metastases are indicated by adding the numeral 1 following M for metastases, or the numeral 0 signifying their absence. Thus, a small lesion that has neither spread to regional nodes nor metastasized to distant sites would be designated as T1 N0 M0. A larger lesion that involved regional nodes but not distant sites might be identified as T2 N1 M0. A large neoplasm associated with both regional and distant metastases would be designated T3 N1 M1. For some tumor types, such as soft tissue sarcoma, a G for grade of malignancy is added. High-grade tumors are less differentiated and tend to metastasize more readily.

The TNM system has four chronologic classifications. The clinical classification (cTNM or TNM) represents the extent of the disease before first definitive treatment as determined from physical examination, imaging studies, endoscopy, biopsy, surgical exploration, and any other relevant findings. The pathologic classification (pTNM) incorporates the additional information available at the time of surgery or derived from pathologic examination of a completely resected specimen. This is especially useful in planning adjuvant therapy. A y prefix may be added to denote pathologic staging after initial systemic or radiation therapy has been performed (ypTNM). The retreatment classification (rTNM) is used to stage a cancer that has recurred after a disease-free interval; it includes clinical and/or pathologic evidence of recurrence. Finally, the autopsy classification (aTNM) is based on postmortem examination.

Patterns of tumor spread

In general, a malignant tumor may spread (1) by direct extension into surrounding structures, (2) via the lymphatics, (3) by hematogenous spread, or (4) by implantation in serous cavities. However, many cancers spread by more than one route, and an orderly course of metastasis is not predictably certain. For example, patients with breast cancer or melanoma can manifest distant metastatic disease in the lungs, liver, or skeleton without ever developing evidence of lymph node metastases. [Table 2](#) summarizes the metastatic patterns of various human tumors.

Table 2 Patterns of neoplastic spread for common human malignancies

Neoplasms	Hematogenous	Lymphatic	Local infiltration (expressed as local recurrence)
<i>Adenocarcinoma</i>			
Breast	++++	+++	++
Endometrium	+	++	+
Ovary	++	+++	++++
Stomach	++++	++++	+++
Pancreas	++++	++++	+++
Colon	+++	+++	+
Kidney	++	++	++
Prostate	+++	+++	+++
Liver	+	+	++++
<i>Epidermal carcinoma</i>			
Lung	++++	+++	++
Oropharynx	++	+++	+++
Larynx	+	+++	++
Cervix	+	++++	+++
<i>Transitional cell carcinoma</i>			
Bladder	++	+++	++++
<i>Cutaneous neoplasm</i>			
Squamous cell carcinoma	+	++	+
Melanoma	+++	+++	++
Basal cell carcinoma	0	0	+
<i>Sarcoma</i>			
Bone	++++	+	+
Soft tissue	++++	+	+++
Brain neoplasm	0	0	++++

Key: Does not occur; 0, <1%; +, 1–5%; ++, 15– 30%; +++, 30– 50%; and +++++, >50%.

Cancer cells may also spread by direct extension through tissue spaces and planes. Some neoplasms, such as soft tissue sarcomas and adenocarcinomas of the stomach or esophagus, may extend for a considerable distance (10–15 cm) along tissue planes beyond the palpable tumor mass. Other neoplasms, such as a basal cell carcinoma of skin, rarely extend for more than a few millimeters beyond the visible margin. Even though most central nervous system (CNS) tumors infrequently metastasize, they may penetrate nearby brain tissue, and their location can cause death by interfering with vital CNS functions.

Tumor cells can readily enter the lymphatics and extend through these channels by permeation or

embolization to regional lymph nodes. Permeation is the growth of a colony of tumor cells along the course of the lymphatic vessel. This commonly occurs in the skin lymphatics in carcinoma of the breast and in the perineural lymphatics in carcinoma of the prostate. Lymphatic involvement is extremely common in malignant epithelial neoplasms of all types, except basal cell carcinoma of the skin, which metastasizes to regional lymphatics in <0.1% of cases, or mesenchymal neoplasms, such as sarcomas, which metastasize to lymph nodes in only 2–5% of cases.

Spread along the lymphatics by embolization to regional or distant lymph nodes is of great clinical importance. Tumor cells travel within local lymphatics and can spread to proximal nodal basins via the collateral lymphatic channels. Lymph node metastases are first confined to the subcapsular space; at this stage, the node is not enlarged and may appear grossly normal. Gradually, the tumor cells permeate the sinusoids and replace the nodal parenchyma, changing the shape and texture of the node. There is little direct spread from node to node because the nodal capsule is not penetrated until a late stage. However, when an involved lymph node is more than 3 cm in diameter, tumor has usually extended beyond the capsule into the perinodal fat.

Lymph from the abdominal organs and lower extremities drains into the cisterna chyli and then into the thoracic duct, which finally opens into the left jugular vein. Using this route, tumor cells can pass freely from the lymphatic system into the bloodstream. Oncologists originally believed that solid neoplasms first involved regional lymph nodes and then spread into the bloodstream by drainage into the thoracic duct and then to other parts of the body. An alternative explanation now favored by most oncologists assumes that the presence of cancer cells in regional lymph nodes indicates an unfavorable host–tumor relationship and the concomitant high likelihood of distant metastases.

Cancer cells may reach the bloodstream either through the thoracic duct or by direct invasion of blood vessels. Capillaries offer no resistance to tumor cell transgression. Small veins are frequently invaded, whereas thicker-walled arteries are rarely violated. Veins frequently form a plexus extending to the subendothelial regions, which provide a portal of entry through the thin vein wall. When the vascular endothelium is destroyed, a thrombus can form that is quickly invaded by tumor. This combination of thrombus and tumor may detach to form large tumor emboli. Vascular invasion is common in both carcinomas and sarcomas and is associated with a poor prognosis. Some types of neoplasms have a remarkable tendency to grow as a solid column along the course of veins. For example, renal cell carcinoma can grow into the renal vein and up the inferior vena cava extending to the right atrium. In this situation, a spectacular en bloc removal requiring cardiopulmonary bypass may still result in long-term survival or even cure.

Tumor cells occasionally gain entrance to serous cavities by growing through the wall of an organ. Many tumor cells can grow in suspension without a supporting matrix and may widely spread within the peritoneal cavity or attach to serous surfaces. Thus, widespread peritoneal seeding is common with gastrointestinal and ovarian cancers. Similarly, malignant gliomas may spread widely within the CNS via the cerebrospinal fluid.

Although much is known about the routes of tumor spread, the mechanisms underlying this process remain unclear. Some cancers are metastatic at the time of clinical discovery, whereas others of the same type and in the same organ tissue may remain localized for years. Metastases may dominate the presenting clinical picture although the primary tumor remains latent and asymptomatic or even undetectable. For example, cerebral metastases from silent cancers in the bronchus or the breast are often mistaken for primary benign CNS neoplasms.

Preoperative preparation

Preparation of a patient for surgical cancer therapy is important in order to minimize perioperative complications, hasten recovery to premorbid state of health, and avoid delay in possible initiation of postoperative adjuvant therapy. Every effort should be made to correct nutritional deficiencies if present, restore depleted blood volume, and correct electrolyte imbalances before extensive surgical procedures. Total parenteral nutrition (TPN) can be used to prepare the extremely malnourished patient for a major operation, although reconstitution is a slow process, and TPN may chiefly serve to interrupt further deterioration by restoring positive nitrogen balance. Surgical morbidity and mortality following extensive cancer operations will predictably be problematic if critical physiologic and biochemical deficiencies are not corrected in advance.

Determining the risk inherent in a given operation is a complicated and inexact assessment based on a number of factors. The physical status of the patient, including cardiopulmonary reserve, comorbid conditions, debility inherent to a specific operation, hepatic and renal function, and the intent of surgical procedure (curative vs palliative), are all pertinent to this assessment. The technical complexity of an operation, the type of anesthetic used, and the relative experience of the involved health care personnel can all impact on the complications of a procedure. Various schema for risk assessment, such as the five-level physical status classification of the American Society of Anesthesiologists ([Table 3](#)) and the Eastern Cooperative Oncology Group Five-Step Performance Scale ([Table 4](#)), may be useful in assessing the appropriateness of a given operation for a specific patient. More recently, it has been the introduction of the American College of Surgeons surgical risk calculator (www.riskcalculator.facs.org), which takes into account 21 patient characteristics that can be entered online and used to predict any of the nine possible procedure-specific outcomes including death, any complication, severe complications, and surgical site infection among others. The calculator was developed based on data obtained from over 1.4 million operations at 393 hospitals participating in the ACS NSQIP project between 2009 and 2012.⁸

Table 3 American Society of Anesthesiologists: Physical status classification

Class	Description
P-1	A normal healthy patient
P-2	A patient with mild systemic disease
P-3	A patient with severe systemic disease
P-4	A patient with severe systemic disease that is a constant threat to life
P-5	A moribund patient who is not expected to survive without the operation
P-6	A declared brain-dead patient whose organs are being removed for donor purposes

Table 4 Eastern Cooperative Oncology Group: Performance scale and corresponding Karnofsky rating

Grade	Description
0	Fully active, able to carry on all predisease activities without restriction (Karnofsky 100)
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, for example, light housework/office work (Karnofsky 80–90)
2	Ambulatory and capable of all self-care but unable to carry out any work activities; up and about more than 50% of waking hours (Karnofsky 60–70)
3	Capable of limited self-care; confined to bed or chair 50% or more of waking hours (Karnofsky 40–50)
4	Completely disabled; cannot carry on any self-care; totally confined to bed or chair (Karnofsky 30 or less)

Operative mortality is defined as mortality that occurs within 30 days of an operative procedure. In cancer patients, the underlying disease is a major determinant of operative mortality. Although it is true that comparable operations are usually more morbid in the geriatric age group as compared with other adults, advanced age per se should not disqualify a patient from a potentially curative surgical procedure. Because of their high-risk nature, decisions about the indications for palliative surgical procedures are particularly difficult. For example, palliative surgery for extensive metastatic disease or symptomatic intestinal obstruction secondary to carcinomatosis has a 20–30% perioperative mortality. In such circumstances, the risk–benefit ratio and ultimate surgical objectives must be defined as clearly as possible and accepted by patient, family, and surgeon.

