Vitespen is an autologous, tumor-derived heat shock protein gp96 peptide vaccine. Patients ($n = 322$) with stage IV melanoma were randomly assigned 2 : 1 to receive vitespen or physician's choice of a treatment. OS in the vitespen arm was statistically indistinguishable from that in the physician's choice arm.¹⁶⁷ A randomized trial provided evidence that a DC vaccine is associated with longer survival compared with a tumor cell vaccine, and is consistent with previous data suggesting a survival benefit from this patient-specific immunotherapy.¹⁶⁸ A Phase II trial of a DC vaccine for metastatic melanoma patients with mainly the HLA-A24 genotype was investigated; OS analysis revealed a significant survival prolongation effect in patients receiving the DC vaccine.¹⁶⁹ Studies were also carried out to detect a pretreatment gene expression signature predictive of response to MAGE-A3 vaccine in patients with metastatic melanoma. An expression signature was associated with the patient's clinical response.¹⁷⁰ A Phase II trial investigated a peptide vaccination against survivin, a protein crucial for the survival of tumor cells, in patients with treatment-refractory stage IV metastatic melanoma. Survivin-specific T-cell reactivities strongly correlated with tumor response and patient survival.¹⁷¹

Several clinical studies have employed autologous melanoma cells as vaccine. Clinical responses were observed when these melanoma-cell vaccines were preceded by cyclophosphamide.^{172, 173} Clinical responses were also observed when autologous melanoma cells were transduced with GM-CSF and given as vaccine.^{174, 175} In addition, intratumoral administration of recombinant vaccinia encoding GM-CSF in patients with cutaneous melanoma has been reported to induce antitumor immune responses.^{31, 32, 176} Several randomized Phase II trials have been carried out using either autologous^{177, 178} or allogeneic^{179, 180} melanoma vaccine in patients with resected melanoma. In these trials, there is evidence of improved disease-free survival (DFS) in the vaccine arm versus control or no-treatment groups. Recent research indicates that immunization with hybrids of tumor cells and APCs can induce protective immunity and rejection of established tumors in various rodent models.^{95, 181, 182} Novel clinical trial strategies incorporating DC-based vaccines have recently been reported.^{183–185} Purified hybrids from the fusion of DCs and tumor cells (dendritomas) have been shown to be safe and to induce both immunological and clinical responses when combined with low-dose IL-2.¹⁸⁴

T-VEC is an intralesional oncolytic immunotherapy comprising an HSV-type 1 engineered to make GM-CSF. In the randomized Phase III trial, 436 patients with stage IIIB-IV melanoma were randomized 2 : 1 to receive intralesional T-VEC versus s.c. GM-CSF. T-VEC significantly improved the proportion of patients with duration of response ≥ 6 months (16% vs 2%) and an overall response rate (26% vs 6%) versus s.c. GM-CSF. Many patients remained in remission with a median follow-up of over 18.4 months.^{186, 187}

Colorectal carcinoma

A prospective randomized-controlled Phase III clinical trial was carried out in 254 patients with stage II and stage III colon cancer using autologous tumor cell vaccine with BCG postsurgery. A 5.3-year median follow-up showed 40 recurrences in the control group and 25 in the vaccine group. The vaccine showed a

statistically significant recurrence-free survival (RFS) in patients with surgically resected stage II colon cancer, but not stage III colon cancer.¹⁸⁸ Further follow-up demonstrated a significant survival benefit in the vaccine arm over surgery alone.¹⁸⁹

Several clinical trials have been conducted employing CEA-based vaccines. Results of vaccination in patients with recombinant vaccinia virus,⁶⁹ recombinant avipox virus,^{66, 190, 191} or a prime with recombinant vaccinia (rV)-CEA and multiple boosts with avipox-CEA⁴⁷ have demonstrated the generation of CEA-specific immune responses in patients with advanced gastrointestinal (GI) carcinomas and other CEA-expressing carcinomas. A trial using both vaccinia- and avipox-CEA vaccines containing TRICOM has suggested improved survival in patients receiving the prime-and-boost regimen plus GM-CSF; 40% had stable disease (SDs) for at least 4 months.^{47, 79, 192, 193} In a multicenter Phase II study, colorectal cancer patients received PANVAC vaccine (rV-, rF-CEA-MUC1-TRICOM) post-metastasectomy for liver and lung metastases.¹⁹² Patients received either PANVAC or PANVAC-infected DCs and there was no statistical difference in clinical outcome in the two arms. Vaccinated patients ($n = 74$) were compared to a contemporary “control” (not randomized) group of colorectal cancer patients ($n = 161$) undergoing metastasectomy and receiving standard-of-care therapies. Both this control group and the PANVAC-vaccinated groups had similar prognostic characteristics and TTP for both groups was virtually identical with a median TTP of approximately 24 months.^{20, 192} However, the OS of PANVAC-vaccinated patients was 95% at 2 years and 90% at 40 months, compared to the contemporary control group with an OS of 75% at 2 years, and 47% at 40 months. The OS values of the control group are similar to 3–5 year survival data in this population from five other clinical studies.^{194–199} This is yet another example (as seen with ipilimumab, sipuleucel-T, and PROSTVAC) of no increase in TTP versus control with an increase in OS.

CEA peptide-pulsed DCs have also been employed in clinical studies using a modified CEA agonist peptide.²⁰⁰ Two of 12 patients with advanced colorectal cancers experienced tumor regression, one patient had a mixed response, and two had SD. Clinical responses correlated with the expansion of CEA-specific T cells. Twenty-six patients who had undergone resection of colorectal metastases were treated with intranodal injections of an autologous tumor lysate- and control protein-pulsed DC vaccine. Patients were randomized to receive DCs that had either been activated or not activated with CD40L. All patients were followed up for a minimum of 5.5 years. Patients with evidence of a vaccine-induced, tumor-specific T-cell-proliferative or IFN- γ response 1 week after vaccination had a markedly better RFS at 5 years (63% vs 18%, $p = 0.037$) than nonresponders.²⁰¹

Clinical studies have also been carried out using anti-Id antibodies directed against anti-CEA MAbs. These studies have demonstrated the induction of immune responses,^{202, 203} slowed disease progression, and prolonged survival.²⁰⁴ MVA containing the gene for an oncofetal antigen found on many tumors (5T4) has been tested in a variety of cancers (TroVax, Oxford, UK). In a trial of 22 patients with mCRC, immune responses appeared to correlate with disease control, which was seen up to 18 months in patients with immune responses.^{205–207}

Pancreatic carcinoma

Allogeneic whole-tumor-cell vaccines modified to secrete GM-CSF have also been employed in patients with pancreatic cancer. Evidence of vaccine-induced immune responses were observed as measured by delayed-type hypersensitivity.^{25, 208} A 60-patient Phase II study of the same vaccine in the adjuvant setting showed that post-chemotherapy induction of mesothelin-specific CD8 cells correlated with progression-free survival.²⁰⁹ The median OS was about 26 months compared with 21 months for chemotherapy alone

in this same patient population at the same institution.²¹⁰ GVAX and CRS-207 are cancer vaccines that have been evaluated in pancreatic ductal adenocarcinoma (PDA). GVAX is composed of two irradiated GM-CSF-secreting allogeneic PDA cell lines administered 24 h after treatment with low-dose cyclophosphamide (Cy) to inhibit regulatory T cells. CRS-207 is recombinant live-attenuated, double-deleted *Listeria monocytogenes*, engineered to express mesothelin. GVAX induces T cells against a broad array of PDA antigens, and mesothelin-specific T-cell responses have been shown to correlate with survival. Mesothelin is a TAA overexpressed in most PDAs. In a prior study, patients with previously treated advanced PDA who received Cy/GVAX had better induction of mesothelin-specific CD8⁺ T cells than those treated with GVAX alone. Median survival was 4.3 and 2.3 months, respectively. Previously treated patients with metastatic pancreatic adenocarcinoma were randomly assigned at a ratio of 2 : 1 to two doses of Cy/GVAX followed by four doses of CRS-207 or Cy/GVAX alone. In a prespecified per-protocol analysis of patients who received at least three doses (two doses of Cy/GVAX plus one of CRS-207 or three of Cy/GVAX), OS was 9.7 months versus 4.6 months. Enhanced mesothelin-specific CD8⁺ T-cell responses were associated with longer OS, regardless of treatment arm.²¹¹

Breast cancer

Sialyl1-Tn (STn) is a glycopeptide contained in carcinoma-associated mucin. Patients were randomized to receive vaccine [STn coupled to keyhole limpet hemocyanin (KLH)] with or without cyclophosphamide. Patients treated with vaccine and cyclophosphamide were reported to have lived significantly longer²¹² than those treated with the same vaccine without cyclophosphamide. In addition, STn KLH vaccine has been administered to breast and ovarian cancer patients after an autologous stem cell transplant following high-dose chemotherapy. Vaccinated patients appeared more likely to survive and less likely to relapse, but further studies are required.²¹³ A multicenter, double-blinded, randomized Phase III trial of STn conjugated to KLH vaccine was completed in 1028 women with metastatic breast cancer who had nonprogressive disease or no evidence of disease after first-line chemotherapy. The women treated with concomitant endocrine therapy and STn-KLH had longer TTP and OS than the control group of women who received KLH alone. Moreover, of the women who received endocrine therapy, those who had a median or greater antibody response to the STn-KLH vaccine had significantly longer median OS than those who had a below-median antibody response.²¹⁴

Several clinical trials have been carried out using MUC-1 as a target, including the use of MUC-1 peptides,^{215–217} recombinant vaccinia virus encoding MUC-1 and IL-2,²¹⁸ MVA expressing human MUC-1,²¹⁹ and mannan–MUC-1 fusion protein.^{220, 221} In studies carried out with the HER2/*neu* peptides with or without GM-CSF, patients with breast cancer were able to generate HER2-specific immune responses.^{222–224} A Phase I/II clinical trial was carried out vaccinating breast cancer patients with E75, an HLA-A2/A3-restricted HER2/*neu* peptide, and GM-CSF. The 24-month analysis DFS was 94.3% in the vaccinated group and 86.8% in the control group ($p = .08$). In subset analyses, patients who benefited most from vaccination had lymph-node-positive, HER2 IHC 1+–2+, or grade 1 or 2 tumors and were optimally dosed.²²⁵ Fusion-cell (DCs and tumor cells) vaccination of patients with metastatic breast and renal cancer was shown to induce both immunological and clinical responses.²²⁶ An anti-Id antibody that mimics the human milk-fat globule antigen has also been utilized as a breast cancer vaccine in conjunction with autologous stem cell transplantation (ASCT). In that study, the 3-year OS rate was 48%, whereas the progression-free survival rate was 32%.²²⁷ A HER2 peptide-based vaccine (nelipepimut-S) has been tested in a Phase II trial of 195 patients with localized breast cancer at high risk of recurrence. HLA-A2-/A3-positive patients received vaccine with GM-CSF and those that were not HLA-A2 or -A3 positive were controls. The 5-year DFS was 89.7% in vaccinated patients versus 80.2% in nonvaccinated

patients. The 5-year DFS was 94.5% in optimally dosed patients. A Phase III study has been initiated.²²⁸

Lung cancer

Three Phase III studies in patients with non-small cell lung cancer (NSCLC) failed to meet their primary endpoints. A MAGE-A3 peptide-based vaccine was evaluated in stages IB, 2 and 3A tumor-resected NSCLC patients whose tumors expressed the MAGE-A3 gene.^{229, 230} The L-BLP25 vaccine consists of a peptide of the tandem repeat region of the MUC-1 gene. A Phase III trial employing this vaccine after chemoradiation in patients with unresectable stage 3 NSCLC did not meet its primary endpoint of increased OS.²³¹ Lucanix is a vaccine composed of four TGF- β 2 antisense modified, irradiated allogeneic NSCLC cell lines. In a Phase III trial in stages IIIA, IIIB, and IV, for those NSCLC patients who did not progress after front-line chemotherapy, a considerable increase in OS was not observed in the vaccine arm; however, the time elapsed between randomization and the end of front-line chemotherapy had a significant impact on survival ($p = 0.002$).^{232, 233} Other vaccines in patients with NSCLC are also being evaluated. A modified vaccinia virus (MVA) encoding the MUC-1 and IL-2 genes was assessed in combination with first-line chemotherapy in patients ($n = 74$) with advanced NSCLC. Six-month PFS was 43.2% in the vaccine plus chemotherapy group versus 31.5% in the chemotherapy-alone group.²³⁴ A Phase II study of a telomerase peptide vaccine in NSCLC patients ($n = 23$) after chemoradiation has also been evaluated.²³⁵ Immune responders recorded a median PFS of 371 days versus 182 days for nonresponders.

Ovarian/cervical cancer

Clinical findings have also been reported in patients with advanced ovarian cancer using a vaccine consisting of an MAb directed against the tumor antigen CA125.²³⁶ A Phase II study examining an anti-idiotypic antibody vaccine that functionally imitated the CA125 antigen reported survival benefit; median OS of the vaccine group was 19.4 months versus 4.9 months for the control group.²³⁷

The purpose of another Phase II single-arm clinical trial was to evaluate whether pretreatment with low-dose cyclophosphamide improves immunogenicity of a p53-synthetic long peptide vaccine in patients with recurrent ovarian cancer. SD was observed in 20.0% (2/10) of patients.²³⁸ Two independent consecutive studies were conducted of combinatorial immunotherapy comprising DC-based autologous whole-tumor-antigen vaccination in combination with anti-angiogenesis therapy. Thirty-one patients had recurrent progressive stage III and IV ovarian cancer. Vaccination was well tolerated and elicited tumor-specific T-cell responses against various ovarian tumor antigens in both studies, and a clinical benefit of 65% correlated with the immune response with some experiencing prolonged PFS.²³⁹ A Phase II clinical trial of recombinant vaccinia-NY-ESO-1 (rV-NY-ESO-1) followed by booster vaccinations with recombinant fowlpox-NY-ESO-1 (rF-NY-ESO-1) in 22 epithelial ovarian cancer (EOC) patients with advanced disease who were at high risk for recurrence/progression was conducted. Median PFS was 21 months, and median OS was 48 months. CD8⁺ T cells derived from vaccinated patients were shown to lyse NY-ESO-1-expressing tumor targets. These data provide preliminary evidence of clinically meaningful benefit for diversified prime and boost recombinant poxviral-based vaccines in ovarian cancer.²⁴⁰

Studies were undertaken to determine the toxicity, safety, and immunogenicity of a human papillomavirus 16 (HPV16) E6 and E7 long peptide vaccine administered to end-stage cervical cancer patients. The HPV16 E6 and E7 long peptide-based vaccine was well tolerated and capable of inducing a broad IFN- γ -associated T-cell response even in end-stage cervical cancer patients.²⁴¹ Vulvar intraepithelial

neoplasia is a chronic disorder caused by high-risk types of HPV, most commonly HPV type 16 (HPV-16). Twenty women with HPV-16-positive, grade 3 vulvar intraepithelial neoplasia were vaccinated with a mix of long peptides from the HPV-16 viral oncoproteins E6 and E7.²⁴² One-half of a group of 20 patients with HPV16-induced vulvar intraepithelial neoplasia grade 3 displayed a complete regression after therapeutic vaccination. There was a strong correlation between a defined set of vaccine-prompted specific immune responses and the clinical efficacy of therapeutic vaccination.²⁴³

Leukemia/lymphoma

The variable regions of B-cell receptor Igs on lymphomas are excellent targets for vaccines. These Ids have now been used successfully in the treatment of B-cell lymphomas.^{50, 244–247} An Id protein vaccine was used in 25 patients after a chemotherapy-induced second complete clinical remission in follicular lymphoma (FL). After vaccination, tumor-specific humoral or cellular immune responses were found in 20 of 25 patients.²⁴⁶ All of the responders with enough follow-up maintained a second CR longer than the first CR, whereas the five patients who did not mount an immune response had a second CR that was, as expected, shorter than the first CR. Vaccination with hybridoma-derived autologous tumor Ig Id conjugated to KLH and administered with GM-CSF induces FL-specific immune responses. A double-blind multicenter controlled Phase III trial of this vaccine was conducted. Of 234 patients enrolled, 177 (81%) achieved CR/CRu after chemotherapy and were randomly assigned. For the 177 randomly assigned patients, median DFS between Id-vaccine and control arms was 23.0 months versus 20.6 months, respectively ($p = 0.256$). For patients who received Id vaccine, median DFS after randomization was 44.2 months for Id-vaccine arm versus 30.6 months for control arm. Vaccination with patient-specific hybridoma-derived Id vaccine after chemotherapy-induced CR/CRu may prolong DFS in patients with FL.²⁴⁸

A multiple myeloma vaccine has been developed whereby patient-derived tumor cells are fused with autologous DCs, creating a hybridoma that stimulates a broad antitumor response. A Phase II trial was conducted in which patients underwent vaccination following ASCT to target minimal residual disease. Seventy-eight percent of patients achieved a best response of CR or PR and 47% achieved a CR/near CR (nCR). Remarkably, 24% of patients who achieved a partial response following transplant were converted to CR/nCR after vaccination and at more than 3 months post transplant, consistent with a vaccine-mediated effect on residual disease. The post-transplant period for patients with multiple myeloma provides a unique platform for cellular immunotherapy in which vaccination with DC/myeloma fusions resulted in the marked expansion of myeloma-specific T cells and cytoreduction of minimal residual disease.²⁴⁹ Clinical responses have also been observed using Id vaccine in patients with multiple myeloma.^{52, 250}

For patients with chronic myelogenous leukemia, vaccination with bcr-abl oncogene breakpoint fusion peptides has generated specific immune responses.²⁵¹ A study investigated the immunogenicity of Wilms tumor gene product 1 (WT1)-peptide vaccination in WT1-expressing acute myeloid leukemia (AML). Vaccination consisted of GM-CSF and WT1 peptide and KLH. AML patients ($n = 17$) received a median of 11 vaccinations. Objective responses in AML patients were 10 SDs including four SDs with more than 50% blast reduction and two with hematologic improvement. An additional four patients had clinical benefit after initial progression, including one complete remission and three SDs.²⁵² A Phase I/II trial investigated the effect of autologous DC vaccination in 10 patients with AML. Two patients in partial remission after chemotherapy were brought into complete remission after intradermal administration of full-length WT1 mRNA-electroporated DCs. In these two patients and three other patients who were in complete remission, the AML-associated tumor marker returned to normal after DC vaccination,

compatible with the induction of molecular remission. Clinical responses were correlated with vaccine-associated increases in WT1-specific CD8⁺ T cell frequencies.²⁵³

Other tumor types

Intravesical BCG has been used successfully in the treatment of bladder cancer, implicating immune mechanisms.²⁵⁴ Intravesical administration of wild-type vaccinia virus has now been shown to be safe, and three of four patients treated were disease free at 4-year follow-up.²⁵⁵ The response of renal carcinoma to high-dose IL-2 and IFN-alpha also implicates immune mechanisms in therapeutic responses.²⁵⁶ An autologous RCC tumor-cell vaccine that was genetically modified to overexpress B7-1 to provide costimulation to tumor-reactive T cells was employed.²⁵⁷ In this single-arm Phase II study, 66 patients enrolled and 39 received at least one dose of vaccine and low-dose IL-2. Best responses were CR (3%), PR (5%), SD (64%), and PD (28%). A *post hoc* analysis suggested that lymphocytic infiltration of the vaccine site determined by biopsy directly correlated with survival (28.4 months versus 17.8 months, $p = 0.045$). A Phase I trial was conducted to evaluate the feasibility, safety, and efficacy of a DC-based vaccination in patients ($n = 21$) with metastatic RCC. Autologous mature DCs were pulsed with HLA-A2-binding MUC1 peptides. In six patients, regression of the metastatic sites was induced after vaccinations with three patients achieving an objective response (one complete response, two partial responses, two mixed responses, and one SD). An additional four patients were stable during the treatment for up to 14 months.²⁵⁸

Vaccination of pediatric solid tumor patients with tumor-lysate-pulsed DCs has been shown to expand specific T cells and mediated some tumor regression.²⁵⁹ In addition to DC fusion vaccination of patients with metastatic breast and renal cancer, clinical trials have examined vaccination of glioma patients with DC/glioma fusions.^{226, 260} Early clinical trials in patients with primary brain tumors have shown immune responses and objective responses with DC vaccines,²⁶¹ autologous formalin-fixed²⁶² or TGF- β -modified²⁶³ whole-tumor-cell vaccines. A pilot study of s.c. vaccinations with glioma-associated antigen (GAA) epitope peptides in HLA-A2-positive children with newly diagnosed brainstem gliomas (BSGs) and high-grade gliomas (HGGs) was undertaken. Twenty-six children were enrolled, 14 with newly diagnosed BSGs treated with irradiation and 12 with newly diagnosed BSGs or HGGs treated with irradiation and concurrent chemotherapy. Five children had symptomatic pseudoprogression, which responded to dexamethasone and was associated with prolonged survival. Only two patients had progressive disease during the first two vaccine courses; 19 had SD, two had partial responses, one had a minor response, and two had prolonged disease-free status after surgery.²⁶⁴

Considerations in the analysis of vaccine clinical trial results

It has now been demonstrated that appropriate vaccine delivery systems and vaccine strategies can elicit immune responses to TAAs in patients with a range of cancers and, in some cases, can mediate prolonged survival, prolonged disease-free interval, drops in serum tumor markers, and/or regression of metastatic disease. Patients with advanced cancers are perhaps the least appropriate population to demonstrate the efficacy of a cancer vaccine; thus, future clinical trials should be carried out in patients with less or with low tumor burden metastatic disease or earlier in the disease process. Optimal use of vaccines should occur immediately prior to, during, or immediately following adjuvant therapy. Several such studies are ongoing. The overall goal is the use of vaccine regimens in combination with front-line cancer therapies, thereby reducing the interval between disease diagnosis and the initiation of vaccine; this would bring the use of cancer vaccines closer to their original intention—use in patients with minimal disease.

Combination therapies

There are numerous ways in which vaccine therapy can be used in combination with the so-called non-immune-based therapies ([Table 3](#)) as well as with other immunotherapies. One of the major advantages of cancer vaccines is their reduced toxicity. One of the conventional thoughts now being reevaluated is that cancer vaccines cannot be used in combination with chemotherapy or radiation therapy. One should not confuse the potential reduced efficacy of a vaccine given to patients who have failed multiple rounds of prior chemotherapy versus administration of vaccine with or prior to chemotherapy. Preclinical studies, and now several clinical studies, have shown that patients can mount an immune response to a cancer vaccine when given in combination with certain cytotoxic drugs, hormones, or local radiation of tumor. Studies have shown that when tumor cells are exposed to sublethal doses of radiation or certain chemotherapeutic agents, the phenotype of tumor cells is actually modulated to make them more susceptible to T-cell-mediated killing ([Figure 1](#)). Indeed, the era of the use of therapeutic cancer vaccines in combination with other immunotherapeutics as well as the so-called nonimmune conventional cancer therapeutics is still in its early stage of development and full clinical potential.

Table 3 Vaccines in combination with other therapeutic modalities

Modality	Mechanism of action to enhance vaccine efficacy
Radiation	Alteration in tumor cell phenotype
Chemotherapy	“Immunologic” tumor cell death Alteration in tumor cell phenotype Enriched effector: regulator cell ratios
Hormonal therapy	Thymic regeneration and induction of naive T cells Alteration of tumor cell phenotype
Small-molecule-targeted therapeutics	Modulate tumor microenvironment Alteration in tumor cell phenotype
Monoclonal antibodies	Enhanced antibody-dependent cell-mediated cytotoxicity Immune checkpoint modulation
Imids ^a (lenalidomide)	Stimulate T-cell proliferation

^a Imids are a novel class of immunomodulators.

Figure 1 Multiple immunogenic consequences of radiation therapy, chemotherapy, endocrine deprivation, or small-molecule inhibitors that can be harnessed to promote synergy with immunotherapeutic regimens. These immunogenic consequences of anticancer therapy, ranging from immunogenic cell death to immunogenic modulation, can be exploited to achieve optimal synergy with therapeutic cancer vaccines.

Vaccination plus other immunotherapies

The recent clinical studies employing MAbs directed against the checkpoint inhibitor PD-L1/PD-1 immune suppressive axis have placed cancer immunotherapy into consideration as a mainstream component of cancer therapy. Results with checkpoint inhibitors have been most impressive in the treatment of the majority of patients with metastatic melanoma and subsets of patients with lung carcinoma.^{266–271} The use of the PD-L1/PD-1 checkpoint inhibitors has also shown some activity in a minority of patients with other tumor types (e.g., bladder cancer) and extremely low levels of activity in other cancers such as colorectal and prostate cancer. The major correlate of clinical response in virtually all of these studies with the PD-L1/PD-1 checkpoint inhibitors is the presence of T cells in the tumor. It would appear that these TILs are inducing PD-L1 on tumor cells and consequently becoming anergized, thus recapitulating the process of the body's defense against autoimmunity. The administration of an anti-PD-L1/PD-1 agent would “release the brakes” on T cells by reducing or eliminating this immunosuppressive phenomenon, leading to the activation of the TILs and subsequent tumor cell

destruction ([Figure 2](#)). One potential reason for the lack of success of some tumor vaccine trials could be due to this upregulation of PD-L1 on tumor cells in response to the presence of TILs. It would thus appear that the use of a therapeutic vaccine prior to or at the same time as the use of an anti-PD-L1/PD-1 agent would induce the presence of T cells in the tumor, which would subsequently be activated by inhibiting the PD-L1 expression on the tumor, leading to tumor cell lysis ([Figure 2](#)). Carefully controlled randomized clinical studies will be required to validate this hypothesis.

Example:

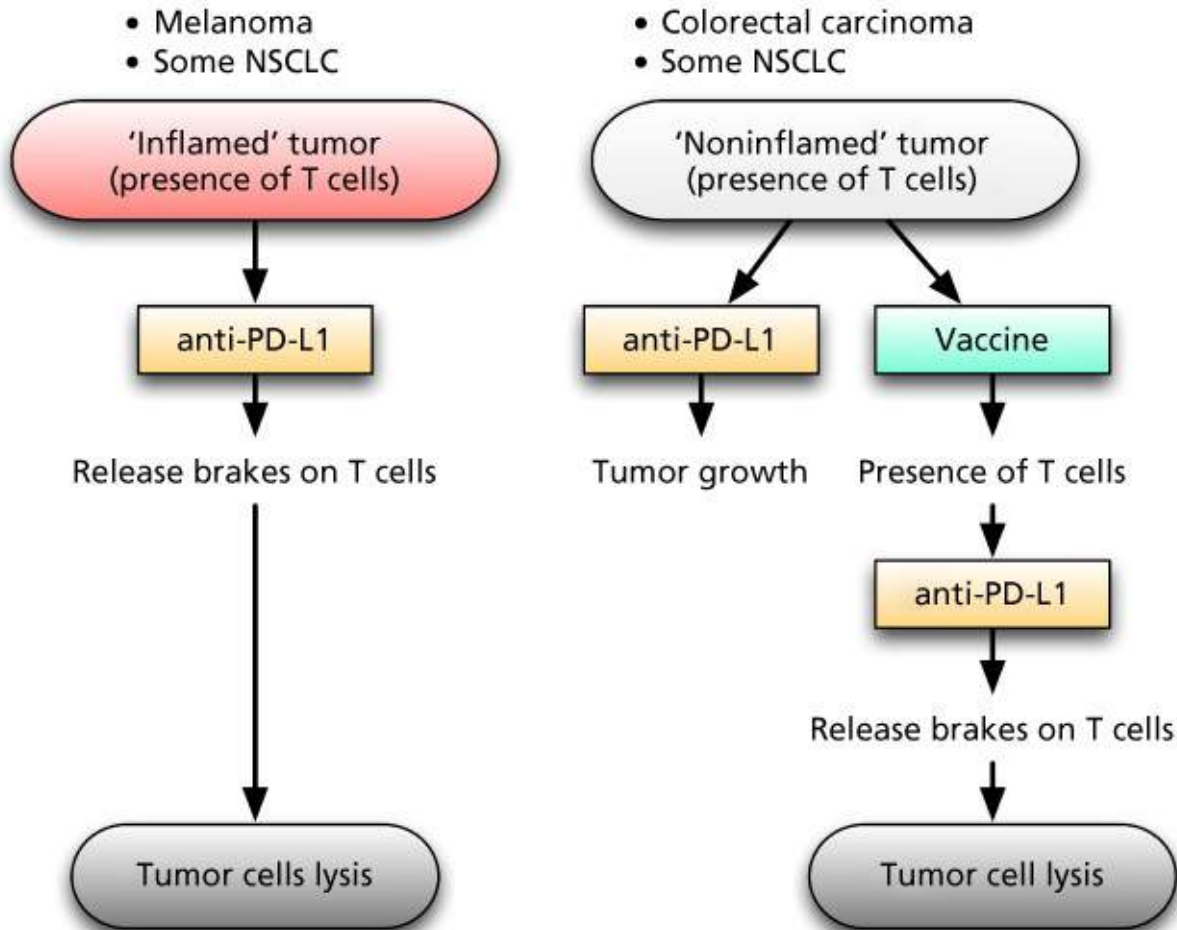

Figure 2 Working model for understanding T-cell-inflamed versus noninflamed tumor microenvironments with implications for vaccine therapy. The potential reasons for lack of spontaneous immune responses against a subset of tumors despite T-cell infiltration include failed immune activation (a) by extrinsic inhibition by PD-L1/PD-1 interactions. This local inhibition may be overcome by blockade with anti-PD-L1/PD-1 checkpoint inhibitor monoclonal antibodies, yielding clinical benefit. Other tumor types, termed “noninflamed,” typically do not respond to PD-L1 inhibition due to lack of potential infiltrating responding T cells. This model suggests that these tumors may be converted to an “inflamed” T-cell-infiltrated phenotype by vaccine regimens (b). These T cells may then be further activated by PD-L1/PD-1 blockade.

Preclinical studies have shown that vaccine plus checkpoint inhibition can act synergistically. The addition of anti-CTLA4 MAb to CEA-TRICOM vaccination was shown to increase the avidity of T-cell responses, resulting in enhanced antitumor activity of the vaccine.^{138, 272} When used in combination with GVAX vaccine, blockade of both PD-1 and CTLA-4 resulted in reversal of CD8⁺ TIL dysfunction and enhanced antitumor activity.²⁷³

In a Phase I clinical study,²⁷⁴ 30 metastatic prostate cancer patients received PROSTVAC vaccine in

combination with increasing doses of ipilimumab (anti-CTLA4). Fifty-eight percent of patients had PSA declines. While this trial was not randomized, median OS for patients receiving the combination was 34.4 months compared to 26.3 months for patients receiving PROSTVAC alone in another trial (Halabi-predicted survival¹⁴⁴ was similar for patients in both trials at about 18 months). A recently completed trial in mCRPC patients using ipilimumab plus radiation showed a median OS of 17.3 months. Also, no additional toxicity above that observed with ipilimumab alone was seen in the vaccine plus ipilimumab-treated patients. In another study, a DNA/peptide vaccine induced T-cell responses in melanoma patients that were “boosted” following CTLA-4 blockade.²⁷⁵ CTLA-4 MAb was also infused into nine previously immunized advanced cancer patients²⁷⁶; evidence of increased tumor immunity was seen in some melanoma and metastatic ovarian cancer patients.

There are also several ways in which vaccine and MAbs can be used in combination. These include (1) the use of therapeutic antibodies such as herceptin or rituxan in combination with vaccine, in which each acts independently, (2) the use of antitumor antibody cytokine fusion proteins such as antitumor antibody/IL-12 to enhance T-cell activity at the site of tumor,^{277–281} and (3) the use of MAbs or fusion proteins directed against regulatory T cells.^{282–284} Vaccines can also be employed in combination with adoptive transfer of antigen-specific T cells. In preclinical studies, point-mutated ras-specific T cells were adoptively transferred into immunodepleted hosts. Donor antigen-specific T-cell responses were greatest in recipient mice that received peptide boosts (with or without IL-2). These results indicate that a vaccine administration after T-cell transfer was more obligatory than exogenous IL-2 to sustain adoptively transferred T cells.²⁸⁵

Immunogenic cell death and immunogenic modulation

Certain cancer therapeutic regimens have the ability to trigger cancer cell death, which leads to stimulating endogenous immune responses against the tumor; this is termed “immunogenic cell death” ([Figure 1](#)).^{286–293} The cardinal signs of immunogenic cell death are (1) calreticulin exposure on the surface of dying cells, (2) the release of high-mobility group box 1 (HMGB1), (3) the release of ATP and, most importantly, (4) cell death.²⁸⁹ Each of these molecules acts on DCs to facilitate the presentation of tumor antigens to the immune system.²⁸⁷ Calreticulin, a chaperone and calcium regulator, when exposed on the surface of a dying cell, serves as a phagocytic signal to DCs.^{291, 294} When HMGB1, a non-histone chromatin-binding protein, is released from dying cells, it engages TLR-4 on DCs, leading to DC maturation.²⁸⁹ The secretion of ATP by dying cells binds receptors on DCs, further supporting T-cell activation.²⁸⁸ In addition, tumor cells that survive therapy have been shown to alter their biology to render them more sensitive to immune mediated killing; this phenomenon is termed “immunogenic modulation” ([Figure 1](#)).^{295–302} Immunogenic modulation encompasses a spectrum of molecular alterations in the biology of the cancer cell that independently or collectively make the tumor more amenable to CTL-mediated destruction. These include (1) downregulation of anti-apoptotic/survival genes,^{297, 298, 303} (2) modulation of antigen-processing machinery (APM) components,^{299, 302} and (3) calreticulin translocation to the cell surface of the tumor ([Figure 1](#)).^{265, 299} One can envision that these immunogenic consequences of anticancer therapy, ranging from immunogenic cell death to immunogenic modulation, can thus be harnessed to achieve optimal synergy with therapeutic cancer vaccines and other immunotherapy regimens, thereby maximizing the clinical benefit for patients receiving combination therapies.

Vaccine plus radiation

Radiation therapy is standard-of-care for multiple malignancies, aimed at direct tumor destruction.

However, systemic disease, treatment resistance, or the need for sublethal dosing to minimize normal tissue toxicity, often translates into surviving tumor cell populations and disease progression.^{304, 305} Radiation can induce a continuum of immunogenic alterations in dying and/or surviving tumor cells (Figure 1). Lethal irradiation has been reported to induce immunogenic cell death.³⁰⁶ Although immune responses in cancer patients receiving radiation alone are often weak and rarely translate into protective immunity, the immunogenic effects of radiation therapy can be exploited to promote synergistic clinical benefit for patients receiving combination regimens with immunotherapy.^{304, 305, 307} It has been demonstrated that the use of relatively low doses of external beam radiation, insufficient to kill tumors, induces immunogenic modulation, altering those tumor cells to render them more susceptible to T-cell-mediated lysis. Cell-surface expression of MHC class I molecules and calreticulin on tumors was increased in a radiation-dose-dependent manner, ultimately rendering tumor cells more susceptible to T-cell-mediated killing.^{265, 298, 302} It has been demonstrated in preclinical studies that radiation combined with a cancer vaccine elicits greater tumor antigen-specific CD8⁺ T-cell responses and/or reduction in tumor burden than either modality alone.^{298, 308–310} Importantly, the induction of CD8⁺ T cells specific for multiple TAAs not encoded by the vaccine was observed after the combination therapy (antigen cascade). This polyclonal T-cell response functionally mediated the regression of TAA-negative metastases at distal s.c. or pulmonary sites.³¹⁰

These findings have translated into promising clinical findings for patients receiving radiation therapy plus immunotherapy.^{304, 305, 307, 311, 312} A Phase I study evaluated the combination of radiation therapy plus injection of an autologous DC vaccine in 14 patients with advanced-stage/metastatic hepatoma.³¹¹ Patients received a single fraction of radiation followed by two intratumoral injections of autologous immature DCs. This combination resulted in tumor-specific immune responses in 7/10 assessable patients, and six patients had objective clinical responses. Utilizing poxviral vaccines, patients in a randomized Phase II study with localized prostate cancer who were treated with radiation and a poxviral-based vaccine had a significant increase in PSA-specific T-cell responses compared to patients receiving radiation alone.³¹² In a multicenter Phase II study, patients with mCRPC ($n = 44$) were randomized to receive ¹⁵³Sm-EDTMP (Quadramet®, an FDA-approved radiopharmaceutical targeting bone metastasis) alone or in combination with PSA-TRICOM vaccine. TTP significantly improved ($p = 0.03$) with combination therapy (3.7 months) compared to ¹⁵³Sm-EDTMP alone (1.7 months).³¹³ In addition, several ongoing clinical trials are investigating this combination strategy,³¹⁴ including a Phase II study of sipuleucel-T plus radiation therapy,⁶² a Phase II study of sipuleucel-T plus stereotactic ablative body radiation,⁶³ and a pilot study of sipuleucel-T plus high-dose single-fraction radiation⁶⁴ in hormone-refractory prostate cancer.

Vaccine plus chemotherapy

If cancer vaccines are to be used early in the disease process, they would most likely need to be used in combination with certain chemotherapeutic regimens. While counterintuitive, it has recently been shown that vaccine therapy may not only be compatible with certain chemotherapies, but also may actually be synergistic (Figure 1).^{296, 315} Various chemotherapy agents have been shown to induce immunogenic modulation in tumors of diverse origin by upregulating various immune-relevant proteins on the surface of cancer cells, including multiple TAAs, calreticulin, adhesion molecules such as ICAM-1, and MHC class I proteins.^{295, 298–300, 303, 316, 317} These phenotypic changes translated into increased murine and/or human tumor sensitivity to CTL-mediated lysis *in vitro* after exposure to sublethal doses of chemotherapy with cisplatin/5-FU³¹⁷ docetaxel,²⁹⁹ paclitaxel²⁹⁹ and cisplatin plus vinorelbine.³¹⁷ These preclinical findings and others have translated into various hypothesis-generating clinical trials, now with encouraging

preliminary data. In a randomized Phase II trial, metastatic breast cancer patients who received docetaxel combined with the therapeutic cancer vaccine PANVAC (poxvirus-based vaccine encoding the tumor antigens CEA and MUC-1, along with three T-cell costimulatory molecules; TRICOM) attained a superior PFS relative to those receiving docetaxel alone (6.6 months vs 3.8 months).³¹⁸ A recent report³¹⁹ demonstrated that the administration of docetaxel to patients with metastatic prostate or breast cancer, as well as that of cisplatin plus vinorelbine to NSCLC patients, significantly increased the ratio between effector T cells and Tregs and reduced the immunosuppressive activity of the latter in the majority of patients. These studies provide the rationale for the selective use of active immunotherapy regimens in combination with specific standard-of-care therapies to achieve the most beneficial clinical outcome among carcinoma patients. Several things are important in considering the use of chemotherapy with vaccine: (1) the combined use of vaccine and chemotherapy early in the disease process should not be confused with the use of vaccines following multiple regimens of different chemotherapeutic agents in the advanced disease setting, where the immune system would most likely be impaired, (2) not all chemotherapeutic agents will be compatible with vaccine, and (3) dose scheduling of vaccine when used with chemotherapy may be extremely important. Obviously, future studies will be required to optimize the combined use of vaccine and chemotherapy. A recent review on combining antineoplastic drugs with tumor vaccines has been published.³²⁰

Vaccine plus hormone therapy

The use of vaccines with anti-androgen therapy represents an intriguing possibility for the treatment of prostate cancer. It has previously been shown that androgen-ablative therapy induces T-cell infiltration in the prostate. T-cell infiltration was readily apparent after 1 to 3 weeks of therapy.³²¹ The immunogenic modulation potential of androgen deprivation has been described with a second-generation androgen-receptor antagonist (ARA), enzalutamide, using the murine TRAMP model of prostate carcinoma.³²² *In vitro* exposure of TRAMP-C2 prostate tumor cells to enzalutamide significantly enhanced cell-surface expression of Fas and MHC class I, consequently improving their sensitivity to immune-mediated lysis. These immunomodulatory properties of enzalutamide were exploited upon combination with a therapeutic cancer vaccine targeting a transcription factor associated with the metastatic process. Combination treatment significantly increased antigen-specific T-cell proliferation and OS compared to the levels observed in mice receiving no treatment or enzalutamide alone. In addition, enzalutamide or abiraterone, an inhibitor of androgen biogenesis, were both able to render androgen receptor positive LNCaP human prostate tumor cells more sensitive to T-cell-mediated lysis.³¹⁶ Findings from these and other studies provided a rationale for the use of ADT in combination with active immunotherapy. A clinical trial has been conducted in prostate cancer patients who had received prior hormonal therapy and had increasing serum PSA without radiographic evidence of metastases. The trial was randomized for a second-line hormone therapy (nilutamide) versus vaccine with a crossover at disease progression so that each arm would receive combination vaccine plus hormone therapy. Time to treatment failure and survival at 4+ years³²³ was prolonged in patients initially receiving vaccine alone and then receiving vaccine plus nilutamide. Further studies are obviously needed to validate such observations and are under way (NCT01867333, NCT01875250).

Vaccine plus small-molecule inhibitors

A number of recent studies have indicated that antiangiogenic tyrosine kinase inhibitors (TKIs) target multiple components of the tumor microenvironment and are an ideal class of agents for synergizing with cancer vaccines.³²⁴ TKIs are well known to modulate tumor endothelial cells, leading to vascular

normalization; however, these agents have also been recently shown to decrease tumor compactness and tight junctions, thereby reducing solid tumor pressure and allowing for improved perfusion of collapsed vessels and increased tumor oxygenation.³²⁵ In addition, select TKIs are capable of inducing immunogenic modulation ([Figure 1](#)). The alteration of the immune landscape, direct modification of tumor cells, and improved vascular perfusion lead to improved antitumor efficacy when antiangiogenic TKIs are combined with immunotherapy. These data support the clinical combination of multitargeted antiangiogenic TKIs, including, but not limited to, cabozantinib,³²⁶ sunitinib,^{325, 327–329} and sorafenib,³²⁵ as well as to other antiangiogenic therapies, such as the anti-VEGF antibody bevacizumab, with cancer vaccines for improved treatment of solid tumors.

Dose scheduling of vaccine with other therapies

Arguably the most unique feature of cancer vaccine therapy is a vaccine's ability to initiate a dynamic process of host immune responses that can be exploited in subsequent therapies ([Table 4](#)). In a Phase I study, patients with advanced-stage progressive cancer received a vaccine directed against cytochrome P4501B1. Most patients who developed immunity to vaccine but required salvage therapy on progression showed marked responses to their next treatment regimen; most of these responses lasted >1 year.³³¹ In another study in patients with extensive-stage small cell lung cancer,³³² a high rate of objective clinical responses to chemotherapy immediately followed vaccine therapy. These clinical responses were also closely associated with induction or augmentation of immune response to vaccine.

Table 4 Therapeutic vaccines versus conventional therapy

	Therapeutic vaccines	Conventional therapy
Target	Immune system	Tumor or its microenvironment
Pharmacodynamics	Delayed (adaptable, may get better over time)	Often immediate action
Memory response	Yes	No
Tumor evolution/new mutations	New immunogenic targets	Resistance to therapy
Limitations	Requires adequate immune system function (both systemically and at tumor site)	Toxicity

Source: Adapted from Ref. 330.

Three randomized clinical trials in prostate cancer provided further evidence of this phenomenon. In the first trial, patients with metastatic CRPC were randomized to receive vaccine alone or vaccine plus weekly docetaxel.³³³ Patients on the vaccine-alone arm were allowed to cross over to receive docetaxel at time of progression. After vaccine, median PFS on docetaxel was 6.1 months compared with a PFS of 3.7 months with the same docetaxel regimen and patient population at the same institution. Similar findings were observed using the sipuleucel vaccine.³³⁴ In a randomized multicenter study, patients in both the vaccine and placebo arms received docetaxel at progression. There was a statistically significant ($p = 0.023$) increase in OS with docetaxel in patients who had prior vaccine versus placebo.

In a Phase II trial,³³⁵ patients with nonmetastatic CRPC and rising serum PSA were randomized to receive either vaccine or nilutamide, an ARA. After 6 months, patients with rising PSA were allowed to cross

over to a combination of both therapies. Median time to treatment failure was similar in the vaccine and ARA arms. However, for patients who received vaccine first and then received vaccine plus ARA, time to treatment failure was 13.9 months from the initiation of ARA and the time to treatment failure from the initiation of any therapy was 25.9 months. Of the initial randomized population, for those patients who first received nilutamide alone or nilutamide and then vaccine, 5-year OS was 38% versus a median OS of 59% for patients who first received vaccine alone or nilutamide plus vaccine.³³⁶

With traditional cytotoxic agents, it is widely believed that improved TTP is a prerequisite for improved OS. A recent study³³⁷ evaluated tumor regression and growth rates in four chemotherapy trials and one vaccine trial in patients with mCRPC. Cytotoxic agents affect the tumor only during the period of administration; soon after the drug is discontinued, due to drug resistance or toxicity, antitumor activity ceases and the growth rate of the tumor increases ([Figure 3](#)). The mechanism of action and kinetics of clinical response with vaccine therapy appears to be quite different ([Table 4](#)).³³⁷ Therapeutic vaccines do not directly target the tumor, but rather target the immune system. Immune responses often take time to develop and can potentially be enhanced by continued booster vaccinations; any resulting tumor-cell lysis can lead to cross-priming of additional TAAs, thus broadening the immune repertoire via a phenomenon known as antigen cascade or epitope spreading ([Figure 4](#)). This broader, and perhaps more relevant, immune response may also take some time to develop. Although a vaccine may not induce any significant reduction in tumor burden, vaccines as monotherapy have the potential to apply antitumor activity over a long period of time, resulting in a slower tumor growth rate ([Figure 3](#)). This deceleration in growth rate may continue for months or years and, more importantly, through subsequent therapies. This process can thus lead to clinically significant improved OS, often with little or no difference in TTP and a low rate of or lack of objective response³⁴⁰; thus, treating patients with lower tumor burden with vaccine may result in far better outcomes. It is hypothesized that the combined use of vaccine and cytotoxic therapy may result in both tumor regression (via the cytotoxic therapy) and reduced tumor growth rate (via vaccine therapy) ([Figure 3](#)).^{337, 338} Early clinical trials with vaccine may thus well have been terminated prematurely with the observance of tumor progression before sufficient vaccine boosts could be administered. This phenomenon has actually led to modifications in how vaccine clinical trials are now designed and to “new immune response criteria” for immunotherapy.³⁴¹

Figure 3 Tumor growth rates in patients with metastatic prostate cancer, from four trials with chemotherapy and one with PROSTVAC (PSA-TRICOM) (adapted from data in Refs). (a) Tumor growth rate with no therapy. (b, blue line) Chemotherapy-induced initial tumor reduction, but tumor growth rate at cessation of therapy due to toxicity or drug resistance was similar to pretreatment tumor growth rate. (c, red line) PROSTVAC vaccine reduced tumor growth rate following therapy. Thus, patients who received vaccine showed little if any tumor reduction (and virtually no increase in time to progression), but showed an increase in overall survival. (d, green line) Predictions of enhanced overall survival for patients treated with both vaccine and cytotoxic therapy. Combination therapy couples the reduced tumor burden from cytotoxic therapy with the reduced growth rate from immunotherapy, culminating in both objective clinical responses and increased overall survival. This phenomenon could potentially be further enhanced if vaccine were initiated earlier in the disease process or in patients with low tumor burden. Arrows indicate the initiation of treatment; crosses indicate time of death from cancer.