Preoperative chemotherapy and or radiation therapy is being administered with increasing frequency in patients undergoing cancer operations. In some cases, these therapies can be associated with increased perioperative complications. For example, the antivascular endothelial growth factor antibody bevacizumab is associated with increased risk of wound healing complications when administered within several weeks before surgery.⁹ As this targeted therapy has a 21-day half-life, discontinuation of bevacizumab is recommended at least 6–8 weeks before elective surgery.

Operative considerations

Once a decision has been made to proceed with surgical therapy, the operative procedure itself must be carefully planned for the specific surgical patient. It is essential to realize that the best (and often the only) opportunity for cure is with the first resection, at the time of initial tissue plane, lymphatic, and blood vessel potential exposure to tumor cells that may be dislodged within the operative field. A subsequent recurrence may be difficult to distinguish from the normal postsurgical inflammatory reaction and scarring.

The principle of the “no touch technique” has maintained some traction in the surgical lore. This opinion is based on the theoretical concept that direct contact with and manipulation of the tumor during resection can lead to an increased risk in local implantation and embolization of tumor cells. Although little clinical evidence exists to support this principle, there may be some validity to this concept with respect to tumors that extend directly into the vascular system, such as hepatocellular or renal tumors with extension to the large veins or vena cava. Although not definitively proved to be detrimental, the general tenet of avoidance of forceful handling of the tumor and care to avoid any tumor disruption during surgical

resection is sound technique. Similarly, every attempt should be made to extirpate a tumor with meticulous attention to detail while avoiding excessive blood loss or operative time. Although the need for contiguous multivisceral resection may, by its nature, result in prolonged operation with high blood loss, familiarity and experience with such complicated operations such as major hepatectomy, pancreatectomy, and retroperitoneal tumor removal potentially minimizes operative morbidity and maximizes oncologic benefit

Types of cancer operations

Wide local resection with removal of an adequate margin of normal peritumoral tissue may be adequate treatment of low-grade neoplasms that very rarely metastasize to regional nodes or widely infiltrate adjacent tissues. Basal cell carcinomas and mixed tumors of the parotid gland are examples of such tumors. In contrast, neoplasms that spread widely by infiltration into adjacent tissues, such as soft tissue sarcomas and esophageal and gastric carcinomas, must be excised with a wide margin of normal tissue. This wide tissue margin between the line of excision and the tumor mass may also act as a protective barrier against intraoperative tumor cell traversal into severed lymphatics and vessels. Tumor cells may have been implanted in the incision when an incisional biopsy alone had been previously performed. To encompass potentially contaminated tissues, it is extremely important to remove a wide segment of skin and underlying muscle, fat, and fascia beyond the limits of the original incision.

Malignant neoplasms are usually not truly encapsulated. The tumor is commonly encased by a pseudocapsule comprising a compression zone of normal tissue interspersed with neoplastic cells. This pseudoencapsulation offers a great temptation for simple enucleation in that the tumor may be easily dislodged from its bed. However, this approach must be resisted because microscopic extensions of tumor from the primary through the pseudocapsule will be left behind after simple enucleation, dooming the patient to a local recurrence. Ideally, the surgeon should operate through normal tissues at all times and never encounter or even directly visualize the neoplasm during its removal. Dissection should proceed with meticulous care to avoid tumor cell spillage. Many neoplasms metastasize via the lymphatics, and operations have been designed to remove the primary neoplasm and draining regional lymph nodes in continuity with all intervening tissues. Circumstances favor this type of operative approach when the lymph nodes draining the neoplasm lie adjacent to the tumor bed or when there is a single avenue of lymphatic drainage that can be removed without sacrificing vital structures. It is important to avoid cutting across involved lymphatic channels, which markedly increases the possibility of local recurrence.

At the present time, it is generally agreed that en bloc regional lymph node dissection is indicated for clinically demonstrable nodal involvement with metastatic tumor. However, in many cases, the tumor has already spread beyond regional nodes. Although the cure rates following resection in such circumstances may be quite low (20–50%), undue pessimism should not prevent such patients from receiving appropriate surgical treatment. En bloc removal of the involved lymph nodes may offer the only chance for cure and can at least provide significant palliative local control. Regional lymph node involvement should therefore not be viewed as a contraindication to surgery but as a possible indication for adjuvant therapies, such as radiation or chemotherapy.

The routine dissection of regional nodes in close proximity to the primary malignancy is recommended for most cancer types even when these structures are not clinically involved with tumor. This recommendation is based on the high rate of locoregional recurrence following surgical resection when multiple lymph nodes are microscopically involved and the high error rate when palpation alone is used to assess possible lymph node involvement with tumor. Microscopic tumor dissemination to regional

lymph nodes can be detected in 20–40% of clinically node-negative carcinomas and melanomas.

The extent of lymph node dissection remains controversial. Sentinel lymphadenectomy is now a well-established technique for detection of early nodal disease in selected tumor types. First introduced by Morton et al.¹⁰ for melanoma, it is now being applied as well for the management of breast carcinoma¹¹ and other neoplasms.¹² Initially, the technique relied on the injection of a vital blue dye at the tumor site and visual tracking of this dye along the lymphatics draining to the nodal basin, sentinel node mapping has been facilitated by adding a radiolabeled isotope to the dye and monitoring its path using a handheld gamma probe. Sentinel lymphadenectomy is a low-morbidity procedure that accurately stages the regional lymph nodes and identifies the 60–80% of melanoma and breast cancer patients who do not require complete lymphadenectomy.

Advances in surgical technique, anesthesia, and supportive care (blood transfusion, antibiotics, and fluid and electrolyte management) permit the more radical, extensive, and lengthy operative procedures to be done more safely. Such procedures offer a chance for a cure that cannot be achieved by other means and are justified in selected situations, if there is no evidence of distant metastases. For example, some slow-growing primary tumors may reach an enormous size and widely infiltrate locally without metastasizing to distant sites. Supra-radical operative procedures should be considered for these extensive and nearly inoperable tumors because the occasional patient is cured. However, such operations should be undertaken only by experienced surgeons who can select those patients most likely to benefit. As an example of carefully indicated radical surgery, pelvic exenteration is a well-conceived operation capable of curing patients with radiation-treated recurrent cancer of the cervix and certain well differentiated and locally extensive adenocarcinomas of the rectum. This operation removes all pelvic organs (bladder, uterus, and rectum) and soft tissues within the pelvis. Bowel function is restored with colostomy. Urinary tract drainage is established by anastomosis of the ureters into a segment of the bowel (ileum or sigmoid colon). The 5-year relapse-free survival is 25% when pelvic exenteration is used to manage these problems. It is also imperative that the surgical oncologist be willing to accept responsibility for helping to optimize the postoperative emotional and psychological rehabilitation of the patient before embarking on extensive resections, such as hemipelvectomy, forequarter amputation, mutilating operations for head and neck carcinomas, or total pelvic exenteration.

Although logic might suggest that once a neoplasm has metastasized to a distant site, it is no longer curable by surgical resection, experience shows otherwise. The removal of metastatic deposits within the liver, lung, or other sites can occasionally result in long-term cure. In others, often with favorable biology and good response to systemic chemotherapy, metastatectomy can significantly prolong survival beyond that of chemotherapy alone, not infrequently turning advanced disease into a chronic condition. Before undertaking resection, an extensive work-up should be performed to rule out metastatic spread to other body sites outside of the proposed operative field.

Some patients with liver-only metastases may benefit from surgical resection, particularly when of colorectal origin. Advances in preoperative evaluation, surgical technique, and systemic therapies have all contributed to an increasingly aggressive approach to such patients. Although in the past, resectability was defined by the number, size, and distribution of hepatic metastases, more recently, resectability is defined by the capability to resect all disease with negative margins (R0) and have a sufficient functional remnant liver, regardless of the tumor number. Even patients with limited and resectable extrahepatic disease combined with liver metastases may be candidates for surgical therapy provided all disease can be safely removed. Moreover, when not initially optimally resectable, approaches to (1) reduce tumor size with preoperative chemotherapy, (2) expand the remnant liver with preoperative portal vein embolization or staged liver resections, or (3) application of thermal ablative approaches combined with

resection, all can contribute to increasing the number of patients eligible for surgical therapy of liver metastases with curative intent. Even with increasingly aggressive approaches, contemporary series are reporting 5-year survival rates following complete resection in excess of 50%.¹³

Surgical procedures are sometimes indicated to palliate symptoms without attempting to cure the patient, thereby prolonging a useful and comfortable life. A palliative operation may be justified to relieve pain, hemorrhage, obstruction, or infection when it can be done without untoward risk to the patient. Palliative surgery may also be applicable when there are no better nonsurgical means of palliation or when the procedure will improve the quality of life, even if it does not result in prolonged survival. In contrast, surgery that only prolongs a miserable existence is not of benefit to the patient. Examples of indicated palliative surgical procedures include (1) colostomy, enteroenterostomy, or gastrojejunostomy to relieve intestinal obstruction; (2) cordotomy or celiac block to control pain; (3) hepaticojejunostomy to relieve biliary obstruction and pruritis; (4) amputation for intractably painful tumors of the extremities; (5) simple mastectomy for carcinoma of the breast, when the tumor is infected, large, ulcerated, and locally resectable (even in the presence of distant metastases); and (6) resection of obstructing colon cancer in the presence of disseminated metastatic disease. Surgery for residual disease is a special application of palliative surgery. In some patients, extensive yet isolated local spread of malignancy precludes gross total resection of all disease. In these patients, cytoreductive surgery may be of benefit, such as biologically indolent disease or that which is producing local or hormonal symptoms such as metastatic neuroendocrine tumors.