Source: Adapted from Gulley 2011³³⁸ and Madan 2010.³³⁹

Figure 4 Antigen cascade. Multiple antigens are released from dying tumor cells that can activate an immune response. (a) Cancer therapy induces death of cancer cells. (b) As these tumor cells die, they release a range of tumor protein antigens (including mutated proteins) that are taken up by scavenger cells called antigen-presenting cells. (c) These antigen-presenting cells then travel to regional lymph nodes where they present these multiple antigens to T cells, initiating or potentiating an antitumor immune response. (d) Activated polyclonal tumor-specific T cells can then traffic to areas of tumor to participate in immune-mediated tumor killing, destroying more cancer cells and further potentiating the cascade.

Mechanisms involved in vaccine activity

Recent studies have shown that a range of effector cells can be involved in antitumor effects. In most preclinical studies, the $CD8^+$ CTL is involved in antitumor effects and the $CD4^+$ helper T cell is important for supplying help via cytokines to further activate the CTL. Other effector cells, however, can be involved, including macrophages and natural killer (NK) cells, and studies have also shown that in certain cases the generation of antitumor antibodies can mediate antitumor effects via antibody-dependent cell-mediated cytotoxicity.³⁴² T-cell activation has been shown to be a complex phenomenon involving the interaction of the peptide–MHC complex on the APC with the TCR on the T cell; for weak antigens such as TAAs, however, accessory molecules are necessary for efficient T-cell activation. These have been termed T-cell costimulatory molecules. At this time, over a dozen such costimulatory molecules have been identified. Costimulatory molecules are found on professional APCs, such as DCs, but are not found on

the vast majority of solid tumors. It has also recently been shown that combinations of these costimulatory molecules act synergistically to further enhance T-cell activation.¹³⁹ Recent studies have also shown that it is not necessarily the quantity of T cells generated that is essential, but their quality, or avidity.^{138, 343, 344} This is measured by the ability of different populations of T cells to actually kill targets. It has recently been shown that the use of vaccines with T-cell costimulation and certain cytokines can actually enhance T-cell avidity.¹³⁸

Several different types of regulatory T cells have now been identified.^{345–348} The evolutionary reason for their existence is most likely to reduce autoimmune phenomena. Since TAAs for the most part are self-antigens, regulatory T cells appear to have a major role in reducing immune responses to TAAs. Several types of regulatory T cells that have now been identified are CD4⁺CD25⁺FoxP3⁺ (Tregs), immature macrophages, and CD4⁺ NKT⁺ cells.^{347, 348} Studies are ongoing employing reagents that can potentially reduce the activity of these regulatory T cells, including the fusion protein Ontak,³⁴⁹ cyclophosphamide,^{212, 221, 350} and anti-CD25 Abs.^{351, 352} The inhibition of these cells will most likely be a part of cancer vaccine therapy in the future.

Antigen cascade

The phenomenon of antigen cascade ([Figure 4](#)) is now evolving as an important facet in the evaluation of cancer vaccines. This was first defined using the term epitope spreading, in which a given peptide was used as a vaccine and the host immune response post vaccination was not only directed to that epitope, but also to other epitopes of the same tumor antigen.^{308, 352, 353} This phenomenon has now been expanded using the term antigen cascade, in which a given antigen is used as a vaccine and the host immune response post vaccination is not only directed against the antigen in the vaccine but also to other antigens in the tumor. The explanation for these phenomena is that as a consequence of some tumor-cell destruction induced by the vaccine, APCs will engulf tumor fragments and then cross-present those tumor fragments to T cells, thus initiating the antigen cascade phenomenon. It has also been shown that 1/8 prostate cancer patients receiving radiation developed antibodies to an array of TAAs, while 15/33 patients receiving PROSTVAC plus radiation developed such antibodies.^{354, 355} Antigen cascade has now been observed in preclinical models³⁵⁶ and several trials have shown that antigen cascade correlated with antitumor activity.^{142, 357–361} This phenomenon of antigen cascade is also a mechanism by which the host will direct an immune response to the many mutated gene products in the tumor. Some studies have also suggested improved clinical outcomes for patients who demonstrated a broadened immune response to epitopes not found in the vaccine.^{359, 362–364}

Immune monitoring

One is always asked for immune correlates of patient benefit in therapeutic cancer vaccine clinical studies. See Ref. 365 for an excellent review. The extreme complexity of the human immune system, the genetic diversity of the human population, and the diversity among cancer patients in terms of type and stage of disease make this a truly daunting task. In addition to the analysis of antigen-specific CD4 and CD8 immune cell subsets, numerous other immune subsets may play an important and/or interdependent role in patient responses; these include regulatory T cells and myeloid-derived suppressor cells as examples. Over 130 different human immune cell subsets have now been identified. Soluble factors produced by tumors or in the tumor microenvironment can also influence immune responses; these include, among others, TGF- β , IL-8, VEGF, IFN- γ , TNF, CD40L, and sCD27. Confounding factors other

than those mentioned above include number and type of prior therapies, age and sex of the patient, and size of tumor lesions. Differences in immune cells in the periphery versus different locations within the tumor are of extreme importance. These types of data are more easily obtained in melanoma patients, but biopsies of metastatic lesions are not as easily obtained in most patients with solid tumors.

Newer techniques are currently being employed to investigate patients' immune responses; these include, among others, gene chip RNA arrays of tumor and peripheral blood samples, analysis of changes in TCR clones pre- versus post vaccination, and changes in over 100 immune cell subsets via multilaser FACS analyses. In addition, analyses of numerous immune cell subsets of patients prior to therapy are emerging as a valuable tool in determining which patients are more likely to benefit from vaccine therapy.^{318, 366}

Paradigm shifts

The evaluation of cancer vaccines in clinical trials may well necessitate new paradigms.^{20, 315} Cancer vaccines and cytotoxic drugs act differently in terms of mode of action dynamics, as well as limitations ([Table 4](#), [Figure 3](#)). Cytotoxic drugs either kill or do not kill tumor cells. Lack of efficacy is due to either drug resistance by tumor cells, inadequate amounts of drug delivered to the tumor, and/or drug-induced toxicity in the host. Thus, if a patient's disease is progressing on a cytotoxic drug, that drug is immediately withdrawn. The use of a cancer vaccine involves the initiation of a dynamic process in which the patient's own immune system is activated. It is clear from decades of preclinical studies, and now clinical trials, that to maximize the host immune response, one must not only give a primary vaccination but also multiple booster vaccinations over a period of weeks or months to further enhance the level of the immune response. Multiple vaccinations are especially important because factors that will blunt the immune response may be given off by the tumor. Thus, it is not unusual to see disease progression following early vaccinations, only to see disease stabilization or a reduction in tumor burden following multiple vaccinations. Thus, the paradigm of “drug withdrawal upon progression” should be revisited with the use of cancer vaccines.

Clinical trials with a new drug are traditionally evaluated in patients with advanced tumors (many times with a large tumor burden) who have failed prior cytotoxic therapies. Objective clinical responses are evaluated by RECIST criteria, looking for a sustained $\geq 30\%$ reduction in the sum of the longest diameter of target lesions. The scenario is all too familiar where antitumor activity is observed with cytotoxic agents or small-molecule targeted therapies via a reduction of tumor burden by RECIST criteria, but no statistical difference in survival is seen. Unfortunately, there is still a “paradigm paralysis” by some who hold on to this paradigm for the evaluation of immunotherapy agents as the only means of evaluation of efficacy.

Since generation of an immune response to a vaccine is a dynamic process in which T cells can be continually generated upon booster vaccines, a more appropriate endpoint for evaluation should be TTP and, more importantly, survival. Since only a finite amount of T cells can be generated by a vaccine, it may be inappropriate to evaluate a cancer vaccine by its ability to drastically reduce a large tumor burden; this is especially true in patients whose immune system has been compromised due to numerous rounds of prior chemotherapy. A more appropriate setting would be the evaluation of cancer vaccines earlier in the disease setting (e.g., neoadjuvant or adjuvant setting), or in metastatic patients with a small tumor burden. This should particularly be considered in light of the relatively low level of toxicity seen in the use of cancer vaccines.

Summary

The U.S. Food and Drug Administration approvals of (1) the prostate cancer therapeutic vaccine sipuleucel-T, (2) anti-CTLA-4 monoclonal antibody (MAb) ipilimumab, and (3) the MAbs directed against the programmed death ligand 1 (PD-L1)/PD-1 immunosuppressive axis, along with the results of recent clinical studies involving cancer vaccines and other immunotherapeutics, have placed immunotherapy into the mainstream of the management of many cancer types. Many potential TAA targets and vaccine platforms for cancer immunotherapy have been identified. The evaluation of cancer vaccines in clinical trials may well necessitate new paradigms. Cancer vaccines and cytotoxic drugs act differently in terms of mode of action and dynamics. Cytotoxic drugs either kill or do not kill tumor cells; lack of efficacy is due to drug resistance by tumor cells, inadequate amounts of drug delivered to the tumor, and/or drug-induced toxicity in the host. The use of a cancer vaccine involves the initiation of a dynamic process in which the patient's own immune system is activated. Thus, it is not unusual to see disease progression following early vaccinations, only to see disease stabilization or a reduction in tumor burden following multiple vaccinations. Thus, the paradigm of “drug withdrawal upon early progression” should be revisited with the use of cancer vaccines. Preclinical studies, and now several clinical studies, have shown that patients can mount an immune response to a cancer vaccine when given in combination with certain cytotoxic drugs, hormones, or local radiation of tumor. Studies have shown that when tumor cells are exposed to sublethal doses of radiation, certain chemotherapeutic agents, hormone manipulating therapeutics or small-molecule targeted therapeutics, the phenotype of tumor cells is actually modulated to make them more susceptible to vaccine-mediated T-cell-mediated killing. It would also appear that the use of a therapeutic vaccine prior to or at the same time as the use of an anti-PD-L1/PD-1 agent would induce the presence of T cells in the tumor, which would subsequently be activated by inhibiting the PD-L1 expression on tumor, leading to tumor cell lysis.

Chapter 66

Cell-based cancer immunotherapy

Krina K. Patel, MD ■ Judy S. Moyes, MA (Cantab), MB, BChir, FRCPC, FRCPCH ■ Laurence J. Cooper, MD, PhD

Overview

For decades, scientists have applied cell-based immunotherapies for treatment of cancers. The successful administration of polyclonal populations of donor-derived or autologous T cells is based in part on defining the precise cellular effectors and identifying tumor-associated antigens (TAAs) that can be targeted to safely achieve an antitumor effect without engendering on-target, but off-tissue toxicity, such as manifested by graft-versus-host-disease (GvHD). The adoptive transfer of T cells can reconstitute or enhance resident immunity, which is in contrast to the apparent limitations associated with vaccine-based strategies in recipients whose endogenous immune system may fail to respond to immunogen. Other cytolytic circulating lymphocyte populations can be harnessed for infusion. These include allogeneic NK cells that may mediate an antitumor effect without *a priori* defining the TAA and perhaps without the risk of GvHD. In some cases, a TAA can be identified, for example, the B-lineage TAA CD19, but host immune tolerance prevents the emergence of an effective immune response. Genetic engineering has been combined with T-cell therapy to generate antigen-specific cells *ex vivo*, through the enforced expression of chimeric antigen receptors (CARs). The adoptive transfer of CD19-specific CAR⁺ T cells has shown promise in initial clinical trials for successful disease control in patients with B-cell malignancies resistant to conventional therapeutic modalities. Here, we describe the current status of cell-based immunotherapy for cancer.

Introduction

Allogeneic hematopoietic stem-cell transplantation (HSCT) can be considered as the first effective form of cellular-based therapy for hematologic malignancies. Successful outcome for patients undergoing allogeneic-HSCT is directly linked to the emergence of a graft-versus-tumor (GvT)-effect mediated by donor-derived immune cells. The relevant cellular immune components of the allograft include T cells, natural killer (NK) cells, and B cells that are recognized as potential effectors of the GvT-effect. The observation that engrafted T cells can eliminate residual tumor cells led to the use of donor leukocyte infusions (DLI) to treat a subset of relapsed leukemias, which provided direct evidence for a GvT reaction.¹ While cytotoxic T cells are the primary mediators of the GvT effect, unfortunately, they also are closely associated with development of graft-versus-host-disease (GvHD)² as major and minor histocompatibility antigens can be shared between malignant and normal cells. In practical terms, DLI and allogeneic HSCT are limited by GvHD offsetting the benefits of the GvT effect.

For several decades, scientists have applied cell-based immunotherapy for cancer. The successful administration of polyclonal populations of donor-derived or autologous T cells is based in part on defining the precise cellular effectors and identifying tumor-associated antigens (TAAs) that can be targeted to safely achieve an antitumor effect without engendering on-target, but off-tissue toxicity, such as

manifested by GvHD. The adoptive transfer of T cells can enhance resident immunity, which is in contrast to the limitations associated with vaccine-based strategies in patients whose endogenous immune system may fail to respond to an immunogen.^{3, 4} Other lymphocyte populations can be harnessed for infusion. These include allogeneic NK cells that may mediate an anti-tumor effect without *a priori* defining the TAA and without the risk of GvHD.^{5–7} In some cases, a TAA can be identified, for example, CD19, but tolerance prevents the emergence of an effective immune response. Genetic engineering has been combined with T-cell therapy to generate antigen-specific cells *ex vivo*, through the enforced expression of chimeric antigen receptors (CARs). Indeed, the adoptive transfer of CD19-specific CAR⁺ T cells has shown promise in initial clinical trials for successful disease control in patients with B-cell malignancies resistant to conventional therapeutic modalities, as summarized in [Table 1](#). In this chapter, we will describe the current status of cell-based immunotherapy for cancer.

Table 1 Selected CD19 CAR T-cell trials

Type of CAR	Costimulatory domain	Cancer type	Outcomes	Total number of patients	Toxicities	References
Lentivirus	4-1BB	ALL	27 CR	30	Severe CRS	Maude et al. ⁸
Gammaretrovirus	CD28	ALL, NHL	14 CR	19	Severe CRS	Lee et al. ⁹
Gammaretrovirus	CD28	ALL	14 CR	16	Severe CRS	Davila et al. ¹⁰
Gammaretrovirus	CD28	DLBCL, indolent lymphoma, CLL	8 CR, 4 PR, 1 SD, and 2 were not evaluable	15	Neurologic, delirium	Kochenderfer et al. ¹¹
Lentivirus	4-1BB	CLL	3 CR, 5 PR, and 6 no response	14	Fever	Porter et al. ¹²

ALL, acute lymphoblastic leukemia; NHL, non-Hodgkin lymphoma; DLBCL, **diffuse large B-cell lymphoma**; CLL, chronic lymphocytic leukemia; CR, complete remission; PR, partial response; SD, stable disease; CRS, cytokine-release syndrome.

Generation of cellular therapy products

T cells

The immune system of the patient with cancer can be manipulated through the administration of lymphocytes as well as immunomodulatory approaches aimed at enhancing the endogenous T cells' adaptive ability to kill tumor cells. Both of these approaches have led to antitumor effects. Clinical trials infusing antibodies to break checkpoint blockade against CTLA4 and the PD-1/PDL-1 axis lead to activation of an endogenous antitumor immune response and have reported significant long-lasting responses.^{13–15} Analysis of biopsy samples reveals that by blocking the PD-1/PDL-1 axis, the antitumor effect is correlated with the baseline density and location of T cells in metastatic melanomas.^{16, 17} For some tumors, there may not be sufficient quality or quantity of infiltrating T cells in the tumor microenvironment. These tumor types may be targeted by an exogenous source of *ex vivo* expanded

effector cells. Thus, adoptive cellular therapy (ACT) has emerged as a highly effective modality capable of eliciting sustained clinical responses for some hematologic malignancies as well as solid tumors as described in [Table 2](#).

Table 2 Selected cellular therapy trials for solid tumors

Cancer type	Type of ACT	Target antigen	Outcomes	Total number of patients	Toxicities	References
Melanoma	TCR	MART-1; gp-100	8 PR; 1 CR	36	Skin, eyes, and ear	Johnson et al. ¹⁸ and Morgan et al. ¹⁹

In general terms, five forms of T cells have been manipulated for human application. These are (1) lymphokine-activated killer (LAK) cells; (2) cytokine-induced killer (CIK) cells; (3) tumor-infiltrating

lymphocyte (TIL) using lymphocytes expanded from a tumor biopsy; (4) antigen-specific T cells based on identification and/or selection of endogenous and typically circulating T cells; and (5) genetically engineered T cells that express a TAA-specific T-cell receptor (TCR) or CAR.

Infusion of LAK cells, produced from peripheral blood after culturing with high doses of interleukin-2, was one of the first applications of ACT.³⁰ Unfortunately, high dose IL-2 led to terminal differentiation and inability to recycle effector function. Furthermore, the positive responses seen in early clinical trials with LAK cells could have been the result of the IL-2 coinfusion.³¹ However, the clinical data associated with LAK cells led to the development of TIL, which have antitumor activity, especially for patients with melanoma. CIK cells are a heterogeneous subset of *ex vivo* expanded T-lymphocytes that present a mixed T-NK phenotype and are endowed with major histocompatibility complex (MHC)-unrestricted antitumor activity³²; antitumor cytotoxic activity is represented by surface markers for both T cells (CD3⁺TCR $\alpha\beta$ ⁺) and natural killer T (NKT) cells (CD3⁺CD56⁺).³³ T cells that express a TCR composed of $\alpha\beta$ heterodimers are the most prevalent T-cell population in peripheral blood; thus, they have been the most widely studied for ACT. Both effector (CD8⁺) and helper (CD4⁺) T cells have been evaluated for ACT as bulk populations, antigen-specific clones, or subsequent to genetic modification to express TAA-specific receptors.

Tumor infiltrating lymphocytes (TILs)

Animal studies demonstrated that TIL were significantly more effective than LAK cells in eliminating tumors,³⁴ prompting clinical trials infusing *in vitro* expanded TIL for patients with metastatic melanoma.^{35, 36} These trials were begun at the NIH and are now being undertaken worldwide.^{37–39} These clinical data reveal that subsets of the inoculum recognize TAAs that can be identified as mutated epitopes based on whole-exon sequencing of tumor samples.^{40, 41}

Rosenberg and colleagues at the Surgery Branch of the National Cancer Institute (NCI) pioneered and standardized methods for TIL expansion for ACT.⁴² First, during the pre-expansion phase, surgically excised tumor specimens were digested and cultured in single-cell suspensions with media containing IL-2, examined for growth and reactivity, and then selected for further expansion and characterization. Early studies showed promising results³⁵ with remarkable objective response rates of about 50% in metastatic melanoma. Inopportunately, only a subset of patients who were initially enrolled in most of these trials actually underwent infusion of TIL.⁴³ The lack of an available tumor for surgical harvest, difficulty to isolate and grow TIL from harvested tumor, or inability to show robust, specific effector function of isolated TIL were all reasons that have confined this treatment strategy to academic centers skilled in the generation of this type of cellular product. Toxicities such as hypotension, arrhythmias, and vascular leak syndrome were attributed to the high doses of recombinant IL-2, which was coinfused to improve TIL persistence. The judicious selection of recipients for TIL therapy and management of patients receiving high-dose IL-2 has improved outcomes in subsequent trials. Specifically, those patients who achieved complete remissions (approximately 1/5 of all patients treated) remained disease-free 3 years or greater after treatment.⁴⁴ Furthermore, it appears that IL-2 at high doses may not be needed, which will likely broaden the application of this therapy.^{45, 46}

In efforts to improve the outcome of TIL therapy, a lymphodepletion regimen was added before TIL transfer.^{47–49} Lymphodepletion is thought to enhance the persistence of T lymphocytes by providing a pro-proliferative environment through elimination of cytokine sinks (which leads to increased availability of prosurvival cytokines, e.g., IL-7 and IL-15), myeloid-derived suppressor cells and T regulatory cells.⁵⁰ The addition of lymphodepletion led to the engraftment of TIL and improved the clinical responses. As a

consequence though, the loss of a normal immune defense system led to increased rates of opportunistic infections.

The degree of lymphodepletion appears to impact the antitumor response. Non-myeloablative lymphodepletion regimens with cyclophosphamide and fludarabine achieved response rates reaching 51%.^{51, 52} When total body irradiation (TBI) was included at doses that required rescue of hematopoiesis with autologous hematopoietic cell transplantation, the overall response rate increased to 70% with complete remission (CR) of 40%; however, the increased intensity of the conditioning regimen was associated with more serious adverse toxicities including febrile neutropenia, infections, and thrombotic microangiopathy.^{44, 48}

A limitation of using TIL has been patient attrition owing to disease progression or overall clinical decline while waiting for TIL to meet release criteria for administration. Thus, strategies are being developed to decrease the time in culture from TIL collection to infusion.⁵³ In a recent trial, shortening of the pre-expansion phase allowed TIL to be produced within 28 days which led to a 74% enrollment. These “younger TIL” may also have improved therapeutic benefit as they contain T cells that are not terminally differentiated and avoid replication senescence.⁵⁴ Approaches using activation and propagation cells (AaPC) as irradiated feeders to numerically expand TILs are also emerging.⁵⁵ These feeder cells may thus help broaden the number of patients who can benefit from TILs and enable tumor-specific T cells to be generated without the need to harvest tumor.

As knowledge about immunotherapy grows rapidly, the number of current clinical trials employing TIL therapy also increases. These include comparing lymphodepleting regimens (NCT01807182; Fred Hutchinson Cancer Center), combination immunotherapy with CTLA-4 (NCT01701674; Moffitt Cancer Center) or PD-1/PDL-1 axis blockade or vaccines (NCT00338377; MD Anderson Cancer Center), and evaluating TIL efficacy in tumor types other than melanoma (NCT01174121; National Cancer Institute).

Peripheral blood T cells

TAA-specific T cells can be collected from peripheral blood using MHC multimers containing peptide epitopes. These are complexed to a fluorescent reagent to stain circulating T cells. The desired population of autologous effector cells can then be sorted, activated, and expanded *in vitro* and infused into the patient to induce tumor regression and long-term immunoprotection.^{45, 56} The prevalence of TAA-specific effector T cells in peripheral blood can be rare (on the order of 0.2%); however, some studies in melanoma have reported T cells specific for melanocyte antigens such as gp100, tyrosinase, and MART-1 at frequencies reaching 2%.⁵⁷ This *in vitro* study also suggested that even though systemic TAA-specific T-cell responses can develop *de novo* in cancer patients, antigen-specific unresponsiveness may explain why such cells are unable to control tumor growth. Therefore, activation of the TCR in the presence of costimulatory molecules, followed by cytokine-induced expansion, is needed to enrich the TAA-specific effector T cells.⁵⁸ TCR engagement is mediated by the peptide–MHC complex that presents the antigen to the T cell.

The very low frequency of T cells recognizing commonly expressed antigens limits the applicability of this approach. To overcome this instability, Pollack et al.⁵⁹ tested the strategy combining IL-21 modulation during *in vitro* stimulation with tetramer-guided cell sorting to generate TAA specific cytotoxic T lymphocytes. T cells stained with the TAA NY-ESO-1 tetramer were enriched from frequencies as low as 0.4% to >90% after single pass through a clinical grade sorter. NY-ESO-1-specific T cells were generated from all patients included in the study and the final products expanded on average 1200-fold were oligoclonal and contained 67–97% CD8⁺, tetramer⁺ T cells with a memory phenotype

that recognized endogenous NY-ESO-1.

Peripheral blood dendritic cells

Autologous dendritic cells (DCs), a class of professional antigen-presenting cells, are used to selectively propagate autologous T cells by coculture *in vitro*. To obtain DCs, monocytes from peripheral blood are cultured in IL-4 and granulocyte-macrophage colony-stimulating factor (GM-CSF) to dedifferentiate into immature DCs. These immature DCs can then be loaded with tumor antigen or lysate and cultured in cytokines to mediate maturation and upregulation of costimulatory ligands such as CD80 and CD86. Alternatively, the use of peptide to pulse mature DCs generates high-affinity CD8⁺ and CD4⁺ T cells recognizing only a single antigenic epitope. Artificial antigen-presenting cells (aAPCs) have also been developed as an alternative to DCs, derived from the human erythroleukemia cell line, K562. These cells express HLA (human leukocyte antigen) C alleles and no other classical HLA class I or II molecules and can be genetically modified to express TAA, HLA, and costimulatory molecules to optimize generation of the antigen-specific T-cells.^{55, 60}

Both TIL and antigen-specific T-cell therapy provide complementary strategies for the treatment of patients with solid tumor malignancies and represent promising prospects in the development of ACT as a treatment modality. They not only provide effective treatment for patients but also supply a rich source of data for immunobiological discovery.

Table 3 Methods typically used to eliminate mispairing between introduced and endogenous alpha/beta TCR

Various methods to facilitate introduced αβ TCR pairing	References
Use of full or partial mouse TCR α and β	Cohen et al., ⁷⁴ Sommermeyer and Uckert, ⁷⁵ and Cohen et al. ⁷⁶
Addition of another disulfide bond within constant region	Kuball et al. ⁷⁷ and Cohen et al. ⁷⁸
Use of Knob-into-hole configuration	Voss et al. ⁷⁹
Application of short hairpin RNAs (shRNAs) against TCRαβ constant regions to suppress endogenous TCRαβ expression	Okamoto et al. ^{80, 81}
Introduction of zinc finger nucleases (ZFNs) or other artificial nucleases to completely disrupt endogenous TCRαβ expression at genomic level	Provasi et al., ⁸² Poirot, et al., ⁸³ Torikai et al. ⁸⁴

Genetically engineered T cells

With advancements in immunology and gene transfer, T-cell function has been enhanced by altering receptor specificity and signaling functions that control ability to recycle antigen-dependent effector functions.⁶¹ A justification for genetic retargeting of T cells is that the endogenous TAA-specific T-cell repertoire undergoes immune-mediated tolerance rendering these cells unable to either recognize or effectively respond to malignant cells. Two types of genetically modified T cells are in current clinical trials for oncology based on redirecting specificity through enforced expression of defined TCRs or CARs.

Efficient gene transfer into T cells is necessary to generate both TCR and CAR cellular products. γ-

Retroviral and lentiviral transduction techniques rely on the propensity of these viruses to integrate permanently into the host genome. GMP (good manufacturing practice)-grade viral vector production is a costly, time-consuming, and specialized technique. Despite early concerns about insertional mutagenesis, decades of experience with transduction of primary T cells have failed to show any examples of this theoretical complication.⁶² Nonviral gene transfer is an alternative and relatively cheaper approach. The most commonly used approaches are transposon/transposase systems such as Sleeping Beauty. This system results in sustained expression of CAR on T cells, and anti-CD19 transposon CAR T cells are in early-phase clinical trials.⁶³ Another novel approach is the electroporation of T lymphocytes with *in vitro* transcribed RNA.⁶⁴ This leads to high, but transient, expression of the CAR. With the exception of the mRNA electroporation technique, gene transfer into T cells is typically carried out at the beginning of a period of *in vitro* culture and stimulation. This system leads to more efficient transduction and a greatly expanded number of T cells for subsequent adoptive transfer.

T-cell receptors (TCRs)

The rationale for engrafting high-affinity TCRs is that the endogenous repertoire for TCRs is generally of low affinity when targeting self-TAAs. The assumption is that as such low-affinity TCR chains are unable to control malignancy, increasing the affinity will initiate an effective antitumor response.⁶⁵ Indeed, there is precedent based on animal studies.⁶⁶ There are three general approaches to increasing the affinity of TCRs (1) *in silico* changes to antigen-binding domains, especially CDR3⁶⁷; (2) using combination platforms such as the XPRESIDENT technology that uses mass spectrometry, gene expression profiling, literature-based functional assessment, *in vitro* human T-cell assays, and bioinformatics to select the most appropriate tumor-associated peptides⁶⁸; and (3) CARs that recognize peptide in context of restricting HLA molecules.^{69, 70} The TCR is composed of a complex of six polypeptide chains (α , β , γ , δ , ϵ , and ζ), which connect on the cell surface as part of the immunological synapse to initiate a T-cell activation signal. The α and β chains comprise a heterodimer to form the primary binding domain of the TCR, which recognize intracellularly processed peptides presented on the surface of target cells by classical HLA class I and II molecules. Other constituents of the immunological synapse such as costimulatory and adhesion molecules increase the strength and quality of the TCR-HLA-peptide engagement leading to a fully competent T-cell activation event, defined at a minimum as (1) serial killing, (2) sustained proliferation, (3) T_c1 cytokine production, and (4) protection from activation-induced cell death (AICD). The genetic modification of T cells to enforce expression of TCR has been translated from the bench⁷¹ to the bedside. Initial clinical efforts adoptively transferred autologous T cells that had been rendered specific for melanoma.¹⁹ The clinical responses were inferior to recipients of (nongenetically modified) TIL. However, these data established the proof-of-principle that T cells could be engineered to target TAAs and provided justification for targeting tumors other than melanoma. They also provided a glimpse of the future as T cells expressing high-affinity TCRs participated in on-target and off-tissue recognition of normal melanin expressing cells in the inner ear and retina.¹⁸

The broad human application of T cells genetically modified to express TAA-specific TCR faces two significant challenges. The first is the unwanted mispairing between the introduced $\alpha\beta$ TCR and endogenous $\alpha\beta$ TCR, which could (1) reduce the number of appropriately paired chains that can recognize HLA-peptide and (2) generate TCR heterodimers that have not undergone thymic selection and tolerance, which could lead to deleterious recognition of normal structures. This has been demonstrated in the mouse^{72, 73} but has not led to clinical compromise in human trials. [Table 3](#) provides a current list of approaches to eliminate mispairing between introduced and endogenous TCR. The second problem is associated with the affinity of the engrafted TCR. Methods to increase affinity are also not subject to

thymic selection and tolerance mechanisms, which, when coupled with an incomplete understanding of their specificity, exposes the recipient to on target but off-tissue side effects. Most approaches currently rely on targeting nonmutated self-antigens, the most promising of which may be gene products from the cancer testis family of genes.²² An affinity-enhanced NY ESO-1-specific and HLA-A2-restricted TCR was tested in patients with melanoma and synovial cell sarcoma and no serious toxicity was seen.²² However, the adoptive transfer of autologous T cells expressing an affinity-enhanced²¹ HLA-A1-restricted MAGE A3-specific TCR led to lethal cardiac toxicity in two patients owing to off-target recognition of Titin. In another trial,²⁰ in which autologous T cells with affinity-enhanced TCR recognizing MAGE A3 in the context of HLA-A2 were infused in patients with melanoma, significant neurotoxicity from a cross-reactive antigen MAGE A12 present on brain cells occurred; specifically, three patients experienced mental status changes and two lapsed into comas and died. Systemic administration of corticosteroids did not help to reverse the toxicities. While these events illustrate the potency that engineered autologous T cells can display, they highlight the urgent need for improved preclinical systems to uncover off-target adverse events before initiation of clinical trials.

Although TCR-based ACT approaches have great potential, they do have inherent limitations. The HLA-restricted specificity of engineered TCR limits the number of potential patients to those expressing the relevant HLA allele recognized by the T cells. In addition, because tumors often downregulate HLA alleles and interrupt proteasomal processing pathways, antigen escape variants and lack of complete remissions are relevant.

Chimeric antigen receptors (CARs)

Prototypical CARs combine an extracellular single-chain variable fragment (scFv) of an antibody with a transmembrane (TM) domain and intracellular signaling domains derived from molecules involved in T-cell signaling complex. Typically, clinically appealing CARs use the signaling motif from the CD3- ζ chain in combination with signaling domains from molecules involved in T-cell activation or costimulation.^{85, 86} As the scFv domain binds directly to target cell surface epitopes, CARs can bypass the need for MHC-restricted antigen presentation and, therefore, are immune to tumor escape mechanisms related to HLA downregulation. CARs can overcome T-cell triggering limitations related to epitope density, as the scFv can have a high affinity for the TAA. Multigeneration CARs have been developed which have a combination of signaling domains attached to the cytosolic activation domain. These CAR species are designed to provide a fully competent T-cell activation event in the tumor microenvironment. It appears that CARs that are capable of signaling in addition to the phosphorylation of the immunoreceptor tyrosine-based activation motif (ITAM) in CD3- ζ have improved *in vivo* persistence⁸⁷ and thus antitumor effects. Two second-generation CARs have resulted in dramatic antitumor effects in patients with CD19⁺ malignancies. CAR⁺ T cells with the chimeric CD137 signaling domain (i.e., 4-1BB) have resulted in dramatic antitumor effects in patients with acute and chronic B-cell leukemias.^{88–90} In addition, CAR⁺ T cells with chimeric CD28 signaling domain have potent antitumor effects in patients with B-cell leukemias and lymphomas.^{9, 10, 91} Patients with B-lineage acute lymphoblastic leukemia (ALL) that is refractory to conventional therapy have had high response rates with more than 90% achieving a CR.⁸ The sustained antitumor effect associated with these two CAR designs appears to be related to two events: the *in vivo* proliferation of genetically modified T cells, and whether the patient relapses with leukemic blasts that have lost expression of CD19.

The clinical data targeting acute versus chronic CD19⁺ leukemias have revealed differences in the ability of autologous CAR⁺ T cells to eliminate these hematologic malignancies. The targeting of ALL with

CD19-specific CARs activated through CD28 or CD137 appears to achieve superior rates of remission when compared to these same two CAR designs targeting chronic lymphocytic leukemia (CLL). These clinical data underscore the need to understand the microenvironment in which genetically modified T cells operate as well as nongenetically modified T cells in their ability to participate in a fully competent T-cell activation event.

CAR T cells targeting CD19 with a CD28 signaling domain have shown significant effects in patients with ALL⁶³; however, the outcomes for CLL patients with this CAR have been modest.⁹² Unlike the CARs with 4-1BB, these CARs with CD28 have not displayed long-term engraftment or persistence. Second-generation CD28-based CARs have shown improved survival over first-generation CD3 ζ CAR T cells, but the average survival of CAR T cells in patients with ALL treated at the Memorial Sloan Kettering Cancer Center was approximately 28 days.¹⁰ A phase I trial at NCI also demonstrated loss of persistence of CD19 CAR with CD28 signaling domain by 28 days in the majority of patients.⁹ However, both trials showed significant responses with maximum expansion of CAR T cells occurring within the first 14 days of infusion, which coincided with the disappearance of peripheral blasts in those patients with a positive response. Remarkably, most patients had regeneration of nonmalignant B cells by day 28, contrary to those patients on trials who had long-lived persistence of CD19 CAR T cells and sustained B-cell aplasia. The short duration of engraftment has made it more appealing to use as a bridge to transplant. Third-generation CARs, such as the CD20-specific CAR T cell with CD28 and 4-1BB costimulatory domains, have also shown early potential but need further evaluation.⁹³ Recently, Long et al. identified that 4-1BB diminishes exhaustion in persistently stimulated CAR T cells, implying a basis for its improved persistence in patients compared to those CAR T cells with CD28 signaling which likely augments exhaustion. They are conducting essential ongoing studies to elucidate potential pathways involved in CAR T-cell exhaustion.⁹⁴ Time will tell whether CAR T cells will replace the need for allogeneic stem cell transplantation, or if they will serve as a bridge to transplantation or as a form of consolidation therapy. It is not yet known if every tumor cell is eradicated in patients in remission, or if there are dormant tumor cells that are controlled by the long-term persistence of CAR T cells. Likely, different CAR designs may be needed for varying levels of “bioburden” of tumor cells.

Multiple early phase clinical trials have also highlighted the potential toxicities for CAR T-cell therapies. On-target, but off-tumor, toxicities are a consequence of varying levels of expression of the targeted tumor-associated antigen in normal tissues. Redirected T cells can be highly potent and toxic to normal tissues that express low levels of the targeted antigen. This can be extremely detrimental as described in 2006 by the Erasmus University in Rotterdam.⁹⁵ Here, patients infused with T cells modified with a CAR specific for carbonic anhydrase 9, which is physiologically expressed on bile duct epithelial cells, had significant levels of cholestasis. The severity of on-target, but off-tumor toxicities is dependent on whether the tissues expressing the targeted antigen are essential for survival, and if the injuries are manageable by other means. For example, in clinical trials investigating T cells modified with a CD19-specific CAR, the resulting profound B-cell aplasia post-therapy has been managed successfully by gamma-globulin replacement.⁸⁹ Conversely, low-level ERBB2 expression on lung epithelia may have led to fatal lung toxicity in a patient with colon cancer who received a high dose of third-generation CAR-modified T cells after intensive lymphodepletion, as reported by the NCI in Bethesda.²⁶ Baylor College of Medicine (BCM) is targeting ERBB2 in patients with glioblastoma multiforme; thus far, significant toxicities with lower doses of second-generation CAR-modified T cells without lymphodepletion have not been reported. When developing CARs/TCRs, analyzing in detail the target antigen expression on normal tissues and verifying normal cells' susceptibility to being killed by the genetically targeted T cells is critical. *In vitro* experiments will not always accurately predict these important data as the targeted

antigen could be expressed only at certain stages of differentiation (i.e., CD123) or could be altered by environmental signals (i.e., CD44v6). Therefore, *in vivo* experiments in appropriate preclinical models should be considered.

The most severe toxicity observed in patients treated with CAR-modified T cells has been the cytokine-release syndrome (CRS), which manifests as a rapid immune reaction driven by the massive release of a large group of cytokines, including IFN-gamma and IL-6.⁹⁶ The high levels of IFN-gamma result from a robust effector function of CAR-modified T cells, while increase in IL-6 is likely a consequence of a macrophage activation syndrome (MAS). In different trials, patients infused with second-generation CD19-specific CAR T cells developed a clinical picture resembling MAS (fever, hypotension, and hemophagocytic syndrome). Furthermore, because administration of the IL-6 receptor antagonist mAb tocilizumab leads to improvement in patients with this clinical picture,⁹⁶ it is believed that abnormal activation of macrophages may be the driving force behind CRS. A range of precautions has been proposed for mitigating the risk of life-threatening CRS, including splitting the initial dose of CAR-modified T cells over 3 days, strict monitoring of vital parameters during the first hours after infusion, early detection of clinical and laboratory signs heralding the syndrome such as C reactive protein (CRP),⁹⁷ and therapeutic interventions, including high-dose corticosteroids and tocilizumab. Although these measures have been variously effective, CRS remains a matter of serious concern for the overall safety of CAR-modified T cells. However, CRS may also serve as a biomarker indicating that the T-cell therapy is working. Interestingly, not all trials have reported CRS; disease status at time of infusion as well as type of CAR being infused may be variables influencing the risk for CRS.

The type of T-cell subset that is engineered for adoptive immunotherapy is associated with various clinical outcomes.⁵⁶ Initially, effector T cells (Teff) were postulated to be superior cellular substrate for adoptive immunotherapy because of their high cytotoxic ability. However, early clinical trials demonstrated that highly differentiated, tumor-specific Teff CD8⁺ T cells engrafted inadequately, were less capable of tumor killing compared with heterogeneous populations of TIL and had inferior clinical outcomes when infused in patients compared to those infused with less differentiated cell products. Animal studies have revealed that transfer of less differentiated T-cell populations has resulted in better *in vivo* expansion, persistence, and antitumor activity.⁹⁸ In nonhuman primates, the transfer of Teff CD8⁺ T cells derived from central memory T cells (Tcm), as opposed to effector memory-derived T cells, demonstrated long-term *in vivo* persistence and reacquired memory T-cell properties.⁸⁷ Continuing along this line of reasoning, Teff cells derived from the naive T-cell subset (Tn) have been shown to possess greater antitumor activity and enhanced *in vivo* persistence than transferred Tcm-derived Teff.⁹⁹ Recently, a stem cell memory T-cell subset (Tscm) has been newly identified and is described to be a long-lived memory T cell that has the capability of self-renewal, as well as multipotent capacity to derive all other T-cell memory subsets.¹⁰⁰ *In vivo* experiments demonstrated that Tscm were superior in antitumor response in comparison to all other T-cell memory subsets,¹⁰⁰ whereas recent clinical observations have indicated that expansion of CAR-modified T cells in patients was correlated solely with the frequency of a subset characterized to be closely related to Tscm,⁵¹ putatively making this the ideal T-cell subset for cellular engineering.

With a shifting paradigm focusing on utilizing lesser differentiated T-cell subsets and preserving their memory characteristics, several avenues are being investigated to manufacture the best quality T-cell product for adoptive transfer. One main approach has been to modify the culture conditions by selection of choice cytokines, and their combination, from the common gamma chain cytokine receptor family. Interleukin-7 (IL-7), IL-15, and IL-21 have emerged as key factors in the generation of desired Tcm and

Tscm subsets^{51, 101–103} Delving into the details of pathway signal transduction, accumulating evidence illustrates the importance of several pathways in dictating T-cell differentiation based on the strength of stimulation. Activation of the phosphatidylinositol 3-kinase (PI3K)/Akt pathway and mammalian target of rapamycin complex 1 (mTORC1) results in induction of T-cell differentiation programs in a progressive manner, and the use of AKT and mTOR inhibitors has been shown to enhance the generation of memory T cells,^{104–107} whereas activating Wnt signaling can enhance memory CD8⁺ T-cell formation including the Tscm subset.¹⁰⁸ While these pathways tie into nutrient sensing and signal integration, more specific details have emerged recently on the effects of T-cell metabolism on memory formation. Enhancing CD8 T-cell memory can be achieved by accentuating fatty acid oxidation in T cells or inhibiting glycolytic metabolism.^{107, 109, 110} The generation of such T cells with preserved memory characteristics is of great value and implementation in culture methods for clinical manufacture of such T cells is critical in the continued efforts to enhance T-cell quality for improved therapeutic potential.

Gamma delta T cells ($\gamma\delta$ T cells)

Gamma delta T cells (CD3⁺TCR $\gamma\delta$ ⁺) are a distinct population of T cells, although they represent only a minority of T cells in peripheral blood (1–5%). This specialized group of T cells recognizes an extensive range of targets in an MHC-unrestricted approach and manifests lytic activity and proinflammatory cytokine secretion. A better recovery of $\gamma\delta$ T lymphocytes after unmanipulated allogeneic bone marrow transplantation has been associated with an increased probability of leukemia-free survival, without an augmented risk of GvHD.¹¹¹ Aminobisphosphonates, for example, zoledronic acid, resulted in *in vivo* propagation of $\gamma\delta$ T cells, and the use of aminobisphosphonates has been translated into laboratory practice to grow $\gamma\delta$ T cells *ex vivo*¹¹²; however, only the V γ 9V δ 2 T-cell subset expands out with this approach. Recent advances using immobilized antigens, agonistic monoclonal antibodies (mAbs), tumor-derived aAPC, or combinations of activating mAbs and aAPC have been successful in expanding $\gamma\delta$ T cells with oligoclonal or polyclonal TCR repertoires.^{113, 114} These cells are being tested for ACT,^{115, 116} as both unmodified cells following *ex vivo* expansion¹¹⁷ and postgenetic engineering using CARs, as described earlier.¹¹⁸

NK cells

Approximately 10% of peripheral blood lymphocytes are NK cells,¹¹⁹ typically defined as CD56⁺ CD3[–], which are the primary cytotoxic component of the innate immune system. Having both cytotoxic and regulatory activity, NK cells recognize virus-infected or malignant cells that express danger signals (stress ligands and antibodies) and/or lack class I MHC¹²⁰ and are potent mediators of antibody-dependent cell cytotoxicity (ADCC).¹²¹ NK cells have been used in various ACT applications, and most commonly with peripheral blood NK cells from donor sources that have been collected and activated.¹²² Many *ex vivo* expansion protocols have been developed to increase both number and function of adoptively transferred NK cells.^{123–126} In addition to antitumor activity when delivered as ACT in nontransplant settings,^{127–132} NK cells may have potential for moderating infection and GvHD in the HSCT setting.^{133–137}

NKT cells

Smaller lymphocyte subsets, phenotypically in-between typical NK and T cells, have been tested for ACT. These NKT cells (CD3⁺CD56⁺), Invariant natural killer T cell (iNKT) cells (CD3⁺CD56⁺V α 24-J α 18), and CIK cells (CD3⁺CD56⁺) are effector lymphocyte subpopulations with potential advantages.

NKT cells modulate immune responses against malignant cells and stimulate effector cell functioning. Furthermore, NKT cells traffic to solid tumors in response to chemokines produced by tumor cells and tumor-associated macrophages (TAMs),^{138, 139} colocalize with TAMs and can kill or inhibit these growth-promoting cells¹⁴⁰ in a CD1d-dependent manner.¹⁴¹ Heczey et al.¹⁴² have shown in a mouse model that GD2-specific CAR renders NKT cells cytotoxic against neuroblastoma cells and results in potent *in vivo* antitumor activity without graft-versus-host disease. iNKT cells recognize a distinctive glycolipid molecule (α GalCer) in the context of the CD1d molecule, which can specifically expand them *ex vivo* as well as *in vivo*. Other NKT cell subsets have been delineated but have not been developed yet for ACT.

Regulatory T cells

Naturally occurring regulatory T cells (Treg) have potential for prevention of GvHD.^{143, 144} Novel methods of Treg expansion to generate clinically relevant numbers have been discovered recently.^{145, 146} Furthermore, in a xenogeneic model of GvHD, prophylactic injection of third-party, cord blood (CB)-derived, *ex vivo* expanded Treg led to the prevention of GvHD that translated into improved GvHD score, decreased circulating inflammatory cytokines and significantly superior overall survival.¹⁴⁷ Early clinical trials for prevention and treatment of GvHD by infusing regulatory T cells are currently under investigation. Several early clinical trials are being conducted to assess the effect on GvHD of infusing regulatory T cells following hematopoietic stem cell transplantation¹⁴⁸ and also the infusion of Treg in type I diabetes¹⁴⁹ (NCT01210664).

Dendritic cells

Sipuleucel-T is a type of autologous cellular immunotherapy that stimulates an immune response against the antigen prostatic acid phosphatase (PAP) expressed in most prostate cancer tissues and is FDA (Food and Drug Administration) approved for the treatment of metastatic hormone-refractory prostate cancer (HRPC) in patients who are asymptomatic or minimally symptomatic. Peripheral blood is collected from the patient via leukopheresis, from which peripheral blood mononuclear cells (PBMCs) are isolated. Antigen presenting cell (APC) precursors, consisting of CD54-positive cells that include DCs, are isolated from the PBMCs. The APCs are then activated *in vitro* with a recombinant human fusion protein, PAP-GM-CSF, and cultured for 40 h. The final product is reinfused into the patient, inducing T-cell immunity to tumors that express PAP. Full treatment included three infusions with two weeks between successive infusions.