Problems with exsanguinating hemorrhage, perforated viscus, abscess formation, or impending obstruction of a hollow viscus, such as gastrointestinal organs, critical blood vessels, or respiratory structures, are sometimes amenable to emergency surgical intervention. Emergency surgery may also be indicated to decompress tumors that are invading the CNS or that are destroying critical neurologic components by exerting pressure in closed spaces. The cancer patient being evaluated for emergency surgery may be neutropenic or thrombocytopenic as a consequence of recent myelosuppressive chemotherapy. Sometimes, a potential catastrophe can be avoided by operating on such patients expectantly just after they have gone through the nadir of their most recent myelosuppressive chemotherapy. Because of the high risks involved, each patient and the patient's family must be made aware of the dangers and benefits of the proposed surgery, as well as of other potentially effective treatments that might be available if the patient survives this emergency operation.

Reconstructive surgery after tumor resection has remarkably improved the quality of life for many cancer patients. The routine application of microvascular anastomotic techniques has enabled the free transfer of composite grafts containing skin, muscle, and/or bone to surgically created bodily defects. Breast reconstruction after mastectomy, tissue transfers as part of extremity surgery for sarcoma or mandible reconstruction, and aerodigestive reconstruction using jejunal-free grafts are examples of these dramatic improvements in the combined surgical management of complex cancer problems. In the future, applications of the new discipline of tissue engineering will remarkably extend the reconstructive armamentarium. Using these approaches in the future, it may be possible to custom-grow nerve, fat, muscle, bone cartilage, or other body components as replacements for tissues that will need to be resected as part of a composite cancer procedure.¹⁴

Cancer/surgical quality control

Constant and ongoing assessment of personal and institutional outcomes provides opportunity to improve systems that can result in safer operations and identify new markers or therapies that can improve oncology outcomes. Oncologists, particularly surgeons, are well positioned to develop databases that can

be used to identify etiologic factors for cancer development, predictors of surgical complications, markers of cancer outcomes, and potential changes in management schemes. Such comprehensive data sets can be combined across institutions to provide insight for uncommon cancers and/or procedures. When combined to create annotated tumor banks, these become very powerful tools that can be used to identify potential targets for drug discovery in addition to process improvement. The American College of Surgeons Commission on Cancer provides a forum by which more than 1500 associated institutions monitor quality of cancer care. Through this accreditation mechanism, institutions are required to have state-of-the-art clinical cancer services, cancer committee leadership, cancer conferences for care planning and provider education, quality improvement program in part through compliance with accepted cancer treatment guidelines (e.g., NCCN), and a comprehensive cancer registry to monitor quality of care. The surgical oncologist is well suited to lead these efforts.

The future of surgical oncology

Within the next decade, cancer is predicted to replace cardiovascular disease as the leading cause of death among Americans. The aging of the population will generate an enormous growth in demand for oncological procedures. By 2020, the number of patients undergoing oncological procedures is projected to increase by 24–51% ([Table 5](#)).¹⁵ If a shortage of surgeons performing these procedures does occur, the result will inevitably be decreased access to care. To prevent this from happening, the ability of surgeons to cope with an increased burden of work needs to be critically evaluated and improved. Given that there are no more than approximately 50 surgical oncologists produced yearly in the United States, it is clear that the traditional surgical oncology educational roles in academic medical centers as well as in the larger health care community will continue and perhaps come under increasing pressure to expand.

Table 5 Projected numbers of surgical oncological procedures: 2010–2020

Variable	2000 ^a	2010 ^b	2020 ^b	Increase (2000–2020)
Breast (diagnostic)	364,800	416,100 (14.1%)	464,100 (27.2%)	99,300
Breast (excisions)	392,700	440,200 (12.1%)	485,600 (23.7%)	92,900
Outpatient total	757,500	856,300 (13.0%)	949,700 (25.4%)	192,200
Breast (mastectomy)	90,400	106,000 (17.3%)	123,700 (36.8%)	33,300
Colon resection	96,300	113,700 (18.1%)	141,100 (46.5%)	44,800
Rectal resection	27,800	33,300 (19.7%)	40,900 (47.0%)	13,100
Stomach resection	9400	11,100 (17.6%)	13,700 (45.1%)	4300
Pancreas resection	3900	4700 (19.7%)	5800 (47.4%)	1900
Esophageal resection	1400	1700 (24.0%)	2100 (51.2%)	700
Inpatient total	229,200	270,500 (18.0%)	327,100 (42.7%)	97,900

^a Figures listed for inpatient procedures in 2000 are the numbers of procedures performed that year, based on NIS 2000. Figures for outpatient procedures (breast diagnostic and breast excisions) represent projections based on data from the NSAS 1996.

^b Figures listed for 2010 and 2020 are projections; percentages listed indicate percent growth relative to the year 2000.

As multimodality care grows in complexity and chemotherapy/radiotherapy move more prominently into the neoadjuvant position, surgical oncologists will have to become increasingly involved in clinical trial

design. To be effective in this arena, understanding the natural history of specific malignancies will require an expanded knowledge base about the mutated genes and their cognate proteins that drive solid-tumor proliferation and metastasis. Surgical oncologists will have to become more knowledgeable about these factors, both during training and as a lifelong commitment to self-education.

An important effort to strengthen the position of surgical oncology in medical community has been establishing board certification in surgical oncology, beginning in 2014. The past half-century has seen the unprecedented evolution of surgical specialties into their current status as discrete disciplines, with specialized knowledge, techniques, anatomic challenges, and diseases of focus. This is especially true in surgical oncology, which has attracted many owing to its strong allure as a combination of the technical and the cognitive. There is an emerging understanding that the surgical oncologist has specialized knowledge that is not acquired in general surgical training: knowledge of the natural history of malignant disease, knowledge of the multidisciplinary care for the cancer patient, and, certainly, knowledge of how to perform some very unusual and technically demanding oncological operative procedures. These factors, coupled with an awareness of the rapidly increasing manpower need, have led to creating a board certification mechanism for surgical oncology. Entitled board certification in *complex general surgical oncology*, the assessment process includes both a written and oral examination component. Eligibility to sit for these examinations is limited to graduates of American Council of Graduate medical Education (ACGME) accredited surgical oncology fellowship programs, meaning that graduates of such fellowship program that were not ACGME accredited at the time of an individual fellowship graduation renders such individuals ineligible for *complex general surgical oncology* board certification. This stipulation effectively limits the annual total number of board eligible candidates, yet has resulted in a doubling of the fellowship applicant pool in the United States over the past several years. Board certification will strengthen the position and impact of surgical oncologists practicing in the community and academic environments and might also aid in the development of comparable certification mechanisms in other countries, leading to enhanced cancer care worldwide.

†This chapter is dedicated in memoriam of Dr. Donald Lee Morton, one of the giants of Surgical Oncology who had direct and indirect impacts on the career of three other current chapter authors. In honor and recognition of Dr. Morton's coeditor contribution to many editions of *Cancer Medicine*, we have chosen to maintain his position as the senior author of this chapter as well. Born into less than propitious circumstances in rural West Virginia during the Great Depression, Dr. Morton was a graduate of the University of California, Berkeley, and the University of California, San Francisco, from which he received his MD degree. An initial period of time in the Surgery Branch at the National Cancer Institute was followed by a 20-year stint at the University of California, Los Angeles. This was followed by his role as the founding President of the John Wayne Cancer Institute, an institutional affiliation maintained in multiple capacities, until his death from lymphoma in 2014. Dr. Morton was the consummate academic surgical oncologist, maintaining a vigorous clinical practice as well as laboratory and clinical trials presence throughout his career. His formal and informal mentorship of so many young surgical oncologists and immunologists worldwide is a remarkably leveraged legacy. His contributions to immunomodulatory therapies on behalf of melanoma patients as well as his development of sentinel node approaches for melanoma and carcinoma of the breast have revolutionized our treatment of these diseases, and comprise an enduring contribution of transcendent magnitude.

Chapter 44

Principles of radiation oncology

Philip P. Connell, MD ■ Ralph R. Weichselbaum, MD

Overview

In recent decades, we have witnessed major technologic advances that have influenced how radiotherapy is delivered to cancer patients. Simultaneously, our understanding of the underlying basic biology that governs radiation effects in human cells and tissues has grown rapidly. Here, we summarize some of these key advances and place them into the context of the evolving paradigms that shape cancer therapeutics more generally. Key biologic topics covered in this chapter involve the molecular responses of cells to DNA damage by ionizing radiation, including the repair of DNA damage, cell cycle arrest and death, cellular signaling, and the influence of tumor-initiating cells (tumor stem cells) on post-treatment outcomes. As radiation generates an inflammatory microenvironment in tumors, drugs that modulate immune functions also represent a potential therapeutic opportunity. We also describe newer biology-based technologies that can accurately predict the intrinsic sensitivity of cells to radiation, and pharmacologic agents that can modulate this radiation sensitivity. Finally, this chapter reviews the major physics-based technologic innovations that have improved the accuracy and utility of clinical radiotherapy. Despite these advances, several unmet challenges continue to limit the impact of radiotherapy, and these remaining hurdles should be the factors that guide future innovations of our field.