Sipuleucel-T showed overall survival benefit to patients in three double-blind randomized phase III clinical trials: D9901, D9902a,¹⁵⁰ and IMPACT.¹⁵¹ The IMPACT trial served as the basis for licensing approval of sipuleucel-T by the FDA. This trial enrolled 512 patients (randomized in a 2 : 1 ratio) with asymptomatic or minimally symptomatic metastatic HRPC. The median survival time for patients receiving sipuleucel-T was 25.8 months compared to 21.7 months for placebo-treated patients ($P = 0.032$).

Sipuleucel-T was predicted to become a blockbuster. Unfortunately, Dendreon, the company which invented this innovative treatment, filed for bankruptcy in November 2014. Sales were hampered by the drug's high cost of \$93,000 for a course of treatment, the complexity of customizing the therapy for each patient, and competition from new oral therapies for prostate cancer that were recently FDA approved.

Off-the-shelf (OTS) therapy

To eliminate the need for patient-specific products for ACT and, therefore, decrease the time needed to

generate cellular therapy, efforts have been focused on generating “universal donor T cells” by the use of artificial nucleases to eliminate the expression of the endogenous TCRs, for example, zinc finger nucleases (ZFNs)^{84, 152} or transcription activator-like effector nucleases (TALENs).¹⁵³ Furthermore, reducing the allo-recognition of engineered T cells will lead potentially to an OTS (off-the-shelf) therapy by generating universal allogeneic TAA-specific T cells from one donor that may be administered to multiple recipients.

Cord blood

Umbilical CB is increasingly used to restore hematopoiesis in patients undergoing hematopoietic stem cell transplantation who lack a suitable HLA-matched donor. CB offers the advantage of lower incidence of graft-versus-host disease compared with bone marrow or mobilized peripheral blood. CB transplantation is limited by low cell doses and delays in neutrophil and platelet engraftment; however, CB progenitors expanded *ex vivo* before transplantation provide more rapid hematopoietic and immune reconstitution as well as less engraftment failure compared with unmanipulated CB. Infusion of expanded CB products is safe and associated with a low likelihood of severe reactions. Recent studies demonstrate that *ex vivo* fucosylation of CB can enhance engraftment in murine models, and *ex vivo* treatment of CB with fucosyltransferase (FT) VI before transplantation is currently under clinical evaluation.^{154–157}

CB also provides a source of cells for cellular therapy. Virus infections after stem cell transplantation are among the most common causes of death, especially after cord blood transplantation (CBT) where the CB does not contain appreciable numbers of virus-experienced T cells that can protect the recipient from infection. Hanley et al. developed a strategy to generate autologous CB T cells specific for CMV (cytomegalovirus) and adenovirus. On the basis of this approach, a clinical trial led by Bollard et al. has been testing the use of CB-derived multivirus-specific T cells targeting EBV, CMV, and adenovirus for the prevention and treatment of viral infections after transplantation.¹⁵⁸

As described previously, NK cells and Tregs can also be expanded from CB for use as cellular therapy. Resting CB NK cells are reported to have significantly less cytotoxicity compared with peripheral blood NK cells. However, after cytokine stimulation, the cytotoxicity of CB NK cells can be rapidly increased to levels comparable to peripheral blood NK cells. Brunstein et al. expanded Tregs obtained from a third party CB unit and infused them into 23 patients undergoing double CBT. No severe Treg-related acute toxicities were observed and incidence of GvHD was decreased.¹⁵⁹ Further studies indicate a higher incidence of viral infections in the first 30 days post Treg infusion; however, there were no adverse long-term effects.¹⁶⁰

Safety

In case of adverse events, a safety mechanism which would allow the rapid elimination of the infused cells is required for adoptively transferred cells, especially those that have been manipulated genetically. One such mechanism involves using an inducible safety switch that is based on the fusion of human caspase 9 to a modified human FK-binding protein, allowing conditional dimerization.¹⁶¹ When exposed to a synthetic dimerizing drug, the inducible caspase 9 (iCasp9) becomes activated and leads to the rapid death of cells expressing this construct. At the 2014 annual meeting of the American Society of Hematology, Bonini et al.¹⁶² presented their preliminary data from a phase III trial evaluating T cells genetically modified to express the HSV-TK suicide gene. In the phase II study, they showed that these cells can safely induce early immune reconstitution when given after a T-cell depleted haploidentical transplant and can be killed with a dose of ganciclovir if graft versus host occurs.¹⁶³

Conclusion

The potential of cellular therapy as an effective anticancer treatment is being realized, and as a result, immunotherapy was celebrated as the 2013 Science Breakthrough of the Year.¹⁶⁴ ACT utilizing engineered T cells has illustrated impressive effectiveness in clinical studies by attaining complete and deep responses in patients with treatment refractory disease. Major hurdles include incomplete understanding of TAA and the need for safer TAAs. Currently, hundreds of patients are being treated per year at individual academic centers. With ACT now being commercialized, the infrastructure to provide access to tens-of-thousands of patients across the United States and around the world is still needed.¹⁶⁵

Acknowledgments

The authors would like to thank Drs. Dean Lee, Hiroki Torikai, Lenka Hurton, and George McNamara for their contributions to this chapter.

Chapter 67

Cancer immunotherapy

Padmanee Sharma MD, PhD ■ Sumit K. Subudhi, MD, PhD ■ Karl Peggs, MD, MA, MRCP, FRCPath ■ Sangeeta Goswami, MD, PhD ■ Jianjun Gao, MD, PhD ■ Sergio Quezada, PhD ■ James P. Allison, PhD

Overview

The basic principles that guide cancer immunology are immune surveillance, immune editing, and immune tolerance. Rapid increase in the knowledge of the mechanistic details of these basic principles has led to clinical success in the treatment of cancer. In this chapter, we discuss the basic principles and recent advances in the field of basic and clinical immunotherapy that has given credence to the long-held belief that the immune system can be used to treat cancer. Further, we also focus on the role of combining different types of immunotherapies and other therapeutic modalities in the treatment of cancer.

Immunosurveillance

The idea that the immune system is capable of recognizing and responding to cancer is not novel. Paul Ehrlich (1854–1915) was perhaps first among the early visionaries to speculate that the immune system played a key role in suppressing tumors and that the incidence of cancer would be much greater were it not for the ability of the immune system to identify and eliminate nascent tumor cells, a concept that would later become known as the “immune surveillance” hypothesis when revisited over 50 years later by F. Macfarlane Burnet and Lewis Thomas.^{1–3} However, proof of concept remained elusive. While it was established that chemically induced tumors were immunogenic in murine models, spontaneously arising tumors behaved differently and were not rejected in similar experimental systems.⁴ These data informed a growing consensus that naturally arising tumors were nonimmunogenic and that the antigens targeted by the immune system in chemically induced tumors were perhaps unique to this setting. Moreover, profoundly immunosuppressed athymic mice did not have an increased frequency of tumors induced by a chemical carcinogen.⁵ Even though a notable excess of a variety of cancers occurring in immunosuppressed organ transplant recipients was recognized as inferential that immune surveillance occurred in humans, it remained frustratingly apparent by the early 1980s that definitive support from murine models was still lacking.³ Furthermore, while certain tumors were many hundred-fold more common in immune-suppressed individuals (e.g., some skin cancers, Kaposi's sarcoma, and lymphomas), the frequency of noncutaneous, nonvirally induced cancers was generally not increased, suggesting a potentially unique role for immune surveillance in malignancies associated with oncogenic viruses.^{6, 7} It was at this time that further inferential evidence in humans was beginning to emerge from the demonstration of increased rates of malignancies in patients with the newly defined acquired immunodeficiency syndrome.^{8, 9} However, the marked association with virally induced cancers was similarly striking.

Multiple strands of evidence would need to coalesce to rekindle enthusiasm for the therapeutic potential

of immune-based strategies. Aline van Pel, Thierry Boon, and Pierre van der Bruggen demonstrated that specific immunity to spontaneous tumors could be induced by vaccinating mice with mutagenized tumor cells¹⁰ and that tumor-specific antigens could be recognized by human cytolytic T cells.¹¹ Their studies showed that spontaneous tumors were not inherently deficient in tumor antigens but rather failed to stimulate an effective immune response. Critically, this failure could be overcome by vaccination in mouse models. The molecular definition of tumor antigens revolutionized the field of tumor immunology by legitimizing the mechanism by which the adaptive immune system discriminates between normal and neoplastic cells. The detection of tumor-specific responses in humans fueled speculation that these responses could be similarly manipulated to induce tumor eradication.¹² Simultaneously, it engendered rapid development of a new field within tumor immunology searching for tumor-associated antigens. Many tumor antigens have since been cloned. They can be broadly segregated into five major categories: (1) differentiation antigens, for example, melanocyte differentiation antigens, tyrosinase, gp-100, and Melan-A/MART-1; (2) mutational antigens, for example, abnormal forms of the tumor suppressor p53; (3) over-expressed normal antigens, for example, HER-2/neu and galectin-9; (4) cancer–testis (CT) antigens, for example, MAGE, LAGE, and NY-ESO-1; and (5) viral antigens, for example, EBV and HERV.^{13, 14}

Immunoediting

The demonstration of tumor-specific antigens in spontaneously arising tumors that could be recognized by the immune system gave further credence to the theory of immune surveillance but fell short of providing definitive proof. Antigenicity is necessary but not sufficient for immunogenicity. In 2001, Robert Schreiber in collaboration with Lloyd Old demonstrated that T lymphocytes and the immune stimulator IFN- γ cooperated to inhibit the development of spontaneous and carcinogen-induced tumors in mice genetically engineered to lack a functional immune system (RAG-2^{-/-}),¹⁵ but that some tumor cells escape detection and eventually cause cancer. They posited that driven by the selective pressure exerted by the immune system, the tumor cell population undergoes “immunoediting” becoming serially less immunogenic than the starting population, through a Darwinian environmental selection. Tumor cells from immunodeficient mice were more immunogenic than those from immunocompetent mice. Although sustaining the concept of immune surveillance, these data raised a potentially formidable obstacle to the delivery of clinically useful immunotherapies, suggesting that by the time a cancer becomes detectable it is already beyond the capabilities of the host immune system to eradicate it. Critically from the therapeutic standpoint, however, they showed that it was possible to make these cells visible to the immune system by increasing their antigen expression. Similar findings were obtained in RAG-1^{-/-} mice,¹⁶ and additional studies in mice specifically deficient in $\alpha\beta$ or $\gamma\delta$ T cells demonstrated that both cell types play critical and distinct roles in immune surveillance.^{17–19} Natural killer (NK) and natural killer T (NKT) cells were also implicated as mediators of protection in experiments in which they were depleted with either anti-NK1.1 monoclonal antibody or anti-asialo-GM1 before challenge with a chemical carcinogen.¹⁶ Further dissection of the critical effector mechanisms underlying host resistance to both chemically induced and spontaneous tumors has emerged from studies on IFN- γ and perforin demonstrating that deficiencies in either of these key immunologic molecules increases susceptibility to tumor growth.^{15, 20–26}

Immunoediting consists of three processes that occur either concurrently or sequentially.^{27–30} First, “elimination” in which immunity functions as an extrinsic tumor suppressor (equivalent to the original concept of immunosurveillance); second, “equilibrium” in which cancer cells survive but are held in check by the immune system; and third “escape” in which variant cancer cells with either reduced

immunogenicity or the capacity to attenuate or subvert immune responses grow into clinically apparent cancers. Data documenting the equilibrium process has remained relatively elusive and largely inferred from clinical observation. For example, the development of melanoma of donor origin in two recipients of renal allografts from the same donor who had been considered cured of melanoma treated 16 years previously.³¹ More recently, Schreiber's group has shown clearer evidence to support the existence of equilibrium in a chemically induced primary murine cancer model.³² Following exposure to the carcinogen, approximately 20% of animals developed fatal tumors but some survived with no overt evidence of tumor growth (apparent elimination). Immune suppression in these mice, however, resulted in the unmasking of dormant tumors, which then spread, ultimately killing the host. This effect was observed either following T cell depletion or following neutralization of IFN γ or IL-12 but not following depletion of NK cells suggesting a specific role for adaptive immunity in the maintenance of equilibrium. Furthermore, examination of stable dormant lesions revealed cancerous cells with similar morphological features to those in progressive lesions but with a lower proliferative index and increased apoptosis. The lesions were infiltrated with T cells suggesting a possible ongoing interaction with the host immune system. Engraftment of these cancerous cells into immunodeficient mice following a short period of *ex vivo* culture resulted in tumor growth. In contrast, transfer into immunocompetent recipients failed to induce tumor growth. Finally, tumor outgrowth occasionally occurred following a period of dormancy in immunocompetent animals, and in these cases, tumor cells were able to grow following transfer to immunocompetent mice, suggesting they had become less immunogenic. These data support the idea that tumor cells are unedited in equilibrium but become edited when they spontaneously escape immune control.

Immune tolerance

In 2005, Gerald Willmsky and Thomas Blankenstein suggested that sporadic tumors do not lose immunogenicity as would be predicted by models invoking immunoediting as the major reason for tumor escape but rather induce tolerance to evade immune detection.³³ The idea itself was not new and indeed had been part of the original immunoediting model. The message was simple and had major implications for the successful application of immune-based therapies. Progression of cancer may not depend solely on intrinsic adaptations of the tumor cells to evade detection but rather on changes exerted on host immunity to permit tumor growth. These mechanisms are neither mutually exclusive nor entirely separable, as upregulation of the surface expression of immunoinhibitory ligands by tumor cells can potentially abrogate immune responses just as efficiently as downregulation of immunostimulatory elements. Their studies involved the use of mouse model in which a viral cancer-promoting gene (SV40 large T) was controlled to activate rarely in random tissues. Although immune responses to the SV40 large T protein were initially detected in the mice, they subsequently developed immune tolerance, while the tumors remained capable of eliciting vigorous immunity when transferred into identical but tumor-free mice (with no clear evidence for immunoediting).

The apparent contradictions between this study and those supporting a more central importance for tumor-intrinsic editing may reflect differences in inherent tumor immunogenicity. More immunogenic tumors will, by definition, generate a more robust immune response. This likely relates partly to the ability of dendritic cells (DCs) to present tumor debris in an “immunogenic” manner, which in itself may reflect activation by secondary signals. In this setting, evolutionary pressures may be higher and immunoediting may be critical to immune evasion. For less immunogenic tumors that do not efficiently activate cellular antigen-presenting machinery, arousal of the immune system is minimal and escape variants are therefore less likely to be sculpted by immunoediting. In these cases, tolerance or immunological ignorance may

play variable roles.

Early failures—lessons learnt

The apparent confirmation of the validity of the immune surveillance hypothesis led to great enthusiasm for the development of immune-based anticancer therapies. However, attempts to target human cancers by immunotherapy have been significantly less successful than initially envisaged, leading to the marginalization of immunotherapies from the mainstream of oncologic practice. In patients presenting with cancer, endogenous antitumor immunity has been insufficient to eliminate the tumor. Immunological ignorance may contribute to tumor outgrowth, but antitumor responses are detectable in many of these patients. Indeed, it is clear from the detailed studies of immunoediting in mouse models that even when immunosurveillance fails, the relationship between the immune response and cancer continues to evolve. It is, therefore, likely that failure to eradicate tumors relates to limitations of effector function of the tumor-specific T cells. For maximal antitumor responses, it is necessary for appropriately targeted and activated effectors expressing T cell receptors (TCR) of sufficient avidity to migrate into tumor sites and maintain effector function within immunologically hostile tumor microenvironments. The presence of even large numbers of T cells capable of recognizing tumors is not singularly sufficient to mediate tumor regression, as evidenced by unrestricted tumor growth in TCR transgenic mice in which all of the T cells are capable of recognizing the tumor antigen.³⁴ Clinical studies of active immunization that have shown tumor growth can go unimpeded despite expansion of cancer cell-reactive T cells to 40% of the circulating CD8⁺ T cell repertoire.³⁵ There is now ample experimental evidence that functional systemic antitumor activity may not translate into tumor rejection, either because of lack of infiltration of T cells into the tumor³⁶ or because of local suppression of function within the tumor microenvironment. Although tumor-specific immunity is compromised in tumor-bearing mice, there is often no generalized immune deficiency,³⁷ indicating that tumors can specifically suppress the induction of effective antitumor immunity. This concept is perhaps best highlighted by concomitant immunity, wherein a mouse injected with a tumor will reject a subsequent challenge with the same tumor at a distant site, despite continued growth at the site of initial challenge.^{38–40} Intriguingly, however, it has been known for some time that the initial generation of concomitant immunity is eventually subverted during primary tumor progression by the establishment of CD4⁺ T cell-mediated immune suppression.^{41, 42} Despite these findings, the majority of approaches to tumor immunotherapy have until recently remained grounded in infectious disease principles. It had been established in the 1980s that antigen-specific CD8⁺ cytotoxic T cells (CTLs) were able to induce fully protective immunity against the influenza virus, leading to the development of effective vaccines.⁴³ The critical role of DCs in mediating these immune responses was recognized soon thereafter in the work of Ralph Steinman and others.⁴⁴ On the basis of growing evidence that tumors express antigens that can be presented by professional antigen-presenting cells (APCs) to induce the generation of tumor-specific CTLs, tumor immunotherapists aimed to parallel the successes achieved in developing vaccines for infectious diseases. Strategies have included vaccination with peptide, DNA, or antigen-pulsed DCs. Alternate approaches have been pursued based on directly enhancing effector number or function by adoptive transfer of T cells expanded from tumor-infiltrating lymphocytes (TILs), T cells activated *ex vivo* with cytokines, T cells together with cytokines, and more recently, T cells engineered to express receptors specific for tumor-associated antigens [either TCR or chimeric antigen receptors (CAR)].^{45–49} While these approaches have resulted in some impressive responses (reviewed later), they all potentially remain limited by the locally immunosuppressive microenvironment within the tumor, as evidenced by the evolution of such strategies to incorporate lymphodepleting or nonmyeloablative conditioning to enhance responses. As tumors can be viewed as taking advantage of

immunological ignorance, anergy, and suppression, effectively subjugating host responses to create isolated nodes of immune privilege within an otherwise immunologically intact host, they share many similarities with chronic pathogens such as *Mycobacterium tuberculosis*, *Listeria monocytogenes*, and *Leishmania major*. In this context, the challenges of delivering effective vaccines or immunotherapies are much more closely aligned with those associated with therapy of these established chronic infections than with acute infectious pathogens, in which the majority of the successes have come with prophylactic vaccination strategies. Further consideration of the mechanisms underlying the tumor escape phase of the immunoediting model may enlighten strategies to enhance the effectiveness of immunotherapies.

Mediators of immune escape

As previously discussed, the significant changes occurring in the escape phase may be broadly considered as those intrinsic to the tumor cells themselves and those involving the local tumor microenvironment, although the two overlap. Classic examples of the former include downregulation of costimulatory molecules (e.g., B7 molecules) by the tumor leading to activation of tumor-reactive T cells in the absence of appropriate costimulation and induction of anergy⁵⁰ or tumor antigen loss or downregulation of major histocompatibility complex (MHC) molecules, which can render the tumor cells essentially invisible to the immune system.⁵¹ Further examples include mutations conferring increased resistance to apoptosis induction or cell-mediated cytotoxicity, such as overexpression of antiapoptotic molecules (e.g., FLIP and BCL-X_L),^{52, 53} and mutations in FAS or the TRAIL-R (TNF-related apoptosis-inducing ligand receptor) death receptor 5 (DR5).^{54–56} Increased expression of T cell inhibitory molecules such as programmed cell death ligand 1 (PD-L1), B7-H3, B7x, HLA-G, and HLA-E by the tumor cells themselves or surrounding parenchyma (stromal or APCs) can directly inhibit effector T cell function, and in many cases, expression levels by the tumor or its microenvironment have been found to correlate inversely with tumor outcomes.^{57–65} Further proposed mediators of local immune suppression include soluble suppressive factors elaborated by the tumor or parenchyma such as IL-10, TGF- β , VEGF, or gangliosides.^{66–72} Indoleamine 2,3-dioxygenase (IDO) expression by tumor cells or IDO-competent APCs, such as some plasmacytoid dendritic cells (pDCs), can also contribute to acquired tolerance, both by direct suppression of T cells and by enhancement of local regulatory T cell-mediated suppression.^{73, 74} IDO catalyzes the rate-limiting step in tryptophan degradation, and the combination of local reduction in tryptophan levels (possibly via the intermediacy of causing cellular stress responses in effector T cells) and the production of immunomodulatory tryptophan metabolites appears to exert tolerogenic activity. Furthermore, IDO-expressing pDCs resident within tumor-draining lymph nodes appear to directly activate mature regulatory T cells, which can subsequently cause upregulation of PD-L1 by other DCs, which in turn inhibits effector T cell proliferation.⁷⁵ It has become clear that these regulatory networks are therefore extremely complex.⁷⁶ The presence of an array of other cell types capable of actively suppressing immune reactions such as CD4⁺CD25⁺ regulatory T cells (T_{reg}), IL-10-secreting regulatory T cells, CD1d-restricted (NKT) T cells, immature and plasmacytoid DCs (iDCs and pDCs), and myeloid-derived suppressor cells (MDSCs) (noncell-autonomous suppression) within the tumor or tumor-draining lymph nodes is clearly critical to induction and/or maintenance of local immune privilege in a number of systems.^{74, 77} Such cells may be preferentially recruited to these sites or expanded or induced therein.

Noncell-autonomous suppression

A number of CD4⁺ T cell subtypes with regulatory or suppressive activity are now recognized. They fall

broadly into one of two categories: those which are produced by the thymus, express CD4, CD25, GITR, OX40 and CTLA-4, and appear crucially dependent on the expression of the X-linked forkhead/winged helix transcription factor, Foxp3, for their development (so-called “naturally occurring” regulatory T cells)^{78–84} and those which arise from naïve CD4⁺ T cells as a result of “tolerogenic” encounters in the periphery. The latter “inducible” or “adaptive” regulatory T cells include interleukin (IL)-10-producing, Foxp3-negative Tr1 cells,^{85–87} transforming growth factor- β (TGF β)-producing Th3 cells,^{88, 89} and extra-thymically generated CD4⁺CD25⁺Foxp3⁺ iT_{reg} cells.^{90–95} In addition, CD4⁺CD25⁺Foxp3⁺ T cells with regulatory capabilities have been recognized.⁹⁶ The acquisition of regulatory phenotype and suppressive functions by conventional nonregulatory CD4⁺ T cells following exposure to antigens under certain conditions is now recognized as a major contributor to the maintenance of T cell homeostasis and control of inflammation. Of particular note, as thymic involution occurs relatively early in humans compared to mice and telomere length in human T_{reg} is considerably shorter, it is conceivable that peripheral conversion plays a far more important role in the maintenance of tolerance (and perhaps in immune subversion by tumors) in humans than in mice.^{97–99} Furthermore, if antigen encounter is required for conversion, it seems plausible that the regulatory pool expands at the expense of potential effector T cells, as precursors recognizing tumor antigens will be redirected into a suppressor rather than effector phenotype.^{96, 100, 101} Characterization of the conditions that drive such peripheral conversion is ongoing, but factors such as suboptimal antigen stimulation in combination with TGF- β appear to be important, both of which are likely to be relevant within the tumor microenvironment.^{93, 102} IDO produced by either tumor cells or parenchyma (e.g., pDCs) also favors conversion,^{75, 103, 104} and retinoic acid appears to be a key mediator in establishing intestinal tolerance.^{105–108} Regulatory T cells require TCR triggering to become functional, and at least some tumor-associated T_{reg} are specific for tumor antigens,¹⁰⁹ but once activated, they suppress in an antigen-independent manner. While adaptive Tr1 and Th3 cells exert suppression mostly through soluble factors (IL-10 and/or TGF- β), their Foxp3⁺ counterparts suppress via a variety of mechanisms, the relative importance of which remain to be fully elucidated in any given situation. Possible mechanisms include those involving CTLA-4, membrane-bound TGF- β , and pericellular generation of adenosine.^{110–116} Their expansive capacity to suppress multiple immune effector populations, including CD4⁺ and CD8⁺ T cells, B cells, and NK cells,¹¹⁷ makes them potentially attractive “nodal” targets for therapeutic intervention within immunosuppressive networks. To add further to this complexity, CD8⁺ T cells with suppressor activity have also been described.^{118–121} The dominant inhibitory potential of regulatory T cell populations in murine models of malignancy is well established,¹²² and more recently, their potential role in human malignancies has been demonstrated.¹²³ The mechanisms driving regulatory T cell expansion and accumulation in patients with cancer are not fully understood, but both proliferation of pre-existing T_{reg} and conversion from naïve precursors are likely to be involved.^{101, 124, 125} Their relative abundance predicts for tumor outcomes in murine models^{126, 127} and correlates inversely with outcomes in several epithelial carcinomas, including ovarian,^{123, 128} breast,¹²⁹ and hepatocellular carcinoma.¹³⁰ Intriguingly, in hematological malignancies, this association is reversed and high levels of regulatory T cells appear to confer improved prognoses (e.g., cutaneous T cell, follicular, and Hodgkin lymphoma).^{131–133} The level of infiltration of a tumor by regulatory T cells alone may not be the best predictor of outcome. Hodgkin lymphoma tumors contain significant populations of both IL-10-secreting Tr1 and CD4⁺CD25⁺ regulatory T cells, which induce a profoundly immunosuppressive environment.¹³⁴ Combined assessment of cells expressing Foxp3⁺ and of cells expressing TIA-1 (cytotoxic granule-associated RNA binding protein) offers a better predictor of response than either alone,¹³³ highlighting the potential importance of assessing the relative prevalence of

multiple infiltrating cellular populations. Indeed, identification of specific immunological signatures (based on flow cytometry, PCR, or microarray analyses¹³⁵) that predict outcomes or guide the institution or monitoring of therapies would be useful adjuncts to modern clinical practice. For example, it is plausible that tumors that contain few TILs, including T_{reg}, will respond well to treatments that aim to enhance CTL numbers, function, or migration, while those that contain significant numbers of T_{reg} would benefit from therapies aimed at reducing T_{reg} number or function. In addition, T_{reg} represent another regulatory mechanism that may be enhanced in response to, and hence limit the efficacy of, current immunotherapeutic interventions. For example, IL-2 has entered clinical trials for a number of human cancers such as melanoma, renal cell carcinoma, rhabdomyosarcoma, and ovarian cancer. Its initial use was based on the idea that it may directly enhance effector function of both innate and adaptive immune systems. However, IL-2 is recognized as crucial for the homeostasis and function of CD4⁺CD25⁺ regulatory T cells *in vivo*,^{136–138} and administration to patients with cancer results in increases in the numbers of peripheral T_{reg} cells and stimulation of expression of CXC-chemokine receptor 4 (CXCR4) and CCR4 on T_{reg} promoting their migration toward CXCL12 and CCL2 within the tumor microenvironment.^{139–141} As the targets of many cancer vaccination strategies are self-antigens, it is perhaps no surprise that “therapeutic” cancer vaccines can induce amplification of tumor-specific regulatory T cells.^{96, 142, 143} The “immunogenicity” or “tolerogenicity” of DCs thus becomes an increasingly important consideration in vaccination programs as even conventionally “mature” DCs can activate and expand autoantigen-specific T_{reg} cells.^{144, 145}

Multiple suppressive APC populations play a part in the generation of local immune privilege within tumors. Developing tumors may selectively recruit suppressive APCs or convert stimulatory APCs into suppressors, mirroring the situation with suppressive T cell populations. The molecular mechanisms underpinning active immune suppression by DC and myeloid populations have not been fully elucidated but include secretion of IL-10 and TGF- β , expression of FAS ligand, PDL1, and elaboration of intracellular IDO.^{146–150} IDO-competent DCs can induce apoptosis of activated T cells or either T cell anergy or conversion of effectors into T_{reg} as previously outlined.^{75, 103, 151, 152} The local balance of stimulatory versus suppressive APCs is probably critical in determining the eventual outcome of T cell encounter with antigen in these sites. It has also become clear that the interaction between DCs and T_{reg} is likely a two-way process.^{153–155} MDSCs are a heterogeneous group of cellular precursors of macrophages, granulocytes, DCs, and myeloid cells at earlier stages of differentiation, which express both the myeloid differentiation antigen Gr-1 (Ly6G and Ly6C) and CD11b in mice, and are generally defined as CD14[−]CD11b⁺ cells in humans (expressing CD33 but lacking expression of mature myeloid or lymphoid markers).^{156–158} Specific phenotypic markers that are reflective of suppressor function remain relatively poorly defined.¹⁵⁹ They consist of two major subsets of Ly6G⁺Ly6C^{low} granulocytic and Ly6G[−]Ly6C^{high} monocytic cells in mice. Numbers may correlate with clinical outcomes in human cancer.¹⁶⁰ Several tumor-derived cytokines have been implicated in the expansion of MDSC, including VEGF, IL-1 β , and GM-CSF.^{161–163} The mechanism of MDSC-mediated suppression is complex, involving contributions from either iNOS or arginase 1,^{147, 164–167} which enable MDSCs to inhibit T cell responses in various ways, including induction of apoptosis, inhibition of proliferation, or induction of a regulatory phenotype. Nitration of tyrosines in the TCR-CD8 complex appears to render CD8-expressing T cells unable to bind peptide-MHC complexes and to respond to the specific peptide, although they retain their ability to respond to nonspecific stimulation.¹⁶⁸ Type 2 macrophages found at tumor sites have also been implicated in suppression of tumor immunity and seem to share some functional properties with immature

myeloid cells.^{169, 170}

Even in those cancer immunotherapies that succeed in inducing systemic immunity, translation into clinically significant effects has been rare. It is likely that these mechanisms will need to be addressed in order to improve outcomes. What remains wholly unclear is how effectively this aim can be met and how many of the disparate targets will need to be tackled at any one time in order to generate locally curative immunity.

Moving toward clinically effective immunotherapies

In 1891, William Coley (1862–1936), a surgeon at New York Cancer Hospital which later became part of the Memorial Sloan-Kettering Cancer Center, found a patient who had been seen 7 years earlier with an inoperable malignant tumor in his neck, which had disappeared following cutaneous erysipelas caused by *Streptococcus pyogenes*.¹⁷¹ Coley reasoned that somehow the infection had been the precipitant of the remarkable recovery and found more than 20 published accounts before 1890 linking infection with erysipelas and antitumor responses. On this background, he pursued his own clinical trial using live bacteria, evolving to the use of heat-killed bacteria following some infection-related deaths.^{172, 173} It is remarkable to consider that even a minority of these patients were cured. The first patient he infected with erysipelas was apparently cured, dying 10 years later of unknown causes, as was the first patient treated with his mixed Coley Toxins, dying 25 years later of a heart attack. Ultimately, the antitumor effects were probably attributable to the production of tumor necrosis factor (TNF) in response to bacterial endotoxins.^{174, 175} While TNF itself has proven too toxic for reliable clinical usage, it is perhaps fitting that members of the TNF superfamily and their receptors remain important targets for current approaches to immunotherapy.

Adoptive cell therapy and the development of personalized immunotherapies

The growing appreciation that tumor-bearing hosts often do mount antitumor responses and that the greatest concentration of accessible tumor-specific cells may reside within the tumor itself (albeit held in check by local immunosuppressive factors) has informed the development of the field of adoptive cellular therapy (ACT). Furthermore, the failure of active immunization to affect major clinical responses has clearly not always reflected a lack of systemic antitumor immunity, although it has been argued that at least part of this failure relates to stimulation mainly of low-avidity effector T cells, itself reflecting the impact of central deletional tolerance on the anti-self T cell repertoire. These cells may be detectable by conventional immune monitoring techniques but have little chance of rejecting established tumors, particularly as access to and function within the tumor microenvironment are also likely to be limiting factors. Adoptive immunotherapy allows the identification of rare cells with relatively high affinity for tumor antigen that can be selected *in vitro* and expanded before transfer to the host. These cells can be activated *ex vivo* and directly administered, in the hope of avoiding the tolerizing factors present at the tumor site. Initially based on the idea that significantly increasing the number of tumor-reactive T cells will bypass all peripheral and local regulatory mechanisms, flooding the tumor and leading to prompt tumor rejection, modern approaches now recognize the importance of further manipulation of the host to optimize the chances of therapeutic success. These approaches have been developed in parallel with, and in many cases informed, studies advancing our knowledge of the factors limiting antitumor immunity, establishing that the administration of large numbers of activated high-affinity “tumor-specific” T cells to

a lymphodepleted host can overcome inhibitory factors and mediate effective cancer immunotherapy in some cases of human malignancy, particularly melanoma. Approaches to date have been largely based on the *in vitro* expansion of T cells obtained from tumor infiltrates and to a lesser degree from peripheral blood or lymph nodes biopsies. Transfers are often combined with administration of the T cell growth factor IL-2. It is likely that such strategies will continue to evolve, incorporating advances in immunostimulatory antibody research (see the following text).

Much of the pioneering work that laid the foundations for subsequent investigation of passive anticancer immunotherapy through ACT was performed by Nicholas Mitchison in the early 1950s,^{176, 177} and it is perhaps germane to reflect that the enhancing activity of host irradiation and the significance of antigen dose in determining immune response were already established in these seminal works.^{178–180} The further development of ACT owes much to work of the groups of Alexander Fefer, Martin Cheever, and Philip Greenberg at University of Washington, as well as those of Steven Rosenberg and Nicholas Restifo at National Cancer Institute. Fefer advanced the concept of “chemoimmunotherapy” in the late 1960s, demonstrating that an established syngeneic lymphoma (FBL-3 or Friend virus-induced lymphoma) could be eradicated after therapeutic combination of high doses of the alkylating agent cyclophosphamide and the transfer of immune cells from a mouse previously sensitized (or challenged) with the same tumor.¹⁸¹ Further studies helped to define some of the mechanisms underpinning this antitumor activity, demonstrating that it was either directed against tumor or virus antigens,^{182, 183} that T cells were the major mediators,¹⁸⁴ and that this activity could also be isolated from nonsensitized mice, although with a much diminished potency.¹⁸⁵ This last point is significant as it suggests that a population of tumor-reactive T cells may be present in naive animals. The work was extended to show that antitumor activity was enhanced in cells that had been resensitized and expanded with irradiated tumor *in vitro*,^{186–192} or even with cells that had been only primarily sensitized *in vitro*.¹⁸⁹ An important advance during this work was the introduction of IL-2 in the *in vitro* system that allowed further expansion of tumor-reactive T cells.¹⁸⁹ Finally, it was demonstrated that tumor-reactive T cells could be cultured *in vitro* for long periods of time and that after adoptive transfer they would proliferate and mediate specific tumor rejection that could be significantly augmented by the *in vivo* administration of IL-2.^{190–192} These studies were among the first to highlight the potential benefits of the use of IL-2 both *in vitro* and *in vivo* in mediating efficient expansion and enhancing tumor rejection.

Contemporaneously, Rosenberg also demonstrated the benefits of IL-2 in cancer immunotherapy. In what would become one of the cornerstones of ACT, a series of studies were published on the use of “T cell growth factor” (TCGF or IL-2) to clone and expand T cells,^{45, 193, 194} including its use for the isolation and expansion of T cells infiltrating solid tumors.¹⁹⁵ Importantly, human lymphocytes grown in TCGF were capable of killing autologous tumor cells *in vitro*.¹⁹⁶ This initial observation led to a series of publications documenting the role of IL-2 in the “Lymphokine-Activated Killer” (LAK) cell phenomena¹⁹⁷ and the capacity of these cells to kill fresh tumor cells *in vitro* and to induce regression of established disseminated lymphoma after adoptive transfer in animal models.¹⁹⁸ These studies were not limited to lymphoma and follow-up studies rapidly transitioned to treatment of established murine melanoma.¹⁹⁹ One notable feature of Rosenberg's approach to immunotherapy was its fast translation into clinical trials. In early 1984, the first phase I study on the use of LAK cells in humans was published.²⁰⁰ This trial demonstrated proof of concept, showing that large numbers of cells could be obtained by *in vitro* expansion of lymphocytes derived from peripheral blood, which could then be safely transferred back into patients with cancer. The study also documented evidence of migration of these cells into several organs and tissues including tumor. Two additional studies would be instrumental in the

advancement of ACT into the clinical setting, both relating to the *in vivo* administration of IL-2 in murine models.^{201, 202} Following phase I assessment of the safety of systemic administration of IL-2 in humans,²⁰³ a much larger study combining LAK and IL-2 administration was performed^{204, 205} in which more than 100 patients were treated with several courses of IL-2 and very high numbers of autologous LAK cells (up to 18.4×10^{10} cells). Complete or partial responses were seen in 21% of patients.²⁰⁵ Despite the favorable results obtained in these early clinical trials, data from murine models would redirect research away from LAK cells and toward the transfer of highly specific tumor-reactive T cells. The new approach was based in the isolation and *in vitro* expansion of TILs with IL-2.¹⁹⁵ These expanded TILs were 50–100 times more efficient than LAK cells in the treatment of various types of tumors and their potency was significantly enhanced when their transfer was combined with *in vivo* administration of cyclophosphamide and IL-2.⁴⁵ Clinical trials mirroring the murine experience and combining cyclophosphamide, TILs, and IL-2 have yielded complete and partial responses in up to 31% of patients with metastatic melanoma.²⁰⁶

These early studies have helped to inform the evolution of ACT as a form of personalized immunotherapy.^{207–209} The transition of ACT into the clinical setting has, however, not been without difficulties. These can be considered in two groups: factors relating to difficulties in generating appropriate products for adoptive transfer and factors relating to host or tumor resistance to transferred populations.

Generation of cellular therapy products

One major limitation has been the difficulty in accessing tumor samples containing sufficient numbers of viable TILs for successful isolation and expansion, which remains a limiting step in 60–70% of cases.²¹⁰ Alternative strategies for isolation of tumor-reactive lymphocytes (TRLs) would facilitate more widespread application. Such approaches include the use of T cells from peripheral blood or lymph node biopsies.^{211–214} Stimulation with antibodies directed against CD3 and the costimulatory receptor CD28 expressed on T cells are now widely used for the *ex vivo* expansion of large numbers of TRLs, while 4-1BB (see below) has recently attracted more attention both for activation and selection protocols.^{214–218} The identification and cloning of T cells with specificity to antigens that are either more abundant on or, less commonly, specific to tumor cells (NY-ESO-1, MART-1, tyrosinase, gp100, p53) have also contributed greatly to the development of alternatives to isolation of TILs. *In vitro* enrichment of such TRLs from peripheral blood by stimulation with their cognate antigen can be followed by expansion protocols as previously outlined. Much has been learnt about the optimal characteristics of the transferred cells, in terms of maximizing persistence and antitumor activity. Long-term *in vitro* culture has been demonstrated to be detrimental and the level of differentiation of T cells to be critical.²¹⁹ IL-2 drives differentiation of T cells to intermediate and late effector stages of differentiation. Furthermore, IL-2 may not be the optimal cytokine to use to enhance activity *in vivo* as it also expands T_{reg} and is associated with significant toxicity. The first issue may be addressed by the use of IL-7, IL-15, and IL-21, which seem to more specifically target effector T cells when applied either alone or in combination,²²⁰ rescuing tolerant $CD8^+$ T cells,²²¹ and generating less differentiated cells that appear to mediate greater antitumor immunity.^{222–224} IL-2 seems to be required not only for the expansion but also for the long-term persistence of the adoptively transferred T cells. More recent work in murine models suggests that cotransfer of $CD4^+$ T cells can supply IL-2 and sustain TRLs for long periods of time therefore increasing the antitumor effect of ACT.^{225–227} Numerous studies have demonstrated the requirement for $CD4^+$ T cell

help in the generation and/or maintenance of CD8⁺ T cell memory. In addition to provision of cytokine support, they have roles in DC conditioning and in recruitment and activation of macrophages and eosinophils, which can mediate antitumor effects.^{224, 228, 229}

More recent efforts have focused on genetic modification of T cells to engineer improved antitumor effects. Such approaches include the transfer of CAR that have antibody-based external receptor structures and cytosolic domains that encode signal transduction modules of the TCR.²³⁰ These allow redirection of T cell specificity in an MHC unrestricted manner, while delivering the equivalent intracellular signaling of TCR ligation. Furthermore, the impact of triggering can be enhanced by engineering the cytosolic domain for additional provision of counterfeit costimulatory signaling following ligation (mimicking CD28, 4-1BB, or OX40 ligation). Although incorporation of a CD28 component results in IL-2 release and limited proliferation (plus enhanced resistance to the suppressive effects of T_{reg}²³¹), T cell activation remains incomplete and can be further enhanced by inclusion of the 4-1BB or OX40 signaling domains within the construct.^{232, 233} A number of early trials have suggested that persistence of transgene-expressing cells may be limited to periods of days to weeks following transfer.^{49, 234–237} This may relate in part to the potential immunogenicity of the CAR. However, lessons learnt from earlier ACT studies may also be pertinent, and current approaches are focusing on the use of central rather than effector memory populations^{238, 239} and on the use of T cells specific for herpes viruses that are maintained at relatively high levels in humans owing to persistent stimulation via their native TCR by the “latent” viral reservoir.⁴⁹ Central memory cells represent the least differentiated end of the spectrum of antigen-experienced T cells and retain the developmental options of naive T cells including the capacity for marked clonal expansion. An alternative strategy to redirect T cell specificity relies on transduction of TCR genes from tumor-reactive clones, although this has the relative disadvantage of conferring MHC-restricted targeting.^{240–242} In the first clinical trial using this approach, a MART-1-reactive TCR was transduced into human lymphocytes, inducing the capacity to secrete effector cytokines and display lytic activity when cocultured with MART-1⁺ tumor cells. Following recipient lymphodepletion, these cells were infused into patients with melanoma who subsequently received infusions of IL-2 with the suggestion that the T cells may have effected clinical responses in 2/17 patients.⁴⁸ Potential factors limiting efficacy in this study include variable persistence of gene-modified cells and relatively low levels of surface expression of the introduced TCR. The latter relates to competition of exogenous TCR chains with endogenous TCR chains for assembly with CD3 components and also to the formation of mixed dimers of exogenous and endogenous TCR chains, restricting avidity.²⁴³ Indeed, gene optimization that elicits only modest increases in TCR expression may result in marked enhancement of antitumor activity.²⁴⁴ An alternate and perhaps complementary approach is to engineer cells in ways to enhance survival, for example, by transducing cells with chimeric GM-CSF-IL-2 receptors (designed to deliver an IL-2 signal when binding GM-CSF in an autocrine loop²⁴⁵), CD28,²⁴⁶ or the catalytic subunit of telomerase.²⁴⁷ The ability to further modify these lymphocytes, to make them less subject to the suppressive influences present in the tumor microenvironment such as the introduction of genes encoding dominant-negative TGF- β or inhibitory RNAs to prevent the expression of inhibitory molecules such as CTLA-4 and PD-1, could potentially further enhance the activity of the transferred cells.²⁴⁸ Alternatively, overexpression of selected costimulatory ligands may induce auto- and transcostimulation, resulting in potent antitumor activity.²⁴⁹

The role of lymphodepletion

Transfer of tumor-specific T cells into unmanipulated hosts is often accompanied by a failure to demonstrate engraftment or persistence of transferred cells, or only modest antitumor effects on bulky tumors,^{250–252} and it is likely that further attention to both intrinsic and extrinsic inhibitory factors will be critical to successful clinical application. Profound lymphodepletion of the host substantially increases the effectiveness of cell transfer therapy, likely by a number of mechanisms including elimination of cytokine sinks (lymphocytes competing with transferred cells for homeostatic cytokines such as IL-7 and IL-15), elimination of T_{reg} and myeloid suppressor cells, and provision of an environment driving homeostatic proliferation.^{225, 238, 253–255} The T_{reg} content of the adoptively transferred population may also be important.²²⁵ In addition to effects on immune cells, host irradiation can sensitize the stromal cells surrounding the tumor²⁵⁶ and induce upregulation of adhesion molecules on tumor vasculature.^{257, 258} Finally, host irradiation releases LPS from commensal gut micro-flora, which further matures DCs to activate tumor-reactive T cells,²⁵⁹ and escalation to ablative conditioning with hematopoietic stem cell rescue may further promote the expansion and function of adoptively transferred CD8⁺ T cells.²⁶⁰

Current position of adoptive T cell transfer

Experience with ACT is, therefore, generally encouraging, but it is important to recognize that use of TILs may favor inclusion of those with an immune system inherently more capable of mediating antitumor activity. As the level of tumor infiltration with TILs has been shown to correlate with outcome in a number of studies of human malignancy, the ability to generate a therapeutic product from TILs could be a predictive biomarker for outcome. The achievement of higher response rates in the significantly less selected groups receiving CAR- or TCR-transduced ACT will be an important step forward in this regard, but current results have demonstrated results more typical of other single-agent immunotherapeutic approaches. In the absence of large randomized studies, it is impossible to assess the relative contributions of lymphodepleting chemoradiotherapy, IL-2, and ACT to overall results. The number of randomized studies performed in the field remains limited (reviewed in²¹¹) and only one of these had a positive outcome. Intriguingly, this was in patients with hepatocellular carcinoma rather than the more commonly treated melanoma or renal cancer. Patients received peripheral blood T cells activated *in vitro* with anti-CD3 and IL-2 in the adjuvant setting following surgical resection of the primary tumor ($n = 150$). Tumor recurrence was reduced 41% in those receiving ACT with longer progression-free survival ($p = 0.01$), and a trend toward longer overall survival ($p = 0.09$).²⁶¹ There was no such benefit in a more recent trial of patients with stage III melanoma randomized to receive TIL plus IL-2 or IL-2 alone.^{262, 263} One further major problem with the application of ACT is that it is a highly personalized treatment and does not easily fit into current modes of oncological practice. Generation of appropriate cellular products is labor-intensive and requires significant laboratory expertise. Furthermore, each patient essentially requires the generation of new reagent limiting the opportunities for easy commercialization, and suggesting that delivery may be considered more service-oriented rather than product-related (as in the case of most drugs). This aspect, combined with increasing awareness that minimizing *ex vivo* T cell manipulation may be advantageous in terms of clinical outcomes, is driving the current evolution of clinical strategies. The issue is also informed by topical debate concerning the nature of the best targets for immunotherapy in terms of public versus private antigens. While we have historically focused on “public” or shared tumor antigens such as MART-1 and gp100, accepting that antitumor efficacy may then be inextricably linked to tissue-specific toxicity, “private” or patient-specific antigens generated as a consequence of the evolution of the malignant phenotype and inherent genetic instability within these lesions have a number of attractive advantages,^{264, 265} an idea we shall return to later.²⁶⁶ The acceptance

of tissue-specific toxicity leads to the concept of “dispensable tissues,”²⁶⁷ which may be acceptable in the case of vitiligo with therapies targeting melanoma or B cell deficiency following anti-CD20 therapy but will be more of an issue if the target is shared by a vital organ.²³⁵ The parallel development of “off the shelf” reagents for enhancing immunity offers a number of interesting approaches to further enhance the efficacy of ACT. The recently reported clinical successes with genetically modified T cell therapies²⁶⁸ and renewed interest by pharmaceutical companies to develop these strategies for eventual approval of ACT for the treatment of patients holds great promise for the future.

Promoting DC function

Detailed discussion of the newer approaches aimed at enhancing antigen presentation in efforts to improve antitumor immunity is beyond the scope of this chapter. However, a few deserve brief mention. DCs are uniquely specialized to present processed antigens to stimulate antigen-specific effector responses. Progress in our understanding of factors associated with DC-induced immunogenicity rather than tolerogenicity has informed the development of clinical therapeutics, yet it remains apparent that even conventionally “mature” DCs (with high levels of expression of costimulatory molecules) can mediate immune suppressive activity.^{142, 269–271} Cytokines known to enhance DC immunogenicity (e.g., IFNs, IL-15, TNF, and IL-1) are generally insufficient to induce robust adaptive immunity when given in isolation.²⁷²

Toll-like receptor (TLR) agonists are showing some early promise in clinical studies, particularly in combination with other therapeutic modalities. Unmethylated CpG oligodeoxynucleotides (ODNs) bind TLR9 on pDCs and B cells, inducing Th1 polarized immune responses and regression of established tumors in mice, as well as activity in phase I and II clinical trials.^{273–280} TLR9-activated APCs activate NK cells, enhance expression of Fc receptors on polymorphonuclear leukocytes, and promote CTL activation. However, it is important to remain aware that in some settings TLR ligands provoke immunosuppressive or tolerogenic responses.^{281, 282} The context of TLR signaling may well be important and much remains to be learnt about how the immune system discriminates between pathogenic inflammatory insults and the “beneficial” inflammation associated with commensal organisms or wound healing in order to iterate either immune activation or suppression in the light of apparently similar inflammatory signaling. The imidazoquinolone Imiquimod ligates TLR7 (and to a lesser degree TLR8) and when applied topically stimulates recruitment of pDCs and myeloid-derived DCs into tumors, both of which are implicated in subsequent antitumor activity.²⁸³ It may also directly induce upregulation of vascular E-selectin and inhibit regulatory T cell function (including both T_{reg} and novel $\gamma\delta$ suppressor populations),^{284–286} and has been demonstrated to exhibit exciting clinical activity in vulval intraepithelial neoplasias.^{287, 288} Activation of invariant NKT cells by the CD1d-reactive glycolipids α -galactosylceramide (α -GalCer) or its analog α -C-galactosylceramide (α -C-GalCer) provides an alternative route to DC maturation, enhancing antitumor activity in a number of murine models.^{289–291} Both CpG and imiquimod also induced increased levels of tumor antigen-specific T cells in melanoma patients vaccinated with recombinant protein tumor antigen NY-ESO-1.^{292, 293}

Another attractive target for enhancing APC performance is CD40. This molecule belongs to the tumor necrosis factor receptor (TNFR) superfamily (see below), and ligation is crucial for development of competent cellular immune responses, at least in part through the induction of IL-12 secretion by DCs. It is also critical for affinity maturation and heavy chain class switching during humoral responses.^{228, 294} It is constitutively expressed by B cells and DCs and is also expressed by macrophages, T cells, and

nonhematopoietic cells such as vascular endothelium.²⁹⁵ Its ligand CD40L is principally expressed by activated CD4⁺ T helper cells, although it is also expressed by plasmacytoid DCs, activated NK cells, and platelets. CD40 ligation is critical for licensing of DCs, providing the temporal bridge between CD4⁺ T cell help and effective generation of CD8⁺ CTL responses by “conditioning” DCs (enhancing activation and costimulatory capacity). This activity may be reliant on CD27:CD70 interactions, as blocking CD70 during anti-CD40 treatment abrogates protection in a murine lymphoma model.²⁹⁶ CD40 stimulation can potentially effect antitumor responses in a number of ways.^{297, 298} Firstly, the expression of CD40 by a number of lymphoma and carcinoma tumor cells suggests that monoclonal antibodies to CD40 could elicit complement-dependent cellular cytotoxicity (CDC) or antibody-dependent cellular cytotoxicity (ADCC). Secondly, CD40 signaling has been reported to directly induce apoptosis in some tumor cells, notably in high grade B cell non-Hodgkin lymphomas and epithelial carcinomas.^{299–301} Finally, by enhancing antigen-presenting capacity CD40 ligation may directly, particularly in the case of B cell lymphomas, or indirectly enhance presentation of tumor antigens to the immune system, at least partially overcoming the requirement for CD4⁺ T cell help in the generation of effective and durable antitumor CTL responses.^{302–304} CD40 ligation by either CD40L or stimulatory anti-CD40 monoclonal antibodies *in vitro* or *in vivo* enhances antitumor vaccine efficiency in a number of murine models of malignancy.^{297, 305} By extension, forced expression of CD40L by either DC vaccines or B cell tumors such as chronic lymphocytic leukemia using recombinant adenoviral vectors can enhance antitumor T cell responses and induce some level of clinical response.^{306, 307} Of note, however, these responses may be transient and associated with rapid engagement of host immune inhibitory circuits (e.g., T_{reg}), suggesting that combinatorial approaches might be more effective.¹⁴³ Clinical trials with recombinant CD40L trimer or anti-CD40 antibodies have suggested that *in vivo* triggering of CD40 on tumors and/or APCs can induce responses in a minority of patients, particularly in B cell lymphomas or melanoma, although toxicities including systemic inflammatory syndromes and venous thromboses have been documented.^{308–310} A novel approach utilized electroporation to introduce mRNA encoding CD40 ligand, constitutively active TLR4, CD70, and multiple melanoma tumor antigens into autologous DCs (TriMix-DC). Tumor regressions were observed in 6 of 17 patients who had received interferon- α -2b in combination with TriMix-DC.³¹¹ Further, combination of anti-CD40 antibody and chemotherapy agent, gemcitabine, showed tumor regression in both human and mice.³¹² Antitumor responses were attributed to activated macrophages that infiltrated tumor stroma. These agents may prove to be valuable components of future therapeutic combinatorial strategies.³¹³

Directly promoting T cell function

Immune activation is critically regulated by two major families of coreceptors expressed by T cells: the immunoglobulin-like (Ig) superfamily and the TNFR superfamily.^{314, 315} Costimulatory members of the former include CD28 and inducible T-cell costimulator (ICOS), while OX40, CD27, 4-1BB, CD30, GITR (glucocorticoid-induced TNFR family related gene), and HVEM (herpes-virus entry mediator) are members of the latter. The most well-established inhibitory members of the immunoglobulin “costimulatory” family include cytotoxic T-lymphocyte-associated-antigen 4 (CTLA-4) and programmed cell death 1 (PD1). B- and T-lymphocyte attenuator (BTLA) is the most recently described member of the family and also appears to mediate inhibitory effects on T cell activation.³¹⁶ The identities of the receptors for the newer members of the B7 ligand family (B7-H3 and B7x/B7-H4) remain elusive, but these receptors may also mediate significant inhibitory activity, perhaps more so in the periphery given the tissue distribution of these more recently identified ligands. Stimulatory or blocking monoclonal

antibodies ([Figure 1](#)) are being extensively investigated for their abilities to enhance T cell numbers, function, and maintenance of immunological memory.^{317, 318}

Figure 1 Potential targets for immunostimulatory therapies. The majority of T cell coreceptors that are upregulated upon activation of effector cells are also expressed by regulatory T cell populations and both cell types may be important targets for therapeutic interventions.

Stimulatory antibodies to 4-1BB (CD137), OX40 (CD134), and GITR—accentuating the positive?

A number of the members of the TNFR family are appealing candidates for the development of targeted therapeutics. To date, there has been relatively little data regarding agonistic anti-CD27 antibodies in murine tumor models, although it does appear to be a potentially interesting target for boosting antitumor immunity.²⁹⁶ Greater attention has been focused on 4-1BB and OX40. 4-1BB is expressed on activated T cells (including T_{reg} and NKT cells), activated NK and DCs, eosinophils, mast cells, and endothelial cells in some metastatic tumors.^{315, 319–321} Its ligand 4-1BBL is expressed on activated DCs, B cells, and macrophages. Ligation on T cells results in upregulation of antiapoptotic genes and protection from activation-induced cell death (AICD),³²² enhancing establishment of durable memory CTLs.³²³ The upregulation of 4-1BB on antigen-experienced T cells suggests that anti-4-1BB may differentially target these primed T cells, preferentially influencing those T cells with highest avidity receptors and partially

explaining why 4-1BB costimulation may be superior to CD28 costimulation for the generation of antigen-specific cells for adoptive therapies.²¹⁷ While it is assumed that costimulation of CD8⁺ T cells is the principal mechanism of action of anti-4-1BB, various other immunomodulatory activities may contribute. In this respect, a common theme developing in our understanding of the function of immunostimulatory antibodies is their possible multiplicity of function, reflecting the cellular distribution of the receptors. Thus, (1) activation of APCs,³²⁴ (2) reduction in T_{reg} suppressive capacity³²⁵ or enhancement of effector resistance to suppression,³²⁶ and (3) costimulation of CD4⁺ and CD8⁺ T cells are all supported by experimental data. Furthermore, activated NK cells (possibly equivalent to interferon-producing killer DCs), IKDC,^{327–329} and NKT cells may be relevant targets for antitumor activity.^{320, 321, 330, 331} Reverse signaling into cells expressing the ligands for a number of Ig or TNFR superfamily members (see also GITR:GITRL, CTLA-4:B7, and PD-1:PD-L1 below) is another recurring theme of recent investigations into immune modulating functions of these molecules. In the case of 4-1BBL, this may result in enhanced production of inflammatory mediators or enhanced cell adhesion, facilitating egress of immune effectors into sites of inflammation.^{332, 333} There are conflicting data as to whether 4-1BB ligation on T_{reg} results in enhanced or reduced suppressive capacity,^{325, 334, 335} and synergy of antitumor activity with approaches that are thought to target T_{reg} number or function has been taken as evidence that any 4-1BB-mediated inhibitory effects on T_{reg} function may be relatively modest.^{336–338} Forced expression of 4-1BBL in murine tumors enhances immunogenicity, reducing engraftment rates in immune competent recipients, although growth of untransfected cells is only modestly affected in relatively poorly immunogenic tumors.³²⁰ Agonistic anti-4-1BB monoclonal antibodies enhance antitumor CTL responses, enabling rejection of established syngeneic tumor cell lines.^{339–341} Activity appears critically dependent on CD8⁺ T cells and (in most studies) NK cells, with the role of CD4⁺ T cells varying in different tumor models.^{320, 340–343} Just as with other immunostimulatory antibodies, combination with vaccination strategies enhances activity in poorly immunogenic tumor models.^{344, 345} Coadministration with transgenic tumor-specific CTL enhances antitumor activity, apparently via a reduction in AICD rather than enhanced proliferation.³⁴⁶ These data demonstrate the activity of anti-4-1BB antibodies in the absence of CD4⁺ T cell help, albeit in immunodeficient hosts (RAG2^{-/-}) lacking normal regulatory mechanisms. Early experience with a humanized clinical grade antibody (BMS-663513/Urelumab) has targeted mainly patients with melanoma and renal cell carcinoma.³⁴⁷ The antibody initially appeared to be well tolerated with some evidence of activity (6% partial responses in melanoma patients), once again demonstrating the probable need to evaluate combinatorial approaches (and also define the optimal dosing strategy).^{336, 348, 349}

Two particularly intriguing and seemingly paradoxical features of anti-4-1BB monoclonal antibodies are their ability to ameliorate autoimmunity^{350–352} and to suppress humoral immunity in mice.³⁵³ Although the precise mechanism(s) remain obscure, possibilities include effects on T_{reg} function, interference with CD4⁺ T cell activation (possibly via the intermediacy of expansion of IFN γ -secreting CD11c⁺CD8⁺ T cells³⁵⁴), or IFN γ -dependent induction of IDO.^{351, 352} This highlights the potential importance of the timing of immunomodulatory interventions, as CD4 downregulation may be induced by AICD, which can also occur in CD8⁺ T cells if exposure to anti-4-1BB occurs immediately after antigen encounter.^{355, 356} While this suppressive activity has been proposed to be advantageous in terms of limiting possible antibody-mediated toxicities, it is recognized that it might also be deleterious to the development of optimal anticancer immunity. Preclinical studies with anti-CD137 in murine models showed promising activity in combination with antibodies directly targeting the tumor. Most recently, it was shown that anti-CD137 increases efficacy of cetuximab (anti-EGFR mAb) in murine xenograft models,³⁵⁷ making it another

suitable target for combination therapy. Clinical studies with PF-05082566 (Pfizer, anti-CD137) in combination with rituximab in B cell lymphoma and MK-3475 (anti-PD-1) in solid tumor is currently ongoing.

OX40 is expressed transiently on activated CD4⁺ and CD8⁺ T cells, functioning as a late costimulatory receptor.^{315, 358} It is also expressed by NKT cells, where triggering may be required for optimal activation by α -GalCer,³⁵⁹ and T_{reg}. Its ligand OX40L is expressed in a similar distribution to 4-1BBL, on activated DCs, B cells, and macrophages, as well as activated T cells and endothelial cells.³¹⁵ OX40 ligation regulates CD4⁺ and CD8⁺ T cell survival and memory generation, preventing T cell tolerance.^{360–363} It also impairs the suppressor functions of T_{reg}.^{364, 365} Furthermore, OX40 triggering appears to be antagonistic for Foxp3 induction in antigen-responding naïve CD4⁺ T cells, effectively suppressing the generation of iT_{reg},^{366, 367} and blocks the generation of IL-10-producing Tr1 cells,³⁶⁸ suggesting that OX40 may antagonize the generation of a number of different inducible regulatory T cell populations. 4-1BB and OX40 act independently to facilitate robust CD8 and CD4 recall responses, overlapping in their intracellular signaling pathways,³⁶⁹ yet neither 4-1BB nor GITR signaling seem to block the generation of Tr1,³⁶⁸ and there are currently no reports illustrating whether they influence Foxp3⁺ iT_{reg} induction. As with 4-1BBL, forced expression of OX40L by tumor cells increases immunogenicity, with tumor rejection dependent on both CD4⁺ and CD8⁺ T cells.³⁷⁰ Furthermore, intratumoral injection of DCs modified to have enhanced expression of OX40L can effect tumor rejection in murine models that is dependent on CD8⁺ CTL responses, themselves dependent on CD4⁺ T cells and NKT cells.³⁵⁹ Agonistic anti-OX40 antibodies also increase antitumor activity in a number of transplantable tumor models.³⁷¹ Concomitant activity on both effector and regulatory compartments may be a prerequisite of effective rejection of established tumors.⁸¹ In preclinical models, OX40 ligation enhances several other immunostimulatory approaches.^{372–376} A phase I clinical trial using a mouse monoclonal antibody that agonizes human OX40 signaling in patients with advanced cancer showed that patients treated with one course of the anti-OX40 mAb (9B12) had an acceptable toxicity profile and regression of at least one metastatic lesion in 12 of 30 patients.³⁷⁷

In common with both 4-1BB and OX40, GITR is transiently expressed on activated T cells.^{378, 379} It is also constitutively expressed at high levels on T_{reg} with further induction following activation.^{380, 381} Its ligand GITRL is expressed at low levels on B cells, macrophages, and some DCs, transiently increasing following activation. GITR ligation stimulates both proliferation and function of CD4⁺ and CD8⁺ T cells.³⁸² Its activity on T_{reg} has remained more contentious.^{383, 384} Anti-GITR antibodies reduce suppression in cocultures of CD4⁺CD25[−] effectors and CD4⁺CD25⁺ T_{reg}, but whether this relates to reduced T_{reg} suppressor function, increased resistance of effectors to the preserved suppressor function of T_{reg}, or a combination of both, has yet to be definitively demonstrated. Experiments using mixtures of GITR^{+/+} and GITR^{−/−} effector and regulatory cells suggest that ligation of GITR on the effector population rather than the regulatory population is critical for abrogating suppression,³⁸⁴ suggesting that enhanced effector resistance to suppression may be key in *in vitro* assays. Injection of adenovirus expressing recombinant GITRL into B16 melanoma promotes T cell infiltration and reduced tumor volumes,³⁸⁵ while agonistic anti-GITR antibodies have been shown to enhance both rejection of established methylcholanthrene-induced fibrosarcomas and to enhance systemic antitumor responses and concomitant immunity when given following B16 melanoma challenge.^{386, 387} Furthermore, the same antibody also enhances the impact of DNA vaccination in terms of generation of systemic immunity and enhancing

Stimulation through checkpoint blockade of CTLA-4 (CD152), PD-1 (CD279), PD-L1 (CD274)—eliminating the negative

In contrast to the TNFR superfamily, the existence of coinhibitory receptors mediating direct downregulation of lymphocyte activation and/or effector function has been a recognized feature of the Ig superfamily for some time. Indeed, the coinhibitory receptor–ligand members outnumber the costimulatory members within this superfamily, engendering the idea of regulatory or inhibitory checkpoint blockade as a therapeutic anticancer strategy by James Allison two decades ago.³⁸⁹ Blockade of inhibitory immune checkpoints for therapeutic benefit offers considerable promise, particularly as combination with other treatment modalities that promote cross-priming of antitumor immunity may yield additive or synergistic activity. The first strategy shown in both murine models and patients to elicit regression of tumors was antibody blockade of CTLA-4.^{389, 390}

CTLA-4 is expressed by activated CD4⁺ and CD8⁺ T cells, although its surface expression is tightly regulated with a short half-life. While expression is difficult to detect on resting T cells, it influences some of the earliest events in T cell activation,^{391, 392} being rapidly mobilized from intracellular vesicles in the proximity to the MTOC to the immune synapse after TCR engagement.³⁹³ In the unphosphorylated state, an intracellular localization motif mediates rapid binding to AP-2, endocytosis, and lysosomal targeting.³⁹⁴ It is constitutively expressed by natural and inducible Foxp3⁺ T_{reg}, although the majority of CTLA-4 is again found intracellularly, even following activation. CTLA-4 shares the B7-1 (CD80) and B7-2 (CD86) ligands with CD28, a critical costimulatory molecule. Ligation of CD28 in concert with TCR stimulation enhances T cell proliferation by inducing production of IL-2 and antiapoptotic factors, decreasing the number of ligated TCR that are required for a given biological response.³⁹⁵ CTLA-4 engagement selectively blocks augmentation of gene regulations by CD28-mediated costimulation but does not ablate gene regulation induced by TCR triggering alone.³⁹⁶ The function of CTLA-4 as a negative regulator of CD28-dependent T cell responses is most strikingly demonstrated by the phenotype of CTLA-4 knock-out mice, which succumb to a rapidly lethal polyclonal CD4-dependent lymphoproliferation within 3–4 weeks of birth.^{397, 398} CTLA-4 has significantly higher affinities for both B7 ligands than does CD28 and has a higher affinity for B7-1 than B7-2, whereas that of CD28 for B7-2 appears greater than that for B7-1.³⁹⁹ Although initial measurements suggested a 100- to 1000-fold increased affinity and avidity for CTLA-4:B7 interactions, more recent data using surface plasmon resonance experiments revealed that the interactions between these molecules are 10-fold weaker owing to rapid dissociation rates. Accumulation of both CD28 and CTLA-4 at the synapse is influenced by ligand binding. CD28 is recruited to the synapse in the absence of B7-1 and B7-2 binding but is not effectively stabilized there, and its localization can be disrupted by CTLA-4. The latter is more critically dependent on ligand binding for concentration at the synapse.⁴⁰⁰ CTLA-4 may, therefore, both out-compete CD28 for ligand, particularly when ligand densities are limiting and be able to exclude CD28 from the immunological synapse by virtue of the generation of extended high-affinity lattices of alternating CTLA-4 and B7-1 homodimers.⁴⁰¹ For this reason, the tight spatial and temporal regulation of CTLA-4 expression is likely to be critical for determining the outcome of CD28-mediated signaling. Furthermore, CTLA-4 ligation induces decreased production of cytokines (particularly IL-2 and its receptor) and cell cycle arrest in G₁, suggesting that both ligation-dependent and ligation-independent mechanisms contribute to its negative regulatory function. Finally, CTLA-4 has an important role in T_{reg}-mediated suppression, as evidenced by

the recent demonstration that T_{reg}-specific CTLA-4 deficiency in conditional knock-out (CKO) mice is associated with a profound reduction in their suppressive capacity.¹¹² CKO mice developed a lethal autoimmune lymphoproliferative syndrome with a slightly slower tempo than CTLA-4^{-/-} mice. The mechanism(s) by which CTLA-4 mediates these T_{reg}-associated effects remain(s) unclear but may be dependent on reverse signaling into B7-expressing cells.^{110, 111} Certain subsets of DCs are induced to express IDO subsequent to CTLA-4 binding to DC-associated B7,^{110, 402} and induction of constitutive expression of inducible cAMP early repressor/cAMP response element modulator (ICER/CREM) attenuates IL-2 production in activated CD25⁺Foxp3⁻ T cell effectors following similar B7-mediated “signaling”.¹¹¹ Furthermore, T_{reg}-mediated suppression during *in vitro* suppressor assays is associated with reduced activation of APCs (evidenced by reduced surface expression of B7 molecules¹¹²).

Antibody-mediated blockade of CTLA-4 is particularly effective at enhancing secondary immune responses, more markedly in CD4⁺ T cells. While often having only modest effects as a monotherapy in preclinical tumor models of poorly immunogenic tumors, anti-CTLA-4 synergizes with a number of other antitumor immunotherapies (reviewed in Refs ^{314, 318}). These promising preclinical results of CTLA-4 inhibitors led to the clinical development of two humanized monoclonal antibodies that block the function of CTLA-4: ipilimumab (IgG1) and tremelimumab (IgG2). Tremelimumab demonstrated durable responses in early clinical trials^{403–405}; however, in a phase III randomized clinical trial, it failed to demonstrate an overall survival advantage when compared with chemotherapy (dacarbazine or temozolomide) in patients with advanced melanoma.⁴⁰⁶ The failure to demonstrate a survival advantage by tremelimumab may be related to clinical trial design problems rather than lack of biological activity of the agent. Clinical development of ipilimumab is quite advanced, with objective responses observed in patients with melanoma, prostate, ovarian, renal, colorectal, and lung cancers. In two randomized controlled phase III clinical trials in patients with advanced melanoma, ipilimumab improved survival.^{407, 408} More remarkable is that the survival benefit persisted for approximately 20% patients for greater than 4 years, with the benefit extending up to 10 years in some patients.⁴⁰⁹ The success of these trials led to the FDA approval of ipilimumab as a first- and second-line agent in advanced melanoma. It should be noted that the phase III results of ipilimumab in chemotherapy-refractory advanced prostate cancer was recently reported, and it improved median progression-free survival when compared to placebo; however, it barely failed to meet statistical significance ($P = 0.053$) in promoting a survival benefit.⁴¹⁰ A second trial compared the efficacy of ipilimumab and a placebo in chemotherapy-naïve metastatic prostate cancer patients. This phase III trial has completed accrual, and the results will be reported shortly.

A number of factors have been proposed to potentially serve as biomarkers for response to ipilimumab therapy. Recent studies suggest that an increase in TILs correlates with clinical response of anti-CTLA-4 therapy.⁴¹¹ In addition, sustained ICOS expression on CD4 T cells has also been observed to correlate with survival of melanoma patients treated with anti-CTLA-4 therapy.^{412, 413} Consistent with this observation, increased frequency of ICOS⁺ CD4 T cells can also serve as a pharmacodynamic biomarker for anti-CTLA-4 therapy.⁴¹⁴ As described above, ICOS is one of the costimulatory receptors of T cells. Preclinical study shows that engagement of the ICOS pathway markedly enhances efficacy of CTLA-4 blockade in cancer immunotherapy.⁴¹⁵

PD-1 is more broadly expressed than CD28 or CTLA-4. It can be detected on activated CD4⁺ and CD8⁺ T cells, as well as B cells, monocytes, and at lower levels on NKT cells. It binds to two separate ligands, PD-L1 and PD-L2, which exhibit distinct expression profiles (reviewed in Ref. ¹⁵⁰). PD-L1 is broadly expressed and can be detected on resting and activated T cells (including CD4⁺CD25⁺Foxp3⁺ regulatory

T cells), B cells, macrophages, DCs, and mast cells. In addition, its expression on nonhematopoietic cells (including cornea, lung, pancreatic islets, placental syncytiotrophoblast, keratinocytes, and vascular endothelium) may have relevance to the function of this receptor–ligand pair. This broad nonhematopoietic expression pattern suggests that inhibition through the PD-L1/PD-1 axis may not be restricted solely to the interaction of T cells and professional APCs but that it may also be relevant during the effector phase of the immune response in peripheral tissues, perhaps helping to prevent immune mediated tissue damage directly at the tissue interface. By comparison, PD-L2 has a much more limited expression profile. It is not expressed on naïve nor activated T cells but is instead restricted to activated macrophages, myeloid DCs, and mast cells, suggesting that it fulfills a role that differs from that of PD-L1. The phenotype of PD-1^{-/-} mice provides perhaps the most direct evidence for an inhibitory role of this receptor.^{416, 417} These mice can develop an array of autoimmune pathologies characterized by high titers of autoantibodies, in keeping with a negative regulatory effect on T and/or B cells. PD-L1 and PD-L2 may also regulate T cell responses through reverse signaling. Cross-linking antibodies against PD-L2 directly induce DCs to produce immunomodulatory cytokines such as IL-6 and TNF- α ,^{418, 419} at the same time as protecting them from cell death.⁴²⁰ In addition, PD-1-Ig inhibits DC activation and increases IL-10 production independently of any influence on IDO.⁴²¹

PD-L1 was shown to bind B7-1 with an affinity intermediate between those of CTLA-4 and CD28 for B7-1.⁴²² This interaction was specific and bidirectional, allowing suppression of T cell proliferation and cytokine production either through B7-1 or PD-L1. T cell activation signals delivered through the TCR and CD28 will thus be integrated with cell intrinsic coinhibitory signals delivered through CTLA-4 and PD-L1 (via B7-1 on the APC, and potentially also via B7-1 and PD-1 on other T cells), and PD-1 and B7-1 (via PD-L1 on the APC, and potentially via CTLA-4, PD-1, and PD-L1 on other T cells). Finally, inhibitory signaling through PD-1 and B7-1 (via PD-L1 on nonhematopoietic tissues) may influence the final outcome of antigen encounter in the periphery. This leads to an almost bewildering complexity of possible cell intrinsic inhibitory signals, that is, almost certainly further complicated by the influence of the temporal expression profiles of the various “receptors” and “ligands”. The hierarchy of the relative importance of individual elements remains unclear and is likely to differ between T cell subsets. It is also likely that there is some redundancy within such complex and apparently overlapping systems. The physiological relevance of some of these findings also remains uncertain, but members of the PD-1:PD-L1/PD-L2 grouping clearly make attractive therapeutic targets for attempts to enhance antitumor immunity. Combinatorial blockade of CTLA-4 and PD-L1 might concomitantly eliminate cell intrinsic negative signaling through CTLA-4, B7-1, PD-L1, and PD-1 while favoring positive signaling through CD28. Recent data highlights the relevance of this pathway to chronic T cell responses to pathogens.^{423–426} During chronic LCMV infection, antigen-specific CD8⁺ T cells are impaired. These “exhausted” T cells demonstrate a selective upregulation of PD-1 and *in vivo* administration of anti-PD-L1 antibodies restores their activity as indicated by increased proliferation and cytokine production and by a significant reduction in viral load.⁴²³ Similarly, upregulation of PD-1 on HIV-specific CD8⁺ T cells has been associated with T cell exhaustion and disease progression in humans.⁴²⁴ Finally, it was shown that in HIV patients with progressive disease both PD-1 and CTLA-4 are upregulated on virus-specific CD4⁺ T cells and that their expression directly correlates with disease progression and inability to produce IL-2 upon restimulation.⁴²⁷ Together these data suggest that blockade of PD-1 and/or PD-L1 can restore functionality of the T cell compartment and could be applied, not only to reinvigorate responses to chronic infections but also to enhance T cell activity toward other chronic pathologies such as cancer.

PD-L1 is expressed by a variety of human and murine tumors, and PD-1 expressed by TILs, leading to the hypothesis that they may be important in restricting intratumor effector T cell responses. In humans,

myeloid DCs isolated from tumor or lymph nodes from ovarian carcinoma patients express high levels of PD-L1 and are capable of enhancing T cell activity only following PD-L1 blockade.⁴²⁸ Likewise plasmacytoid DCs in tumor-draining lymph nodes produce high levels of IDO, which results in regulatory T cell activation, upregulation of PD-L1 on the DCs, and negative regulation of T cell responses.⁷⁵ PD-L1 is expressed on several human carcinomas (mammary, cervical, lung, ovarian, colonic, renal), as well as melanoma, glioblastoma, and some hematopoietic malignancies.^{57, 429–433} Its expression has been directly correlated with poor prognosis in bladder, breast, kidney, gastric, and pancreatic cancer.^{59, 431, 434} Forced expression of PD-L1 on murine tumor lines diminished T cell activation and tumor killing *in vitro*, and markedly enhanced tumor growth *in vivo*, while anti-PD-L1 antibodies blocked these effects.^{435, 436} In the 4T1 mammary carcinoma model, PD-L1 is upregulated *in vivo* by the tumor, making it refractory to immunotherapy with the anti-4-1BB antibody. Coadministration with anti-PD-L1 resulted in dramatic tumor rejection.⁴³⁷ Likewise, anti-PD-L1 antibody delayed *in vivo* growth of PD-L1-expressing murine myeloma cell lines. PD-L1 blockade has also been shown to synergize with ACT to induce rejection of squamous cell carcinoma.⁴³⁶ Furthermore, adoptive transfer of PD1^{-/-} tumor-reactive CD8⁺ T cells caused rejection of B16 melanoma while neither wild type nor CTLA-4^{-/-} tumor-reactive CD8⁺ T cells were capable of inducing rejection.⁴²⁹ In this study, blockade of PD-L1 in the effector phase but not during T cell priming also mimicked the results obtained with CD8⁺ PD-1^{-/-} T cells. This is in keeping with a model wherein CTLA-4 may play a more vital role in the control of CD4⁺ T cell responses,⁴³⁸ whereas PD-1 is essential in the regulation of CD8⁺ effector T cell responses within the tumor.

While PD-L1 blockade has been proven effective at enhancing antitumor T cell responses, very few studies have examined the ability of PD-1 blockade to directly promote antitumor T cell responses *in vivo*. Among these, anti-PD-1 antibodies (as well as genetic ablation) were shown to reduce dissemination of B16 melanoma to the liver following injection into the spleen. In the same study, CT26 colon carcinoma injected intravenously was prevented from disseminating to the lungs by anti-PD-1 therapy.⁴³⁹ A more recent study also demonstrated that PD-1 (as well as PD-L1) blockade resulted in a small but significant decrease in growth of murine pancreatic carcinoma.⁴⁴⁰

These preclinical successes have translated into the clinic. In a phase I clinical trial, a fully human IgG4 anti-PD-1 mAb (nivolumab) was evaluated in patients with relapsed or refractory Hodgkin's lymphoma and demonstrated objective responses in 20 patients (87%), including 17% with a complete response.⁴⁴¹ In a separate phase I clinical trial, nivolumab showed an 18%, 27%, and 28% objective response rates in patients with advanced NSCLC, RCC, and melanoma.⁴⁴² A randomized controlled phase III clinical study compared nivolumab versus chemotherapy (dacarbazine) in patients with previously untreated melanoma (without the BRAF mutation), and the overall response rate favored nivolumab (40% vs 14%).⁴⁴³ Another phase III clinical trial compared nivolumab versus chemotherapy (dacarbazine or carboplatin plus paclitaxel) in ipilimumab-refractory advanced melanoma patients induced an overall response rate of 32% versus 11%, respectively⁴⁴⁴; leading to the accelerated FDA approval of nivolumab for patients with unresectable or metastatic melanoma who no longer respond to other drugs.

Consistent with these findings, another drug targeting PD-1, pembrolizumab (humanized IgG4 mAb), demonstrated an overall response rate of 26% in ipilimumab-refractory advanced melanoma patients in a phase I clinical trial, which prompted its accelerated FDA approval.⁴⁴⁵ Pembrolizumab also had an overall response rate of 53% in patients with Hodgkin's lymphoma who had failed brentuximab vedotin.⁴⁴⁶ These studies show that nivolumab and pembrolizumab have significant clinical activity in a variety of heavily pretreated patients with solid tumor malignancies, but they also appear to be highly active in a greater proportion of patients with hematological malignancies.

Promising clinical results were also observed with drugs targeting the ligand to PD-1, PD-L1. A phase I trial with anti-PD-L1 (human IgG4 mAb; BMS-936559) demonstrated an objective response rate of 6–17% in patients with advanced NSCLC, melanoma, and RCC.⁴⁴⁷ Another agent targeting PD-L1, MPDL3280A (human IgG1), was engineered with a modification in the Fc domain that eradicates ADCC. MPDL3280A showed objective responses rate 13–26% in multiple solid tumor malignancies, including NSCLC, melanoma, RCC, colorectal cancer, gastric cancer, and head and neck squamous cell carcinoma.⁴⁴⁸ Remarkably, MPDL3280A also had a 26% objective response rate in bladder cancer, a malignancy in which there have been no successful therapeutic developments in the past three decades.⁴⁴⁹ It should be noted that other drugs targeting PD-1, pidilizumab (humanized IgG1 mAb) and MEDI0680 (humanized IgG4 mAb), and PD-L1, MEDI4736 (human IgG1 mAb) and MSB0010718C (human IgG1 mAb), are currently being evaluated in a number of different malignancies. These results show that monotherapies drugs targeting the immune checkpoints, CTLA-4, PD-1, and PD-L1, are likely to become the standard of care in multiple malignancies other than just melanoma.

Other inhibitory members of the Ig superfamily offer further possible targets for coinhibitory blockade although the impact such interventions would have on antitumor activity remains more speculative at present. Thus, the as yet unidentified receptor for the B7x (B7-H4) ligand^{450–452} offers one such possibility.^{453, 454} The current literature on B7-H3 and antitumor responses remains somewhat contradictory (reviewed in Ref. ³¹⁴). BTLA (B- and T-lymphocyte attenuator, CD272) is also a potential target, offering the unique example of an Ig superfamily member whose ligand is a member of the TNF receptor family (HVEM),⁴⁵⁵ establishing a previously unsuspected link between these two important families of costimulatory molecules (reviewed in Ref. ⁴⁵⁶).

Targeting T_{reg} suppressive capacity

Approaches aimed at reducing suppressor function or T_{reg} numbers are attractive therapeutic strategies given the apparent importance of T_{reg} populations in mediating local immune privilege within tumor sites. Small molecule inhibitors of T_{reg} function would be useful additions to our current therapeutic armamentarium. From the preceding discussions, it is apparent that therapies directed toward members of both the Ig and TNFR superfamilies potentially act on regulatory and effector compartments. This duality of function simultaneously enhancing effector function and reducing suppressor function (and/or increasing resistance to suppression) may be critical to the early successes these approaches have enjoyed in preclinical and clinical applications. TLR8 triggering also appears to reverse T_{reg}-mediated suppression and to have additional inhibitory effects on suppressive $\gamma\delta$ populations.^{285, 286}

An alternative approach to reducing suppressive capacity of T_{reg} is that of depletion. The recognition that subversion of regulatory T cells may play a critical role in establishing and maintaining intratumoral tolerance is partly based on observations of tumor outcomes following CD25-directed depletion. Anti-CD25 monoclonal antibodies (e.g., PC61) have antitumor activity in a number of murine tumor models^{122, 457–460} While effective when given before tumor engraftment, they have only limited activity in the therapeutic setting once tumor growth is established. Rather than relating to depletion of activated effectors as initially surmised, it is now recognized that failure in the therapeutic setting may relate to lack of effector infiltration and accumulation within established tumors, further illustrating the principle that systemic generation of immune responses may be insufficient to effect antitumor activity.³⁶ Furthermore, depletion of T_{reg} may be relatively short-lived, both because of rapid proliferation of naturally occurring

T_{reg} and peripheral conversion of $CD4^{+}Foxp3^{-}$ precursors.^{97, 100} The duration of depletion likely relates to the functional half-life of the depleting agent. Studies in humans have used either IL-2 or anti-CD25 as a delivery vehicle for a variety of toxins. Denileukin difitox (Ontak) is a fusion protein consisting of the IL-2 and the diphtheria toxin that directs the cytotoxic action of diphtheria toxin to cells that overexpress the IL-2 receptor. *Ex vivo* studies indicate that it interacts with the high- and intermediate-affinity IL-2 receptor on the cell surface and undergoes internalization. Subsequent cleavage in the endosome releases the diphtheria toxin into the cytosol, which then inhibits cellular protein synthesis, resulting in rapid cell death. It is characterized by a relatively short half-life (60 min) compared with monoclonal antibodies. Preliminary studies in ovarian and renal cell carcinoma demonstrate an early reduction in circulating T_{reg} cells following denileukin difitox therapy with preservation of the $CD4^{+}CD25^{int}$ memory T cell pool,⁴⁶¹ but possible depletion of $CD25^{+}$ effector cells with prolonged/repeated administration.⁴⁶² Administration before tumor RNA-transfected DC vaccines enhanced tumor immunity as measured by subsequent *in vitro* analyses of cytokine production in recall responses to the DC vaccine.⁴⁶¹ The *in vivo* antitumor efficacy is still under preclinical evaluation. However, the data from murine models suggest that the demonstration of antitumor activity may be more difficult than enhancement of systemic immunity, and the issue of the duration of depletion that can be achieved remains perhaps critical.^{463, 464} The same issues may pertain to other depletion strategies, such as those using fusions of anti-CD25 monoclonal antibody to a truncated form of the bacterial *Pseudomonas* exotoxin A,⁴⁶⁵ or conjugated to ricin.⁴⁶⁶ For these reasons, approaches that target T_{reg} function rather than number have potential advantages. Furthermore, if such approaches could be targeted to the tumor microenvironment, systemic toxicities, and particularly the risk of harmful autoimmunity, might be restricted. Our knowledge of the pathways involved in T_{reg} generation and accumulation within the tumor now allows consideration of a number of novel therapeutic strategies. Thus, inhibition of the IDO pathway or TGF- β might reduce the rate of peripheral conversion and influence immune privilege status within the tumor.^{125, 467–470}

Cytokines—intercellular mediators of immunity

Some of the possible uses of cytokines have been described in the section on ACT. Few have shown evidence of a potent ability to enhance antitumor activity *in vivo*, partially because of their pleiotropic effects and adverse side effect profiles at high doses (e.g., IL-2 and type I IFN). IL-15 and IL-21, both members of the common γ -chain group, have attracted more attention recently. IL-15 is likely to have differing roles in mouse and human $CD4^{+}$ memory T cell homeostasis, as human $CD4^{+}$ memory cells constitutively produce and proliferate in response to it while it is not produced by mouse T cells.^{471, 472} Other sources of physiologically active IL-15 include monocytes, macrophages, DCs, and stromal cells. It is recognized to activate NK cells, be critically involved in the maintenance of durable high-avidity $CD8^{+}$ memory T cell responses, and to promote MHC class I expression by DCs.^{473, 474} IL-15 is capable of enhancing $CD8^{+}$ T cell responses to vaccines and to enhance antitumor activity when either supplied exogenously or engineered to be secreted by tumor vaccines.^{220, 223, 475} IL-15-based superagonist ALT-803 promotes the antigen-independent conversion of memory $CD8^{+}$ T cells into innate-like effector cells with antitumor activity in murine models of cancer.⁴⁷⁶ Currently, phase I studies are going on using ALT-803 in hematological and solid malignancies. IL-21 is produced by NKT and $CD4^{+}$ T cells and enhances the proliferation and function of $CD8^{+}$ T cells, NK, and NKT cells, as well as influencing B cell differentiation.⁴⁷⁷ Furthermore, it appears to reduce the suppressive capacity of T_{reg} .⁴⁷⁸ It has been demonstrated to enhance antitumor activity in a number of preclinical murine models either as a

monotherapy or in combinatorial approaches with other cytokines (IL-15, IL-2), apoptosis-inducing antibodies (anti-DR5), CD1d reactive glycolipids (aGalCer), or costimulatory agonists.^{479–482} Early phase clinical studies of recombinant human IL-21 suggest that it is relatively well tolerated and mediates biological activity in terms of activation of NK and CD8⁺ T cells, although it is too early to assess possible antitumor efficacy.^{483, 484}

Not all cytokines are immunostimulatory. Tumor cells can produce immunosuppressive cytokines or induce their production by regulatory infiltrates or stromal cells. Both IL-10 and TGF- β provide possible targets for therapeutic intervention. Targeting TGF- β has shown efficacy in murine tumor models^{67, 69} and clinical grade antibodies (used in systemic sclerosis) are available, as are those for IL-10.

Combinatorial immunotherapeutics

It is clear from preclinical models and early clinical experience that multimodal approaches may be required to successfully eradicate poorly immunogenic tumors. The recent literature demonstrates the potential for many combinations to give synergistic or additive effects. Attempting to rationally choose which are likely to be the best approaches is very challenging, but considering approaches under a number of basic headings allows the identification of potentially attractive combinations. We can perhaps simplistically think of modern strategies as (1) improving antigen presentation or immunogenicity (e.g., vaccines, CpG), (2) improving T effector function, numbers, or persistence directly (e.g., agonistic anti-TNFR antibodies, cytokines), (3) removing or disabling immunological checkpoints, either cell intrinsic or cell extrinsic (e.g., CTLA-4 or PD-1 blockade, regulatory T cell depletion, and possibly agonistic anti-TNFR antibodies), (4) “resetting” the system and taking advantage of proliferative advantages in a lymphopenic environment (e.g., ACT), and (5) improving antigen specificity or TCR avidity for tumor antigens (e.g., CAR and TCR gene therapies). It has also become apparent that some agents bridge these categories, so the duality of enhancing effector function and reducing suppression afforded by, for example, CTLA-4 blockade, or OX40 stimulation, may be achieved with one agent. As recent data highlight the ability of regulatory checkpoints to limit the efficacy of any directly stimulatory strategy, the inclusion of at least one therapy aimed at disabling immune checkpoints is theoretically attractive. So, for example, combination of anti-CTLA-4 with vaccines,^{466, 485, 486} regulatory T cell depletion,⁴⁸⁷ or anti-4-1BB⁴⁸⁸ markedly enhances activity. Similarly, diverse synergy is seen when combining anti-4-1BB antibodies with other modalities.^{330, 348, 372} One example of combining three of these strategies is provided in a preclinical model using antibodies directed toward the death-inducing TRAIL-R, CD40, and 4-1BB, which has been shown to augment antitumor activity in TRAIL-sensitive murine tumor models.³¹³ Induction of tumor apoptosis and antigen release from tumor cells and recruitment of innate immune cells into the tumor site by anti-DR5 (anti-TRAIL-R), coupled with augmentation of DC function induced by anti-CD40, and improved induction, activation and survival of tumor-specific CTL facilitated by anti-4-1BB (possibly with further effects on T_{reg}), are all likely to be important contributors to the favorable antitumor activity.^{489, 490} Furthermore, anti-CD40 can be substituted by CpG, utilizing NKT activation to amplify DC function, with similar results.³³¹ One potential advantage of approaches relying on the synergy of multiple components is that they might reduce the toxicity induced by higher doses of each agent administered as monotherapy (e.g., immune responses may be constrained toward tumor-related antigens rather than ubiquitous self-antigens). Appropriate timing of sequential therapies is likely to become an important factor in such combinatorial approaches.

Preclinical studies have shown that concurrent targeting of CTLA-4 and PD-1 significantly improves therapeutic efficacy when compared to the monotherapies.⁴⁹¹ A phase I clinical trial evaluated the

concurrent treatment of advanced melanoma with ipilimumab plus nivolumab using various doses of both drugs (four cohorts). The objective response rate was 40% when all four cohorts were included and 53% in the cohort representing the maximum dose that was associated with an acceptable level of toxicities.⁴⁹² This latter cohort was also associated with an unprecedented 1- and 2-year overall survival rate of 94% and 88%.

In patients with metastatic renal cell carcinoma, optimal combination of ipilimumab and nivolumab resulted in a response rate of about 40% at 6 months of treatment.⁴⁹³ Combination strategies using anti-PD1 (nivolumab) with targeted agents tyrosine kinase inhibitors sunitinib and pazopanib have also led to 6-month response rate of 52% and 45%, respectively, in patients with metastatic renal cell carcinoma.⁴⁹⁴ Phase III trials with anti-CTLA-4 and anti-PD-1 are now ongoing.

Immunotherapy agents elicit different toxicities

As is the case for clinical responses, adverse events associated with anti-CTLA-4 and anti-PD-1 therapies are different from those seen with conventional chemotherapeutic agents and appear to be related to the systemic activation of the immune system and development of inflammatory-like conditions such as colitis, uveitis, hypophysitis, and dermatitis.^{495–500} These adverse events have been termed immune-related adverse events or irAEs. Most irAEs have been manageable and reverse either spontaneously or with corticosteroids. Unlike previously approved cytokine therapies such as high-dose IL-2, which requires a medical setting comparable to an intensive care unit for administration owing to its potential serious toxicities related to capillary leak syndrome,⁵⁰¹ anti-CTLA-4 therapy is administered in clinical trials as a single intravenous infusion per dose in an outpatient setting. Most irAEs that occur as a result of treatment can be managed in the outpatient setting. The use of corticosteroids to treat irAEs does not appear to affect the antitumor action of anti-CTLA-4 antibody.⁵⁰²

Paradigm shift—from immune adjuvants to immunosupportive therapies?

Recent attention has also focused on the potential for immunotherapies to augment conventional chemotherapy or radiotherapy⁵⁰³ and trying to optimize the immunogenicity of cell death. Cytotoxic chemotherapies appear to be capable of inducing an appropriate milieu for presentation of tumor antigens.⁵⁰⁴ Further beneficial effects likely include increased antigen cross-presentation,⁵⁰⁵ partial activation of DCs,⁵⁰⁶ and partial sensitization of tumor cells for cytotoxic T cell-mediated lysis.⁵⁰⁷ While there is currently scant evidence from studies in humans to define the relative importance of these considerations to therapeutic outcomes, the attraction of enhancing the immunogenicity of cell death *in vivo*, and one shared by agents such as CpG, is that the tumor might be turned into its own polyvalent cellular vaccine, allowing presentation of private tumor epitopes and favoring tumor-specific immunity. This would obviate the requirement for an absolute knowledge of the relevant target antigens. We are beginning to appreciate the impact of genetic instability within tumors on the generation of potentially immunogenic neo-antigens,^{508, 509} and it is possible that we will shift to a position wherein conventional anticancer therapies become viewed as immunosupportive, rather than one in which cancer immunotherapies are viewed as adjuvants.

Major challenges will need to be faced in the coming years. Identification of the best combinatorial strategies will continue to be informed by careful mechanistic studies in mouse models. The identification

of robust predictors of response will perhaps parallel attempts to tailor chemotherapeutics according to the genetic profile of the tumor or of tumor infiltrates. Finally, attempts to manipulate the host in order to achieve such favorable immunological profiles will be required to prove the therapeutic worth of cancer immunotherapies in comparative studies, confirming them to be much more than modern biomarkers for disease outcome.