Introduction

The medical specialty of radiation oncology began shortly after the discovery of X-rays and their effects on tissue in 1895.¹ This first consisted of single large radiation exposures, using low-energy cathode ray tubes or radium-filled glass tubes positioned in close proximity to tumors. Technological developments between 1920 and 1950 improved the beam output and levels of deliverable energy. This was important because low energy (200–500 kV) X-rays used in these early periods had poor penetration into tissue, resulting in burned skin. The development of cobalt-60 units and linear accelerators in the 1950s to deliver “supervoltage” radiation energies (≥ 1 MeV) was a major advance, because these higher energy photons could penetrate more deeply into tissue. Another important advance was the use of fractionated therapy, in which treatment is divided into multiple small doses rather than one large dose. This enabled better tolerance of normal tissues to radiation. Additional improvements in treatment delivery technology, imaging, and cancer biology over subsequent decades have advanced the field of radiation oncology closer to the idealized goal of maximizing local cancer control while minimizing normal tissue toxicity.

General principles of radiotherapy in cancer treatment

Cancers tend to grow locally and spread systemically via lymphatic or hematogenous routes. Therefore, successful cure often requires therapies that are targeted toward all sites of involvement. The three major modalities of oncological therapy—surgery, radiotherapy, and chemotherapy—can be used alone or

combined to address all sites. Surgery and radiotherapy are generally used to address local–regional areas of cancer risk. By its nature, surgery can be both therapeutic and diagnostic, as tumor removal provides tissue for histologic examination. Radiotherapy alone can sometimes offer a noninvasive alternative to surgery, with the possibility for organ preservation. In the adjuvant therapy setting, radiotherapy can be used before surgery to render tumor more resectable or to treat microscopic residual disease after surgery is completed. By contrast to these local therapies, chemotherapy can be used to address metastatic disease or to reduce the risk of potential micrometastasis. Chemotherapy can also act as a radiosensitizer, thereby increasing local tumor control provided by radiotherapy. The optimal use of these three modalities is tailored to the tumor type, anatomic location, stage of cancer, and other patient factors. Each modality carries a different set of risks that need to be balanced against one another to provide the optimal risk-benefit ratio for each individual patient.

Most clinical radiation regimens consist of fractionated therapy, in which treatment is divided into multiple small doses [expressed in units of Gray (Gy)] rather than one large dose. A common course of modern radiotherapy can average 6–8 weeks of treatment, with 5–6 daily treatments per week. The concept of fractionation is based on early empiric clinical observations that small daily radiation exposures can induce death in cancerous cells while allowing for normal tissue recovery. Radiobiologists have proposed various mechanistic explanations for this effect, but our understanding of this process continues to evolve. For example, the ability of normal tissue to repopulate itself with healthy cells represents one important component of normal tissue tolerance.

The impact of radiotherapy at the tissue level is commonly represented graphically by a sigmoid-shaped curve, as a function of increasing radiation dose on the x-axis ([Figure 1](#)). Ideally, the sigmoidal curve that describes tumor control probability is situated to the left of the curve that depicts normal tissue toxicity. The amount of separation between these two curves defines the therapeutic window, which describes the dose range wherein treatment may successfully eradicate tumor while maintaining normal tissue tolerance. These curves imply that for any given tissue, there exists a dose threshold above or below which incremental changes in dose yield little additional impact. However, within the steep portion of each curve, small changes in dose may yield large differences in terms of clinical impact. For any clinical situation there exists a unique relationship between the dose–response curves representing tumor kill and surrounding normal tissue toxicity, and these vary widely for different clinical circumstances. One should note that the curves in [Figure 1](#) describe an idealized case, and in reality the relationship in sensitivity of actual tumors versus adjacent normal tissues is usually far more complex.

Figure 1 Effects of radiotherapy at the tissue level are graphically represented. The solid sigmoid-shaped curves denote idealized probability of tumor control and normal tissue complication risk. The dashed curves denote these same predicted effects following administration of drugs that modulate radiation sensitivity.

Biologic impact of radiation therapy

Radiation effects in cells and tissues

The molecular responses to radiotherapy in cells

One Gy leads to the formation of about 10^5 ionization events per cell, which yields approximately 1000–2000 single-stranded DNA breaks (SSBs) and about 40 double-stranded DNA breaks (DSBs) per nucleus. This DNA damage elicits the activation of a growing list of non-DNA repair/checkpoint-related mechanisms that mediate important cellular responses.² Radiation-induced DSBs are generally thought to represent the principal lethal events occurring at doses relevant to clinical radiotherapy. This damage elicits numerous cellular responses including DNA damage recognition, transduction of the signal resulting in cell cycle checkpoint activation, induction and coordination of stress response genes, DNA repair, and/or activation of the apoptotic cascade (Figure 2). The MRN protein complex (Mre11, Rad 50, and Nbs1) and ataxia telangiectasia-mutated (ATM) protein are central sensors of DNA damage, and these proteins accumulate at DSBs rapidly. ATM, the related protein ataxia telangiectasia, and RAD3-related (ATR) are members of the PI-3 kinase family, which have central roles in recognizing DNA damage and initiating responses. ATM and ATR appear to perform partially overlapping functions; however, ATM preferentially recognizes DSBs, while ATR preferentially senses replication-blocking DNA lesions. They both phosphorylate downstream targets that modulate pathways that invoke cell cycle checkpoints, apoptosis, senescence, autophagy, and DNA repair. The chromatin protein histone H2AX is one such phosphorylation target, and its activation leads to chromatin structure becoming less condensed and receptive to the recruitment of repair proteins. Because H2AX phosphorylation is easily visible with fluorescent microscopic methods, it has become a commonly used marker of DSB formation and repair.

Phosphorylated H2AX is centrally important to radiation response because it promotes the recruitment of other sensor/effector proteins including 53BP1, MDC1, and BRCA1.