Chapter 68

Cancer gene therapy

Haruko Tashiro, MD, PhD ■ Malcolm Brenner, MB, PhD

Overview

Gene therapy of cancer has shown increasingly encouraging results and now is ready to enter mainstream oncological practice. Gene transfer can modify the cellular phenotype and behavior of malignant cells or host immune cells in order to modulate tumor responses. In this chapter, we discuss both of the above approaches and describe the vector systems that are able to produce the intended genetic modifications. We describe current clinical successes of gene therapy and outline the challenges it has yet to overcome. The success of either approach depends on efficient, safe gene transfer with vectors that can either integrate (e.g., retroviral, lentiviral, or adeno-associated viral, or transposons) or not integrate (e.g., adenoviral, herpesviral, or nonviral) into the human genome. To date, reversing the phenotype of all stem cells within a cancer has not proven feasible, and infectious cytolytic viral therapy has not yet had a significant impact in the clinic. Enhancement of active cancer immunotherapy with forced expression of antigens and cytokines or the enhancement of adoptive immunotherapy by engineering T lymphocytes with specific T-cell receptors and chimeric antigen receptors shows greater immediate promise, although ultimately a combination of multiple approaches will prove optimal.

Introduction

A range of tumor-targeted and immunomodulatory antibodies have recently been added to the conventional therapeutic tools of cancer, which until recently consisted of surgery, chemotherapy, and radiotherapy. In this chapter, we describe gene transfer, another treatment approach that has been in development and is now showing remarkable results, though currently only in a limited range of disorders. The intent of gene transfer in cancer is to modify the cellular phenotype and behavior of normal or malignant cells and thereby control or eradicate the tumor. The new genetic material may be transferred to cells *ex vivo* followed by cell infusion, or directly to the cells *in vivo*; the modification may be intended to be permanent or temporary.

Delivery of genetic material to target cells

The ideal gene delivery system (vector) is safe, efficient, and suitable for use in a wide range of applications; such a vector does not yet exist. Instead, gene delivery vectors, which may be of viral or nonviral origin, each have their own strengths and limitations ([Table 1](#)) and should be chosen for any given application based on balancing their desirable properties with their limitations.

Table 1 Advantages and disadvantages of cancer gene therapy vectors

	Advantages	Disadvantages
<i>Integration of vector sequence into the genome</i>		
Retrovirus	Stable genome integration	Integration only in dividing cells
	Long-term gene expression	Potential insertional mutagenesis
	Low immunogenicity	Inefficient <i>in vivo</i> gene delivery
	Relatively large insert size: 7–8 kb	
Lentivirus	Transduces nondividing cells	Potential insertional mutagenesis
	Long-term gene expression	Inefficient <i>in vivo</i> gene delivery
	Low immunogenicity	
Adeno-associated virus	Long-term gene expression	Potential insertional mutagenesis
	Transduces nondividing cells	Limited insert size: 4 kb
<i>Nonintegration of vector sequence into the genome</i>		
Adenovirus	High titer	Transient expression
	High transduction efficacy	Immune-related toxicity with repeated administration
	Transduces nondividing cells	Limited insert size: 7–8 kb (first generation)
	Limited immunogenicity	
Herpes virus	Large insert size: 30 kb	Cytotoxic
	Neuronal tropism	Transient expression
Nonviral DNA delivery	Large insert size	Transient gene expression
	Low immunogenicity	Inefficient <i>in vivo</i> delivery
	Can be used repeatedly	

Viral vectors

Viruses reproduce by efficiently inserting their genetic information into target cells. Investigators have exploited this property by modifying viruses in such a way that they retain their ability to insert therapeutic genetic material but no longer cause disease in the host. Several different vectors have been used for this purpose.

Integrating vectors

Retrovirus vectors

Retroviruses are enveloped, single-stranded RNA viruses, and vectors have been derived from several different retroviral family members, including γ -retroviruses (e.g., murine leukemia virus or MLV—one of the first and still most widely used retroviral vectors)¹ and human immunodeficiency virus (HIV-1, also now widely used^{2, 3}). Other retroviruses including simian immunodeficiency virus (SIV), bovine immunodeficiency virus, feline immunodeficiency virus, equine infectious anemia virus (EIAV), foamy

virus, bovine leukemia virus, Rous sarcoma virus (RSV), spleen necrosis virus, and mouse mammary tumor virus have also been developed as potential vectors. These vectors integrate in the host cell DNA and therefore can provide stable expression even in a dividing cell population.

γ-Retroviral vectors (e.g., MLV)

Wild-type MLV retrovirus contains 5' and 3' long-terminal repeats (LTRs) that are responsible for integration and act as promoters. Between the LTRs are three sequences necessary for viral replication and packaging: *gag*, which encodes three proteins that contribute to the virion structure; *pol*, which encodes reverse transcriptase, integrase, and ribonuclease H (RNaseH) necessary for replication; and *env*, which encodes the envelope glycoprotein. Recombinant retroviral vectors are made replication-defective by removing the *gag*, *pol*, and *env* gene sequences from the viral nucleic acid backbone and replacing them with a cargo consisting of the therapeutic sequences of interest. These “guttled” vectors are manufactured in a producer cell line, in which the missing viral genes have been stably integrated in trans and are therefore able to produce infectious but nonreplicative particles containing enough reverse transcriptase to initiate the formation of a double-stranded DNA molecule that is then integrated into the DNA of the cell targeted for gene transfer.

As mentioned above, stable integration of retroviral sequences into the host cell genome⁴ means that any modification is stable and will be passed to all daughter cells. Although this property is a critical advantage when stable alteration is required in a rapidly dividing population, γ -retroviral vectors have several limitations. As stable transduction and integration occur in S-phase cells and the preintegration complex is unstable, γ -retroviruses only integrate efficiently in actively dividing cells and not in slowly dividing or quiescent cells. Moreover, retroviral vector integration is by definition a mutational event, and as integration may favor the control regions of active genes, insertional mutagenesis can result—and has resulted—in transformation of the transduced target cell.^{5, 6} In addition, insert size is limited. Replication-incompetent γ -retroviral vectors made by a producer cell contain only the retroviral LTRs and the packaging signal. In principle, therefore, these vectors should have room for 7–8 kb of sequences of interest. Unfortunately, packaging constraints of the substituted “alien” sequences substantially reduce this limit.⁷ Finally, retroviruses are unstable in primate complement and cannot be used readily for *in vivo* transduction. Owing to these limitations, generally retroviruses have been used for *in vitro* transduction of specific target cells before their transfer to the patient.

Lentiviral vectors

HIV-derived lentivirus vectors were the first to be developed and have been widely used both experimentally and clinically. Lentiviral vectors are usually engineered from the HIV-1 genome that contains the *gag-pro-pol* and *env* genes and two regulatory genes, *rev* and *tat* that are required for viral replication. The HIV-1 genome also has four accessory genes, *vif*, *vpf*, *vpu*, and *nef* that encode critical virulence factors. These genes are flanked by two LTRs. Recombinant lentiviral vectors are engineered by removing the majority of the HIV genes leaving the LTRs, packaging signal, and other regulatory elements.⁸ First-generation packaging plasmids provide all *gag* and *pol* sequences, the viral regulatory genes, and the accessory genes. In second-generation lentiviral vectors, the four accessory genes are removed. To further reduce the risk of recombination and production of genetically modified infectious lentiviruses, third-generation vectors consist of a split-genome packaging system in which the *rev* gene is expressed from a separate plasmid and the 5' LTR from the transfer construct⁹; moreover, in the latest generation vector, *rev* and *tat* genes are provided by a fourth plasmid.¹⁰ As opposed to the stable packaging cell lines used for γ -retroviruses, the requirement for a multiple plasmid system to produce

lentiviral vectors for human use has made it difficult to scale up production or reduce costs of manufacture for larger clinical trials. Efforts continue to be made to generate a stable producer line that is safe and produces high-titer vector. Despite difficulties in production, lentiviruses have several advantages over γ -retroviruses. They can more readily infect nondividing and dividing cells,¹¹ although integration of the stable preintegration complex occurs at a high rate only when the cell enters cycle. Substitution of different viral envelopes modifies and broadens the viral tropism for target cells.¹² Initial clinical studies with lentiviral vectors evaluated the safety of an antisense gene against the HIV envelope in patients with HIV, but more recent attention has focused on the use of lentiviral vectors to transduce T cells to express tumor-directed receptors.¹³

Adeno-associated virus vectors

Adeno-associated viruses (AAV) are small, nonenveloped, single-stranded DNA viruses that are not known to cause disease in human or other animals¹⁴ and require a helper virus (adenovirus, herpes simplex, or vaccinia virus) for the replication and production of new viral particles.¹⁵ The AAV genome is composed of *rep*, which is required for virus replication, and *cap*, which encodes the viral capsid. There are at least 11 serotypes of AAV that differ primarily in their external capsid proteins and that bind to different cellular receptors and hence infect different targets. Recombinant AAV vectors are engineered by the removal of *rep* and *cap* genes but retain the AAV inverted terminal repeats (ITRs) flanking a gene of interest. rAAV has limited cargo capacity, and although widely and successfully used for the treatment of monogenic disorders, production is difficult to scale. So far, the virus has been rarely used in clinical cancer gene therapy.^{16, 17}

Nonintegrating viral vectors

Adenovirus vectors

Adenoviruses are nonenveloped, linear double-stranded large DNA viruses. A set of early genes (E1A, E1B, E2A, E2B, E3, and E4) encode regulatory proteins that serve to initiate cell proliferation, DNA replication, and down modulation of host immune defenses. The late genes (L1–L5) encode structural proteins. Importantly, adenoviruses are assigned to a species (A–F) and serotype according to the composition of their capsid, the knob/fiber of which attaches to one or more cellular receptors; cellular receptor usage is influenced by both species and serotype.¹⁸ These molecular interactions lead to receptor-mediated endocytosis,¹⁹ internalization, and uncoating of the virus. Adenoviruses can infect many normal and malignant cell types, irrespective of whether they are dividing or nondividing, but they do not integrate in host cell DNA and so the genetic modification is gradually lost in succeeding generations of dividing cells.

Recombinant adenovirus vectors are engineered from adenoviruses by the removal of one or more early genes including E1, which regulates replication, and E3, which diminishes immune recognition. The missing E1 genes are provided in trans by a packaging (or helper) cell line to produce replication-incompetent adenoviruses with room for up to 7–8 kb of new genetic material.²⁰ Second-generation adenoviruses have been developed in which E2 and E4 along with E1 and E3 are deleted, providing up to a 14 kb insert. They are, however, usually produced at a lower titer.²¹ As adenovirus vectors do not integrate into the host cell genome, insertional mutagenesis does not occur but gene expression is only transient in dividing cells. Adenoviral vectors are also highly proinflammatory and favor an immune response against transduced cells and the transgenes they express.^{22, 23} While both of these characteristics make adenoviral vectors unsuited for long-term treatment of monogenic disorders, they may be beneficial

for applications in cancer therapies, such as tumor vaccines, in which transient, high-level expression of an immunogenic transgene may be highly desirable.

Two major variants of adenoviral vectors are currently in clinical development.^{22, 23} Removal of all viral genes, except those that are required for packaging and replication, produces helper-dependent (or “gutless”) adenoviral vectors (HD-Ad) that have lower immunogenicity and greater cargo capacity. Conversely, limitation or modification of the gene deletions can produce conditionally replication-competent adenoviral vectors (CRAD), capable of replicating in—and hence destroying—malignant cells, while sparing normal tissues. These oncolytic CRADs are made selective for tumor cells either because of their requirement for transcriptional regulators present at higher level in malignant than in normal cells or because investigators substitute tumor-“specific” promoters for viral promoters of critical replicative genes.^{24, 25}

Other nonintegrating viral vectors

Herpes viruses (HSV) are large (~186 nm), enveloped, double-stranded DNA viruses. Their linear double-stranded DNA genome is composed of unique long (UL) and unique short (US) coding regions, both flanked by terminal repeat sequence.²⁶ Although HSV encodes ~90 genes, many of these genes can be removed without inhibiting genome replication or the packaging of the virus.²⁷ Therefore, HSV vectors are able to carry large DNA sequences (up to 30 kb). Replication-competent HSV have also been developed and are being studied as oncolytic viruses in several different tumor types.^{28–30} Vaccinia viruses are large DNA viruses that replicate cytoplasmically. Modified vaccinia virus Ankara (MVA) has had 31 kb deleted from the parental vaccinia genome, including the K1L, N1L, and A52R genes that regulate innate immune responses,³¹ while MVA and Copenhagen-derived vaccine strains are being investigated currently as oncolytic viruses in cancer.³² High immunogenicity that terminates the oncolytic response is one of the problems for clinical use.³³

Nonviral vectors

Although viral vectors deliver genes with reasonably high efficiency, they have several drawbacks including cost and complexity of manufacture and the scalability of the production of some of the agents (e.g., lentiviruses and rAAV). Moreover, recognition of viral proteins by antibodies or cell-mediated immunity may limit systemic and/or repeated delivery of the vector, or the durability of transgene expression. Other limitations of viral vectors include insertional mutagenesis produced by some viral vectors and the limited size of the encoded transgenes.

Therefore, much effort has been devoted to increasing the efficiency of nonviral delivery of plasmid DNA in a way that efficiently allows the DNA to escape nuclease-mediated degradation.³⁴ Plasmid delivery can be effected by physical methods that disrupt the cell membrane (e.g., by electroporation, ultrasound, and hydrodynamic injection) or by chemicals that induce endocytosis,³⁵ such as cationic polymers or lipids. Unlike conventional nonviral vectors, a plasmid that adds transposons/transposase elements to the genes of interest will integrate in host cell DNA, and is being used *ex vivo* to produce stable gene transfer and expression in T lymphocytes. Nonviral gene delivery methods are generally less immunogenic and toxic, but efficiency *in vivo* remains low and transgene expression is modest. As yet, these approaches have not been widely adopted for cancer therapy.

Targets of gene therapy

As cancer is an acquired genetic disorder, in principle, gene therapy could be used to correct the disorder by, for example, replacing an inactive gene with an active one or neutralizing hyperfunctional genes. Although in several reports gene therapy has proven successful for the treatment of *p53*-deficient tumors,³⁶ engineering gene therapies that directly target cancer cells is difficult for many reasons. Unlikely monogenic hereditary diseases, gene therapies targeting cancer cells require modification of the complete population of tumor cells, which is usually extremely large. As described above, highly efficient gene delivery systems have not yet been established. Even if they were available, correction of a single abnormality may be insufficient to repair the transformed phenotype. Therefore, alternative strategies have been explored that target normal host tissue for anticancer therapy.

Gene therapy strategies that directly attack tumors

Prodrug-metabolizing enzymes

Transfer of genes encoding prodrug-metabolizing enzymes may partially overcome inefficient gene transfer, as these genes encode enzymes that convert harmless small molecule prodrugs into lethal cytotoxins that are then released into the general area of the tumor. Herpes simplex virus-derived thymidine kinase (HSV-tk) gene has been widely investigated for this purpose. The HSV-tk, which is encoded by the transferred gene, phosphorylates nontoxic prodrugs, such as acyclovir, valacyclovir, and ganciclovir, into toxic metabolites that inhibit cellular DNA synthesis and replication. Aside from the direct cytotoxic effect to the transduced cancer cells, this approach also has an indirect bystander cytotoxic effect,³⁷ as the metabolites can be transported from the transgene-expressing cells to adjacent nontransduced cells through gap junction intercellular communication.^{38, 39} One randomized Phase 3 clinical trial of HSV-tk gene therapy for patients with glioma employed this concept by injecting adenoviral vectors peri-lesionally.⁴⁰ As perilesional injections are not always feasible, tumor cells can be targeted through other means, such as vectors that can only transduce dividing cells, the use of enzyme-prodrug systems whose products are pharmacologically active only in dividing cells, or the use of a vector that is targeted to a receptor of tumor-restricted distribution.⁴¹

Virotherapy or viral oncolysis

Several case reports have documented spontaneous tumor regressions after viral infections.^{42, 43} As more detailed knowledge of the molecular biology of viruses and cancers has developed, oncolytic viruses that enter or replicate only in tumor cells have been engineered. Several of these oncolytic viruses are natural viral species that selectively infect and kill cancer cells. For example, H1 autonomously replicating parvovirus, reovirus, Newcastle disease virus, Mumps virus, and Moloney leukemia virus are all cancer specific. Other viruses such as measles, adenovirus, vesicular stomatitis virus, vaccinia, and herpes simplex virus require genetic modification to become cancer specific.⁴⁴ For example, in ONYX-015, there is deletion of the E1B region that normally binds to and inactivates the *p53* gene to allow viral replication. As a result, ONYX-015 is unable to block *p53* function and can replicate only in malignant cells, most of which are functionally *p53* defective.⁴⁵

Oncolytic virus can kill tumor cells not only by direct lysis (their cytopathic effect) but also by indirect mechanisms such as the destruction of tumor blood vessels or amplification of specific anticancer immune responses. Thus, oncolytic viruses can be further modified to deliver therapeutic genes that induce T-cell chemotaxis (e.g., Rantes) or immunomodulation [e.g., GM-CSF (granulocyte-macrophage colony-stimulating factor), IL-2, IL-12, or IL-15]^{46–50} or to deliver a prodrug-converting enzyme that turns an otherwise inert agent into a cytotoxic drug at high concentration in the tumor (see section titled “Prodrug-

metabolizing enzymes”).⁵¹

Although several oncolytic virus clinical trials have proven the safety of this approach, with few exceptions⁵² the clinical efficacy has not met the high expectations raised by promising preclinical studies. There are a number of obstacles that hamper the spread of viruses into target cells. When viruses are injected systemically, they can be cleared from the bloodstream before they reach the tumor cells by neutralizing antibodies, complement proteins, or the reticuloendothelial system.^{53–55} In addition, the initial tumor transduction rate may not be high enough for efficient subsequent viral replication. To overcome these obstacles, several strategies have been investigated, such as delivering OV using mesenchymal stem cells to shield them from the immune response⁵⁶ and prior administration of immunosuppressive drugs.⁵⁷

Induce host immunity to cancer by vaccines

Unlike vaccines against infectious agents, cancer vaccines are not used for the prevention of disease, but for its treatment, by augmenting the patients' own immune systems to recognize and attack the cancer cells. Although vaccines against human tumors have been investigated for more than 100 years, effective agents have yet to be fully established, and less than 10% of cancer vaccine recipients benefit from the treatment.⁴¹ There is nonetheless a strong rationale for the continued exploration of these agents. Many cancer cells express tumor-associated antigens (TAAs), but effective immunity against TAAs are lacking because cancer cells escape from host immune surveillance ([Figure 1](#)). Tumor escape mechanisms include the downregulation of costimulatory molecules, expression of immune-inhibitory receptors/ligands such as PDL-1, secretion of a multiplicity of soluble immune-inhibitory factors, such as transforming growth factor- β (TGF- β), IL-10 and enzyme inhibitory ligands such as FasL or TRAIL, and the induction of regulatory T cells (T reg) or myeloid-derived suppressor cells.⁵⁸ Vaccination is intended to elicit host immunity against tolerized TAAs by coadministering the antigen with potent immunostimulatory signals. Target antigens have included oncoproteins, oncofetal antigens, differentiation-associated proteins, and viral proteins. Efforts have also been made to capture immune responses against an individual's unique tumor-associated neoantigens (antigens arising from mutations specific to each tumor).⁵⁹ Thus, TAAs have been given as (1) injections of peptides or proteins in immune adjuvants,⁶⁰ (2) components of recombinant viruses or other recombinant microorganisms to capitalize on the proinflammatory innate and adaptive immune responses induced by these organisms,⁶¹ (3) protein, peptide-activated dendritic cells (DCs),⁶² or (4) mRNA from tumor cells or tumor cells themselves modified to express immunostimulatory genes, both of which are intended to capture immune responses against neoantigens.⁶³ For this last application, investigators often use combinations of immunomodulatory genes to elicit robust T-cell responses including IL-2⁶³ and GM-CSF⁶⁴ with costimulatory molecules such as CD40L.^{63, 65}

Figure 1 Transgenic T-cell receptors. (a) Transgenic α and β T-cell receptors, which need HLA to recognize the targeted antigen, and (b) chimeric antigen receptors, which recognize the antigen in HLA unrestricted manner. For endodomains, first-generation CAR has only CD3 ζ and second- and third-generation CARs also have costimulatory molecules. scFV, single chain variable fragment.

Despite many years of effort, only one cancer vaccine (Provenge) has been licensed by the FDA. This vaccine is used to treat advanced prostate cancer and expresses a fusion protein of prostatic acid phosphatase with GM-CSF.⁶² Provenge is produced following the *ex vivo* transduction of the patients' own antigen-presenting cell population in peripheral blood. While vaccine therapy alone has rarely been powerful enough to elicit curative immune responses, the combination of vaccines and checkpoint antibodies for T cells, such as CTLA4 mAb or PD-1 mAb, may augment this therapy's efficacy and reanimate the field.

Modifying host immune effector cells

One of the limitations of cancer vaccines is that the immune responses they are supposed to induce *in vivo* may be blocked or subverted by the immune evasion strategies of malignant cells and the tumor microenvironment these cells produce (Figure 1). An alternative approach is to prepare effector cells *ex vivo* that are engineered to be specific for the tumor and are also engineered to counteract whatever immune evasion strategies the tumor uses. These modified effector cells can then be returned to the patient.

Generating tumor specificity

T cells can be engineered to be tumor specific by transferring sequences encoding standardized TAA-specific receptors into bulk T-cell populations. Two types of receptors have been used: "natural" α and β T-cell receptors (TCRs) or artificial chimeric antigen receptors (CARs), so called because they are chimeras of a tumor-antigen-binding domain and a TCR-signaling domain. The TCR α and β chains are encoded by *TRA* and *TRB* genes and have been cloned for several different TAA epitopes.⁶⁶ These synthetic TCR can be modified to be of high affinity in an attempt to increase their effectiveness once

transferred into T cells,⁶⁷ but sometimes at the cost of generating unwanted cross-reactivities.^{68–71} Several clinical trials have been performed,^{68–70} some of which have shown significant efficacy such as in melanoma, colorectal cancer, and myeloma, although off-target or “on-target antigen but off-tumor” toxicities remain a concern.

The major limitations of TCR-gene therapy are that each TCR recognizes only a small portion of a total tumor antigen (an epitope), which may be lost (“edited”) by the tumor, and that the recognition of this epitope is moreover limited to a particular MHC polymorphism, restricting activity to those individuals who share that human leukocyte antigen (HLA) type. CAR-transduced T cells may allow engagement of a larger antigenic component than the 9–14 peptides recognized by the TCR. CAR T cells can also overcome the limitation of HLA restriction and recognize carbohydrate and other nonprotein antigens. CARs are composed of an extracellular domain that binds to the intended antigen, a transmembrane domain, and one or more intracellular signaling domains ([Figure 2](#)). Most commonly, the extracellular domain is derived from the antigen-binding portion of a monoclonal antibody targeting the intended antigen and the intracellular signaling domain (endodomain) comes from the CD3 ζ component of the TCR.⁴¹ Initial CAR T-cell efficacies were modest because CAR stimulation alone was insufficient to fully activate CAR T cells, producing limited expansion and persistence *in vivo*. Second-generation CARs were created that added one or more of the costimulatory signals that T cells need to pass through sequential activation barriers, such as the signaling domains from CD27, CD28, 41BB, OX40, or ICOS. When these second-generation CARs are coupled with an exodomain that binds CD19, an antigen present on most normal and many B cell malignancies, CAR T cells produce striking results in the treatment of B cell malignancies. For example, CD19 CAR T cells have a 90% CR rate for relapsed/resistant B-ALL.^{13,}

Figure 2 Tumor evasion mechanism. The tumor microenvironment consists of tumor cells and several kinds of immunosuppressive cells, such as T_{reg} and MDSCs. Tumor cells themselves express FasL to induce cytotoxic T lymphocytes (CTLs) apoptosis and PD-L1 to inhibit CTL functions. In addition, they secrete immunosuppressive molecules TGF- β , IL-10, IL-4, and IL-13.

Engineering T cells for efficacy against solid tumors

Extending CAR T cell successes from B cell malignancies to solid tumors will be challenging. One of the unwanted effects of CD19 CAR T cells is the destruction of normal B cells, which also express CD19, but this effect may be compensated for by infusion of immunoglobulin preparations. Solid tumors also share antigens with other organs, and few other normal cell types are as dispensable as B cells. There are a limited number of truly unique TAAs that can be recognized by antibodies or other antigen-recognition domains suitable for inclusion in CARs. Moreover, T cells traffic poorly to many tumor sites. In addition, once there, T cells encounter an immunosuppressive tumor microenvironment⁷³ (Figure 1) mediated by the recruitment of inhibitory cells (e.g., myeloid suppressor cells and regulatory T cells), the expression of inhibitory molecules (e.g., PDL1 and FasL), and the production of soluble inhibitory molecules/Th2-polarizing cytokines (e.g., adenosine, IDO, TGF- β , IL-6, IL-10, and PGE-2). Therefore, investigators are engineering T cells to improve the tumor migration of adoptively transferred T cells and their proliferation and survival *in vivo*. For example, to resist TGF β , a dominant-negative TGF- β receptor type II has been expressed in tumor-directed T cells. TGF- β receptor type II expression induces resistance to tumor-secreted TGF- β and is showing promising clinical benefits.^{74, 75} Other engineering countermeasures to tumor immune evasion are currently under investigation (Table 2).

Table 2 Countermeasures to tumor immune evasion

Targets	Gene modification	References
TGF-β	Dominant-negative TGF-β receptor	74
Fas L	Downregulation of Fas	76
IDO, arginase	GCN2 knockdown	77 78
IL-10	IL-10 receptor 1/IgG1-Fc fusion proteins	79
IL-4	IL-4/IL-7 chimeric receptor	80

Genetic modification of other immune system cells

Both natural killer (NK) cells and invariant chain or natural killer T (NKT) cells can be activated and expanded *ex vivo*. These cells form part of the bridge between the innate and adaptive immune responses, and once retargeted to tumors may have significant antitumor activity. All of the studies described for T cells are in the process of being replicated for NK and NKT cell populations; the next few years will reveal their potency, safety, and the durability of any antitumor activity.

Safety

Although immunotherapy with adoptively transferred T cells has produced striking results, like any potent therapy, the risk is considerable. Apart from fatal cross-reactivities with normal tissues, induction of cytokine release syndrome (or systemic inflammatory response syndrome) has been reported after the administration of some T-cell therapies, particularly CD19 CAR T cells. As these events may be lethal, investigators are developing and testing several safety or suicide systems that may allow rapid control of the treatment. They include cytotoxic antibodies, prodrug-metabolizing enzymes, and inducible apoptosis genes.^{81–84}

Conclusion: How will cancer gene therapy enter clinical practice?

Now that the role of gene therapy for cancer is becoming clearer, the pharmaceutical industry and healthcare providers will have to begin to assess the high cost of developing, manufacturing, and delivering these individualized therapies. As optimal results may be obtained only when multiple biological therapies are combined (e.g., engineered T cells, oncolytic viruses, and checkpoint antibodies), the pharmacoeconomics will need to be carefully addressed by healthcare services experts and an adequate case made for their widespread substitution for conventional therapy. Although we believe that such a case will indeed be made, this remains one more in the long list of the challenges that cancer gene therapy will face before it truly becomes frontline treatment of cancer.

Chapter 69

Cancer nanotechnology

Yanlan Liu, PhD ■ Danny Liu ■ Jinjun Shi, PhD ■ Robert S. Langer, ScD

Overview

The advances in state-of-the-art nanotechnologies have offered exciting opportunities to overcome many obstacles that contribute to the high mortality and recurrence of cancer, such as suboptimal pharmacokinetics and therapeutic efficacy of anticancer drugs, severe adverse effects, development of drug resistance, and cancer metastases. Here, we highlight the clinical stage nanoparticle technologies applied in conventional cancer therapies and for the development of novel classes of anticancer therapeutics. We also discuss recent cutting-edge research efforts in this exciting field, which could lead to more effective therapeutic nanoparticles for cancer treatment.

Introduction

Despite the exciting progress in cancer biology, diagnosis, and therapy, the global burden of cancer—one of the most devastating diseases worldwide—continues to grow at an alarming pace. According to the *World Cancer Report 2014*, it is expected that new cancer cases will rise from an estimated 14 million annually in 2012 to 22 million within the next 20 years, and cancer deaths from 8.2 million to 13 million per year over the same period.¹ Considering limitations in conventional cancer therapeutics, such as unfavorable pharmacokinetics, adverse effects, and development of drug resistance,² new strategies are therefore essential to improve therapy outcomes and address the rising cancer burden.

Over the past 20 years since the FDA approval of the first anticancer therapeutic nanoparticle Doxil (liposomal doxorubicin), nanotechnology has demonstrated tremendous potential for enhanced cancer treatment.^{3–5} For example, nanoparticles can favorably modulate pharmacokinetic and biodistribution profiles of drug molecules to improve their therapeutic efficacy and/or reduce unintended adverse effects.⁶ With unique physicochemical features, some nanomaterials themselves possess therapeutic action, such as iron oxide nanoparticles for hyperthermia cancer treatment.⁷ To date, approximately 10 cancer nanotherapeutics have been approved for clinical use, and many are currently in clinical trials ([Table 1](#)).⁸ This chapter overviews the clinical stage nanotechnologies in cancer therapies, and discusses recent cutting-edge research in the cancer nanotechnology field.

Table 1 Representative clinical stage nanotechnologies in cancer therapies

Category		Product	Description	Indications	Clinical state
Chemotherapy	Passive targeting	Doxil	PEGylated liposomal doxorubicin	Ovarian cancer, Kaposi sarcoma, multiple myeloma	FDA approval in 1995
		DaunoXome	Daunorubicin-loaded lipid	Advanced HIV-	FDA

			vesicles	related Kaposi sarcoma	approval in 1996
		Mepact	Liposomal muramyl tripeptide phosphatidyl-ethanolamine	Nonmetastatic, resectable osteosarcoma	Approved in Europe, Phase III in the United States
		Myocet	Liposomal doxorubicin	Metastatic breast cancer	Approved in Europe and Canada
		Abraxane	Nanoparticle albumin-bond (Nab)-paclitaxel	Metastatic pancreatic cancer, nonsmall-cell lung cancer, breast cancer	FDA approval in 2005
		Genexol-PM	Paclitaxel-loaded polymeric micelles	Breast cancer	Approved in South Korea, Phase IV in the United States
	Active targeting	BIND-014	Docetaxel-loaded polymer nanoparticle coated with a small molecule for targeting PSMA	Nonsmall-cell lung cancer, metastatic castration-resistant prostate cancer	Phase II
		MM-302	Doxorubicin-loaded liposome modified with antibody fragment for targeting tumor antigen	HER2 positive breast cancer	Phase III
		MBP-426	Oxaliplatin-loaded liposome coated with transferrin for targeting transferrin receptor	Gastric, esophageal, gastroesophageal adenocarcinoma	Phase Ib/II
	Stimuli-responsive targeting	MTC-DOX	Doxorubicin is bound to microscopic beads of activated carbon and iron as a magnetic-targeted carrier (MTC)	Adult primary hepatocellular carcinoma liver cancer	Phase III
		ThermoDox	Doxorubicin is encapsulated in thermally sensitive liposomes	Hepatocellular carcinoma	Phase III
Radiotherapy		NBTXR3	Hafnium oxide nanoparticles	Soft tissue sarcoma, locally advanced	Phase I

				squamous cell carcinoma of the oral cavity or oropharynx	
	Hyperthermia	NanoTherm	Aminosilane-coated iron oxide nanoparticles	Glioblastoma	European Union regulatory approval
		AuroLase	Silica core with a gold nanoshell	Refractory head and neck cancer, and primary and/or metastatic lung tumors	Phase I
	Gene therapy	CALAA-01	Transferrin-decorated cyclodextrin polymer nanoparticle containing siRNA against the M2 subunit of ribonucleotide reductase	Solid tumors	Phase I
		ALN-VSP02	A lipid nanoparticle containing siRNAs against kinesin spindle protein and VEGF	Solid tumors	Phase I
		Atu027	Liposome containing a modified siRNA against protein kinase N3	Advanced or metastatic pancreatic cancer	Phase I/II
		SGT53-01	p53 gene-loaded liposome coated with antibody fragment for targeting transferrin receptor	Solid tumors	Phase Ib
	Active immunotherapy	Lipovaxin-MM	Liposome-based vaccine loaded with melanoma antigens	Melanoma	Phase I
		dHER2 + AS15	Liposomal vaccine consisting of a HER2/neu peptide (dHER2) combined with the immunoadjuvant AS15	Metastatic breast cancer	Phase I/II
		DPX-0907	Multitumor-associated antigens-loaded liposome	HLA-A2 positive advanced stage ovarian, breast, and prostate cancer	Phase I
		Tecemotide	Liposome-encapsulated	Nonsmall-cell lung	Phase III

Clinical stage cancer nanotechnologies

What makes nanotechnology particularly impactful in cancer therapy is that it possesses a variety of distinctive features for drug delivery. With nanotechnology, it may be possible to (1) improve the delivery of therapeutic molecules (e.g., hydrophobic drugs) and protect them from premature degradation, clearance, or interaction with biological environments;^{9, 10} (2) deliver drugs more selectively to tumor cells by modifying the nanoparticles with targeting ligands;^{11, 12} (3) pack both imaging and therapeutic agents together for real-time feedback on drug delivery and for patient selection;¹³ (4) cross-tight endothelial and epithelial barriers;^{14, 15} (5) codeliver multiple drugs to improve therapeutic efficacy through synergistic effects and/or to overcome drug resistance;^{16, 17} (6) control sustained drug release to reduce administration frequency; (7) protect nucleic acids from enzymatic degradation and facilitate their intracellular uptake and endosomal escape;¹⁸ among others. Furthermore, some nanoparticles have inherent thermotherapy capabilities activated upon local stimulation, which make them invaluable in terms of surmounting the resistance of tumor cells to chemotherapeutic drugs and avoiding systemic adverse effects. Given these merits, nanotechnology has extraordinary potential to address obstacles existing in conventional cancer therapies and to develop novel classes of anticancer therapeutics. Here, we discuss the clinical stage nanotechnologies used in different cancer therapy modalities, such as chemotherapy, radiotherapy, hyperthermia therapy, gene therapy, and active immunotherapy ([Table 1](#)).

Chemotherapy

One major advantage of chemotherapy lies in its ability to systemically attack cancers. Unfortunately, owing to the suboptimal pharmacokinetic profiles, only a small fraction of the administered drugs can be delivered to tumor. Their nonspecific delivery to healthy cells also makes severe side effects inevitable. Nanoparticle technologies have thereby emerged as a promising way for efficient delivery of drugs to tumor tissue while reducing their side effects.^{19, 20} It has been recognized that the tumor surroundings are dense with leaky blood vessels. Together with the lack of functional lymphatic drainage, nanoparticles are allowed to extravasate out of circulation and accumulate in tumor tissue ([Figure 1a](#)), which is denoted as the enhanced permeability and retention (EPR) effect.²¹ On the basis of the EPR effect, various nanoparticle platforms have been developed and approximately ten were introduced into the market, including Doxil, Abraxane, and Genexol-PM.⁸

Figure 1 Schematic illustration of different nanotherapy strategies in cancer treatment. (a) Nontargeted nanoparticles passively extravasate out of the leaky vasculature for tumor accumulation through the EPR effect. The drug molecules may be released from the nanoparticles and diffuse throughout the tissue for bioactivity. (b) For active tumor cell targeting, the nanoparticles are modified with targeting ligands, which recognize receptors present on tumor cell surface. The receptor-mediated endocytosis leads to enhanced accumulation and cell uptake of nanoparticles. (c, d) By incorporating ligands that bind to the receptors on the surface of endothelial cells (c) or stromal/immune cells (d), nanoparticles can actively target tumor microenvironment for cancer therapy. (e) Some nanoparticles can generate heat under an alternating magnetic field or laser irradiation for cancer hyperthermia therapy. (f) Some nanoparticles become therapeutically active by releasing the payloads under either endogenous stimuli (e.g., pH, enzyme, and redox) or exogenous stimuli (e.g., light, heat, magnetic field, or ultrasound).

To further improve specificity of nanoparticle delivery, active targeting has been proposed and advanced into clinical investigation by modifying the nanoparticle surface with targeting moieties, which can selectively recognize tumor cell-specific receptors. The targeting ligands can be antibodies, aptamers, peptides, carbohydrates, small molecules, or others.²² Through receptor-mediated endocytosis, targeted delivery can increase nanoparticle retention and cellular uptake, thus significantly enhancing therapeutic efficacy ([Figure 1b](#)).²³ A recent representative example is BIND-014, a docetaxel-loaded polymer nanoparticles decorated with small molecules against prostate-specific membrane antigen (PSMA), which has been developed by BIND Therapeutics and is now in phase II clinical trials for the treatment of solid tumors. In xenograft animals treated with BIND-014, the docetaxel concentration in tumor was sevenfold higher than that treated with conventional docetaxel (taxotere) 12 h after intravenous injection. Clinical data in patients with metastatic cholangiocarcinoma showed that tumor shrinkage was achieved at a dose of docetaxel that corresponds to only 20% of the typical dose for doctaxel.²⁴

In addition to increasing specificity, avoiding the premature release of drugs before they reach the tumor may be equally important for maximizing therapeutic efficacy and minimizing adverse effects. Stimuli-responsive nanoparticles have shown promising potential for this purpose, as they only become active in the tumor microenvironment (TME) ([Figure 1f](#)).²⁵ Generally, these nanoparticles are designed to recognize subtle environmental changes associated with tumor pathological situations (e.g., pH, redox, and enzyme) or to be activated by external stimuli (e.g., heat, light, magnetic field, and ultrasound).²⁶ To some extent, external stimulation allows for tailored drug release profiles with excellent temporal, spatial, and dosage control.²⁷ In particular, noninvasive magnetic field- and ultrasound-responsive nanoparticle delivery systems have gained a lot attention as there are nominal limits in tissue penetration for these modalities.^{25, 26} At present, doxorubicin-loaded thermo-responsive liposomes are being investigated in phase II trials for the treatment of colorectal liver metastasis, bone metastases, and breast cancer and have even reached phase III trials for hepatocellular carcinoma therapy.²⁶

Radiotherapy

In conventional radiotherapy, high-energy ionizing radiations such as gamma and X-rays are generally used to ionize cellular components and/or water to generate free radicals for DNA damage in tumor cells. However, the effectiveness of radiotherapy is limited by the tolerance of normal tissue to ionizing radiation dose and the development of radiation resistance of cancer cells.²⁸ Nowadays, several approaches have been proposed to address these issues. Introducing nanoscale radiosensitizers (e.g., gold, gadolinium, and iron oxide nanoparticles) into the X-ray pathway is considered an effective way to eradicate tumors at a lower dose of radiation.²⁹ These materials have higher electron density than water

in tissues, enabling strong interaction with X-rays and allowing for more localized and consolidated damage to tumor. Currently, a new radiation NanoXray (developed by Nanobiotix) based on hafnium oxide nanoparticles is in clinical testing for patients with different soft tissue sarcoma.

An alternative way to enhance radiotherapeutic efficacy is to protect surrounding healthy tissues from damage or make them less radiation sensitive. Nanoparticles containing small molecules with radioprotective effects (e.g., cysteine, citicoline, and amifostine) have been investigated. Oral administration of these particles has shown radioprotective effects in both mammalian cells and rats during radiation exposure.^{30–32} Furthermore, nanoparticles loaded with therapeutics against radiation-resistant biological pathways (e.g., survivin and epidermal growth factor receptor) have shown the ability to overcome the resistance of tumor to radiation therapy.^{33, 34} All these nanoparticle strategies could lead to further improvement in clinical radiotherapy.

Hyperthermia therapy

Owing to low host toxicity, ease of control, and absent/low resistance, hyperthermia treatment methods such as photothermal therapy (PTT) and magnetothermal therapy may be considered for cancer therapy, especially for drug-resistant cancers. Distinct from traditional therapies, PTT relies on photosensitizers to absorb light and convert it into heat to kill cells in its vicinity.³⁵ Its key advantage over traditional chemotherapy is that photosensitizers are minimally toxic without light exposure and thus damage to healthy tissues is minimal even with photosensitizer accumulation. Unlike radiotherapy, the light used in PTT is nonionizing [usually near-infrared light (NIR)], hence its effect on tissues is much less invasive. Considering hypoxia in most tumors, PTT is more attractive for cancer therapy than photodynamic therapy (PDT) currently used in the clinic because PTT does not require oxygen, while PDT utilizes UV or visible light to activate photosensitizers to generate toxic reactive oxygen in the presence of oxygen.³⁶ Moreover, NIR involved in PTT has much deeper penetration than UV or visible light typically used in PDT.³⁷ Nevertheless, low molecular weight PTT agents tend to aggregate in aqueous solution, nonspecifically bind to proteins and lack target specificity. A large number of nanoparticles have therefore been investigated as PTT agents including carbon-based nanomaterials, semiconductor nanocrystals, metallic nanoparticles, rare earth ion-doped nanocrystals, and organic nanoparticles. *In vivo* preclinical results of these PTT nanoparticle agents demonstrated that tumor shrinking was achieved with minimal damage to surrounding healthy tissues.³⁸ Currently, AuroLase (a gold nanoshell-encapsulated silica nanoparticle developed by Nanospectra) is under phase I trials for PTT of refractory head and neck cancer, and primary and/or metastatic lung tumors. In addition to PTT, magnetothermal therapy also shows significant potential for cancer treatment. One successful example is NanoTherm (iron oxide nanoparticles), which recently received EU Regulatory Approval as medical devices for glioblastoma treatment. Interestingly, these nanoparticles could also be used for X-ray CT or MRI imaging, thus enabling diagnosis, patient selection, and/or response tracking.

Gene therapy

Advances in cancer genetics and tumor-specific signaling pathways that are critical for tumor development/metastasis have given rise to the application of gene therapy in cancer treatment. The advantage of gene therapy over other anticancer strategies is that, in principle, we can rationally design nucleic acids (e.g., DNA, siRNA, antisense, and mRNA) to specifically regulate the expression of virtually any gene of interest. RNA interference (RNAi) technology, which can specifically silence the expression of target genes, represents a revolution in gene therapy and holds great promise for cancer research and therapy.^{39–41} For instance, it provides a rapid approach to study the genetic alterations in

human cancers, many of which are considered as “undruggable” targets and/or require complex and time-consuming development of effective inhibitors.^{42, 43} However, the ubiquitous application of RNAi in cancer treatment is hindered by the challenge of safe and effective delivery of RNAi agents such as small interfering RNA (siRNA) to tumors. As siRNA molecules are susceptible to degradation by endogenous enzymes and cannot readily cross cellular membrane owing to their polyanionic and macromolecular characteristics, a variety of nanoparticle vehicles have been extensively explored to protect siRNA and facilitate its delivery into the tumor cell cytosol where the RNAi machinery resides.^{18, 44} To date, several cationic lipid- or polymer-based siRNA nanoparticles, including CALAA-01, ALN-VSP02, Atu027, and others, have entered phase I or II clinical trials to treat different types of cancer.¹⁸ RNAi nanotechnology has also shown potential in reversing drug resistance. By downregulating overexpressed antiapoptotic regulators (e.g., Bcl-2) and transporters (e.g., P-glycoprotein), or by suppressing of DNA repair pathways, drug resistant tumor cells can be resensitized.^{45–47}

Distinct from gene silencing by siRNA or antisense, DNA-mediated gene therapy aims to replace a mutated gene in tumor cells with a functional, therapeutic gene. However, similar to siRNA delivery, the main problem restricting the *in vivo* applications of gene therapy is the difficulty of delivering the fragile, large, and negatively charged DNA molecules into the nucleus of tumor cells. Over the past few decades, an astounding amount of positively charged materials have been designed for enhancing the safety and efficacy of DNA delivery.⁴⁸ Today, SGT53-01, a p53 gene-loaded liposome coated with transferrin, is currently undergoing phase I clinical trials for treatment of solid tumors.⁴⁹ In addition to DNA, mRNA is also emerging as a promising therapeutic nucleic acid in recent years. Its therapeutic mechanism is similar to that of DNA-mediated gene therapy, but to some extent, mRNA would be more efficient as it does not require nuclear localization/transcription. Furthermore, mRNA has little chance of interacting with the host genome, thus excluding potentially detrimental genomic integration.⁵⁰ Naked and protamine-protected mRNAs are currently in active clinical trials for cancer treatment.^{51, 52} Although there is no clinical trial underway, a growing number of studies have shown that mRNA formulated in nanoparticles exhibited enhanced translation and generated a more robust immune response owing to improved intracellular uptake/endosomal escape.⁵³

Taken together, the idea of using nucleic acids as therapeutics for cancer therapy is straightforward, but successful application of gene therapy faces the major challenge of safe and effective gene delivery *in vivo*. While remaining elusive, development of nanoparticle delivery vehicles with long blood circulation time, high tumor accumulation, uniform tissue penetration, and efficient cellular uptake and endosomal escape represents a great opportunity in the gene therapy field.

Active immunotherapy

In contrast to the therapy modalities mentioned above, active immunotherapy (or cancer vaccine) provides a unique strategy for cancer treatment by provoking the host's immune system to fight tumor cells. As immune systems are robust, have the capacity for memory, and possess exquisite specificity, active immunotherapy might achieve complete and long-lasting cancer cures with minimal detriment to health.⁵⁴ However, only a few vaccines have demonstrated sufficient efficacy for clinical use. The major reasons that contribute to these limited clinical responses may be the physical barriers imposed by the TME, host-derived immunosuppressive effects, or tumor escape from immune effector function.⁵⁵ Nanotechnology is gaining momentum in this field and becoming increasingly attractive as potent carriers for effective delivery of vaccine antigens and adjuvants. First, nanoparticles can be engineered for rapid phagocytosis by immune cells and can protect antigens (e.g., peptides, proteins and nucleic acids) from

premature enzymatic and proteolytic degradation.⁵⁶ In particular, they allow for more effective antigen uptake in some immune cells such as dendritic cells (DCs), as compared to free antigens.⁵⁷ By surface coating with a proprietary DC-specific antibody fragment, a targeted liposomal vaccine, lipovaxin-MM (currently phase I study) can deliver multiple antigens to DCs effectively owing to the ligand-receptor interactions. Second, nanoparticles can package antigen and adjuvant for transport to the targeted site simultaneously, which could be crucial for ideal immunotherapy. For instance, by coloaded tumor-associated antigen HER2/neu and adjuvant AS15 with potential immunostimulatory and antineoplastic activities into the liposome, this vaccine can stimulate the host immune response to mount a cytotoxic T-lymphocyte response, leading to tumor cell lysis, and is now in phase II clinical studies for metastatic breast cancer. Compared to liposomes, biodegradable polymer nanoparticles can not only regulate the pharmacokinetic and distribution profile of antigens/adjuvants but also exhibit additional unique features such as sustained release of antigens/adjuvants at the target site and eliminating the need for repeated doses.⁵⁸ A recent study by Selecta Biosciences further shows that adjuvant-carrying polymeric nanoparticles can augment the immune response to encapsulated antigen and exhibit strong local immune activation without inducing systemic cytokine release.⁵⁹

Recent advances in cancer nanotechnologies

Despite the fascinating achievements mentioned earlier, the potential of cancer nanotechnologies may be far from being fully realized. In the following section, we briefly discuss some recent exciting advances in this field, which from our perspective may enable the development of more effective cancer nanotherapeutics.