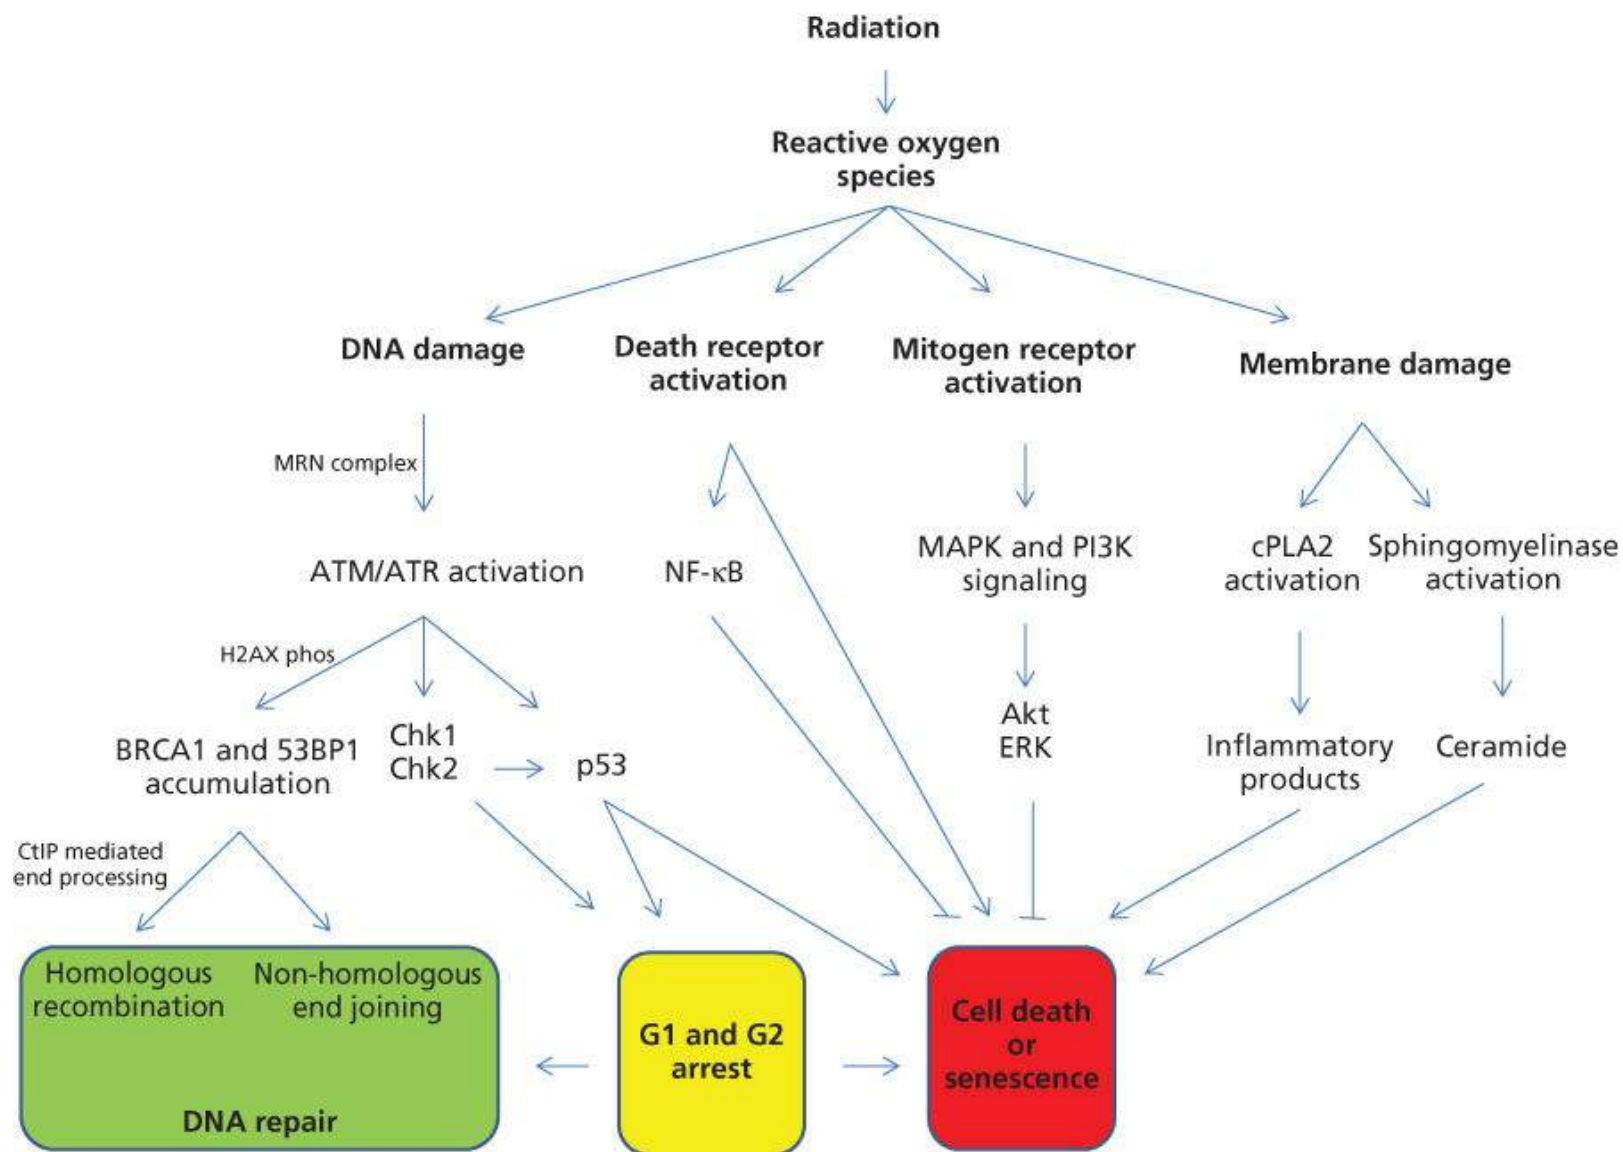

Figure 2 An overview is displayed for molecular responses that occur after radiation exposure.

Repair of DSBs in cells

Homologous recombination (HR) and nonhomologous end joining (NHEJ) are the dominant pathways that repair of DSBs. Both pathways act following the recruitment of the sensor/effector proteins, as previously reviewed.² In HR, cells identify a stretch of homologous DNA and replicate the missing genetic information from this homologous DNA template.³ By comparison, the NHEJ pathway processes the broken DNA ends and religates them, sometimes using a region of microhomology.⁴ The NHEJ pathway is considered the dominant pathway for repairing radiation-induced DSBs during G0/G1. The generally accepted model involves the binding and processing of DNA ends by Ku70/80, Artemis, and DNA-PKcs complexes. The DSB is subsequently religated by the Ligase IV/XRCC4 complex.⁵ Because NHEJ sometimes requires processing of the DSB ends before religation, repair by this pathway has the potential to be error prone. HR, by comparison, is a generally error-free mode of DSB repair because the repair template is an undamaged sister chromatid. HR requires the action of many proteins including the key recombinase RAD51 and additional factors that promote its assembly on DNA, including BRCA2, RAD52, and the RAD51 paralogs.³ In addition to this DSB repair function, HR proteins promote tolerance of replication-blocking lesions (like damage by interstrand DNA cross-linkers) and collapsed

replication forks. The ability of some common chemotherapeutic agents to act as radiosensitizers may result from their interference with these pathways.

Radiation-induced cell-cycle arrest and death

Cell-cycle arrest in G1 and G2 following radiation exposure was described by early pioneers like Hartwell, Nurse, and Hunt.² Activated ATM and ATR lead to the phosphorylation of key downstream effector kinases such as Chk1 and Chk2. Following activation, Chk1 and Chk2 phosphorylate the phosphatase CDC25A, which in turn becomes degraded. As a result of this, CDC25A is unable to dephosphorylate and activate CDK2. The net result is cell-cycle arrest. Importantly, Chk2 also phosphorylates p53, leading to p21-mediated cell-cycle arrest. These damaged cells subsequently face a critical period, particularly if radiation damage is not completely repaired.⁶ Damaged cells may progress unrepaired into mitotic catastrophe. Alternatively, cells may simply lose proliferative capacity by undergoing senescence. Radiation-induced senescence is associated with the activation of the p16/RB and p53/p21 tumor suppressors. Alternatively, cells may undergo apoptotic death, which classically involves p53-dependent activation of the caspase cascade. Additionally, apoptotic death can occur via radiation-induced activation of cell surface “death receptors” (receptors of TNF, Fas, or TRAIL). Paradoxically, these death receptors can also generate cyto-protective effects in some situations by activating transcription factor nuclear factor kappa B (NFκB) to oppose apoptosis.

Major pathways involved in cellular signaling following radiation

Irradiation of tissue leads to the formation of radical oxygen species (ROS), which interact with many cellular contents including DNA. These ROSs, including superoxide and hydroxyl radicals, can deplete cellular stores of antioxidants such as glutathione,⁷ creating cellular stresses that stimulate a complex set of signaling cascades.⁸ For example, pathways normally used by cells to respond to mitogens are activated, which in turn promote survival, antiapoptotic responses, and transcriptional changes. The net effect can be variable and cell-type dependent, but this generally includes activation of cell surface receptors like the ErbB family that includes epidermal growth factor receptor (EGFR), which consequently activates other downstream pathways like the mitogen-activated protein kinase (MAPK) superfamily of cascades (ERK, JNK, and p38) and the phosphatidyl inositol 3 kinase (PI3K) pathways.² These pathways tend to promote antiapoptotic signals via Akt and Erk signaling. Radiation can also trigger autocrine mechanisms, including the release of transforming growth factor alpha (TGFα), which binds and activates EGFR.⁸ Additional proinflammatory cytokines like tumor necrosis factor-alpha (TNF-α) and interleukin-6⁹ are also released, and these contribute to the bystander effect—a phenomenon where adjacent nonirradiated cells exhibit similar responses (described in detail in Dr. Grdina's chapter on Ionizing Radiation). Finally, radiation induces the breakdown of membrane-based sphingomyelin into ceramide, which is proapoptotic, independent of DNA damage.¹⁰ Similarly, radiation activates cytosolic phospholipase A2 (cPLA2), an enzyme that recognizes phospholipids on the cell membrane and degrades them into inflammatory products such as arachidonic acid and eventually eicosanoids. For example, lysophosphatidylcholine (LPC) is a product of cPLA2 that leads to activation of Akt and enhanced cell death.¹¹

Tumor-initiating cells (tumor stem cells) in irradiated tumors and normal tissues

Despite some disagreements surrounding the nomenclature and basic biology of “tumor stem cells,” there clearly exists a population of tumor cells that exhibit an exclusive ability for self-renewal and differentiation into the heterogeneous lineages that promote tumor maintenance.^{12–14} These studies predict

that targeting cancer stem cells may improve therapeutic outcomes. Interestingly, radiation of tumor cell populations is known to enrich cells expressing putative markers of “stemness,” suggesting that tumor stem cells are treatment resistant. For example, radiation leads to the enrichment of glial cancer stem cells that exhibit preferential activation of the DNA damage checkpoint responses and increased DNA repair capacity.¹⁵ The underlying mechanisms that mediate this radiation resistance remain unclear; however, aldehyde dehydrogenase 1 (ALDH1) may represent a partial explanation. High expression of ALDH1 protein in tumor cells confers a survival advantage, perhaps due to aldehyde-catabolizing activity. ALDH1 is also known to cooperate with Fanconi anemia-associated DNA repair genes. This suggests that ALDH1 activity might play a role in repairing adducts on DNA,¹⁶ thereby promoting radioresistance in stem cell clones. Another interesting feature of cancer stem cells is their propensity to repair DSBs using HR repair,¹⁷ suggesting that HR inhibitors might represent a therapeutic strategy for depleting cancer stem cell reservoirs in tumors. Additionally, salinomycin and thioridazine are compounds developed to target cancer stem cells^{18, 19}; however, they have not yet been tested clinically with radiotherapy.

Development of radio sensitizing drugs

Tumors are frequently located immediately adjacent to radiosensitive normal tissues, which limits the level of radiation that can be safely administered. Therefore, a drug that could preferentially radiosensitize tumors would be very useful. In malignant gliomas, for example, lethality occurs as a direct consequence of local tumor recurrence after treatment: a tumor-selective sensitizer might increase tumor curability. By contrast, some tumors such as prostate cancers are already curable with radiotherapy; however, this requires very high doses, which carry significant toxicity. In such situations, a tumor-specific radiosensitizer might allow for dose de-escalation and reduction of side effects. Standard chemotherapeutic agents remain the most commonly used for increasing the local efficacy of radiotherapy. We recently published a review that details the progress of newer strategies of targeted radiosensitizers.² An exhaustive discussion of these novel drugs is not possible in this chapter; however, various classes of agents are shown in [Table 1](#). Many of these agents target proteins that sense radiation injury and coordinate the cellular responses, while others take advantage of the hypoxic or abnormal redox environments that exist in tumors. The ultimate success of any of these drugs will depend on their ability to improve the therapeutic index of radiation (see illustration of this concept in [Figure 1](#)). Unfortunately, the development of truly tumor-selective radiosensitizers has proved elusive.