One major challenge for effective systemic drug delivery to tumor tissues is to avoid the recognition of nanoparticles by mononuclear phagocyte system (MPS) in liver and spleen for long blood circulation. This can therefore facilitate time-dependent extravasation of nanoparticles through the leaky tumor microvasculature and lead to effective tumor accumulation. Nanoparticle physicochemical properties, such as size, shape, surface charge, and surface modification (e.g., PEGylation), were previously shown to impact the circulation and tumor accumulation.^{60–64} Recently, a new concept for effectively evading the MPS system by incorporating cellular membranes on NP surface has moved into the spotlight. By using natural erythrocyte membranes as coating shells, it was observed that the circulation half-life of cell membrane-coated nanoparticles in blood was 2.5-fold higher than PEG-coated nanoparticles.⁶⁵ Furthermore, the cellular membrane can also retain its inherent functions, leading to the active delivery of nanotherapeutics to tumor. For example, by coating with leukocyte membranes, a new generation of nanotherapeutics has demonstrated the ability to avoid opsonization, delay liver clearance, and recognize and bind tumor endothelium in an active manner.⁶⁶ Another thought-provoking concept to inhibit phagocytic clearance is to decorate nanoparticles with a “marker of self” ligand such as CD47 or its peptide variant.⁶⁷ Such ligands can impede phagocytosis of “self” cells or nanoparticles by signaling through the phagocyte receptor CD172a, thus delaying macrophage-mediated clearance of nanoparticles and promoting blood circulation for more effective drug delivery to tumors.

TME has been gradually recognized as a key contributor to tumor growth, progression, and metastasis and can therefore be considered as a potential target for effective cancer therapy.⁶⁸ Vascular endothelium performs critical functions such as transporting oxygen and nutrients from the bloodstream to tissues, controlling blood flow and trafficking blood cells. Its abnormalities are always implicated in the pathogenesis of tumor progression and metastasis.⁶⁹ Nanoparticles carrying drugs or siRNAs targeting dysfunctional tumor vascular endothelium have thus been a growing interest in cancer treatment ([Figure](#)

1c).⁷⁰ A specific polymeric nanoparticle platform has recently been developed for selective siRNA delivery to lung endothelial cells, leading to effective silencing of five endothelial genes (Tie1, Tie2, VEcad, VEGFR-2, and ICAM-2) without significant reduction of gene expression in pulmonary immune cells, hepatocytes, or peritoneal immune cells.⁷¹ Another strategy is to target tumor-associated inflammation, such as inhibiting the infiltration of tumor-associated macrophages ([Figure 1d](#)).^{72, 73} Attention has also been given to targeting the communication between cancer cells and TME. One recent example is the active delivery of Bortezomib using biodegradable PLGA-PEG polymer to increase osteogenic differentiating and bond strength, which in turn significantly inhibited tumor growth in bone, the most common metastatic site for many cancers.⁷⁴ In addition, some highly cytotoxic chemotherapeutic drugs can be administrated as “prodrugs” and then activated by TME (e.g., pH, enzyme, and hypoxia) into cytotoxic products.⁷⁵

Although in an early state, the development of nanotherapeutics for noninvasive administration through oral, nasal, or ocular routes is constantly growing and showing many merits over systemic injection. Drug delivery through a nasal route is advantageous for treatment of lung cancer because it allows nanotherapeutics to bypass high liver uptake and avoid repeated administration. In a recent *in vivo* study using inhalable doxorubicin-encapsulated nanoparticles to treat lung cancer, highly significant improvement in survival was observed compared to intravenous injection groups.⁷⁶ On the other hand, cancer patients who require frequent administration of drugs would benefit from oral delivery because of the convenience and compliance, but this approach is limited by insufficient intestinal absorption of drugs owing to intestinal mucosal barrier. Very recently, IgG Fc fragments have been conjugated to polymer nanoparticles, which can effectively target neonatal Fc (FcRn) receptors and be transported across intestinal epithelium after oral administration and reach systemic circulation with mean absorption efficiency 10 times higher than nontargeted nanoparticles.¹⁵ These targeted nanoparticles offer new hope for developing oral delivery nanotherapeutics for cancer treatment.

Summary

Clinical success in cancer nanomedicine has become a driving force behind the development of new nanoparticle technologies for safer and more effective treatment and the pursuit of personalized nanotherapeutics. Meanwhile, we have also realized how challenging the cancer nanotechnology field is due to the complexity and heterogeneity of cancer and the encumbrances in clinical translation. The convergence of nanotechnology with tumor biology and other biological/biomedical sciences will therefore be crucial for realizing the full potential of cancer nanotechnology. We expect that this chapter can encourage physicians, scientists, engineers, and others from different areas of expertise to become involved in this exciting field and promote the widespread application of nanotechnologies for cancer management.

Chapter 70

Hematopoietic cell transplantation

Roy Jones, MD, PhD ■ Elizabeth Shpall, MD ■ Richard Champlin, MD

Overview

Hematopoietic cell transplantation is an effective therapy for a variety of hematologic malignancies and selected other cancers, immunodeficiency states, and genetic disorders. Refinement of methods has allowed the application of this technique to older patients as well as the use of human leukocyte antigen mismatched donors and products. While toxic, the majority of these treatments have curative potential for otherwise fatal cancers. The immunotherapeutic activity of allotransplantation provides both therapeutic benefit and lessons for future immune treatments of cancer.

Hematopoietic cell transplantation involves engraftment of stem cells that can be collected from the bone marrow, peripheral blood, or umbilical cord blood (UCB). Allogeneic transplants are obtained from another individual. Autologous transplants involve use of a patient's own hematopoietic cells, usually after cryopreservation. Syngeneic transplants are between genetically identical twins.

Hematopoietic transplantation is an effective treatment for many life-threatening hematologic, immune, metabolic, and neoplastic diseases ([Table 1](#)).^{1, 2} The basis for autologous hematopoietic cell transplantation is to use patient-derived hematopoietic stem cells to prevent otherwise lethal myelosuppression from intensive treatment. More recently, autologous cells manipulated *in vitro* to produce augmented immune effects are being explored. The basis of allogeneic hematopoietic transplantation is the engraftment of donor-derived stem cells; in the recipient, these cells reconstitute hematopoiesis and immunity. Following successful transplantation, recipients are considered chimeras with hematopoietic and immune cells derived from the donor. Recently, it has been recognized that hematopoietic stem cells are capable of limited differentiation into nonhematopoietic tissues⁴ including mesenchymal cells,^{5, 6} liver,^{7, 8} cardiovascular tissues,⁹ and, possibly, neural tissue.¹⁰ There is considerable interest in stem cell transplantation for restoration of damaged or diseased organs and tissues.^{11, 12}

Table 1 Diseases treated with hematopoietic transplantation

Malignant

- Acute myelogenous leukemia
- Myelodysplastic syndromes
- Acute lymphoblastic leukemia
- Chronic myelogenous leukemia and myeloproliferative disorders
- Chronic lymphocytic leukemia
- Non-Hodgkin lymphoma
- Hodgkin disease
- Multiple myeloma and amyloidosis
- Solid tumors: breast, testicular, ovarian, and small cell lung cancer
- Pediatric solid tumors: neuroblastoma, Ewing sarcoma, medulloblastoma, renal cell cancer, melanoma

Nonmalignant

- Aplastic anemia and related bone marrow failure states
- Hemoglobinopathies: thalassemia, sickle cell anemia
- Congenital disorders of hematopoiesis
- Fanconi anemia and related syndromes
- Congenital immune deficiencies: severe combined immune deficiency, Wiskott–Aldrich syndrome, chronic granulomatous disease, and related syndromes
- Inborn errors of metabolism
- Autoimmune disorders

Methods of transplantation

In most cases, transplanted hematopoietic cells are infused following intensive chemotherapy, irradiation, or other therapies such as antibodies. Over time, a variety of chemotherapeutic agents has been explored for use in transplantation, emphasizing the alkylating agents cyclophosphamide, busulfan, melphalan, thiotepa, and carmustine (BCNU). Total body radiation (TBI) is also employed. In allogeneic transplantation, these drugs are often combined with agents designed to produce additional tumor killing and immunosuppression, such as fludarabine.¹³

The existence of graft-versus-malignancy (GVM) effect is now well-established as an important component of therapeutic activity for allotransplantation.¹⁴ This alloimmune effect is often associated with normal tissue toxicity and termed graft-versus-host disease (GVHD). A major focus of allotransplant research is the exploration of specific cell types and techniques that might produce GVM without GVHD.¹⁵ Donor lymphocyte infusions (DLI) following transplantation can be used to augment the GVM

Hematopoietic transplantation as treatment for malignancies

Most hematopoietic transplants have been performed for treatment of hematologic malignancies.¹⁷ Many chemotherapy drugs (predominantly alkylating agents¹⁸) and irradiation produce a dose-dependent antitumor response. Myelosuppression is the dose-limiting toxicity of many chemotherapeutic agents and whole-body irradiation. Doses of many agents can be escalated three- to fivefold above conventional maximally tolerated dose if followed by autologous or allogeneic transplantation to restore hematopoiesis ([Figure 1](#)).

Figure 1 Scheme of allogeneic hematopoietic transplantation. The recipient receives a myeloablative preparative regimen designed to eradicate malignant and normal cells. The recipient then receives donor hematopoietic cells that restore hematopoiesis. Abbreviations: D, donor hematopoietic cells; HSCT, hematopoietic stem cell transplant; R, recipient's normal bone marrow cells; RL, recipient's leukemia cells in bone marrow.

Autologous transplantation

As a general rule, autologous hematopoietic transplantation is most effective in patients with malignancies shown to be responsive to conventional treatment immediately before the transplant regimen.¹⁹ Factors known to predispose to treatment failure include higher volume residual tumor,^{20, 21} tumor types not known to exhibit a steep dose-killing relationship,²² or treatment of patients at high risk for toxicities from

the proposed treatment regimen.

Immune augmentation strategies used in the posttransplant setting are being actively explored to avoid the prolonged immunosuppression that follows transplantation and may increase the risk of relapse.²³ An additional factor that might predispose to relapse is contamination of the harvested cells with tumor. Although limited investigation using gene-marked tumor cells has shown that cryopreserved tumor cells can engraft and contribute to relapse, the clinical importance of this phenomenon is unclear.²⁴ Malignancies shown to be cured by autologous hematopoietic cell transplantation include intermediate grade and other selected lymphomas,²⁵ Hodgkin's disease,²⁶ acute lymphoblastic leukemia,^{27, 28} and acute myelogenous leukemia (AML).^{29, 30} Although not proven to be curative, major improvement in survival in myeloma patients receiving autologous transplantation has made the technique a standard treatment for appropriate patients with this condition.^{31, 32} Benefit is likely for patients with germ cell cancers,³³ low grade lymphomas,³⁴ and a variety of pediatric solid tumors.³⁵

Allogeneic transplantation

Allogeneic hematopoietic transplants combine cytotoxic treatments with the immune-mediated GVM effect. Donor-derived lymphoid cells may react against and eradicate malignant cells that survive high-dose cytotoxic therapy.^{36, 37} Patients with acute or chronic GVHD have reduced risk of relapse, suggesting a relationship between GVM and GVHD.^{38, 39} The most direct evidence for GVM comes from the observation that DLI can reinduce remission in patients who relapse posttransplant.^{40, 41}

There are major differences among malignancies in their susceptibility to GVM effects. Indolent myeloid and lymphoid malignancies are highly sensitive to this process, as evidenced by durable remissions after modulation of immunosuppression or DLI in patients who have relapsed after an allogeneic transplant. GVM effects have been best documented in patients with chronic myelogenous leukemia (CML).

GVM effects also occur but with lesser intensity against other hematologic malignancies including AML, multiple myeloma (MM), Hodgkin's disease, and intermediate-grade lymphoma. In these diagnoses, allogeneic transplants produce a greater frequency of durable remissions than syngeneic or autologous transplants, but these disorders respond less frequently to DLI and responses are usually transient. Acute lymphoblastic leukemia and high-grade lymphoma appear relatively insensitive to graft-versus-leukemia (GVL) effects,⁴² although patients with GVHD do have a reduced risk of relapse in some studies.⁴³

GVM effects may be directed against a number of potential target antigens. Development of methods to separate GVM effects and GVHD and generate antigen-specific antitumor responses is a major goal of ongoing research. For example, natural killer (NK) cells may produce GVM with decreased risk of GVHD,⁴⁴ and regulatory T cells (Treg) may moderate GVHD with lesser effects on GVM.⁴⁵

Donor selection

Autologous transplantation

Autologous transplants use the patient as their own donor. In the closely related special case, syngeneic transplants are donations from a genetically identical twin. Autologous transplants require no histocompatibility matching but often come from patients who have received extensive prior chemotherapy. This treatment often compromises marrow stem cell function making adequate stem cell collection more difficult. Stem cells can be collected from the peripheral blood following mobilization with hematopoietic stimulants [G-CSF (granulocyte colony-stimulating factor), chemotherapy] or from

bone marrow. A minimum of 2×10^6 CD34 cells/kg recipient body weight is required for satisfactory engraftment. Tumor contamination of collected cells represents a possible source of relapse and patients with significant tumor infiltration of marrow may be less desirable autotransplant candidates.^{46, 47} Various “purging” techniques to reduce or eliminate tumor cell contamination *in vitro* are being investigated.

Patients undergo collection of bone marrow or peripheral blood progenitor cells that are then cryopreserved in a viable state. Patients subsequently receive high-dose myelosuppressive therapy to eradicate the malignancy, followed by reinfusion of the stored cells to reconstitute hematopoiesis. Autologous hematopoietic cells can potentially be used as vehicles for gene therapy designed to correct deficiency states.

Allogeneic transplantation

Allogeneic transplants are collected from related or unrelated donors. The human leukocyte antigen (HLA) system is the major histocompatibility complex (MHC) in man, and the results of allogeneic transplantation depend on the histocompatibility between donor and recipient. The HLA system is encoded by several closely linked loci on the short arm of chromosome 6.^{48, 49} Class I loci include HLA-A, -B, and -C alleles. The class II region includes DR, DQ, and DP loci.

Historically, transplants have been from HLA-identical sibling donors. The HLA genes are inherited as a haplotype with one haplotype derived from each parent. There is approximately a one in four chance that any given sibling will be HLA matched with a potential recipient. Registries of potential unrelated donors have been established to provide hematopoietic transplants for patients lacking a histocompatible relative. HLA gene frequencies vary considerably among racial and ethnic groups, and patients are most likely to find transplants among potential donors of their own genetic background. Linkage disequilibrium occurs such that some haplotypes occur commonly, but approximately half of the population have rare haplotypes. There are now over 18 million potential unrelated bone marrow donors accessible in registries worldwide, and approximately half of patients can access an HLA-A, -B, -C, -DR-, and -DQ identical donor. Ten-antigen matched unrelated donor transplants now have outcomes that approximate those for histocompatible sibling donors.^{50, 51}

Transplant recipients who are mismatched at one or more loci are at higher risk of graft rejection, GVHD, and associated complications. One haplotype-identical related donors are readily available for most patients. The use of posttransplant high-dose cyclophosphamide has been shown to moderate GVHD risk and make haploidentical-related transplants increasingly possible.⁵² In addition, UCB is now frequently used.^{53, 54} Constraints for HLA matching of UCB are much less than that for other cell sources, with mismatches at 2 of 6 HLA-A, -B, and DR loci being acceptable.⁵⁵ Owing to the size of the units, UCB transplants have been most successful in children but can also be accomplished in adults when large or multiple cord products are used. Delayed immune reconstitution and a high frequency of opportunistic infections remain major complications of both these techniques.

Like autotransplantation, allogeneic cells are usually administered after an intensive chemotherapy program. In addition to tumor killing, these programs are also designed to produce immunosuppression sufficient to facilitate engraftment of the allo cells. The intensity required is, in part, proportional to the immunocompetence of the recipient. After hematopoietic recovery, the degree of donor engraftment relative to host hematopoiesis (termed chimerism) is most commonly measured by PCR of DNA-restriction fragment length polymorphisms of the donor. In some circumstances, reduced-intensity chemotherapy is used to decrease regimen-related toxicity or to produce a mixed chimeric state. Delayed DLI can be used subsequently to produce full donor chimerism.⁵⁶ This technique is particularly useful

when older patients are treated.^{57, 58}

Nonablative hematopoietic transplant

The recipient, a patient with normal and malignant leukemia cells in the bone marrow, receives a nonmyeloablative preparative regimen designed to prevent rejection of the transplant. The patient receives hematopoietic cells from the donor, which, after engraftment, produces a state of mixed chimerism in which both donor- and recipient-derived cells coexist ([Figure 2](#)). A subsequent graft-versus-hematopoietic effect may then occur, which eradicates residual normal and malignant cells of host origin, resulting in complete chimerism (presence of only donor derived hematopoietic and immune cells). A DLI may be administered to augment the GVM effect.

Figure 2 Scheme of nonablative allogeneic hematopoietic transplantation. Abbreviations: D, donor hematopoietic cells; DLI, donor lymphocyte infusion; HSCT, hematopoietic stem cell transplant; R, recipient's normal bone marrow cells; RL, recipient's leukemia cells in bone marrow.

Selection of autologous or allogeneic transplantation

Selection of the type of transplantation for a patient, autologous or allogeneic, depends on the type of malignancy, age of the recipient, availability of a suitable donor, ability to collect a tumor-free autograft, stage and status of disease (bone marrow involvement, bulk of disease, chemosensitivity to conventional chemotherapy), and the malignancy's susceptibility to GVM effects.

Autologous transplantation is readily available, and there is no need to identify an HLA-matched donor.

Autologous transplants have a lower risk of life-threatening complications; there are no risk of GVHD and no need for immunosuppressive therapy to prevent GVHD and graft rejection. Immune reconstitution is more rapid than after an allogeneic transplant and there is a lower risk of opportunistic infections. Graft failure occurs rarely. Treatment-related mortality is lower than 5% in most studies, and elderly patients can tolerate treatment relatively well.^{59, 60} However, autologous transplants have several drawbacks. Clonogenic tumor cells involving blood or bone marrow can contribute to relapse. Autologous transplantation relies solely on the effect of high-dose cytoreductive treatment for tumor eradication and lacks the immune-mediated GVM effect resulting after allogeneic transplantation. In most malignancies, relapse rates are higher after autologous transplants than after allogeneic transplantation, although this is often offset by a lower rate of treatment-related mortality. Patients with extensive prior therapy are at high risk for developing myelodysplasia and secondary acute leukemia after autologous hematopoietic transplantation.^{61, 62}

Allogeneic transplantation has the advantage that the graft is free of contaminating tumor cells and includes donor-derived immunocompetent cells that may produce an immune GVM effect. Allogeneic transplants may be associated with a number of potentially fatal complications such as regimen-related organ toxicity, graft failure, and GVHD. Immune reconstitution is slower after allogeneic transplantation and opportunistic infections are more frequent. Treatment-related mortality is significantly higher than with autologous transplantation.

In general, allogeneic transplants have been used in the treatment of leukemias and myelodysplastic syndromes (MDS). Autologous transplants have been used more often in solid tumors, lymphoma, and myeloma, although nonablative allogeneic transplants are under evaluation in these disorders as a means to induce GVM effects.

The outcome of transplantation relates to the selection of patients and timing of transplant during the natural history of the malignancy. The best results occur when the transplant is performed early in the disease course, when the malignancy is still sensitive to chemoradiotherapy treatment, and when the tumor burden is low. Conversely, transplants done as a last resort are associated with high rates of both relapse and treatment-related toxicity. Responsiveness to conventional-dose chemotherapy is a major predictive factor for the outcome of hematopoietic transplant. The best results have been achieved in patients with chemosensitive relapse or when transplant is performed in high-risk patients as consolidation of response, particularly in patients with minimal disease at the time of transplant. Primary resistance can sometimes be overcome by dose-intense treatment, such as in patients with acute leukemia, Hodgkin's disease, or MM who have failed to achieve an initial remission. However, patients with bulky disease, refractory relapse, or multiple relapses of their malignancy have a poor prognosis.

Pretransplant therapy

Autologous transplantation

Early autologous treatment regimens were copied from the allogeneic experience and utilized cyclophosphamide plus either TBI or busulfan. TBI has the advantage of being able to be delivered in precise dose and with protection of vulnerable organs such as lungs and kidneys. TBI is suboptimal for the treatment of bulk tumor masses where hypoxia and resistance may characterize deep-seated tumor cells. In contrast, chemotherapy agents such as busulfan penetrate tumor vascularity and reach deep-seated tumors more effectively.

Alkylating agents are the most commonly used drugs in transplant regimens because they usually kill

tumor cells in proportion to increasing dose. The most commonly used alkylating agents include cyclophosphamide, melphalan, busulfan, BCNU, and thiotepa. The platinum derivatives, carboplatin⁶³ and cisplatin,⁶⁴ are also used. Other commonly used nonalkylators are etoposide (VP-16), cytosine arabinoside, and fludarabine. The most frequently used chemotherapy regimen is BCNU, etoposide, Ara-C, and melphalan (BEAM), commonly used for Hodgkin disease and lymphomas.⁶⁵ The ifosfamide, carboplatin, and etoposide (ICE) regimen is also used for these diseases. In recent years, monoclonal antibodies have proven to be useful when added to standard treatments for leukemia and lymphoma. The anti-CD20 monoclonal antibody rituximab, shown to improve the survival of patients with intermediate grade lymphoma when combined with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) chemotherapy, appears to improve the effectiveness of BEAM.⁶⁶

Allogeneic transplantation

The preparative regimen generally involves chemotherapy drugs alone or with TBI. The classical “myeloablative” regimens used in the treatment of leukemia are designed to ablate both hematopoiesis and immunity in the recipient and typically involve the combination of high-dose cyclophosphamide with either TBI^{67, 68} or high-dose busulfan.^{69, 70}

The toxicity of high-dose myeloablative therapy limits the use of this modality to relatively young patients in good medical condition. The discovery of the curative potential of the immune-mediated GVM effect has led to a novel approach using lower dose, reduced intensity preparative regimens as a means to reduce the toxicity of allogeneic hematopoietic transplantation. These reduced intensity conditioning regimens have been designed not to fully eradicate the malignancy, but rather to provide sufficient immunosuppression to achieve engraftment and to allow induction of GVM ([Figure 2](#)).^{71, 72} These regimens can be tolerated by older patients and those with comorbidities who are not eligible to receive an ablative preparative regimen. Most reduced-intensity regimens include a purine analog, such as fludarabine, combined with an alkylating agent (cyclophosphamide, melphalan, or busulfan), or low-dose TBI. Engraftment has been achieved in most patients, and this approach is effective against a range of hematologic malignancies. Antithymocyte globulin is often added to produce additional immune suppression.

Complications of hematopoietic transplantation

Intensive chemoradiotherapy and hematopoietic transplantations may be associated with a number of serious complications as listed in [Table 2](#). These include immune-mediated processes such as graft rejection and GVHD, toxicities resulting from the pretransplant conditioning regimen, infections owing to neutropenia, and posttransplant immune deficiency.

Table 2 Complications after hematopoietic transplantation

Abbreviation: EBV, Epstein–Barr virus.

Graft rejection and graft failure

Graft failure is defined as the failure to establish hematopoietic engraftment (primary graft failure) or loss of an established graft (secondary graft failure). Graft failure after autologous transplant occurs rarely and is most often related to infusion of an inadequate number of viable stem cells.

Graft failure after allogeneic transplantation is also caused by immunologic graft rejection.^{73, 74} With current regimens, rejection occurs in fewer than 2% of transplants from an HLA-identical sibling. The risk is increased in recipients of HLA-mismatched grafts.^{75, 76} Donor CD8+ T lymphocytes provide a graft-facilitating effect, and T lymphocyte depletion from the allogeneic graft increases the risk of graft failure.^{77, 78} Cord blood transplants containing a lower number of CD34+ and CD8+ cells are more prone to engraftment failure.

Secondary graft failure or poor graft function may be caused by administration of myelosuppressive

drugs, GVHD, and infections in the early posttransplant period. Ganciclovir or trimethoprim-sulfamethoxazole can produce pancytopenia, which is usually reversible after discontinuation of drug. Cytomegalovirus (CMV),⁷⁹ parvovirus,⁸⁰ human herpesvirus,^{81, 82} and mycobacterial and fungal infections may also compromise the graft. Poor engraftment may also result from microenvironment or marrow stroma dysfunction related to the patient's underlying disease or prior therapy.

Graft failure that is not due to rejection can often be successfully treated with G-CSF or second hematopoietic stem cell infusion from the same donor or an alternative donor.

Graft-versus-host disease

GVHD is a major, potentially life-threatening complication of allogeneic hematopoietic transplantation. Acute and chronic GVHD are distinct but interrelated syndromes. Acute GVHD typically occurs within the first 100 days posttransplant and results from reactivity of mature donor T lymphocytes present in the graft directed against disparate major or minor histocompatibility antigens of the recipient (the host).⁸³ Acute GVHD involves the skin, gastrointestinal (GI) tract, and liver as the primary target tissues. The hematopoietic and immune systems are also involved. A maculopapular rash is usually the first presentation and is typically pruritic and confluent. When severe, generalized erythroderma, bullae, and desquamation may occur. Acute GVHD of the liver targets the biliary epithelium and produces cholestatic hepatitis with marked elevation of bilirubin and alkaline phosphatase. GVHD can affect the entire GI tract, targeting epithelial cells. GI GVHD characteristically produces secretory diarrhea, abdominal pain, and on rare occasions, ileus. Upper GI GVHD produces nausea, vomiting, and anorexia, all which may occur without lower GI tract or other tissue involvement.⁸⁴ Conjunctivitis and other ocular manifestations, anemia, and thrombocytopenia often occur.

Severe GVHD is associated with a poor prognosis because of direct tissue damage, debilitation, and severe immunodeficiency caused by the GVHD process itself and by its treatment with immunosuppressive drugs.

The most important factor predicting the risk of GVHD is HLA disparity between the donor and recipient.^{85–88} With current immunosuppressive prophylaxis, acute GVHD occurs in 25–50% of patients after transplants from an HLA identical sibling; this may be related to disparity between minor histocompatibility antigens. A higher incidence up to 61–90% has been reported following transplants from mismatched and unrelated donors. Results are improving for unrelated donor transplantation with the use of more precise molecular histocompatibility typing to identify donors. Older age is associated with an increased incidence of acute and chronic GVHD. Less intensive, nonmyeloablative conditioning regimens may also limit the severity of GVHD, presumably owing to reduction in tissue damage limiting the proinflammatory phase that facilitates development of GVHD.

Pharmacologic immunosuppression is generally administered for the first 6 months posttransplant to reduce the incidence and severity of GVHD. The current standard of care combines either cyclosporine or tacrolimus with a short course of methotrexate.^{89, 90} Corticosteroids are the first line of therapy in patients who develop acute GVHD. Approximately half of patients have a sustained response,⁹¹ and the steroid dose can be gradually tapered off. Steroid-resistant GVHD has an unfavorable prognosis. The prognosis is best for GVHD limited to the skin. Acute GVHD involving the liver or multiple organs has a poorer prognosis than other sites. A number of other immunosuppressive agents are being studied. For mismatched grafts, recent studies have demonstrated that the use of post-transplant cyclophosphamide can decrease the risk of GVHD and permit related haploidentical transplants to be performed with acceptable risk.⁹²

Chronic GVHD is a related syndrome affecting 25–60% of recipients of allogeneic transplantation who survive more than 6 months after transplant.⁹³ It most often occurs between 80 and 200 days after transplant, but onset may be delayed to the second year. Chronic GVHD is more common in older patients and in patients with prior acute GVHD although approximately one-third of affected patients have a *de novo* presentation without prior acute GVHD.⁹⁴ Chronic GVHD is more prevalent after transplants with peripheral blood stem cells than with marrow transplantation.⁹⁵

Chronic GVHD has multiple clinical manifestations similar to those seen in several autoimmune disorders such as progressive systemic sclerosis, Sjögren syndrome, and primary biliary cirrhosis. Chronic GVHD is associated with profound immunosuppression and a major risk to the patients of opportunistic infections. Bronchiolitis obliterans without other major manifestations of chronic GVHD and intestinal involvement with anorexia, dysphagia, malabsorption, and wasting may occur. Polymyositis, serositis, and autoimmune manifestations occur rarely. Chronic GVHD may become a chronic debilitating disease affecting quality of life and remains the major determinant of late transplant-related morbidity. Progressive onset of extensive chronic GVHD from acute GVHD and the presence of thrombocytopenia are poor prognostic factors ([Table 3](#)).⁹⁶

Table 3 Clinical staging and grading of graft-versus-host disease (GVHD)

	Acute GVHD					
Stage	Skin ^a		Liver ^b		Gut ^b	
1	Maculopapular rash <25%		Bilirubin 2–3 mg/dL		Diarrhea 500–1000 mL or persistent nausea ^c	
2	Maculopapular rash 25–50%		Bilirubin 3–6 mg/dL		Diarrhea 1000–1500 mL	
3	Generalized erythroderma		Bilirubin 6–15 mg/dL		Diarrhea >1500 mL	
4	Desquamation and bulla		Bilirubin >15 mg/dL		Severe abdominal pain or ileus	
Overall grade ^d	Severity	Skin		Liver		Gut
0	None	0	—	0	—	0
I	Mild	1–2	—	0	—	0
II	Moderate	3	<i>or</i>	1 or	<i>or</i>	1
III	Severe	—	—	2–3 or	—	2–3
IV ^e	Life threatening	4	<i>or</i>	4 or	<i>or</i>	—4
Chronic GVHD						
Limited	Localized skin involvement <i>and/or</i> hepatic dysfunction					
Extensive						
	<div><div>1. Generalized skin involvement <i>or</i></div><div>2. Localized skin involvement <i>and/or</i> hepatic dysfunction, <i>plus</i> any of the following:<div><div>a. liver histology showing chronic aggressive hepatitis, bridging necrosis, or cirrhosis</div><div>b. eye involvement (Schirmer test <5 mm wetting)</div><div>c. involvement of mucosalivary glands or oral mucosa</div><div>d. involvement of any other target organ</div></div></div></div>					

^a Extents determined by rule of nines or burn chart.

^b Downgrade one stage for additional causes of elevated bilirubin or diarrhea.

^c Requires histologic evidence of GVHD in the stomach or duodenum.

^d Minimal organ stage required to determine grade.

^e Grade IV may also be determined with lower organ involvement with extreme decrease in performance status.

Sources: From Refs .

Corticosteroids are the first line of therapy for chronic GVHD.⁹⁷ The chronic nature of this syndrome requires long-term therapy for at least 6–9 months, using the lowest steroid doses, which control

symptoms. Alternate day dosage may be preferable to minimize the complications resulting from chronic steroid therapy. Cyclosporine or tacrolimus may be used in combination with corticosteroids in high-risk patients.^{98, 99} Combinations of immunosuppressive agents may improve control of the direct manifestations of chronic GVHD, but they increase the risk of infectious morbidity and mortality. Photopheresis can be used as a steroid-sparing immune-modulatory treatment.¹⁰⁰

Regimen-related toxicity

Myeloablative preparative regimens used to cytoreduce the malignancy approach the limit of tolerance for several tissues. The GI tract, kidneys, lungs, and liver are the most susceptible to toxic damage, but severe toxicity may also involve the heart, bladder, nervous system, and other tissues. The actual risk for toxicity varies among regimens and their relative dose intensity. Specific determinants include the toxicity profiles of the involved agents and their interactions that are affected by coexisting organ dysfunction, the effects of the diseases and prior therapy, and infections. Most toxicities are experienced during the first 30 days posttransplant, but regimen-related hepatic injury [hepatic veno-occlusive disease (VOD)], pulmonary toxicity, and neurologic effects may be delayed for several months.

VOD of the liver frequently occurs after TBI, busulfan, BCNU, thiotepa, carboplatin, and etoposide-containing regimens.¹⁰¹ The clinical syndrome is characterized by painful hepatic enlargement, ascites, generalized fluid retention, and striking elevation of serum bilirubin. There is no proven treatment other than supportive care, and factors predicting the probability of a fatal outcome from VOD have been described.¹⁰² Pulmonary toxicity directly related to drug injury is most commonly caused by BCNU, the frequency varying from 5% to 60% with increasing dose.¹⁰³ Virtually every alkylating agent used in transplantation has been associated with pulmonary toxicity, however, much less commonly than with BCNU. This injury typically occurs between 3 and 12 weeks following transplant and usually produces progressive shortness of breath, cough, and diffuse interstitial abnormalities on chest radiograph or CT scan. If infection is excluded, steroid treatment can produce total reversal of this side effect.¹⁰⁴ Cardiac toxicity, usually manifests temporary myocardial injury and decline in cardiac ejection fraction, is also produced by a variety of alkylating agent regimens. Although most commonly asymptomatic and lasting only 1–3 months, it can occur in 20–40% of patients in selected regimens.¹⁰⁵ Irreversible cardiac failure can be seen but is much less common.

Hematologic complications

Hemolytic reactions may result from ABO blood group incompatibility between the donor and recipient.¹⁰⁶ ABO incompatibility is not a contraindication for allogeneic transplant. Red blood cells should be removed from the donor graft to prevent acute hemolytic reaction in cases with major ABO incompatibility and plasma should be removed in pairs with minor ABO incompatibility.

Atypical thrombotic thrombocytopenic purpura (TTP) may occur after hematopoietic transplantation.¹⁰⁷ Factors implicated in initiating endothelial injury include chemotherapeutic agents, irradiation, cyclosporine and tacrolimus, CMV and fungal infections, and cytokine-release syndromes.

Immunodeficiency and infections

Recipients of hematopoietic transplants have a severe immunodeficiency involving both T and B cells.¹⁰⁸ HLA-mismatched or unrelated and cord blood transplants have a more severe and prolonged immunodeficiency and risk for opportunistic infections. Recipients of autologous and syngeneic transplants also have a period of immunodeficiency but recovery is more rapid. Recipients of

hematopoietic transplants may be susceptible to unusual opportunistic infections and to acute overwhelming infections. Prophylactic strategies against an array of potential infections and rapid recognition and treatment of infections are an essential part of successful management of transplant recipients.¹⁰⁹ Immunoglobulin replacement therapy should be considered in patients with documented immunoglobulin deficiency. Revaccinations should be performed upon immune recovery and are typically carried out 6 months posttransplant.

Posttransplant lymphoproliferative disease (PTLD) is a life-threatening complication of allogeneic transplantation.¹¹⁰ It is more prevalent in recipients of mismatched or UCB grafts, and especially in those treated with aggressive immunosuppressive treatment including higher doses of ATG. PTLD in hematopoietic transplant recipients arises from the transformation of donor-derived B-lymphocytes by Epstein–Barr virus (EBV) infection. Treatment includes withdrawal of immunosuppression and administration of rituximab. Cellular therapy with donor or EBV-sensitized¹¹¹ lymphocyte infusions can have dramatic results in controlling PTLD.¹¹² Patients with increasing levels of EBV DNA are at highest risk for lymphoproliferative disease and are candidates for preemptive immunotherapy with rituximab.

Late effects

Late complications of hematopoietic transplantation include delayed effects of high-dose therapy, indolent infections, transfusion-related complications, and chronic GVHD. Late toxicity of high-dose therapy can produce cataracts, pulmonary fibrosis, dental abnormalities, hypothyroidism, hypogonadism, growth retardation, osteoporosis, and avascular necrosis of the hip or other bones. Permanent sterility occurs in most patients. There is an increased risk of solid and hematologic secondary tumors after hematopoietic transplantation. Solid tumors such as head and neck cancers, squamous cell carcinomas, melanomas, and brain, breast, and thyroid cancers may be more common in recipients of TBI-containing regimens and the cumulative incidence is up to 7–10% at 15 years. Myelodysplasia and secondary leukemia occur more commonly after autologous transplant, occurring in 4–18% of patients within 2.5–8.5 years of transplant.^{113, 114}

Indications for hematopoietic transplantation

Acute myeloid leukemia (AML)

Hematopoietic cellular transplantation has been extensively evaluated for the treatment of patients with AML.^{115, 116} Myeloablative transplants have been used in younger patients. AML is more common with advanced age, however, so that reduced intensity transplantation, often based on a busulfan/fludarabine regimen, is now commonly used in fit patients up to 70 years of age. Most patients achieve complete remission after high dose therapy and hematopoietic transplantation. The major causes of treatment failure are GVHD, regimen-related toxicity, infections, and recurrent leukemia. More intensive regimens designed to have greater antileukemic activity by increasing the TBI dose or adding additional chemotherapeutic agents have produced additional toxicity, and overall survival has not improved.¹¹⁷ The outcome after allogeneic transplantation is primarily dependent on the disease status (remission versus relapse), cytogenetic and mutational abnormality of the leukemia, patient age, and histocompatibility between donor and recipient.¹¹⁸ For patients in remission, long-term disease-free survival is 40–65%.^{119, 120} An increasing number of patients with intermediate or high-risk prognostic features and fully matched donors are being transplanted in first complete remission. For patients with a favorable prognosis such as those with t8;21, t15;17, or inv 16 abnormalities, transplant is usually deferred until relapse and

reinduction of remission.

The risks of allogeneic transplantation are increased in patients without an HLA-identical donor. Transplants from a related mismatched donor or using an UCB product should generally be considered in younger patients after relapse, those with poor-risk cytogenetic abnormalities, or patients with an antecedent hematologic disorder.¹²¹

Myelodysplastic syndromes (MDS)

MDS are a group of clonal hematologic disorders manifested by peripheral cytopenias and a high risk of transformation to AML. The International Prognostic Score (IPPS) defines low-, intermediate-, and high-risk groups based on marrow blast percentage, cytopenias, and karyotype.¹²² The median survival of patients with low-risk IPPS scores is 5.7 years, but it is only 0.4 years for high-risk patients.

Allogeneic transplantation is a potentially curative treatment for MDS;^{123, 124} however, the timing of transplantation is controversial. Patients with high-risk disease, excess blasts, severe neutropenia, transfusion dependency, and high-risk cytogenetic abnormalities are considered candidates. Stable patients with low-risk disease may have extended survival with conservative therapy and should generally not be offered transplant until disease progression. The conditioning regimens used are similar to those used for AML, and prospect for long-term remission is equal to or perhaps slightly better than that for AML.

Acute lymphoblastic leukemia (ALL)

Intensive chemotherapy regimens have resulted in cure for 80–90% of children with ALL but only 30–35% of adults.¹²⁵ As with AML, poor prognosis adult patients such as those with the t(9;22) Philadelphia chromosome and select other genetic markers are generally transplanted in first remission, others only following one or more relapses. The prognosis of patients with chemotherapy-resistant relapse is poor.

The most common preparative regimen used for transplants in ALL includes high-dose cyclophosphamide and TBI with or without other chemotherapeutic agents. TBI-containing regimens may be associated with improved disease-free survival, in comparison to non-TBI-containing regimens.¹²⁶ Chemotherapy-only regimens are being actively explored.

Chronic myeloid leukemia (CML)

The use of transplantation to treat CML has declined markedly in the past decade owing to the success of inhibitors of the BCR-ABL tyrosine kinase (TK), such as imatinib, to treat this condition. These oral medications produce multiyear remissions for most patients. Several next generation TK inhibitors can overcome common resistance mechanisms. As a result, transplant is reserved for patients with progressive leukemia after failure of two or more TK inhibitors, patients intolerant of these drugs, or those developing blast crisis, the late acute phase of CML.

Transplant regimens are those commonly used for AML and produce similar and often slightly superior outcomes. Early transplant failures can often be returned to complete remission through the administration of DLI.^{127, 128} While these infusions risk GVHD, CML is very sensitive to their use. CML was perhaps the earliest example of the use of PCR-based molecular detection (in this case, BCR-ABL) of minimal disease, which enhances the value of DLI immunotherapy administered at that time.

Hematopoietic transplantation has been used for the treatment of other myeloproliferative disorders.^{129,}

¹³⁰ The appropriate timing of transplantation is less well defined. Most researchers require the patient to be transfusion dependent to justify the risks inherent with hematopoietic transplantation.¹³¹

Chronic lymphocytic leukemia (CLL)

CLL is an indolent lymphoid malignancy; median survival exceeds 10 years.^{132, 133} The National Cancer Institute sponsored Working Group recommends use of the “3-risk group” modification of the original five-stage Rai staging system.¹³⁴ Median survival is >14, 8 and 4 years for the low-, intermediate-, and high-risk groups. Adverse prognostic factors are loss of immunoglobulin gene rearrangement, expression of CD38, and higher levels of beta2-microglobulin.¹³⁵

Chemotherapy is generally recommended if the disease causes symptoms or impaired performance status.¹³⁶ Chemotherapy involving fludarabine, rituximab, cyclophosphamide, and more recently ibrutinib has produced major improvements in disease response and survival for symptomatic patients, but CLL is still considered incurable using standard treatment strategies. Allogeneic transplantation is being increasingly studied.^{137, 138} Patients with chemosensitive disease have better outcome following transplant. An International Bone Marrow Transplant Registry (IBMTR) analysis showed not only a 3-year survival of 46% but also a high risk for transplant-related mortality.¹³⁹ A GVL effect has been shown in this disease¹⁴⁰ and this has led to studies using nonmyeloablative conditioning to reduce toxicity and to extend the use of allogeneic transplantation options to the treatment of patients up to age 75. Encouraging preliminary results have been reported by many groups using this strategy.

The optimal timing of allogeneic transplantation is controversial. Given the risks of allogeneic transplantation and the indolent course of newly diagnosed patients, it is generally recommended that the procedure be considered only after failure of initial therapy. The prognosis is relatively poor if the procedure is delayed until after multiple relapses or after development of refractoriness to chemotherapy.

Non-Hodgkin lymphoma

The non-Hodgkin lymphomas are a heterogeneous group of malignancies with indolent to highly aggressive natural histories. Treatment with both standard and transplant-based therapies depends on the histologic subtype and prognostic factors operative in each patient. Lymphomas can be grouped into major categories: low-, intermediate-, and high grade. The low-grade lymphomas are often associated with t,^{14, 18} resulting in rearrangement of the BCL2 gene. Low-grade lymphoma patients have a median survival of 7–15 years.¹⁴¹ The major factors influencing prognosis include stage, lactic dehydrogenase, and beta2-microglobulin level.

High-dose chemotherapy with autologous hematopoietic transplantation has been extensively evaluated for low-grade lymphoma, producing rates of complete remission over 80%. Many studies have used marrow or blood stem cell autografts depleted of malignant cells using anti-B-cell monoclonal antibodies, a process which may achieve prolonged remissions.^{142, 143} Achievement of molecular complete remissions in which BCL2 rearrangement is undetectable by PCR analysis has been associated with prolonged disease-free survival. There is controversy, however, regarding the role of autologous transplantation in this disease. Long-term survival is similar after autologous hematopoietic transplantation and with conservative forms of standard-dose chemotherapy.¹⁴⁴ There is a risk of secondary myelodysplasia and acute leukemia after autotransplants in this disease, particularly in heavily pretreated patients.^{145, 146} Recent data suggests that a minority of patients treated after failure of initial systemic treatment can achieve multiyear relapse-free survival that may produce outcomes superior to

conventional treatment.

Allogeneic bone marrow transplantation has also been evaluated in patients with low-grade lymphoma. High-dose cyclophosphamide and TBI or BEAM, both often combined with rituximab, are the most commonly used preparative regimens. Several groups have reported extended disease-free survival in patients with far advanced disease. Relapse rates after allogeneic transplants have been substantially lower than with transplantation of purged autologous transplants, most likely due to the GVL effect.^{147, 148} The recent encouraging results using nonmyeloablative preparative regimens reduce the risk of treatment-related mortality and the majority of patients achieve prolonged complete remissions. This option is increasingly being used for younger high-risk patients after failure of initial chemotherapy.¹⁴⁹ Mantle cell lymphoma is associated with a poor prognosis, particularly if the patients have intermediate or high-risk features using the MIPI scale.¹⁵⁰ Autologous hematopoietic transplants can be effective in chemoresponsive patients in first remission. Following relapse, however, most patients are currently treated with allogeneic transplants using reduced intensity conditioning regimens. Like CLL and low-grade lymphomas, a substantial GVL effect enhancing responses is seen.

Intermediate- and high-grade lymphomas are aggressive malignancies with a short natural history in the absence of effective therapy. These disorders are responsive to combination chemotherapy, and a fraction of patients achieve durable remissions. Standard chemotherapy for large cell lymphoma results in cure in approximately 40–60% for newly diagnosed patients with diffuse large cell lymphoma. High-, intermediate- and low-risk groups have been defined.

High-dose chemotherapy and autologous transplantation improve cure rates for patients with recurrent large cell lymphoma who respond to salvage chemotherapy.^{151, 152} The Parma study randomized patients younger than 60 years with chemosensitive relapse to further conventional chemotherapy or autologous transplantation and demonstrated substantial benefit for the latter.¹⁵³ Patients with chemotherapy-resistant disease and those with multiple relapses have poor results but can be considered for novel preparative regimens with autologous transplant or allogeneic transplantation using myeloablative regimens.

High-dose therapy with allogeneic transplantation has been examined in a number of studies in patients with intermediate or high-grade lymphoma. Several studies reported a decreased recurrence rate compared to autologous transplants, but the benefit is off-set by higher rates of treatment-related mortality.¹⁵⁴ Many physicians have reserved allotransplantation for patients having a poor prognosis with alternative modalities, such as a relatively poor response to chemotherapy or patients in which autologous transplants were not feasible.

Hodgkin's disease

Patients failing to achieve a complete remission with initial chemotherapy can be salvaged with autologous transplantation in approximately one-third of cases. For patients with recurrent Hodgkin's disease, particularly with shorter relapse-free intervals, high-dose chemotherapy and autologous hematopoietic transplantation results in a complete remission rate of 50–80% and a 40–60% disease-free survival at 3–5 years posttransplant.^{155, 156} The BEAM and cyclophosphamide, carmustine, etoposide preparative regimens have been most frequently used. Numerous phase 2 studies have suggested that high-dose chemotherapy improves disease-free survival and possibly overall survival compared to standard chemotherapy in this setting.

Allogeneic transplants using nonmyeloablative techniques have been primarily reserved for patients progressing after autotransplantation or patients with inadequate marrow reserve.¹⁵⁷

Multiple myeloma

Standard chemotherapy for myeloma can control the disease for variable periods, but even with newer regimens containing lenalidomide and/or proteasome inhibitors, only 20–30% achieve complete remission. Increasing numbers of randomized and historically controlled trials suggest that the addition of autologous transplantation to standard chemotherapy improves disease-free and overall survival. High-dose chemotherapy with autologous hematopoietic transplantation is now considered a standard treatment for patients with intermediate or high-tumor-mass MM. High-dose therapy and autologous transplantation delays relapse but is not curative, and almost all patients ultimately develop recurrent disease.