Table 1 Drug candidates that may serve in modulating radiation effects

Level (target)	Radiation sensitizer or protector
<i>Reactive oxygen species</i>	
Radicals	Amifostine, pyridoxamine, UROD RNAi
<i>DNA damage response</i>	
DSB recognition	Mirin, ATM/ATR inhibitors (e.g., KU-55933), DT01
HR repair	RS-1, RI-1, modulators of RAD51 expression
NHEJ repair	DNA-PK inhibitors (e.g., NU7441, Salvicine)
PARP	Veliparib, olaparib
<i>Chromatin organization</i>	
HDAC	Vorinostat, belinostat, panobinostat
<i>Cellular response</i>	
Cell cycle arrest	Chk1/Chk2 inhibitors, CDK4/6 inhibitors
Mitogen signaling	Cetuximab
Pro-death signaling	Pifithrin, GSK-3β inhibitors, anticeramide, cytochrome c peroxidase inhibitors
<i>Tumor microenvironment</i>	
Inflammatory products	Statins
Hypoxia	Carbogen, efaproxiral, tirapazamine, MGd, EZN-2968
Tumor stem cells	Salinomycin, thioridazine, HR inhibitors
<i>Effects at tissue level</i>	
Angiogenesis	Bevacizumab
Immune effects	Anti-CTLA-4, anti-PD-1, IL-2 + SBRT
Gene therapy	NFerade, HSV-tk, G207
Cell repopulation	Palifermin

Radiotherapy in combination with gene therapy

Extensive preclinical work and some limited clinical trials have combined gene therapy with radiotherapy, using replication-defective viruses to deliver radiosensitizing prodrugs, cytokines, tumor suppressor genes, and immune-activating compounds. For example, TNFerade (Ad.Egr-TNF11D) is a replication-defective adenoviral vector comprised of radio- and chemo-inducible elements from the Egr-1 promoter upstream to cDNA encoding TNF-α, which acts as a direct radiosensitizer and immune activator. This makes use of radiation-inducible Egr-1 promoter elements, such that TNF-α is specifically secreted within the radiotherapy target volume.²⁰ Early-phase clinical trials with TNFerade have demonstrated impressive tumor response rates in patients with soft tissue sarcomas, as well as carcinomas of the esophagus, head and neck region, and rectum.²¹ However, a randomized phase III trial in pancreatic cancer failed to improve survival, although there was a trend to improve survival in early stage tumors.²²

Other trials have employed enzyme/prodrug strategies such as virus-directed expression of herpes

simplex virus thymidine kinase (HSV-tk), which phosphorylates the prodrug ganciclovir into a toxic metabolite that interferes with DNA replication. While this concept is compelling, a phase III randomized trial was unable to show improved survival for glioblastoma multiforme.²³ Related strategies have combined HSV-tk with an additional “suicide gene” such as cytosine deaminase, which converts the pro-drug 5-fluorocytosine into 5-FU.²⁴ This strategy combined with prostate radiotherapy has yet to demonstrate efficacy in phase II–III trials. Finally, oncolytic viruses have been combined with radiotherapy, to exploit the concept that some viruses can cooperate with radiotherapy by preferentially infecting and lysing cancer cells. For example, a replication-competent herpes simplex virus I (HSV-1) has been delivered with radiotherapy in malignant gliomas and in locally advanced head and neck cancer.²⁵ Similarly, a reovirus was recently combined with palliative radiotherapy in a phase I trial.²⁶

Immune modulation in combination with radiotherapy

Radiation generates an inflammatory microenvironment in tumors, whereby damaged cells increase antigen presentation and immune recognition. These effects include an elevation of major histocompatibility complex class I (MHC-I) expression, changes in antigenic peptide repertoire, decreases in regulatory T cells, and upregulation in cytokines and adhesion molecules that recruit and activate CD8+ cytotoxic T lymphocytes and dendritic cells.² Radiation also leads to a depletion of immunosuppressive processes.^{27, 28} This immune-modulating activity may allow for therapeutic combinations of radiotherapy and immunotherapy.²⁹ This approach has been investigated with prostate cancer, using standard radiotherapy combined with gene therapy-based vaccine that encodes PSA.³⁰ Most of the PSA “vaccinated” patients developed increases in PSA-targeted T cells. Other related strategies have investigated different vaccines, intratumoral injection of immature dendritic cells, or adoptive immunotherapy via infusion with expanded tumor-infiltrating lymphocytes. These trials commonly demonstrate impressive induction of immune responses. As an example, metastatic melanoma or kidney cancers treated with high-dose IL-2 and stereotactic body radiotherapy showed impressive outcomes, compared with historical controls treated with high-dose IL-2 alone.³¹ A related strategy involves combinations of radiotherapy with antagonists of cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) or programmed death 1 (PD-1), which are used by tumor cells to evade the immune system.³²

Hyperthermia in combination with radiotherapy

Localized heat delivery can be administered to patients using external devices that produce microwave, ultrasound, or radiofrequency (RF) sources of energy. Lab-based experiments show that temperatures above 41°C kill cells, and that small increments above 42.5°C generate steep increases in lethality.³³ Heat-induced death is most pronounced when cells are in S-phase, which is consistent with the proposed mechanism involving the denaturation of proteins.³⁴ Combinations of hyperthermia and radiation generate a greater than additive lethal effect,³⁵ which may represent the denaturation of proteins required for radiation-induced DNA damage. This apparent synergy does not, however, translate to the clinical setting, where the two modalities appear to be only additive or independent. Several randomized clinical trials have tested combinations of radiation ± hyperthermia, and the results are conflicting. Additionally, a clinical limitation of hyperthermia is the technical difficulty of delivering homogenous doses of heat to deep-seated anatomic locations. As such, skin and breast cancers remain among the most common uses for this modality.

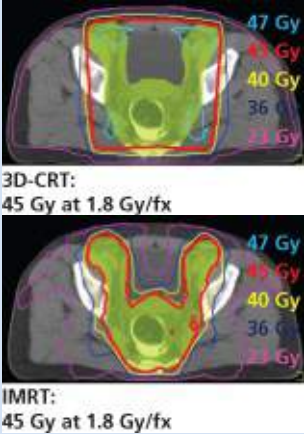

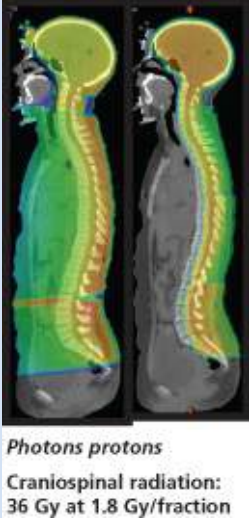

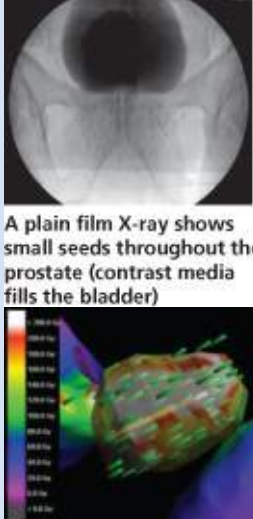

Protection of normal tissues from radiation injury

Acute side effects of radiotherapy in normal tissues are principally caused by damage to rapidly proliferating cell renewal systems, whereas late side effects are generally related to vascular damage, fibrosis, and poor repopulation of normal tissue components by healthy cells. Radiation also generates mutations that can induce secondary cancers, especially in the pediatric patient population. Therefore, efforts are underway to generate radioprotective drugs that minimize this problem. “Radioprotectors” are classified as drugs given prophylactically before radiation exposure, whereas radiation “mitigators” are administered during or after radiation exposure. Finally, “therapeutic agents” are a third class of drugs that modulate normal tissue healing after radiation exposure. The major challenge in generating such drugs is that they must not also protect tumor cells from radiation-induced death.² An exhaustive discussion of these novel drugs is not possible due to space limitations; however, some classes of agents are shown in [Table 1](#). Sulfhydryl-containing compounds such as amifostine act as ROS-scavenging agents, thereby absorbing the ROS generated by radiation.³⁶ Amifostine is the only such drug to obtain FDA (Food and Drug Administration) approval, and it remains the best studied of this class.³⁷ Widespread use of amifostine has been limited due to fears that it protects tumors; however, there is little evidence suggesting that this occurs in clinically relevant situations.³⁸ More recent programs have focused on nonthiol agents, such as drugs that affect cell cycle distribution or radiation-induced apoptosis.^{39–43} Finally, therapeutic agents are those that reduce endothelial cell damage, inflammatory cascades, and tissue ischemia.^{44, 45} Various growth factors have been used in this context to promote normal cell proliferation. One such example is keratinocyte growth factor (palifermin), which reduces mucositis during chemoradiotherapy for locally advanced head and neck cancer.⁴⁶

Molecular classifiers capable of predicting radiotherapy outcomes

Genomic analysis methods are increasingly utilized to classify malignancies and to predict clinical outcomes, based on genetic and epigenetic tumor characteristics. This has helped fuel a vision of personalized medicine, wherein individualized treatment courses are tailored to specific molecularly defined patient and tumor characteristics. Our discussion herein will focus only on systems that predict responsiveness to radiotherapy. The radiosensitivity index (RSI) is one such method, which used the mRNA levels of 10 genes to predict radiosensitivity within a collection of human cancer cell lines.⁴⁷ It was been clinically validated in five independent clinical data sets, which include rectal, esophageal, head and neck, and breast cancers treated with chemoradiation or radiotherapy alone.⁴⁸ A competing method that we developed, called the interferon-related damage signature (IRDS), successfully predicted the efficacy of adjuvant chemotherapy and local–regional control after radiation.⁴⁹ Additionally, we recently reported a new method to quantify the efficiency of DNA repair pathways in the context of cancer therapy.⁵⁰ The recombination proficiency score (RPS) is calculated based on the expression levels for four genes involved in DNA repair pathway preference (Rif1, PARI, RAD51, and Ku80), such that high expression of these genes yields a low RPS. We validated the RPS system clinically in patients with breast and nonsmall-cell lung carcinomas (NSCLCs). Tumors with low RPS were associated with adverse features, suggesting that HR suppression contributes to the genomic instability that fuels malignant progression. This adverse prognosis associated with low RPS was diminished if NSCLC patients received adjuvant platinum-based chemotherapy, suggesting that HR suppression and associated sensitivity to platinum-based drugs counteract the adverse prognosis associated with low RPS. We are currently testing whether this system can similarly predict the radiosensitivity of tumors. An alternative approach for predicting radiosensitivity is to look for genetic alterations with comparative genomic hybridization arrays or next-generation sequencing,^{51, 52} which are rapidly evolving methods that will presumably revolutionize these types of approaches in coming years.

Table 2 Different classes of radiation therapy and clinical examples of their use

	Fractionated XRT with photons	Ablative methods of XRT	XRT with particle beams	Brachytherapy
	3D-CRT, IMRT	SRS, SBRT	Proton or carbon ion beam therapy	Intracavitary or interstitial
Common indications	Many	Brain metastases Early-stage lung cancer Oligo-metastatic disease	Pediatric malignancies Uveal melanoma chordoma	Prostate cancer Cervical cancer
Illustrations	<p>An anal cancer was treated with different types of X-ray-based XRT. The yellow shaded area denotes the target volume, which includes the anus/rectum and the draining lymph nodes. The pelvic bones and bladder represent the adjacent normal tissues in this situation. The IMRT-based plan conforms to the shape of the target more closely, thereby exposing less normal tissue to treatment.</p> <div><p>3D-CRT: 45 Gy at 1.8 Gy/fx</p><p>IMRT: 45 Gy at 1.8 Gy/fx</p></div>	<p>These treatments involve specialized approaches that enable delivery of ablative doses, using a single or a few¹⁻⁵ large fractions. Numerous intersecting beams chosen generate very conformal plans that markedly reduce normal tissue exposure.</p> <div><p>SRS for brain metastasis: 18 Gy delivered in a single fraction</p><p>SBRT for lung cancer: 12 Gy/fraction delivered over 5 fractions</p></div>	<p>Proton beam therapy generates specific dose distributions in tissue. XRT is used to treat the craniospinal axis of a child with medulloblastoma. The proton-based treatment results in less exposure to normal tissues located anterior to the spinal column.</p> <div><p>Photons protons</p><p>Craniospinal radiation: 36 Gy at 1.8 Gy/fraction</p></div>	<p>Radioactive sources are positioned within or near a target volume. This limits exposure to surrounding tissue. This represents a common and effective treatment for prostate cancer, wherein permanent seeds placed from a perineal approach using real-time imaging via trans-rectal ultrasound.</p> <div><p>A plain film X-ray shows small seeds throughout the prostate (contrast media fills the bladder)</p><p>Implant dosimetry: 145 Gy</p></div>

	of radiotherapy	gradients, which allow for tolerance of large fraction sizes. This relies heavily on precise immobilization and imaging	expensive cyclotron facility. In some clinical settings, proton-based treatment may reduce toxic risks of XRT	adjacent normal tissue. Anatomic barriers limit brachytherapy to only a small subset of cancer types
--	-----------------	---	---	--

XRT, external beam radiotherapy; 3D-CRT, three-dimensional conformal radiotherapy; IMRT, intensity-modulated radiation therapy; SBRT, stereotactic body radiation therapy; SRS, stereotactic radiosurgery.

Physical and clinical aspects of modern radiotherapy

A large majority of radiation treatments consist of external-beam radiotherapy (XRT), which involves the use of a linear accelerator to generate high-energy (6–20 MV) photons. Less commonly, XRT consists of particle beams, comprised of electrons, protons, carbon ions, or neutrons. To accomplish treatment, patients are generally immobilized daily on a fixed treatment table, and beams are directed toward the patient's tumor from multiple angles. Each linear accelerator is attached to a “gantry,” which can be rotated around the treatment table. As an alternative to XRT, treatment can also be delivered by placing radioactive sources proximal to tumors (termed brachytherapy). Using various combinations of these modalities, a wide array of radiotherapeutic approaches are possible (outlined in [Table 2](#)). In some circumstances, advanced specialized versions of these modalities can provide better therapeutic ratios. The ultimate selection of a particular modality depends on several factors, including predicted tumor radio-responsiveness, susceptibility of adjacent normal tissue to radiation injury, and nonradiotherapeutic alternatives for a given cancer type.

3D-conformal RT, intensity-modulated radiation therapy, and imaged-guided radiation therapy

In recent decades, the use of axial imaging coupled with three-dimensional (3D) treatment planning software has significantly improved the quality of radiotherapy. Additionally, the ability to shape radiation beams with automated devices has enabled many technologic advances. Beam shaping is now generally accomplished with multileaf collimators (MLCs), which are small metallic robotically controlled blocks located in the head of the linear accelerator. This hardware-based innovation combined with treatment optimizing software packages has yielded a process now generally referred to as three-dimensional conformal radiotherapy (3D-CRT). Dosimetrists, physicists, and physicians collaborate to generate optimized 3D-CRT treatment plans, such that plans are both conformal (i.e., high doses “wrap” closely around the target volume) and homogeneous (i.e., little dose variability occurs within the target). Compared to older methods, 3D-CRT allows for more effective coverage of tumors, while better protecting adjacent normal organs.

Intensity-modulated radiation therapy (IMRT) is another commonly utilized method of XRT. Like 3D-CRT, IMRT utilizes multiple intersecting X-ray beams to “cross-fire” a target volume. In IMRT, the intensity of each beam is modulated in a grid pattern to provide more conformal distributions of doses. IMRT planning software utilizes iterative algorithms to optimize treatment, based on user-defined goals of tumor coverage and normal tissue sparing. This high degree of conformality is particularly useful for treating irregularly shaped tumors that lie in close proximity to critical structures.⁵³ The widespread use of IMRT in recent years has simultaneously enabled dose escalation to tumors and reduced toxicity. For

example, IMRT is standardly used in the organ-sparing treatment of head and neck cancers, thereby allowing for protection of salivary glands and a resulting reduction in xerostomia.⁵⁴ IMRT also enables the ability to differentially dose various parts of a tumor, using methods termed dose painting or simultaneous integrated boost.⁵⁵

While these advances provide better radiotherapy plans, the actual treatment delivered to patients depends highly on the ability to reproducibly deliver the plan daily. Variability in daily patient positioning and internal organ motion (such as respiratory motion) can undermine the accuracy of this treatment delivery. Recent advancements termed image-guided radiation therapy (IGRT) have addressed these challenges. Linear accelerators are now commonly equipped with “onboard” imaging devices, which provide real-time (or nearly real time) diagnostic imaging with kilovolt X-rays or cone-beam CT (computed tomography) scans. In some situations, anatomic structures are implanted with radio-opaque “fiducial” markers used to fine-tune patient positioning.⁵⁶ Other commercially available packages can account for physiologic motion such as respiratory motion. As IGRT methods can reduce the magnitude of positioning setup error, they enable the use of smaller treatment volumes that require smaller margins to account for positional error.²

Ablative radiotherapy methods using large fraction sizes

These improvements in treatment accuracy have enabled a paradigm shift in recent years, favoring shorter treatment courses that utilize higher daily doses of radiation (termed hypofractionated RT). This reduction in overall treatment time offers predicted benefits, in part by counteracting the proliferation of tumor cell clones (termed accelerated repopulation) that occurs during prolonged courses of XRT.⁵⁷ Single-fraction stereotactic radiosurgery (SRS) represents an extreme version of hypofractionated RT used to ablate brain tumors.⁵⁸ Fractionated stereotactic body radiation therapy (SBRT) is a similar method for treating extra-cranial targets, and it typically consists of either a single dose or a small number of large-sized fractions.⁵⁹ SRS and SBRT both rely on the previously discussed methods for improved accuracy of radiation planning and delivery, which in turn enable the use of smaller target volumes. These modalities have proven safe and effective for select situations. For example, high local control rates with a single treatment of 20 Gy for small brain metastases, or 20 Gy \times 3 for liver metastases, have been shown to result in local control rates of >80–85%. Early-stage NSCLCs can also be effectively treated with short courses (3–5 fractions of 12–20 Gy) of SBRT.⁶⁰ However, the best uses of SBRT remain to be completely defined. Multiple factors including tumor volume and the nature of adjacent normal tissue play critical roles in determining whether SBRT or fractionated XRT is most appropriate for a specific clinical situation.^{61, 62}