Chemosensitivity of the tumor is a major determinant of transplant outcome. Patients with chemosensitive disease who received transplants within the first year had a more favorable outcome, and 40–50% may achieve CR. Encouraging results have also been achieved in patients with primary refractory disease if transplanted early in the course of disease,^{158, 159} but treatment is of only limited value in advanced resistant disease, and especially in patients with refractory relapse.¹⁶⁰ High beta2-microglobulin level and several cytogenetic abnormalities are the most prominent adverse prognostic factors.^{161, 162} Autologous transplants for myeloma commonly use single-agent melphalan and produce a toxic mortality risk of only 1–2% even in elderly patients. The use of two sequential (or tandem) transplants may produce superior overall and relapse-free survival and are frequently employed.¹⁶³ Most studies have suggested a better outcome when autologous hematopoietic transplantation is performed early after achievement of a myeloma response. A randomized French study of early versus late transplant did not show any survival difference, but patients randomized to early transplant enjoyed longer periods of time without need for chemotherapy.¹⁶⁴

Allogeneic transplants can cure myeloma in 30–40% of patients but are accompanied by high rates of regimen-related toxicity and infection. Reduced-intensity conditioning and exploitation of GVM effects have increased the effectiveness of allotransplant but its use after failure of autotransplant remains investigational. Other plasma cell dyscrasias have also been effectively treated with high-dose melphalan and autologous hematopoietic transplantation. Amyloidosis may benefit, as suggested by the majority of recent studies. Treatment-related fatality rates are considerably higher than for myeloma, however, often as high as 8–12%.

Solid tumors

High-dose chemotherapy with autologous hematopoietic transplantation has been studied in both breast and ovarian cancer, but results are conflicting and this technique is not currently a part of routine treatment of these diseases.

A similar approach with autologous transplantation has been used for the treatment of other chemotherapy-responsive solid tumors in adults, including testicular or mediastinal germ cell tumors. Recent data suggests improved relapse-free survival for relapsed and refractory patients.¹⁶⁵

Autologous transplants have been studied in a range of pediatric solid tumors such as neuroblastoma and Ewing sarcoma; tumors that are highly sensitive to chemotherapy and irradiation yet have a poor prognosis in patients with advanced disease.^{166, 167}

Aplastic anemia

Severe aplastic anemia (AA) is defined as marrow cellularity of less than 25%, with either neutrophil count $<0.5 \times 10^9/\text{L}$, platelet count $<20 \times 10^9/\text{L}$, or total reticulocyte count $<40 \times 10^9/\text{L}$. Without effective

therapy, more than 50% of patients with severe AA may die within 6 months of diagnosis. Effective treatments for AA include immunosuppressive therapy (such as cyclosporine and ATG)¹⁶⁸ and hematopoietic transplantation.

Allotransplant can provide effective treatment for patients unresponsive to immunosuppressive agents. Multiple blood transfusions may sensitize the recipient against the donor and increase the risk of rejection. With current regimens, early transplant, a judicious transfusion policy, and improved supportive care systems, less than 10% reject the grafts and long-term survival can be achieved in 80–90% of recipients of marrow from an HLA-matched sibling donor. Allotransplant from unrelated or mismatched donors is being actively studied but carries a higher risk of transplant complications.

Congenital metabolic and immune disorders

Allogeneic transplantation is a potentially curative treatment for several congenital disorders of the hematopoietic and immune systems. Thalassemia¹⁶⁹ and sickle cell anemia¹⁷⁰ are among the most common nonmalignant hematological disorders curable with transplant. Fanconi anemia has been treated similarly to AA but with very low-dose conditioning regimen owing to the known sensitivity of these patients to the effects of irradiation and alkylating agents.^{171, 172} Allogeneic transplantation has been the treatment of choice for infants with severe combined immunodeficiency.¹⁷³ Engraftment can be achieved in many patients even without conditioning in this disorder. Allogeneic transplantation has been able to reverse the bone sclerosis in osteopetrosis.¹⁷⁴ The results in lipid storage diseases have been inconsistent.¹⁷⁵ For patients without a matched sibling, both unrelated donor transplants or mismatched-related transplants have been successful.¹⁷⁶ In most disorders, outcome was better when transplants were given early. In the future, gene modification of autologous cells may be a curative approach for some of these disorders.¹⁷⁷

There has been increasing interest over the last few years in autologous transplantation with or without T-cell depletion of the graft for the treatment of autoimmune disorders.¹⁷⁸ The goal is to ablate the abnormal immune response and reconstitute immunity from hematopoietic stem cells and progenitors. Encouraging results have been reported in a limited number of patients with rheumatoid arthritis, systemic lupus erythematosus, multiple sclerosis, myasthenia gravis, and other disorders.

Future directions

Over the last decade, hematopoietic transplantation has become a much safer procedure, applicable to a larger patient population in a variety of disease processes. The use of hematopoietic transplantation is likely to evolve with the development of molecularly directed anticancer therapies and with improved methods to selectively target and modulate immunity. Targeted radiation therapies, such as monoclonal antibody–radionuclide immunoconjugates and bone-seeking isotopes, are under active evaluation as a means to target radiotherapy to the tumor; this approach has little systemic toxicity other than myelosuppression. It may be possible to further improve results by using strategies to overcome drug resistance mechanisms such as administration of inhibitors of DNA repair processes, glutathione conjugation, or other mechanisms. Near-term improvements in autotransplantation will emphasize incorporation of newer therapeutics, particularly targeted agents, and supplementary immune augmentation techniques.

The GVM effect associated with allogeneic transplants illustrates the capability of the immune system in eradicating cancer. Strategies to enhance immune antitumor mechanisms with both allogeneic and autologous transplants are under active investigation. The major goal is to separate the beneficial GVM

effect from GVHD. Tumor vaccines have been generated by *ex vivo* transfection of tumors with genes (to improve antigen presentation), costimulatory molecules, and various cytokines to enhance the immune response directed against the tumor. Selected lymphocyte subfractions (NK cells, regulatory T cells, and cells engineered to express chimeric antigen receptors to facilitate engagement of tumor cells by cytotoxic T cells) are being actively studied to improve antitumor effects while reducing the risk of GVHD. In the allogeneic transplant setting, efforts are being directed at expanding the donor pool and reducing the toxicity of the procedure. The majority of patients who are candidates for allogeneic transplant do not have an HLA-matched sibling donor. Further development of international unrelated donor registries for bone marrow, blood stem cells, and cord blood will increase the likelihood of finding a well-matched donor. Special attention is given to representation of ethnic minorities in these registries. New molecular methods to improve the precision of histocompatibility matching may decrease the risk of rejection and GVHD. Another approach is to use related partially matched donors. This technique, along with greater availability of banked UCB, will hopefully allow the substantial majority of patients requiring allotransplantation to have access to a suitable donor product. Considerable progress in supportive care has made allogeneic transplants increasingly safe by preventing infections and transplant-related complications. The finding that GVL is responsible for much of the therapeutic potential of allogeneic transplants has opened the way for the use of nonmyeloablative regimens as a means to allow engraftment of donor cells with reduced toxicity. Providing GVL as the primary treatment requires carefully planned prospective clinical trials to define the role of this strategy, the diseases, and the patient population for which it will be useful.

Chapter 71

Principles of pediatric oncology

Teena Bhatla, MD ■ William L. Carroll, MD

Overview

Pediatric malignancies differ from those that occur in adults in their relative incidence, pathological type, clinical presentation, and prognosis. The last several decades of the twentieth century have been a period of enormous accomplishment in the field of pediatric cancer research and outcomes have steadily improved largely due to results from large well-controlled clinical trials conducted by various cooperative groups at the national and international level. This chapter seeks to provide a broad overview of pediatric oncology, outlining the several common cancer types that are unique to the pediatric age group.

Introduction and epidemiology

Cancer is a relatively rare disease in childhood, yet cancer remains the second leading cause of death in children after accidents. The spectrum of cancer types in children is distinctly different compared to adults. Although epithelial tumors (carcinomas) dominate the adult cancer spectrum, childhood cancers tend to be of hematopoietic (e.g., leukemias, lymphomas), mesenchymal (sarcomas), and neuroectodermal (e.g., neuroblastomas (NBs), gliomas, medulloblastomas) origin. Acute lymphoblastic leukemia (ALL) and brain tumors are the most common childhood cancers accounting for 25% and 20%, respectively, of all cases. The incidence of the most common childhood tumors is illustrated in [Figure 1](#) and [Table 1](#), but it should be noted that incidence can vary according to ethnic and geographic factors. For example, Burkitt lymphoma accounts for 50% of all childhood cancer in equatorial Africa.

Figure 1 Distribution of pediatric cancer diagnoses by age group. *Abbreviations:* ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; CNS, central nervous system; RMS, rhabdomyosarcoma; STS, soft tissue sarcoma.

Table 1 Age-adjusted and age-specific SEER annual incidence rates per million population for childhood cancer, 2007–2011

Cancer type (ICCC group)	Age at diagnosis						
	0–14	0–19	<1	1–4	5–9	10–14	15–19
All groups combined (including benign CNS tumors)	172.8	191.2	253.4	228.1	137.2	150.9	246.2
All leukemia	54.4	49.4	51.7	95.0	44.5	33.9	34.5
Acute lymphoblastic leukemia (ALL)	41.9	35.9	20.3	79.7	37.1	22.1	18.2
Acute myeloid leukemia (AML)	8.0	8.5	18.9	10.6	4.5	7.4	9.9
All CNS	44.3	45.1	48.8	49.4	43.1	40.6	47.8
Ependymoma and choroid plexus tumors	4.0	3.7	8.8	6.9	2.6	2.4	2.8
Astrocytoma	16.7	15.6	15.5	18.7	17.1	15.2	12.2
Embryonal tumors	7.6	6.4	12.5	11.3	7.4	4.1	2.7
Hodgkin lymphoma	5.9	12.4	—	1.1	5.0	11.6	31.8

There is a suggestion that the incidence of cancer is rising particularly among certain subtypes of childhood tumors, but better reporting of cases and improved diagnostic imaging may account for some of this trend.¹ The etiologies of most childhood cancers remain uncertain. Environmental influences are less likely to play a role in children with radiation being the most well-established risk factor. Breakthroughs in next-generation sequencing technologies also indicate that childhood tumors have a much lower mutational burden compared to malignancies of adults, and this would also suggest that the environment plays a less important role in tumor initiation.²

Genetic predisposition causes about 5% of all cancers in the pediatric age group although this figure may

increase with recent results from next-generation sequencing revealing unrecognized mutations in cancer predisposition genes. About a third of all cases of retinoblastoma (RB) are caused by a germline mutation in *RB1* and children with Down syndrome (DS) have 20-fold increased incidence of leukemia (lymphoid and myeloid). Other hereditary syndromes, such as neurofibromatosis 1 (brain tumors), Beckwith–Wiedemann [Wilm's tumor (WT), hepatoblastoma (HB), rhabdomyosarcoma (RMS)], Li–Fraumeni (sarcomas, carcinomas), Gorlin's (medulloblastoma, skin cancer), and ataxia telangiectasia (leukemia, lymphoma), account for a small, but important fraction of childhood cancers. Often these familial syndromes paved the way for identification of genes that play a role in the much more common sporadic forms of the disease.

In addition, more subtle “host” genetic variation (compared to the syndromes described above) has been suggested by the identification of genetic variations (single nucleotide polymorphisms or “SNPs”) that account for an increased risk of cancer and may impact on outcome and side effects of therapy. For example, germline SNPs in *ARID5B*, *IKZF1*, *CEBPE*, *PIP4K2A*, and *CDKN2A-CDKN2B* influence susceptibility to ALL and *GATA3* variants are associated with a particular subtype of ALL called “Ph-like” ALL (see below).³

The dramatic improvement in outcome for childhood cancer represents one of the greatest success stories in the history of the “War on Cancer” that began in earnest in 1971. At that time, roughly 60% of all children less than 20 years of age survived 5 years from diagnosis, whereas today, the figure is more than 80% ([Figure 2](#) and [Table 2](#)). There are many reasons for these advances including the commitment to multidisciplinary care and highly disciplined clinical trials directed by nation and worldwide consortiums such as the Children's Oncology Group (COG). Interestingly, many of the same chemotherapeutic agents developed decades ago are still used today, but augmentation of doses and schedules have been realized through advances in supportive care and treatment intensification has improved outcome for almost all tumors. Lastly, risk-adapted therapy, tailoring treatment based on prognostically relevant clinical and laboratory variables, has allowed intensification of treatment for those patients most likely to benefit while avoiding more toxic therapy for those patients predicted to have an excellent outcome with standard treatment. Survival rates have been most dramatic for ALL (10% in the 1960s to greater than 90% today), the most common malignancy, but survival rates remain low for patients with certain brain tumors, metastatic solid tumors, and relapsed disease. Moreover, while mortality has decreased by approximately 50%, close to 2000 children die each year in the United States.⁴ Thus, more effective treatments are urgently needed, and the cost of cure is substantial with short and long side effects, so more targeted, less toxic treatments are a priority also.

Childhood acute lymphoblastic leukemia (ALL)

ALL is the most common malignancy in children in the United States. The peak incidence is between 2 and 6 years of age, and there is a slight male predominance. Stepwise gains in outcome in childhood ALL equal or surpass gains in other areas of childhood cancer have come through the results of large international cooperative groups. Refined risk-adapted approaches for therapy allocation and dose/schedule intensification of therapy have been primarily responsible for improving the overall survival rate to more than 90%.⁶

Although the exact etiology of childhood ALL is unclear, genetic factors play a significant role in the etiology of childhood ALL in selected cases. Various constitutional chromosomal abnormalities have been associated with pediatric ALL, such as DS, Bloom's syndrome, Fanconi anemia, and ataxia telangiectasia. Of these, DS-ALL deserves special attention. Children with DS have 10–20 times higher risk of

developing leukemia compared to children without DS. These children have unique clinical and biological characteristics that affect their treatment and outcome. Notably, T-cell and mature B-cell immunophenotype, and favorable cytogenetic features such as hyperdiploidy and the *ETV6-RUNX1* translocation are not as common in this group of patients. Novel somatic alterations such as JAK2-activating mutations are found in about 20% of DS-ALL, while *CRLF2* alterations (*P2RY8-CRLF2* fusion) has been observed in about 50% of DS-ALL cases.^{7, 8} DS-ALL children are more prone to methotrexate-related toxicities, with more frequent mucositis and infectious complications. In general, prognosis of DS-ALL is worse than non-DS ALL, however, enhanced supportive measures have improved the outcome. More recently, genome-wide association studies (GWAS) have identified inherited genetic variation at the *GATA3* locus being associated with ALL in adolescents and young adults (AYAs) population.⁹

Children with ALL usually presents with signs and symptoms suggestive of bone marrow infiltration, manifesting as fever (60%), bleeding symptoms (50%), and bone pain (30%). Child may present with a limp or refusal to walk. Lymphadenopathy and hepatosplenomegaly are present in about half to two-thirds of cases and is usually asymptomatic. Rarely, patients may present with symptoms suggestive of extramedullary spread, such as CNS involvement, testicular enlargement, and ocular changes. The diagnosis is typically made by bone marrow aspiration and/or biopsy. Multiple cell surface antigen markers, cytogenetic, and less commonly histochemical staining abnormalities in the leukemic cells are used to establish the diagnosis of ALL subtype and result in specific therapeutic decisions.¹⁰ About 85% of cases of childhood ALL express membrane markers consistent with B-precursor lineage, and about 15% express T-lineage markers. Although age and initial white blood cell (WBC) count at the time of disease presentation remain important predictors of outcome, other factors such as blast immunophenotype and cytogenetics, CNS involvement, and early response to chemotherapy are currently being utilized for risk stratification. Cytological confirmation of leukemic cells in cerebrospinal fluid (CSF) is required for the diagnosis of CNS leukemia. Standard or average risk patients are defined as age between 1 and 9 years with an initial WBC count of less than 50,000/mm³, while age more than 10 years with a presenting WBC of more than 50,000/mm³ are classified into high-risk disease category. Risk assessment is further refined by presence or absence of favorable [e.g., hyperdiploidy (specifically trisomies 4 and 10) or *EVT6/RUNX1* fusion] and unfavorable cytogenetic features (e.g., hypodiploidy or *iAMP21*), overt CNS and testicular disease at diagnosis, and minimal residual disease (MRD) at day 8 and the end of induction chemotherapy. Philadelphia chromosome positive (ph+) ALL or t(9:22) occurs in 2–3% of pediatric ALL patients, and historically has been associated with a poor prognosis, now have much better outcome with the incorporation of tyrosine kinase inhibitors (TKI) in combination with chemotherapy.

Contemporary therapies include several components, namely, induction, presymptomatic, or prophylactic central nervous system therapy, postinduction intensification, and maintenance therapy. This design of current treatments will cure more than 80–90% of patients overall.⁶

Additional recent advances in therapy include the following:

- Current frontline therapy regimens are tailored to risk category as assessed by clinical features and biologic profile.¹⁰
- The substitution of dexamethasone for prednisone has improved the survival for standard risk patients, while no event-free survival (EFS) advantage has been noted for patients more than 10 years of age. In addition, there was significantly increased rate of osteonecrosis in patients more than 10 years of age.¹¹

- Initial response to therapy determined by day 8 peripheral blood and/or bone marrow assessment of MRD at end induction (day 29) is an important predictor of outcome and is now utilized in risk-adjusted treatment approaches.¹²
- Postinduction intensification (or delayed intensification) improves outcome for both high and standard risk, B-precursor and T-lineage patients particularly when augmented regimens were utilized.¹³ However, there was no additional benefit of second delayed intensification.¹³
- Improved outcome associated with specific cytogenetic aberrations including hyperdiploidy, trisomy 4, 10, and t(12;21) (ETV6-RUNX1) and these patients are now classified as having low-risk disease, and receive less intensive chemotherapy if MRD is negative at day 8 and at day 29.¹⁴
- High-dose methotrexate given during interim maintenance improves outcome in high-risk patients.¹⁵
- Current systemic therapy allows elimination of cranial irradiation for almost all patients except those who have overt CNS disease at diagnosis.¹⁶
- Review of comparative outcome results of AYAs treated with pediatric or adult protocol-based therapy has shown improved outcomes for those treated utilizing the pediatric approach. However, treatment mortality comprises a larger percentage of adverse events than in younger children.^{17, 18}
- Ph+ pediatric ALL can be treated with aggressive chemotherapy and concomitant targeted therapy with tyrosine kinase inhibitor—imatinib or dasatinib—leading to remarkable improvement in EFS without the need for stem cell transplantation.¹⁹
- Hematopoietic stem cell transplantation (HSCT) has a limited role in newly diagnosed ALL, except in refractory settings, those with hypodiploidy and possibly those patients with persistently high MRD at later time points. Early relapsed ALL (bone marrow relapse within 36 months from initial diagnosis or while in therapy) generally undergo HSCT, while late relapsed cases are treated with chemotherapy, and HSCT is considered on individual basis.

In addition to the disease- and treatment-related prognostic variables, recent studies have highlighted the importance of host factors in governing the disease outcome as well. Host factors refer to differences among patients with regard to drug absorption, metabolism, and sensitivity. Considerable heterogeneity has been described with respect to host pharmacology of thiopurines²⁰ and vincristine.²¹ Furthermore, SNPs have been identified to be associated with unfavorable pharmacokinetics of various antileukemic chemotherapeutics, suggesting that drug disposition influences the risk of relapse.²²

The heterogeneity of childhood ALL is reflected in emerging genomic and epigenomic studies. DNA copy number abnormalities were identified in genes that encode regulators of B-cell development, as *CDKN2A/B*, *PAX5*, *IKZF1*, and *EBF1*.²³ In addition, somatic mutations in *JAK2*, alterations in RAS pathway genes (*NRAS*, *KRAS*, *PTPN11*, and *NF1*) and *CRLF2* genomic alterations have been identified with increased frequency in high-risk patients.^{24, 25} *JAK1* and *JAK2* mutations have previously been shown to be mutated in DS-ALL and T-cell ALL as well.⁸ Furthermore, gene expression profiling has identified a subset of patients whose blasts share a gene expression profile observed in patients with Ph+ ALL but who lack the BCR-ABL1 fusion protein. Such patients are called “Ph-like” ALL.²⁶ Ph-like ALL is associated with worse outcomes and deletions or mutations of *IKZF1* are a characteristic feature of both Ph-positive and Ph-like ALL.²⁷ This subgroup harbors tyrosine kinase fusions other than BCR-ABL, including *ABL1*, *ABL2*, *CSF1R*, and *PDGFR* fusions, and are candidates for treatment with tyrosine kinase inhibitors,²⁸ while another subset of these patients harboring *JAK* mutations are candidates for JAK

inhibitors.²⁹ This approach is currently under evaluation in the high-risk ALL trial through COG.

Although significant advances have been made in the outcomes of newly diagnosed ALL over the past four decades, infant ALL and early relapsed ALL are the two subgroups whose outcome remains dismal, and there is an urgent need of innovative strategies for these patients. Because of increased FLT3 (a tyrosine kinase) expression in infant ALL, the incorporation of the FLT3 inhibitor lestaurtinib on the standard intensive chemotherapy backbone in infant leukemia is currently being investigated. Also given the unique biology of infant ALL with the majority of patients having rearrangement of the *MLL* gene on 11q23, the protein DOT1L is recruited to *MLL* target genes resulting in aberrant expression of genes. DOT1L inhibitors are in clinical trials.

For relapsed ALL, various novel treatment strategies are emerging including molecularly targeted agents and cellular therapies. Recently, bispecific T-cell engager antibodies have gained considerable attention. These proteins have both T-cell specific and B-cell specific regions, thereby directing the patient's own cytotoxic T cells to the malignant tumor cells. Blinatumomab, a bispecific CD19-directed CD3 T-cell engager, has shown single agent activity and safety in children with multiple recurrent and refractory B-ALL, and is currently in clinical trial for children with B-ALL at first relapse through COG. Recent developments in cellular- and immune-based therapy have led to another major leap in the treatment of relapsed and refractory ALL. Chimeric antigen receptors (CARs)-modified T cells are genetically engineered to express antibodies directed against tumor antigens (CD19 for B-ALL) as well as T-cell activation molecules. They have shown great promise for long-term remission and possibly cure for this group of patients with extremely poor prognosis.³⁰

Acute myeloid leukemia (AML) in children

AML comprises about 20% of pediatric leukemia and chronic myeloid leukemia is detected in about 1–2%. Similar to ALL, the development of AML has also been associated with various inherited and acquired predisposition syndromes, such as DS, bone marrow failure syndromes such as Fanconi anemia, dyskeratosis congenita, severe congenital neutropenia (Kostmann syndrome), Diamond–Blackfan anemia, as well as acquired aplastic anemia. Patients treated with chemotherapy (particularly alkylating agents and topoisomerase inhibitors) and radiation therapy are at risk of developing therapy-related AML (t-AML). The presentation of AML is similar to that of ALL; occasionally, child may present with violaceous, raised, plaque-like lesions on the skin or gums, called chloromas, which is an extramedullary manifestation of AML. Patients with acute promyelocytic leukemia (APL), a distinct AML subtype, characterized by t(15:17) or *PML-RARA* fusion, often present with severe coagulopathy and frequently have hyperleucocytosis.

Compared to ALL, pediatric AML is less responsive to available chemotherapy. AML survival has recently improved with cure rates approaching up to 60–70% in the pediatric population.³¹ This has been achieved by dose intensification, improved supportive measures, results from large clinical trials, and better understanding of the biology and heterogeneity of this disease. Unlike ALL, age and WBC are not considered as independent prognostic variables for stratification. In fact, cytogenetic and molecular characteristics and response to induction chemotherapy are utilized in current treatment schema for risk-adapted therapy.^{32, 33} Presence of inversion 16, t(8;21) and t(15:17), biallelic *CEBPA* mutations, and *NPM1* mutations are considered as favorable, while monosomy 7, monosomy 5/del(5q), and FLT3-ITD with high allelic ratio are considered unfavorable characteristics. AML therapy consists of remission induction, prophylactic CNS-directed therapy, and postremission therapy. Chemotherapy regimens are intensive requiring prolonged hospitalizations and aggressive supportive measures. After initial 1–2 induction courses and upon achieving morphological remission (less than 5% blasts in marrow),

postremission therapy is administered, which may comprise additional intensive chemotherapy or HSCT depending on the cytogenetic risk factors and the depth of response (MRD status) to induction chemotherapy. Prolonged maintenance courses have been shown to be inferior and are not incorporated in current regimens except in APL. APL treatment requires rapid initiation of all-trans retinoic acid (ATRA), a differentiation-inducing agent, with concomitant chemotherapy along with aggressive supportive measures, followed by prolonged maintenance phase consisting of ATRA, 6-mercaptopurine, and methotrexate. This regimen leads to the EFS of 70–80%, without the use of HSCT in first complete remission in APL.³⁴ Arsenic trioxide has been shown as active agent against APL, and early experience in children with APL has shown encouraging results.

As the more intensive induction regimens have been maximally intensified, new active agents and strategies are needed. Currently, COG is studying in randomized study design the effect incorporating bortezomib, a proteasome inhibitor in FLT3-ITD-negative patients or sorafenib, a multitarget tyrosine kinase inhibitor that targets *FLT3*, *c-KIT*, *PDGF*, *VEGF*, and *MEK/ERK/RAF* pathway, for patients with high allelic ratio FLT3-ITD-positive AML, to the standard chemotherapy backbone for AML. In addition, epigenetic modifiers, such as vorinostat and 5-azacytadine, monoclonal antibodies against myeloid cell surface antigens, and various transplantation conditioning regimen and graft sources are currently being explored to improve the outcomes of pediatric AML.

Non-Hodgkin lymphoma in children (NHL)

Approximately 15% of all childhood cancers diagnosed in the United States are lymphomas. Sixty percent of all childhood lymphomas are classified as NHLs, representing 3% of all childhood malignancies for children younger than 5 years, and 8–9% for children and adolescents 5–19 years of age. In contrast to adults where most NHLs are low or intermediate grade, almost all NHL in children are high grade. There are three major subtypes of childhood NHL: (1) mature B-cell lymphoma predominantly Burkitt's lymphoma (classic and atypical) or diffuse large B-cell lymphoma (DL-BCL), (2) precursor T-cell lymphoma or lymphoblastic lymphoma, and (3) mature T-cell or null cell lymphomas, anaplastic large-cell lymphoma (ALCL). The World Health Organization (WHO) classifies ALCL as a peripheral T-cell lymphoma. The distribution of these histologic subtypes includes approximately 40% Burkitt lymphoma, 30% lymphoblastic lymphoma, 20% diffuse large B cell, and 10% ALCL. Burkitt's lymphoma tumor cells are characterized by a chromosomal translocation juxtaposing the *c-myc* oncogene and immunoglobulin locus regulatory elements t(8:14), rarely t(8:22) or t(2:8). Similarly, more than 90% of pediatric ALCL have a characteristic chromosomal rearrangement involving the *ALK* gene t(2:5).

Presence of bulky disease poses two potentially life-threatening situations that are often the presenting feature in children with NHL. First is the tumor lysis syndrome resulting in major electrolyte imbalances, most notably, hyperuricemia, hyperkalemia, and hyperphosphatemia. Aggressive hydration, allopurinol, or rasburicase (urate oxidase) are used in such situations along with other supportive measures. Second is the presence of large mediastinal masses especially seen in lymphoblastic lymphoma, posing a risk of cardiac or respiratory arrest (superior vena cava syndrome).

The primary modality of treatment of all histologic types and stages of childhood NHL is multiagent chemotherapy. The exact regimen of chemotherapy with or without intrathecal therapy and the intensity and length of treatment are usually dictated by the extent of disease and the histologic subtype. Although Burkitt's lymphoma, DL-BCL, and ALCL are treated with short intensive courses of chemotherapy, lymphoblastic lymphoma is treated based on ALL regimens consisting of long maintenance phase. The role of surgery is critically important in the diagnosis and staging process, but it has a limited role in the overall treatment of childhood NHL. There is minimal to no role of radiation therapy in the overall

treatment of childhood NHL.

The prognosis for children and adolescents with NHL, both with limited-stage and advanced-stage disease, has improved significantly over the past two decades. Except for rare subtypes, the chance of being alive and disease free at 5 years for limited-stage and advanced-stage disease B NHL is 95% and 80%, respectively.³⁵ The prognosis for advanced lymphoblastic NHL in children and adolescents has now increased to over 85% survival.³⁶ The prognosis, however, for the most advanced childhood and adolescent ALCL is still less than 70% at 7 years of follow-up.³⁷

Recently, therapeutic strategies for childhood NHL are incorporating surface, intracellular, and molecular targets in order to not only improve the overall cure rates of advanced-stage disease but to minimize the collateral damage from the chemotherapy agents. Rituximab is a monoclonal antibody targeting the CD20 antigen, expressed by Burkitt's lymphoma and DLBCL in children. The COG has demonstrated safety and tolerability of adding rituximab to the standard chemotherapy backbone in children and adolescents, with a 3-year EFS of 90% in patients with advanced mature B-cell lymphoma (with bone marrow and CNS involvement).³⁸ Likewise, the promising activity of crizotinib (targeting *ALK*)³⁹ and brentuximab vedotin (monoclonal anti-CD30 antibody)⁴⁰ in relapsed ALCL has now led to a randomized phase 2 trial of adding these agents in combination with chemotherapy in newly diagnosed ALCL.

Hodgkin disease (HD)

HD accounts for approximately 5% of pediatric malignancies in developed countries. Reed–Stenberg (RS) cells (multinucleated giant cells) are the hallmark of HD, which are present in a background of inflammatory cells consisting of eosinophils, small lymphocytes, plasma cells, neutrophils, histiocytes, and fibroblasts. RS cells nearly always express CD30, while CD15 is expressed in approximately 70% of cases. Two broad pathologic categories of HD are classical Hodgkin's lymphoma and nodular lymphocyte predominant. Classical Hodgkin's lymphoma accounts for the majority of cases of childhood HD, while nodular lymphocyte predominant Hodgkin's lymphoma occurs only in 5–10% cases.

The cure rate for pediatric patients with HD is greater than 90%. Standard therapy for pediatric patients with HD includes combination chemotherapy and low-dose involved-field radiotherapy (RT). Clinical research in pediatric HD aims to delineate minimal treatment necessary for cure and eliminate or minimize late sequelae of treatment.

PET scans have been demonstrated to be useful biomarkers of early response and useful in response-based therapy approaches to determine which patients would be eligible for treatment with chemotherapy alone or those that require intensification of therapy. The recently completed COG HD trial demonstrated successful omission of involved field RT without comprising outcome in intermediate-risk patients who show rapid response (PET-CT-negative disease), to two cycles of ABVE-PC (doxorubicin, bleomycin, vincristine, etoposide, prednisone, cyclophosphamide) and a complete response after four cycles.⁴¹ Management of relapsed/refractory HD remains challenging, and currently high-dose chemotherapy followed by autologous HSCT is considered standard of care for most patients. Recently, brentuximab vedotin (CD30-directed antibody drug conjugate) is being used in combination with chemotherapy for relapsed/refractory disease. Study of the biology of the RS cell in an effort to identify new therapeutic targets is also receiving significant attention.

Renal tumors

Wilms tumor

WT accounts for over 90% of renal tumors in children and 6% of childhood cancers in general. Today survival rates for all patients exceeds 90% and even patients presenting with metastatic disease have an event-free survival rate of 80% at 2 years.⁴² The typical clinical presentation is that of a well-appearing child who has an abdominal mass noted as an incidental finding. Over 90% of patients have a unilateral tumor with multicentric or bilateral tumors accounting for the remainder of cases. Patients with unilateral tumors present on average at 36.5 months (males) to 42.5 months (girls), while those with bilateral disease present earlier in life (33–35 months) reflecting a genetic predisposition.⁴³

Many congenital syndromes are associated with WT and analyses of such cases led to the discovery of tumor suppressor genes involved in the pathogenesis of both inherited and sporadic cases. Children with the WAGR (WT, aniridia, genitourinary abnormalities, and mental retardation) syndrome have a greatly increased risk of WT, and this syndrome is associated with constitutional (germline) deletions at 11p13. Within the deleted region lies the WT1 gene responsible for the risk of WT (as well as PAX5 responsible for aniridia). Disease pathogenesis follows a classic two-hit model with the tumor having lost both WT1 alleles. Likewise, the Denys–Drash syndrome (pseudohermaphroditism, degenerative renal disease) is associated with constitutional mutations of WT1 and tumors contain mutations in both alleles. Somatic mutations of WT1 are seen in 10–20% of sporadic WT.⁴⁴

A second tumor suppressor gene, WT2, has been mapped to 11p15.5. Abnormalities of this region are associated with another syndrome where the risk of WT is particularly high, the Beckwith–Wiedemann syndrome (macroglossia, omphalocele, visceromegaly, and hemihypertrophy). This region encodes a large number of imprinted genes including insulin-like growth factor 2 (*IGF2*) and *H19*, which encodes a noncoding RNA that acts as a tumor suppressor gene.⁴⁵ Somatic loss of heterozygosity (LOH) of WT2 is the most common defect in sporadic WT occurring in up to 80% of cases. Other mutations are seen in WT including *WTX* (32%), *CTNNB1* (encoding β -catenin, 15%), and *T53* (5%).⁴⁴

WT presents typically as a well-circumscribed heterogeneously enhancing mass originating from kidney ([Figure 3a](#)). Pathologically, WT typically shows a triphasic pattern composed of blastemal, epithelial, and stromal cell types, although in some cases only one or two of these cell types may be visualized. Anaplasia is characterized by markedly enlarged nuclei, pleomorphism, and polyploidy mitotic features, and these are associated with a poor prognosis. Anaplasia may be focal or diffuse and is seen in 5% of tumors.⁴⁶ In the absence of anaplasia, WTs are classified as having “favorable histology.” Nephrogenic rests are precursor lesions and represent persistent nephroblastic tissue that has not undergone full differentiation.⁴⁷ Patients with nephrogenic rests (30% sporadic and 100% bilateral WTs) may be at risk for the development of a subsequent WT. There are two types of nephrogenic rests based on location: perilobar and intralobar. Most nephrogenic rests undergo gradual resolution.

Figure 3 Computed tomographic (CT) imaging characteristics of common childhood abdominal tumors. (a) Wilms' tumor: axial contrast-enhanced CT images of the abdomen showing a large well circumscribed heterogeneous left renal mass that does not cross the midline. (b) Neuroblastoma: axial contrast-enhanced CT images of the abdomen demonstrating a large lobulated heterogeneous mass in the right upper quadrant that crosses the midline with characteristic encasement of aorta and displacement of superior mesenteric vein, splenic vein, and pancreas anteriorly. Dense calcifications are present within the mass.

Therapy for WT involves surgical resection and chemotherapy with radiation reserved for more advanced stages. Worldwide there are two general approaches that lead to equivalent outcomes. In North America (based on practices established by the National Wilms Tumor Study Group (NWTSG) and now COG), most cases are treated by initial surgery (nephrectomy and lymph node sampling) followed by chemotherapy.⁴² In Europe (Societe Internationale d'Oncologie Pediatrique or SIOP), neoadjuvant therapy is advocated with delayed surgery. The advantage of the North American approach is that it allows for full, unaltered evaluation of all tumor tissue and accurate staging, while the SIOP approach allows for preoperative tumor shrinkage thereby making resection easier and decreasing the risk of spillage.^{48, 49}

The usual definitive surgical approach to WT is a radical nephrectomy through a wide abdominal incision. The adrenal gland is removed and regional lymph nodes are sampled. More recently, a flank approach is being used and there is a question whether adrenalectomy is needed.⁵⁰ Given the risk of second WTs, a partial nephrectomy or “nephron sparing” surgery is used for patients with bilateral tumors but also this is increasingly being considered for unilateral favorable histology tumors, especially in the neoadjuvant setting where there is assurance of negative margins due to an excellent response to chemotherapy. Finally, laparoscopic-/robotic-assisted resections are being explored by some surgeons.

Treatment of WT includes nephrectomy and stage-dependent chemotherapy with or without radiation to the abdomen and/or lungs. There are subtle differences in staging between the COG and SIOP approaches, but in general, complete resection of tumor with an intact capsule and no extension to the renal sinus is stage I. Stage II tumors are those completely resected, but the tumor extends beyond the capsule or into the renal sinus while incompletely resected tumors or those with lymph node involvement, tumor spillage, and/or positive surgical margins are declared stage III. Stage IV indicates metastatic hematogenous spread (usually lung but also liver, brain, or bone). Preoperative evaluation includes a CT of the abdomen and pelvis and Doppler ultrasound if there is concern about tumor thrombus in the inferior vena cava. Magnetic resonance imaging (MRI) may be useful for following nephrogenic rests and aid in surgical planning for patients with bilateral tumors.

Once removed, the tumors are evaluated pathologically to validate the diagnosis and examine sections for the presence of anaplasia. In addition, certain molecular markers may portend for a worse prognosis such as LOH at 1p and 16q, and these genetic lesions have been uniformly assessed on recent protocols.⁴²

Patients less than 2 years with stage I favorable histology tumors weighing less than 550 g may be treated with nephrectomy only as the small minority who relapse can be salvaged with chemotherapy and RT. Patients with stage I and II tumors (without LOH at 1p and 16q) are treated with vincristine and dactinomycin (18 weeks), while stage III patients receive vincristine, dactinomycin, and doxorubicin with abdominal irradiation (24 weeks). Patients with LOH at 1p and 16q are upstaged and require additional therapy. Many different drug combinations have been assessed for favorable histology stage IV patients, but none have seemed to improve outcome over the three drug combination given with abdominal and chest irradiation. Those patients whose metastatic lesions regress early in therapy may not require chest XRT, whereas those patients whose lesions do not regress early require chest irradiation and may benefit from additional chemotherapy. The presence of anaplasia is associated with an inferior prognosis and therapy is modified based on whether the anaplasia is diffuse or focal as well as stage. For example, patients with stage II–IV tumors showing diffuse anaplasia are treated with combination therapy including vincristine, doxorubicin, cyclophosphamide, carboplatin, etoposide although the optimal regimen has yet to be established.

Patients with bilateral tumors and those with unilateral tumors and a congenital predisposition syndrome pose a special challenge as these patients are at risk for subsequent tumors. These patients can be treated with preoperative chemotherapy [vincristine, dactinomycin (unilateral tumors with predisposition syndrome) ±doxorubicin (bilateral tumors)] and undergo nephron sparing surgery at weeks 6 or 12 depending on optimal response. Such patients usually do not require an initial biopsy given the typical clinical and radiographic presentation. Therapy after resection is guided by stage and histology of the resected specimen.

The outcomes for all stages of favorable histology WT is excellent with 10-year relapse-free survival rates of 91% (stage I), 85% (stage II), 84% (stage III), and 75% (stage IV) while historically patients with anaplastic tumors have a worse outcome (10-year relapse-free survival 43% (stages I–III), 18% (stage IV)). Patients with bilateral tumors have an intermediate 10-year relapse-free outcome of approximately 65% (overall survival 78%).⁴²

Other renal tumors

Renal cell carcinomas, clear cell sarcomas of the kidney and malignant rhabdoid tumors constitute 5.9%, 3.5%, and 1.6% of all renal tumors in children. Children with renal cell carcinoma present with abdominal pain, hematuria, and an abdominal mass on examination. Many conditions are associated with renal cell carcinoma including von Hippel–Lindau disease, familial renal cell carcinoma and previous therapy for malignancy. Pediatric renal cell carcinomas differ from adults in that a higher proportion are papillary and not otherwise specified, and the clear cell and chromophobe variants are less common.^{51, 52} Most tumors in childhood are characterized by translocations involving *transcription factor E3* gene (*TFE3*) located on Xp11.2 with a variety of fusion partners. Children tend to present at a more advanced stage compared to adults. Radical nephrectomy with lymph node dissection remains the primary treatment. Survival rates at 4 years are 92%, 85%, and 73% for stages I, II, and II respectively while outcome for stage IV disease remains dismal (14%).^{42, 53} Optimal therapy for patients with unresectable or metastatic disease has not been defined but there is great interest in using tyrosine kinase inhibitors (sunitinib and others) in translocation positive renal cell carcinoma.⁴²

Clear cell sarcomas are a distinct group of tumors with the histological appearance of nests of cells separated by organized fibrovascular septa. The molecular pathogenesis is unknown for most tumors although a t(10;17)(q22,p13) is noted in a small subgroup of these cases. Clear cell sarcomas can metastasize to bone and brain in addition to lung and liver but most patients present with localized disease. Historically these patients have been classified as unfavorable but incremental improvements have been achieved over successive NWTs trials. Patients treated on a regimen of vincristine, doxorubicin, cyclophosphamide, and etoposide with radiation therapy to the tumor bed had a 5 year EFS of 79%.^{42, 54}

Malignant rhabdoid tumors present at a younger age compared to WT and symptoms include fever and gross hematuria.⁵⁵ The majority of patients have advanced disease and up to 15% have associated CNS lesions. Histologically, the tumor is composed of large cells, prominent nucleoli, and eosinophilic cytoplasmic granules. These tumors are due to biallelic inactivation (mutation and/or deletion) of the *SMARCB1* gene on 22q (also known as *INI1*) which encodes a member of a chromatin remodeling complex.⁵⁶ About a third of patients harbor a germline mutation in *SMARCB1* and these children present at an earlier age (median 5 months compared to 18 months). Most patients are treated with surgery, radiation, and multiagent chemotherapy but optimal drug combinations have yet to be identified. Young age, advanced stage and the presence of CNS disease are adverse prognostic factor. Four year relapse-free survival is 50%, 33%, 33%, and 21% for stages I, II, II, and IV respectively.⁴²

Congenital mesoblastic nephroma typically occurs in infancy and present as unilateral abdominal tumors. Two patterns exist, classic and cellular. The cellular form of mesoblastic nephroma is characterized by the *ETV6/NTRK3* fusion transcript (t(12;15)(p13;q25) identical to infantile fibrosarcoma.⁵⁷ These tumors are treated by complete resection without need for adjuvant therapy since metastasis is quite rare. Overall survival rates are approximately 95%.⁵⁸

Neuroblastoma

NB is the most common extracranial solid tumor of children and accounts for 8–10% of all childhood cancers. This tumor represents transformation of precursor neural crest cells that were destined to form sympathetic ganglia and the adrenal medulla. It is the most common tumor of infancy and the median age of presentation is 18 months.⁵⁹ Curiously the disease has a wide clinical and biological spectrum ranging from spontaneous regression of widespread disease in infants to unrelenting, aggressive disease usually in older children. About 2% of cases are familial in nature and 50% of these patients carry germline mutations in the anaplastic lymphoma kinase gene, *ALK*, while a much smaller number of familial cases are due to mutations in *Phox2b* in association with other neurocristopathies like Hirschsprung's disease.^{60–62} It is likely that additional steps are required for full transformation since only 50% of germline carriers of *ALK* mutations develop NB.⁶³ Indeed GWAS have identified a number of predisposition loci yet their contribution to most sporadic cases is likely to be quite modest.⁶⁴ *ALK* mutations and amplifications are seen in 8–12% and 2–3% respectively of sporadic cases and *Phox2b* mutations have been detected in 2% of sporadic tumors.⁶⁵

The clinical presentation of NB is dependent on the location of the primary tumor but a majority of patients have symptoms due to widespread disease at initial diagnosis such as fever, weight loss, irritability, bone pain, and cytopenias. Two-thirds of cases are associated with an abdominal primary and the great majority of NBs are located in the adrenal gland ([Figure 3b](#)). Children may present with abdominal pain, constipation, and distention. A large abdominal mass that typically crosses the midline is

detected on physical examination. Cervical and thoracic tumors (posterior mediastinum) can be associated with Horner syndrome. Presacral and paraspinal tumors may present with cord compression such as urinary retention, motor weakness, and clonus. Finally, NB may present with an unusual paraneoplastic syndrome characterized by opsoclonus myoclonus syndrome (OMS), where children typically manifest darting eye movements and myoclonic jerks with or without ataxia.⁶⁶ Interestingly, OMS is often associated with favorable prognosis tumors, but unfortunately, neurological symptoms persist after effective treatment of the NB.

Initial evaluation of NB includes cross-sectional imaging with CT or MRI of the chest, abdomen and pelvis to determine local, regional (including extradural extension), and distant sites of disease. Metaiodobenzylguanidine (MIBG) is a norepinephrine analogue selectively taken up by sympathetic nervous tissue and is used to assess disease location not picked up by CT or MRI. Most tumors are MIBG avid but for those that are not avid, FDG-PET may be used. Bilateral bone marrow aspirates and biopsies are required to detect bone marrow involvement. The diagnosis is confirmed by biopsy of the primary or distant site involvement, or characteristic tumor cell in the bone marrow with elevated levels of vanillylmandelic acid (VMA) and homovanillic acid (HVA) in the urine.

Histologically, tumors can display a range of cellular differentiation from ganglioneuroma (differentiated) to ganglioneuroblastoma to typical NB. Typically, the tumor is composed of small round blue cells with rosettes. Histologically, tumors can be classified as favorable or unfavorable based on age, the degree of differentiation (differentiated associated with better prognosis), Schwannian stromal content, and the karyorrhexis index [MKI, the number of mitosis and karyorrhexis (fragmented nuclei) per 5000 cells, less than 100 or 200 MKI (depending on stroma, age, and degree of differentiation) is associated with a better prognosis].⁶⁷

An International Neuroblastoma Staging System (INSS) was developed to harmonize approaches and analyses of outcome worldwide ([Table 3](#)).⁶⁸ It is noteworthy that children with 4S disease have a high degree of spontaneous regression in spite of widespread disease. More recently, this has been replaced by the International Neuroblastoma Risk Group (INRG) stratification system based on radiographic features that indicate resectability and the presence of widespread metastatic disease: L1 (localized tumors confined to one body compartment), L2 (locoregional tumor with involvement of adjacent structures), M (distant metastasis), and MS (metastatic disease in children <18 months confined to skin, liver, and/or bone marrow).⁶⁹

Table 3 International neuroblastoma staging system (INSS)⁶⁷

Stage I	Localized tumor with complete gross excision (± microscopic disease), ipsilateral lymph nodes negative.
Stage IIA	Localized tumor, incomplete resection, ipsilateral nonadherent lymph nodes negative.
Stage IIB	Localized tumor with or without gross excision, ipsilateral lymph nodes positive, contralateral nodes negative.
Stage III	Unresectable unilateral tumor that crosses the midline (± lymph nodes), unilateral tumor with contralateral lymph node involvement, midline tumor with bilateral extension, or lymph node involvement.
Stage IV	Disseminated disease to distant lymph nodes, skin, liver, bone, bone marrow, and other organs.
Stage IVS	Localized primary tumor (e.g., defined as I, 2A, or 2B) in infants less than 1 year of age with disseminated disease to the skin, liver, and/or limited bone marrow involvement (tumor cells <10% nucleated cells).