Brachytherapy

Brachytherapy is a method where radioactive sources are placed in close proximity to tumors. This can potentially outperform external beam RT for specific clinical situations. By varying the strength, location, and exposure time of the radioactive sources, it is possible to achieve highly conformal and dose-intense radiation distributions within tumors. Simultaneously, this can result in relatively low exposures to adjacent normal organs. Radioactive source placement can be interstitial, such that “seeds” are placed directly into the target tissue. Alternatively, sources can be placed in a cavity (e.g., a body cavity or lumen) that is adjacent to target tissue (termed intracavitary brachytherapy). In some situations, brachytherapy offers major dosimetric advantages. However, brachytherapy is not used as commonly as XRT because only a few clinical situations exhibit a well-defined target anatomy that can be safely accessed with radioactive sources. Given this practical limitation, cancers of the cervix, prostate, breast,

and skin are the most common sites treated with brachytherapy. In prostate cancer, for example, brachytherapy may be superior to dose-escalated XRT for select clinical situations.⁶³ However, many anatomic locations are less well suited for brachytherapy because the therapeutic ratio for XRT exceeds that of brachytherapy. Additionally, brachytherapy carries potential risk for increased morbidity if sources are misplaced or migrate after placement.⁶⁴

Particle beam therapy

Particle therapy is a form of XRT in which beams of particles are delivered rather than photons, and this can consist of electrons, protons, carbon ions, or neutrons.⁶⁵ The use of proton beam therapy in particular has grown in recent years and deserves special attention. As proton beams pass through tissue, most of their energy is deposited immediately before the particle comes to rest. This deposition occurs at a specific depth in tissue (termed the Bragg peak), which can be manipulated by varying the energy of the photon beam. The clinical implication is that proton beams can be used to minimize radiation exposure to normal tissues situated adjacent to the target volume, especially for tissues situated more deeply than the tumor. In some situations this can translate to reduced treatment complications, so proton use has rapidly grown in pediatric diseases—particularly in pediatric brain tumors, where reductions in normal brain exposure can reduce neurocognitive sequela of XRT. Moreover, tumors located near the spine, such as chordomas or para-spinal chondrosarcomas, represent a well-defined indication for proton beam therapy, as it allows these relatively radioresistant tumors to be aggressively treated while respecting the radiation tolerance of the surrounding normal tissues.⁶⁶

Some types of particle beams also generate relative biologic effectiveness (RBE) per unit of energy deposited. For example, the RBE of protons is 1–1.2 times that of photons, whereas for neutrons or carbon ions, the RBE can be 4–10 times that of photons. Further research is necessary to determine whether these RBE differences will translate into better, or possibly worse, therapeutic indices relative to photon-based therapy. As a practical issue, the facilities that generate proton or carbon ion beams are expensive to build, and they require significantly more physical space and highly trained staff.

Conclusions and future directions in radiotherapy

In recent decades, we have witnessed massive technologic changes that have influenced how radiotherapy is delivered to cancer patients. Simultaneously, there has been major growth in our understanding of the basic biology that governs radiation effects in human cells and tissues. However several unmet challenges continue to limit the impact of radiotherapy, and these remaining hurdles should be factors that guide the development of our field in the coming decades.² One such issue is that inherent cellular radioresistance still prevents local control in many tumor types. In tumors such as glioblastoma, for example, the probability of local tumor control remains miserably poor, despite the use of advanced radiotherapy technologies and very high doses of radiotherapy. Avenues to overcome this resistance will require continued growth in our understanding of the underlying biological problems. We will also need a better arsenal of drugs that can specifically sensitize tumor cells or protect normal tissues. Finally, more individualized approaches will be needed in future radiotherapy. Currently, the decision to deliver radiation and the key parameters of radiation (e.g., dose and volume) are standardized based on the stage of disease at presentation. As molecular predictors of radiation sensitivity become more accurate and accessible in the community setting, more personalized information can be used to guide management based on patients' individual biology.

Chapter 45

Principles of medical oncology

William N. Hait, MD, PhD ■ James F. Holland, MD, ScD (hc) ■ Emil Frei III MD (deceased) ■ Donald W. Kufe, MD ■ Robert C. Bast Jr. MD ■ Waun Ki Hong, MD, DMSc (Hon)

Overview

The practice of medical oncology is evolving more rapidly than any field in medicine. The uncovering of the molecular basis of the numerous malignancies and their subtypes created a seemingly bewildering collection of new information that confronts the practicing physician. Since the principles that underlie the practice of this subspecialty, by definition, should remain constant, they can provide the scaffolding on which new information can be attached. To that end, this chapter attempts to define those immutable areas that apply to the care of the oncology patient, and through their understanding the massive amount of new information presented in this text can be organized.

Medical oncology evolved from a subspecialty of internal medicine whose hallmark was the ability to diagnose cancer and to safely administer dangerous drugs to the branch of medicine most directly linked to modern molecular biology; today, it heralds in the era of personalized medicine. A medical oncologist understands the biologic basis of malignant transformation and applies this knowledge to the prevention, early detection, and treatment of cancer patients. An individual with cancer should be viewed in the context of the etiology, pathogenesis, pathology, genetics, immunology, and biochemistry of the neoplastic process and humanistically as a person struggling with a terrifying disease.

Training of medical oncologists originated in cancer institutes, divisions of hematology, and departments of pharmacology. The American Board of Internal Medicine established the subspecialty as a separate discipline in 1971.¹ Medical oncologists and hematologists have overlapping interests in neoplastic diseases of the hematopoietic tissues and share historic interests in training subspecialists in both fields. However, because each discipline became more complex, individual training programs have become the preferred approach.

In this chapter, we introduce the subspecialty by attempting to define a set of principles that underlie the practice of medical oncology.

Principles

Certain principles underlie the practice of medical oncology and are listed in [Table 1](#). These tenets, although not mathematically derived or subject to rigorous validation, should nonetheless serve the purpose of providing both the uninitiated young practitioner and the seasoned veteran with a perspective gleaned from the several vantage points of the authors.

The treatment of cancer is multidisciplinary, requiring consultation with knowledgeable colleagues in related subspecialties

The practice of medical oncology is dependent on highly productive interactions with cognate disciplines,

particularly surgical oncology, radiation oncology, urology, orthopedic surgery, radiology, and pathology. Multiple other interactions occur with nursing oncology, psycho-oncology, neuro-oncology, gynecologic oncology, rehabilitation medicine, and, for young patients, pediatric oncology. Infectious diseases and more recently autoimmune diseases are common complications of cancers and their treatments, forming a natural alliance with specialists in infectious diseases and rheumatology. Today, with the gratifying number of long-term survivors, the medical oncologist must work closely with primary care physicians for follow-up surveillance and psychologists and psychiatrists, who may be required to address the existential complexities of survivorship and the sequelae of treatment.

The medical oncologist is often involved in the final decisions concerning management and is frequently the final common pathway through which decisions are implemented. The timing of surgery and radiotherapy, the decision whether to take a curative or a palliative approach, and the decision whether watchful waiting is the appropriate course, or whether vigorous action is necessary are often entrusted to the medical oncologist.

Most patients have a relationship with other physicians before being diagnosed with cancer; a family physician or internist who referred the patient to a medical oncologist and other specialists may already have been involved with the patient before the recognition of a neoplastic disease. Medical oncologists must recognize their interest and continuing role in the management of patients with multisystem disease and communicate with them effectively. In the absence of such consultants, however, the medical oncologist must also attend to all aspects of internal medicine. This book contains detailed descriptions of various diseases; the modalities used in their treatment; the pharmacologic, immunologic, neurologic, psychological, biochemical, epidemiologic, and the modern emphasis on molecular biologic aspects of cancers; and the complications that cancers cause. Oncologic emergencies, rehabilitation, and the oncologist's relationship to medical informatics and to government are also presented. Familiarity with these topics constitutes a foundation for medical oncology from which the principles derive.

Table 1 Principles of medical oncology

The treatment of cancer is multidisciplinary, requiring consultation with knowledgeable colleagues in related subspecialties
The suspicion of cancer is based on clinical acumen and the diagnosis on examination of tissue
Prevention is more effective than treatment
The medical treatment of cancer patients is based on a clear understanding of the mechanism of drug action, potential for harmful side effects, mechanisms of drug resistance, and the principles of therapeutics
Early stage cancers are more curable than late-stage cancers; the first treatment is more effective than the next
The best treatment is often found through participation in clinical trials
Cancer surveillance must be based on validated assumptions
Oncologic care is for life

The suspicion of cancer is based on clinical acumen; the diagnosis on examination of tissue

Oncologists must be highly competent internists to diagnose, exclude, and treat cancer. Many diseases can mimic the signs and symptoms of cancer, but the medical oncologist must not miss a nonmalignant cause.

Conversely, the internist and the medical oncologist must remember that cancer, like syphilis in the past, is the “great masquerader” and, thus, must be considered in every differential diagnosis.² A medical oncologist must understand the pathophysiology of cancer, the genetic predispositions, the existence of molecular subtypes, and the basic pharmacology that is the bedrock of effective cancer treatment. All cancers are not the same, and all patients with a given type of cancer do not behave in a similar manner. Increasingly, cancers are being segmented into a variety of distinct molecular entities, each with subtle and not so subtle differences in prognosis and treatment. As the more precise classification of leukemias and lymphomas led to improvements in treatment in the past, the use of powerful diagnostic tests is identifying subsets of solid tumors that respond differently to treatment are leading to improvements in treatment today.

When new syndromes appear in a patient who once had cancer, such as pulmonary insufficiency, meningoencephalopathy, or inexplicable pain, it is indispensable to establish by objective criteria that cancer is the proximate cause. Cancer patients are not protected from other symptomatic noncancerous diseases, such as pulmonary fibrosis and central nervous system disorders, or painful conditions, such as a herniated disk. No symptom should be attributed to cancer without persuasive evidence. Yet cancer must be suspected every time.