Treatment stratification is based on a number of clinical and biological variables that allow classification into low-, intermediate-, and high-risk categories. Two of the most important risk factors are age and stage with children less than 18 months of age having a distinctly better prognosis than older children. The overall survival of children with INSS stages 1, 2, 3, and 4S is 91±1% compared to 42±1% for stage IV disease.⁷⁰ NB was one of the first human tumors where genetic stratification has had a significant impact. *MYCN* amplification (>4 fold increase of *MYCN* signals compared to the control) is observed in 20% of cases and portends aggressive disease. Ploidy is also predictive of survival especially in infants and patients with localized disease, where hyperdiploidy is associated with a good prognosis. The COG uses age, stage, histology, *MYCN* status, and ploidy to classify patients into low- (40% tumors, EFS >95%), intermediate- (20%, EFS 80–95%), and high-risk (40%, EFS 40–50%) categories.⁶⁵ Additional genetic risk factors impact prognosis including allelic gains at 17q and LOH at 1p36 and 11q, all of which are associated with a poor prognosis. In addition to the variables used for the COG risk classification, 11q aberrations are used in the INRG classification system.⁷⁰ Newer classification approaches include the integration of segmental chromosome gains or losses. Although gains of whole chromosomes have been associated with a good prognosis, segmental gains or losses are associated with a poor prognosis particularly segmental loss at 1p, 3p, 4p, 11q or gains at 1q, 2p, or 17q. Future studies will factor these variables into classification of lower risk disease.⁷¹

Treatment for patients with low-risk disease (INSS 1, biologically favorable INSS 2A, 2B) is surgery alone with chemotherapy reserved for patients with life-threatening symptoms or for the minority of patients whose disease progresses or reoccurs.⁷¹ There is a subset of patients less than 6 months of age with small adrenal primaries whose tumors may regress without surgery.⁷² Most stage IV-S patients undergo spontaneous regression, but some infants present with massive hepatomegaly and associated respiratory distress necessitating immediate management with low-dose chemotherapy and/or irradiation. Intermediate-risk patients (e.g., INSS stage III and most stage IV <18 months, INRG L2 and M < 18 months if diploid) are treated with surgery and moderately intensive chemotherapy that includes carboplatin or cisplatin, etoposide, cyclophosphamide, and doxorubicin for 2–8 cycles depending on initial tumor response and other prognostic markers such as segmental chromosome abnormalities. In some cases, surgery may be avoided altogether as well as chemotherapy (L2 < 18 months).

Treatment of high-risk disease remains a challenge, but stepwise improvements have occurred through the use of myeloablative regimens, differentiation therapy, and most recently, immunotherapy.^{73, 74} Initial therapy consists of six cycles of dose-intensive chemotherapy with cyclophosphamide, topotecan, cisplatin, etoposide, doxorubicin, and vincristine, or similar agents. Surgery (before consolidation with myeloablative chemotherapy) and irradiation therapy (after consolidation) to minimize tumor burden is routinely used in the high-risk setting. Multiple studies have demonstrated that consolidation with myeloablative chemotherapy followed by autologous peripheral blood stem cell re-infusion improves outcome.⁷⁵ Studies have shown no benefit to purging the stem cell source, and stem cells are usually harvested after two cycles of chemotherapy.⁷⁶ Data exist to indicate that myeloablation with busulfan–melphalan is superior to other regimens and that “tandem” courses of high-dose chemotherapy with stem cell rescue may be beneficial over a single course.⁷⁷ An upcoming COG study will look at the benefit of targeted ¹³¹I-MIBG prior to consolidation in the newly diagnosed setting.⁷¹

The use of biological approaches has also improved outcome for patients with high-risk disease. Cis-retinoic acid has long been noted to differentiate tumor cells in culture, but early use in the treatment of relapsed or refractory disease was disappointing. However, a randomized trial examining its impact when delivered after cytotoxic therapy in the setting of MRD for high-risk patients showed a substantial benefit and its use is currently being evaluated in patients with lower risk disease.⁷⁸ The additional use of the anti-GD2 monoclonal antibody (mab) ch 14.18 in conjunction with granulocyte–monocyte colony-stimulating factor and interleukin-2 increased the 2-year survival significantly (66% ± 5% with mab vs 46%±5% without mab).⁷⁴

Therapy for refractory patients and those who relapse remain unsatisfactory. Whole genome copy number analysis and sequencing have discovered 12% of patients with ALK aberrations, and such patients may benefit from ALK inhibitors such as crizotinib that is the current focus of early phase investigations. Somatic alterations of other genes were much less frequent including *ATRX*, *ARID1A*, and *PTPN11* (regulates ras pathway), but as yet, targeted therapy is not available. The neurotrophin receptor TrkB is expressed on high-risk NBs and targeting these pathways remains a potential therapeutic opportunity even though early experience with lestaurtinib was negative.⁷⁹ The nuclear transcription MYCN, like other transcription factors, has been difficult to target, but new approaches targeting bromodomain and extraterminal (BET) bromodomain proteins that regulate chromatin have shown striking efficacy in preclinical models of Myc-amplified tumors, and therapeutic compounds are in early phase investigation.⁸⁰

Pediatric bone tumors

Malignant primary bone tumors that occur in both younger and older patients have important differences in pathogenesis, presentation, and treatment, and these differences will be highlighted. Although primary bone tumors are rare, they are the sixth most common malignant neoplasm in children and the third most frequent neoplasm in AYAs. Malignant bone tumors occur in the United States at an annual rate of approximately 8.7 cases per million children and adolescents younger than 20 years. Only half the bone tumors in childhood are malignant, and of these, osteosarcoma (OS) is the most frequent, accounting for approximately 35% of all primary sarcomas of bone. Ewing sarcoma (EWS), the second most frequent primary bone cancer, is more common than OS in children younger than 10 years.

Osteosarcoma

OS, the most common primary malignant bone tumor, is composed of spindle cells producing osteoid. It is a highly aggressive neoplasm for which dramatic progress has been made in treatment and outcome during the past several decades. OS is primarily a disease of AYAs, although it can also occur in older patients. OS has a bimodal age distribution, with the first peak in the second decade of life during the adolescent growth spurt, and the second among older adults. It is estimated that approximately 400 children and adolescents less than 20 years of age are diagnosed each year in the United States. It is extremely rare before the age of 5 years. The most common clinical presentation is pain with or without an associated soft tissue mass in the involved region of bone. Among young patients, the most common location is the metaphysis of a long bone. Approximately, half of all OSs originate around the knee joint.

The peak age coincides with a period of rapid bone growth in young people, suggesting a correlation between rapid bone growth and the evolution of OS. Radiation exposure is another well-documented etiologic factor. The incidence of OS is dramatically increased among survivors of RB. In the hereditary form of this disorder, germline mutations of the RB gene are common. This is the likely basis for the increased frequency of secondary cancers in this population, as the rate in survivors of unilateral sporadic RB is much less. Germline mutations in the P53 gene can lead to a high risk of developing malignancies, including OS, which has been described as the Li–Fraumeni syndrome. Most OSs, including those in children and adolescents, are of the osteoblastic subtype. The current WHO classification recognizes two additional subtypes of conventional OS: chondroblastic and fibroblastic based on the predominant pattern of differentiation. Telangiectatic OS is a rare subtype, which appears as a purely lytic lesion on plain radiographs and thus, may be confused with aneurysmal bone cyst or giant cell tumor.

Similar to other sarcomas in young patients (typically high grade), OS metastasizes very early in its evolution. Approximately 20% of patients present with radiographically detectable metastases, most frequently to the lung, while almost all newly diagnosed patients with OS have at least micrometastatic disease as evidenced by the fact that if treated by surgical resection alone, 80% will relapse in the lung within 2 years.⁸¹ Death from OS is almost always the result of progressive pulmonary metastasis with respiratory failure, pulmonary hemorrhage, pneumothorax, or superior vena cava obstruction. The diagnosis of OS is typically suspected by the radiographic appearance of the affected lesion. OS can present as a lytic, sclerotic, or a mixed lytic–sclerotic lesion. The diagnosis of OS is dependent on a biopsy for histologic examination providing a pathological diagnosis. OS is a pleomorphic, spindle cell tumor that forms an extracellular matrix consisting mostly of osteoid. Immunohistochemistry and cytogenetics are not helpful in diagnosing OS. Patients with OS should undergo a staging work-up to determine the extent of disease at presentation, which includes plain radiographs and MRI of the involved bone and should capture the adjoining joints, noncontrast chest CT, a bone scan, and/or a PET scan.

Multiagent systemic chemotherapy, along with local and metastatic disease control with surgery, is the standard of care.⁸¹ The standard chemotherapy of patients with nonmetastatic OS, although variable, includes the use of cisplatin and doxorubicin with the addition of high-dose methotrexate. Advances made in surgical techniques have significantly improved the clinical practice and functional limb salvage options available for patients. *Rosen* et al. introduced the concept of chemotherapy prior to surgical resection.⁸² Although no differences in outcome are reported with the incorporation of neoadjuvant chemotherapy versus upfront surgery followed by adjuvant chemotherapy, neoadjuvant chemotherapy does provide several potential advantages, including better resectability if tumor shrinks, improved surgical planning and endoprosthetic customization, treatment of micrometastatic disease and above all, the ability to assess the response to chemotherapy. A strong correlation between the degree of necrosis and the probability of subsequent DFS was observed,⁸³ which has subsequently been confirmed in multiple clinical trials. Soon after the identification of the prognostic value of the degree of necrosis following

induction chemotherapy, it was suggested that chemotherapy be modified for the patients with less necrosis. Despite an early report of benefit, intensified regimens including ifosfamide and etoposide have not improved outcome for poor responders.⁸⁴ Because complete surgical resection is imperative for the cure of OS, surgical resectability is an important prognostic factor, therefore patients presenting with axial skeleton tumors fare worse than those having tumors in appendicular skeleton.

The standard management for patients with metastatic disease at the time of initial diagnosis follows the same general principles as those who present with localized disease. The outcome of OS patients depends on several factors. The most consistent prognostic factor at diagnosis is the presence of clinically detectable metastases, which confers an unfavorable prognosis. In patients with metastatic disease at diagnosis, the number of pulmonary nodules, as well as, whether they are unilateral or bilateral is also of prognostic significance. With currently available regimens, approximately 60–70% of patients with nonmetastatic OS of the extremity will survive without evidence of recurrence. In most large reported studies, only 10–20% of patients who present with clinically detectable metastatic disease survive. OS is resistant to radiation therapy, thus it is not a part of standard OS treatment and is reserved for pain/symptoms relief in palliative care settings only.

The survival of patients with OS appears to have reached a plateau. At present, none of the agents in early phase clinical trials have shown promise to move them in the frontline therapy. Research is ongoing to elucidate novel molecular targets in OS, of which anti-GD2 antibody and RANKL antibody are of particular interest.⁸⁵

Ewing sarcoma

EWS is the second most common primary malignant bone tumor in children and adolescents. EWS is a part of peripheral primitive neuroectodermal tumors (PPNETs). In the early 1980s, EWS and PPNET were both found to contain the same reciprocal translocation between chromosomes 11 and 22, t(11;22)(q24;q12).^{86, 87} Later that decade, similar patterns of oncogene expression (c-myc, N-myc, c-myb, and c-mil/raf-1) were seen among these tumors. The combination of the shared translocation, cellular physiology, and clinical response has led to categorizing these tumors into the Ewing sarcoma family of tumors (EWSFTs). The EWSFT includes EWS, PPNET, neuroepithelioma, atypical EWS, and Askin tumor (an EWSFT of the chest wall).

Most cases are thought to be sporadic, but family members of EWSFT patients have an increased incidence of neuroectodermal and stomach malignancies.⁸⁸ EWSFT are thought to derive from cells of neuroectodermal origin, possibly postganglionic cholinergic neurons, although the exact cell of origin has yet to be identified. The immunohistochemical hallmark of EWSFT is diffuse membranous staining for CD99 (MIC2), which is present in greater than 90% of EWSFT. Undifferentiated tumors are negative for other markers except vimentin and FLI-1, whereas more differentiated tumors variably express additional markers, including neuron-specific enolase, S-100, neurofilaments, CD57, and synaptophysin. Muscle and lymphoid markers are negative. The translocation t(11;22)(q24;q12), or another related translocation, occurs in greater than 95% of EWSFT. Some argue that such a translocation is pathognomonic and is both necessary and sufficient for a diagnosis of EWSFT. The classic t(11;22)(q24;q12) translocation joins the EWS gene located on chromosome 22 to an ets-family gene, *FLI1* (Friend Leukemia Insertion), located on chromosome 11. Other ets-family partners are *ERG* t(21;22), *ETV1* t(7;22), and *E1AF* t(17;22). Standard cytogenetics and fluorescence *in situ* hybridization (FISH) can reveal this anomaly and additional karyotypic abnormalities, including trisomies 8 and 12, and chromosomes 1 and 16 abnormalities. Some of the t(21;22) translocations remain cryptic by standard cytogenetic techniques and require reverse transcription polymerase chain reaction or FISH.

The incidence of EWSFT peaks in the latter half of the second decade of life. An enigma in EWSFT is its racial distribution. The incidence in whites is at least ninefold higher than in blacks. EWS arises most commonly in the bone, but it can also originate in extraosseous soft tissues. Frequent primary sites include the pelvis (25%), femur (16%), ribs (12%), and spine (8%). Approximately 25% of patients present with metastatic disease. Of these, 37% (or 9% of all patients) have metastases confined to the lung or pleura. The remaining patients have bone and/or bone marrow metastases, either alone or in addition to pulmonary/pleural disease. Rarely, patients with bone marrow metastases have extensive infiltration and present with systemic symptoms. Diagnosis is typically done by tumor biopsy. Staging work-up typically includes MRI/CT of the primary site, CT scan of the chest to evaluate for lung metastasis, bone scan and bone marrow aspiration, and biopsy. Recently, FDG-PET/CT is replacing bone scan for EWS metastatic work-up. The most consistent prognostic factor is the presence of metastatic disease at diagnosis. The presence of an axial tumor, older age at diagnosis, larger size of primary tumor, and poor histologic response after induction chemotherapy are other adverse prognostic indicators in EWS.

The successful management of patients with ESFT requires the use of both local and systemic therapy. Both surgery and radiation therapy are utilized for local control, while systemic control is achieved by chemotherapy. EWS, unlike OS, is quite radioresponsive, and RT is considered a standard option for definitive local control. Radiotherapy can be used as an alternative to disfiguring surgery such as amputation. Alkylating agents (cyclophosphamide, ifosfamide, melphalan, and busulfan) and doxorubicin are the most active single agents in EWS, while addition of ifosfamide plus etoposide has led to significant increase in EFS and OS, particularly for localized disease.⁸⁹ Recently, the COG has shown superior efficacy of dose-intensive therapy administered every 2 weeks with filgrastim support compared to the conventional every-3-week therapy for patients with initially localized disease.⁹⁰ Altogether, these measures have increased 5-year EFS of localized EWS to approximately 75%.

EWS patients with disease metastatic at initial diagnosis have a poor outcome. Patients with multiple sites of metastases have the lowest survival rates. Patients with metastases confined to the lungs may represent a group of patients with better prognosis than patients with bone or bone marrow metastases. Overall cure rates for metastatic EWS remains 20%, utilizing the standard interval-compressed chemotherapy including ifosfamide and etoposide as described above for localized disease along with local control of primary and metastatic sites utilizing surgery and radiation therapy. Myeloablative chemotherapy followed by autologous stem cell rescue has not shown significant improvement in overall survival.⁹¹

Moving forward, based on feasibility of adding topotecan/cyclophosphamide in a pilot study, COG is running a phase 3 randomized trial for patients with localized EWS. The insulin-like growth factor type I receptor (IGF-1R) is critical for transformation and growth of ESFT,⁹² and incorporation of antibody against IGF-1R with intensified chemotherapy backbone is being investigated through the COG for newly diagnosed metastatic EWS patients. In addition, mTOR inhibitors are being tested in relapse and refractory EWS.⁸⁵

Soft tissue sarcomas

Soft tissue sarcomas represent a widely heterogeneous group of malignancies that in aggregate account for 7.4% of cancers in children and adolescents up to 19 years of age. Approximately 800–900 cases are diagnosed per year in the United States.¹ The most common soft tissue sarcoma is RMS that is derived in large part from striated muscle, while others originate from fibrous connective tissue (fibrosarcoma), smooth muscle (leiomyosarcoma), and fat (liposarcoma). Synovial cell sarcoma is now thought to

originate in precursor cells distinct from those that lead to synovium.

Rhabdomyosarcoma

RMS accounts for 50% of soft tissue tumors in children less than 14 years of age. By far, most cases of RMS are sporadic although cases have been described in association with NF-1, Costello syndrome, Beckwith–Wiedemann syndrome, and Li–Fraumeni syndrome. The histologic hallmark of RMS, a small round blue cell tumor, is evidence of skeletal muscle differentiation most often validated by immunohistochemistry (MyoD, myogenin, muscle specific actin, myoglobin, and desmin). RMS is composed of two histologic subtypes. Embryonal RMS (ERMS, 60–75% of cases) is characterized by spindle cells with myxoid areas, whereas alveolar RMS typically shows oval cells forming alveolar spaces surrounded by fibrous septae.⁹³ The majority of alveolar cases are characterized by translocations between the DNA-binding domains of *PAX3* (55% of ARMS) or *PAX7* (20%) and *FOXO1*. About 15% of ARMS are fusion negative. The outcome for ERMS is superior to that of ARMS, and patients with fusion-negative ARMS have a better outcome compared to fusion-positive cases.⁹⁴ Interestingly, ERMS is associated with a higher mutational burden and frequent alterations of RAS pathway genes.⁹⁵

The clinical presentation of RMS depends on location. About 40% of RMS occur in the head, neck, and orbit. Symptoms can include a painless mass (superficial head and neck primary tumors), proptosis, and esotropia (orbital tumors), snoring, recurrent unilateral epistaxis, sinusitis, and cranial nerve palsies (nasopharyngeal and paranasal lesions). Genitourinary RMS accounts for 20% of cases, and bladder/prostate lesions can lead to urinary obstruction. Approximately, 20% occur in the extremities and usually present as a painless mass. Extremity tumors tend to be of the alveolar subtype, whereas the majority of tumors located in the head, neck, and GU sites are ERMS. The botryoid variant of ERMS arises under mucosal surfaces (e.g., vagina, nasopharynx) and can present as a protruding grape-like mass.

The clinical evaluation of patients includes cross-sectional imaging (CT or MRI) of the primary with evaluation of possible metastatic disease (chest CT, bilateral bone marrow aspirates and biopsies, and bone scan). Approximately, 15% of patients will have metastatic disease at diagnosis, most commonly lung followed by bone marrow, lymph node, and bone. RMS is classified according to well-documented determinants of prognosis such as age, location of the primary tumor, extent of disease (group), histologic subtype, and stage. The stage incorporates the site of the primary (favorable site vs unfavorable site) and a pretreatment assessment of tumor size (confined to organ, T1 vs extension, T2; size ≤ 5 cm or >5 cm), nodal status (N_0 uninvolved, N_1 , involved, N_X unknown), and metastasis (M_0 or M_1). Favorable sites include the orbit, nonparameningeal head and neck, biliary, and nonbladder/prostate genitourinary sites. The group is dependent on the surgical resectability (Group 1—completely resected, Group II—gross total resection with evidence of regional spread, Group III—gross residual disease, Group IV—distant metastasis at diagnosis). Regional lymph nodes should be sampled in cases of RMS located in the extremities. Of note, initial response to chemotherapy has not been proven to be prognostic in COG studies. These variables have been used to develop a risk stratification used in COG trials ([Table 4](#)).⁹⁶

Table 4 COG risk stratification for rhabdomyosarcoma

Risk group	Stage	Group	Histology	Percent of cases	EFS
Low, subset 1	I	I–II	ERMS	27%	85–95%
	I	III (orbit)	ERMS		
	II	I–II	ERMS		
Low, subset 2	I	III (non-orbit)	ERMS	5%	70–85%
	III	I–II	ERMS		
Intermediate	II–III	III	ERMS	27%	73%
	I–III	I–III	ARMS	25%	65%
High	IV	IV	ERMS	8%	35%
	IV	IV	ARMS	8%	15%

Treatment for RMS requires a multidisciplinary approach. The chemotherapeutic agents most beneficial are vincristine, dactinomycin, and cyclophosphamide (VAC). Patients with low-risk disease, subset 1, can be effectively managed with a short course of VAC treatment where the dose of cytoxan is minimized to avoid infertility, whereas a higher dose of the drug is required for subset 2 patients.⁹⁷ Patients with Group II and III tumors receive irradiation. There have been many attempts to improve outcome for intermediate-risk patients with the addition of agents such as etoposide, carboplatin, ifosfamide, and topotecan to VAC, but to date such efforts have been disappointing. A recently completed COG study looked at the addition of vincristine/irinotecan (V/I) to VAC, and while EFS was not improved, there was less hematologic toxicity and the total dose of cytoxan was lower. Thus, moving forward VAC/VI is likely the standard of care for intermediate-risk RMS.⁹⁸ There has been little improvement in outcome for high-risk disease, but the use of interval compressed ifosfamide/etoposide and vincristine/doxorubicin/cyclophosphamide may be associated with a substantial gains for high-risk ERMS. A number of drugs are being considered or are under investigation including some of which are aimed at molecular targets such as IGF-1R (autocrine activation), ALK (amplified), C- Met (overexpressed), and RAS (mutated in ERMS).^{96, 99}

Table 5 Nonrhabdomyosarcoma prognostic groups

Risk group	Gross resection	Grade	Size	Distant metastasis	Percent of NRSTS	5-Year survival
Low	Yes	Low	Any	No	60%	90%
	Yes	High	<5 cm	No		
Intermediate	Yes	High	>5 cm	No	30%	50%
	No	Any	Any	No		
High	Any	Any	Any	Yes	10%	15%

Nonrhabdomyosarcoma soft tissue sarcomas

Nonrhabdomyosarcoma soft tissue sarcomas (NRSTS) represent a wide variety of tumors with distinct

genetic, pathologic, and clinical profiles. They tend to occur in older patients and most are located in the extremities. Many are associated with distinct genetic lesions that are diagnostic such as synovial sarcoma (t(X;18)p11;q11) (*SYT-SS1* and *SYT-SSX2*). The mainstay of treatment is surgery, and irradiation is used for patients with high-grade lesions and positive margins. The impact of chemotherapy is less certain, but neoadjuvant therapy may be indicated to improve chances of surgical excision. The use of adjuvant chemotherapy in addition to irradiation for larger grossly resected tumors is more controversial but was recommended in the recent COG protocol for these tumors.¹⁰⁰ [Table 5](#) summarizes risk groups and outcomes.^{96, 101}

Central nervous system tumors

Significant differences in epidemiology, molecular genetics, and biology distinguish CNS tumors of the infant and child from those arising in adulthood. Because of these differences, important aspects of clinical presentation, treatment, and outcome are uniquely related to childhood CNS tumors.

Figure 4 MRI imaging findings of common pediatric brain tumors. (a) Axial T1 image with contrast showing a midline tumor in the cerebellum, and pathology consistent with medulloblastoma. (b) T1-weighted axial MRI image with contrast of typical pilocytic astrocytoma in the cerebellum of a 5-year-old child showing heterogeneously enhancing mural nodule and intratumoral cysts, dilated temporal horns bilaterally suggestive of hydrocephalus. (c) T2-weighted sagittal view showing diffuse enlargement of pons in a patient with diffuse intrinsic pontine glioma.

Malignant CNS tumors are the most common solid tumor of childhood, with 2200 new cases per year in the United States. Pediatric brain tumors vary considerably in their histological, topographical, and gender distribution throughout childhood and adolescence. Boys are more commonly affected than girls in all age groups, but this increase is accounted for mostly by medulloblastoma, PNET, and ependymoma. Over 90% of CNS tumors in children are primary brain tumors. Survival has improved from 60% in 1975–1984 to 65% in 1985–1994 to 73.3% in 1995–2011, and survival is noted to improve with increasing age: 45% in those aged less than 1 year, 59% in those aged 1–4 years, 64% in 5–9 year olds, 70% in 10–14 year olds, and 77% in 15–19 year olds. The main histological entities in children are pilocytic astrocytomas (23.5%), followed by medulloblastomas (16.3%), ependymomas (10.1%), anaplastic astrocytomas and glioblastomas (7.2% each), and craniopharyngiomas (5.6%),¹⁰² while high-grade glial tumors, anaplastic astrocytoma, and glioblastoma account for majority of adult brain tumors, followed by meningiomas and other mesenchymal tumors.

In the United States, CNS tumors are the most common cause of death due to cancer in childhood, accounting for 24% of cancer-related deaths. Morbidity as a result of increasingly successful treatment approaches remains high and includes cognitive, memory, and learning impairment, neuroendocrine deficiencies, hearing deficits, sterility, and secondary cancers.

The etiology of CNS tumors remains mostly unknown. The known risk factors include (1) gender (male), (2) therapeutic doses of ionizing radiation to the head (e.g., for leukemia or prior brain tumor), and (3) genetic syndromes such as neurofibromatosis, tuberous sclerosis, nevoid basal cell carcinoma syndrome (Gorlin syndrome), Turcot's syndrome, and Li–Fraumeni syndrome.

Embryonal tumors of the central nervous system comprise a group of tumors that share a histologically similar, undifferentiated morphology and represent the most common malignant brain tumor group in children (21%). The incidence is constant from infancy to 3 years of age and then a steady decline is observed thereafter. This group includes the primitive neuroectodermal tumors (PNETs), ependymoblastoma, and atypical teratoid rhabdoid tumor (AT/RT). PNETs are a group of highly malignant tumors composed of small round blue cells of neuroectodermal origin. PNETs are further subdivided by anatomic location into medulloblastoma (posterior fossa) and supratentorial PNET. Controversy has existed regarding the class division between supratentorial PNET and medulloblastoma, but the preponderance of molecular genetic, biologic, and clinical evidence validates this division.¹⁰³

Medulloblastoma is the most common malignant brain tumor in children, with a bimodal peak age distribution first being between 3 and 4 years and again between 8 and 10 years of age. It has a typical radiographic presentation of a solid midline posterior fossa mass that arises from cerebellum and occupies the fourth ventricle ([Figure 4a](#)). Surgery (preferred gross total resection) and cranio-spinal irradiation have been essential elements of successful therapy for medulloblastoma. However, to reduce late effects, especially in very young children, the incorporation of chemotherapy has permitted a reduction in radiation dose. Recently, tandem high-dose chemotherapy with stem cell rescue has demonstrated even further benefit without compromising survival in high-risk medulloblastomas.

More recently, medulloblastomas have been categorized into four groups by transcriptional profiling: WNT, Sonic Hedgehog (SHH), group C, and group D.¹⁰⁴ Tumors displaying WNT pathway activation, comprises of 10% of tumors, while approximately 30% exhibit activation of SHH pathway as a result of mutation of *PTCH1* or the *SMO* gene, both associated with favorable prognosis. Group C constitutes tumors with a poor prognosis, irrespective of their metastatic status. Ongoing research is examining treatment stratification by subgroup and potentially new targets for more effective and less toxic therapies.

AT/RT is an aggressively malignant, primitive tumor most often arising in children younger than 2 years of age. These tumors have only recently been recognized as an entity distinct from PNET due to their histological similarity with two-thirds containing foci morphologically indistinct from PNET. Approximately half of AT/RTs arise in the infratentorial compartment with a propensity to invade the cerebello-pontine angle. Because of its association with chromosome 22 deletion and mutation of *SMARCB1/INI1* (tumor suppressor gene), analysis of these markers in infants and children with presumed medulloblastoma/PNET is being used as a molecular diagnostic tool for this tumor. This disease is often fatal despite aggressive treatment.

Ependymoma makes up approximately 10% of childhood CNS tumors with approximately two-thirds occurring infratentorially. Greater than half of these tumors occur in children less than 5 years of age with a peak during the second year of life. The addition of chemotherapy to surgery and RT for childhood ependymoma has not been proven to impact overall survival, although studies are ongoing to investigate

this further.

Glial neoplasms range from benign low-grade gliomas, which can be resected and/or observed to aggressive high-grade gliomas, which have extremely poor outcome. Low-grade gliomas broadly encompass both pilocytic astrocytomas (WHO grade 1) and diffuse fibrillary and pilomyxoid astrocytomas (WHO grade 2), while high-grade gliomas comprises of anaplastic astrocytoma (WHO grade 3) and glioblastomas (WHO grade 4). The incidence of cortical astrocytomas increases with age, having a first peak at age 5 and again at age 13. In children, brain stem and cerebellar astrocytomas are as common as cortical tumors. Cerebellar astrocytoma is found almost exclusively in children, occurring most frequently between ages 4 and 9. Juvenile pilocytic astrocytoma (JPA) is the most common subtype, accounting for 85% of cerebellar astrocytomas ([Figure 4b](#)). Diffuse astrocytoma is the next most common, whereas malignant astrocytoma is rare in this location. Total surgical resection is curative in 95–100%. JPAs may stabilize for long periods of time or even spontaneously regress; however, the behavior of cerebellar astrocytomas in children with neurofibromatosis type I (NF-1) may be more aggressive. Gliomas of the visual pathway, hypothalamus, and thalamus comprise a relatively common form of childhood astrocytoma. Tumors of the optic chiasm and hypothalamus are usually low grade, whereas thalamic tumors tend to be more variable. About 20% of children with NF-1 will develop visual pathway tumors, predominantly JPA, during childhood. These tumors present most frequently between 5 and 10 years of age. Recent studies have highlighted the role of MAPK/ERK pathway in the oncogenesis of these tumors. Although IDH1 mutations characterize the vast majority of low-grade and secondary high-grade gliomas in adults,¹⁰⁵ the majority of pediatric low-grade gliomas harbor BRAF alterations in the form of *BRAF* gene rearrangement and fusion and/or point mutation.^{106, 107} Efforts are underway to exploit these pathways for molecularly targeted therapy for the low-grade gliomas in children.

Brain stem gliomas (BSG) comprise 10–15% of all pediatric CNS tumors and are generally uncommon in the adult population. Peak incidence is between 5 and 9 years of age, but it may occur anytime during childhood. BSGs most commonly arise in the pons (diffuse intrinsic), in which location they typically resemble adult glioblastomas multiforme (GBM) and have an almost uniformly dismal prognosis ([Figure 4c](#)). In contrast, those arising from midbrain or medulla are likely to be low-grade lesions that have a more indolent course and better outcome. Surgery and postoperative radiation therapy are the mainstay of therapy in children with high-grade gliomas. Recently, sequencing studies have shown recurrent but mutually exclusive mutations in histone H3F3A and IDH1 in about 30–40% of pediatric glioblastomas,¹⁰⁸ suggesting disrupted epigenetic regulatory mechanisms, which can be further exploited for therapeutic targeting.

Intracranial germ cell tumors (IGCTs) account for less than 5% of pediatric CNS tumors but are primarily seen in children and adolescents, with 90% occurring in those less than 20 years. Incidence peaks at age 10–12 years. They account for nearly 50% of all pineal region tumors of childhood. Germinomas account for approximately two-thirds of IGCTs, while the remaining third are nongerminomatous germ cell tumors (GCTs), including yolk sac tumor, choriocarcinoma, mixed GCTs, and mature and immature teratomas. Elevation of serum and CSF tumor markers as AFP and β -HCG along with radiologic findings can be used as surrogate diagnostic markers, but when the results of tumor markers are equivocal, tumor biopsy is performed for definitive diagnosis. Germinomas are highly radiosensitive and 5-year overall survival is more than 90% with radiation alone. COG is currently investigating the effect of chemotherapy followed by response-based radiation therapy, in order to minimize the radiation dose and subsequent long-term side effects.

Less-frequently encountered tumors

Individually, RB, GCTs, liver tumors, and carcinomas are less frequently encountered tumors in pediatrics, but collectively, however, these neoplasms account for up to 18% of all cancers seen in children and adolescents. Moreover, the incidence of some of these tumors, such as germ cell (GCT) malignancies and certain carcinomas, is significantly higher in older patients, those aged between 15 and 19 years, a population that has been under-represented in prospective cooperative national trials.

Retinoblastoma

RB is the most frequent neoplasm of the eye in childhood and represents 3% of all pediatric cancers. An estimated 200–300 children develop RB each year. Most patients present in infancy during the first 2 years of life (two-thirds of cases, 95% <5 years) and the tumor originates in the retina with usual extension into the vitreous cavity.¹⁰⁹ Common symptoms are leukocoria and strabismus. RB presents in two distinct clinical forms: (1) bilateral or multifocal, hereditary (25% of cases), characterized by the presence of germline mutations of the RB1 gene either inherited from an affected parent (25%) or as a result of a new germline mutation, and (2) unilateral (75% of cases). About 90% of unilateral cases are nonhereditary. Patients with bilateral RB present at an earlier age (<1 year) compared to children with unilateral nonhereditary disease (2–3 years).

Based on clinical forms of the disease Knudsen proposed the classic “two-hit” hypothesis in 1971 where two mutational events were needed in a retinal cell for transformation.¹¹⁰ Further analyses indicated that the two events were in fact disruption of both alleles of a single gene, a tumor suppressor gene. The RB1 gene, located in chromosome 13q14, was identified and cloned in 1986.¹¹¹ The product of RB1 (pRb) is a 110-kd nuclear phosphoprotein that acts by influencing the transcription of several genes involved in cell cycle progression. The level of pRb phosphorylation varies throughout the cell cycle and inactivation removes the pRb constraint on cell cycle control, with the consequence of deregulated cell proliferation.

Patients with hereditary RB are born with a germline defect in RB1 and inactivation of the other RB1 allele is a somatic event, whereas unilateral or nonhereditary tumors have somatic inactivation of both alleles. The RB1 gene is large containing 27 exons over about 200 kb of DNA, and mutations have been described in almost every exon. Nonsense and frameshift mutations are the most common germline and somatic events (>80%), although deletions are also seen (10–20%).¹¹² Although loss of RB1 is the critical step in tumor pathogenesis, it is clear that additional events are required for tumor development. All patients with RB require genetic counseling and genetic testing. Although there are no mutational hotspots, technology has advanced so that almost all cases of germline predisposition can be identified.

Suspected cases of RB are diagnosed by an experienced ophthalmologist by an exam under anesthesia with a dilated pupil. Imaging studies such as MRI, CT, and ultrasound are helpful in distinguishing RB from other causes of leukocoria (retrolental fibrodysplasia, Coats disease, toxocariasis, and toxoplasmosis) and to assess extraocular extension. CT may be used with caution given the increased risk of secondary tumors associated with radiation in patients with hereditary forms of the disease. Many staging systems are currently in use to predict outcome and guide therapy.¹¹³

The goals of therapy are to eradicate the tumor optimizing cure, preserve vision, and avoid long-term complications particularly second malignancies. Typically patients with unilateral tumors present with large tumors where there is little chance for preserving vision. Enucleation is curative in more than 90% of cases of unilateral tumors. Careful pathological examination of the resected specimen by an experienced ocular pathologist is needed to determine if any features associated with metastatic disease are present: vitreous seeding, massive choroidal involvement, tumor beyond lamina cribrosa, and scleral/extrascleral extension. These features would dictate the use of chemotherapy, usually with

combinations of the effective drugs including vincristine, doxorubicin, cyclophosphamide, carboplatin, and etoposide. For small tumors where vision preservation is possible, chemotherapy and local control with photocoagulation, cryotherapy, and thermotherapy may be considered.¹¹⁴ Direct ocular delivery of chemotherapy via the ophthalmic artery has been used with increasing frequency.¹¹⁵ RB is particularly radiation sensitive, but given concerns about second malignancies, it is usually reserved for salvage. Chemotherapy (systemic \pm periocular or subtenon administration) is given to patients with bilateral tumors to lower tumor burden followed by local control measures.^{109, 116, 117} This has resulted in higher eye salvage rates and decreased and delayed use of radiation therapy.

The risk of secondary tumors is strikingly higher for patients with the hereditary form of RB and risk is further increased by irradiation therapy.¹¹⁸ Bone (OS) and soft tissue sarcomas, tumors of the nasal cavity, and melanoma are the most common secondary cancers. Given the association with radiation, many tumors originate in the head and neck area, but as germline mutations predispose to subsequent cancers independent of irradiation (and chemotherapy), many tumors are outside of the original radiation field.

Germ cell tumors

GCTs account for about 3.5% of tumors in children and adolescents and 60% originate in extragonadal sites. This distribution is related in part to the aberrant migration of primordial germ cells in the developing embryo and persistence at sites outside their normal destination into the ovary or testes. GCTs display a wide spectrum of clinical presentations depending on primary site and pathological features that range from benign to malignant. A single tumor may show a variety of tissue types and both benign and malignant elements. The age distribution follows a bimodal pattern, with a peak during the first 3 years of life and a second peak in late adolescence. In general, females have a higher overall incidence of GCT, although males are more at risk of malignant GCT. Cryptorchidism is a risk factor for the subsequent development of testicular GCT, and interestingly, this increased risk extends to the normally descended contralateral testis.¹¹⁹ Surgical or hormonal correction ameliorates but does not eliminate the risk. Klinefelter syndrome (47 XXY) is also associated with an increased risk of GCT, and all males with mediastinal GCT should be screened for this condition.¹²⁰ Likewise, children with 46 XY gonadal dysgenesis (Swyer syndrome) are predisposed to GCTs.

The pathological classification of GCTs is partly predicated on their histopathological origin (germinoma vs nongerminoma) and whether they are benign or malignant (mature teratomas, immature teratomas, and malignant GCTs).¹²¹ Teratomas contain tissues from multiple embryonic germ layers (endoderm, mesoderm, and ectoderm) with varying degrees of differentiation. They are classified into three categories: benign, immature, and malignant teratomas [malignant GCT of mixed histologies (discussed below)]. Benign teratomas contain well-differentiated tissues such as cartilage, squamous epithelium, smooth muscle, and some may contain more complex structures such as teeth, salivary glands, and so on. Mature teratomas are commonly observed in the sacrococcygeal region and ovary. Immature teratomas contain immature elements usually neuroepithelium, but can also be immature mesenchyma or renal blastema. Immature teratomas usually occur in the ovaries and rarely in extraovarian sites. They are graded into four categories according to the degree of maturation. Grades 0–2 usually have a benign behavior. Another benign GCT is gonadoblastoma that occurs exclusively in dysgenetic gonads.

Malignant GCTs include a spectrum of tumors that are summarized in [Table 6](#). Symptoms are related to the site of the primary tumor. Cytogenetic and molecular studies have confirmed that childhood GCTs constitute a group of distinct entities. A distinct chromosomal aberration, i(12p), is often seen in adult GCT. In children, however, the i(12p) is found almost exclusively in gonadal and extragonadal (usually

mediastinal) tumors of adolescent males.¹²² Gains in chromosomes 1q, 2, 3, 7, 8, 12, and 14 have been described in tumors originating in prepubertal females, whereas tumors in prepubertal males have been found to have gains in chromosomes 1q, 7, and 21, and losses in chromosome 1p.¹²² Finally, del 1p36 is a common finding in extragonadal and testicular tumors in young children with yolk sac tumor (YST).¹²³ Recently, LIN28 a key regulator of BLIMP1, which is essential for the development of embryonic germ cells has been shown to be overexpressed in GCTs.¹²⁴ The sacrococcyx is the most common location of GCTs in children.¹²⁵ Most occur in the first 2 years of life. Two-thirds of these tumors are mature or immature teratomas, and symptoms include a visible mass, urinary retention, constipation, and weakness of the lower extremities due to compression. The ovary is the second most common site and abdominal pain is the most common symptom. Torsion of the ovary may precipitate acute pain. Almost 70% of ovarian GCTs are benign teratomas. Dysgerminoma and malignant tumors of mixed histology account for 80% of malignant ovarian GCTs with most of the remainder being yolk sac tumors. About 10% occur in the testes and these cases present as slowly growing masses. Two-thirds of these cases are yolk sac tumors. Mediastinal GCTs account for 4% of cases, and patients present with wheezing, cough, and shortness of breath. There is a strong male bias and most cases occur in children over 10 years. About 3% of GCTs occur in the CNS.

Table 6 Malignant germ cell tumors

Tumor	Frequency	Clinical features	Histology	Common locations	Tumor markers
<i>Unipotential variants</i>					
Germinoma Seminoma (testes) Dysgerminoma (ovary) Germinoma (extragonadal)	12%	Older age	Large cells with clear cytoplasm	Ovary, anterior mediastinum, brain, testes (much older pts.)	Negative (mildly elevated HCG may be seen in selected cases)
<i>Totipotential variants</i>					
Embryonal carcinoma	8%		Similar to yolk sac tumors, but cells are larger, with a major epithelial pattern	Testes, many locations	Negative or mildly elevated
Yolk sac (endodermal sinus tumor)	55%		Pseudopapillary (Schiller–Duval bodies), reticular, polyvesicular and solid patterns	Ovary, testicle sacrococcygeal location	Elevated AFP, normal HCG
Choriocarcinoma	1% (nongestational)	High likelihood of disseminated disease	Cytotrophoblasts and syncytiotrophoblasts	Ovary, testicle, extragonadal	Elevated HCG
Malignant germ cell tumors of mixed histology	24%		Composed of immature and mature teratoma but also composed of one or more types of malignant GCT	Ovary, testicle, extragonadal	Elevated AFB and/or HCG

The diagnostic evaluation includes cross-sectional imaging to assess the extent of primary disease and potential dissemination (lymph nodes, intracavitary seeding, lungs, liver, and possibly the CNS) and tumor markers. Many staging systems exist for GCTs, and there are current efforts to decide on a consensus staging system to be shared by pediatric, adult, and gynecologic oncologists.¹²⁶ Most of the current systems rely on age, extent of disease including resectability, lymph node involvement, and presence of metastasis.¹²⁶ Therapy is based on the biology of individual tumor subtypes and stage.¹²⁷ Mature teratomas are treated with surgery alone as are immature teratomas. The use of chemotherapy in incompletely resected immature teratomas is controversial. Stage I completely resected testicular and ovarian (dysgerminoma) tumors can be treated with surgery alone and observation (including regression of tumor markers) as most patients (>80%) are cured and salvage with chemotherapy is quite high for the minority who recur. In general, retroperitoneal lymph node dissections are not performed in children with testicular GCT. Note stage I nongerminoma ovarian tumors may also be treated with surgery followed by observation. The relapse rate is significantly higher than for ovarian dysgerminoma, but salvage is also

high.¹²⁸ Surgery and chemotherapy are recommended for stage II–IV ovarian and testicular tumors. The standard chemotherapy used includes cis-platinum, etoposide, and bleomycin (PEB) for four to six cycles depending on stage and response to chemotherapy (including assessment after second look surgery). The cure rate for these tumors is more than 90%. Likewise, all patients with extragonadal GCT benefit from surgery and chemotherapy (four cycles stage I–II, six cycles stage III–IV) with overall survival of 90% and 70% (metastatic mediastinal)—80% respectively for stage I–II and II–IV disease.¹²⁹

Liver tumors

Malignant tumors of the liver account for 1% of all childhood cancers with hepatoblastoma (HB) accounting for 43% of all hepatic tumors (benign and malignant) followed by hepatocellular carcinoma (HCC). HB is a disease of young infants with cases infrequently observed after 4 years of age. The incidence of HB has been rising possibly due to its association with prematurity and low birth weight.¹³⁰ HB has been associated with constitutional syndromes including familial adenomatous polyposis and Beckwith–Wiedemann syndrome. Patients usually present with an asymptomatic abdominal mass noted by parents or pediatrician. HB is an embryonal tumor that histologically recapitulates liver development and there are four recognized subtypes: epithelial (embryonal and fetal patterns, 67%), mesenchymal (epithelial and mesenchymal, 21%), pure well-differentiated fetal (7%), and small cell undifferentiated (5%).¹³¹ The fetal histology is associated with a particularly favorable outcome. The most prevalent somatic lesion in HB is deletion or mutation of exon 3 of *CTNNB1* (β -catenin) that leads to activation of the Wnt pathway.^{132, 133}

The outcome for children with HB has improved due to enhanced surgical techniques and the introduction of platinum-based chemotherapy. Currently, the 5-year overall survival rate is approximately 70%. A pretreatment extent of disease (PRETEXT) is now used to stratify therapy for HB and therefore a detailed assessment of the primary hepatic lesion is mandatory to determine resectability.¹³⁴ As 20–30% of patients may present with lung metastasis, cross-sectional imaging of the lung is also part of staging. AFP is a very sensitive diagnostic marker and is essential for assessing response to therapy. PRETEXT is based on involvement of the four major liver sections and the presence of venous, portal, and extrahepatic involvement as well as metastatic disease. Surgical resection with clear margins is the primary goal of treatment. Although PRETEXT I and II tumors may be candidates for upfront resection, many centers favor neoadjuvant therapy for all PRETEXT stages. Tumors are usually sensitive to therapy (usually cisplatin, 5-fluorouracil, and vincristine \pm doxorubicin). The use of dose dense treatment and integration of new agents including irinotecan and temsirolimus are currently being evaluated for children with high-risk disease.¹²⁷ Patients with PRETEXT IV disease or venous and/or portal involvement following chemotherapy are referred for liver transplantation, although complete regression (by chemotherapy \pm surgery) of all metastatic lesions is required before proceeding with organ transplantation.

Hepatocellular carcinoma (HCC) is a disease of older adolescents and adults. Although HCC in adults is associated with pre-existing liver disease [hepatitis B and C, inflammatory liver disease, cirrhosis (tyrosinemia, biliary)] less than a third of patients diagnosed in Western countries have a history of liver disease.¹³⁵ In contrast to patients with HB, patients with HCC usually have constitutional symptoms such as weight loss, anorexia, and vomiting. Microscopically, HCC differs from HB in that tumor cells are larger, have defined borders, distinct nucleoli, and tumors have a high degree of vascular invasion. Transitional liver tumors display pathologic and genetic features of both HB and HCC. HCCs show an increased overall mutational burden than HB, but far fewer mutations in *CTNNB1* and have multiple copy number variations.¹³⁶ Mutations in *TP53* and epigenetic modifiers are frequent. Outcomes for HCC have been disappointing with no improvement over the past two decades in sharp contrast to advances made

for other childhood tumors.¹³⁷ Complete surgical excision is the most important prognostic variable, but most patients present with advanced disease. For early stage tumors, complete resection followed by adjuvant chemotherapy is recommended, while neoadjuvant chemotherapy (with the hope of improving resection) is recommended for more advanced stages (e.g., PRETEXT III). Patients who present with metastatic disease have a dismal outcome.

Carcinomas and melanoma

Carcinomas and melanoma account for approximately 9% of all cases of cancer in children. In the SEER database, the distribution of these malignancies is as follows: thyroid carcinoma, 35%; melanomas, 31%; adrenocortical carcinomas, 1.3%; nasopharyngeal carcinoma, 4.5%; and other skin carcinomas, 0.5%. Most carcinomas (75%) occur in the 15- to 19-year-old age group. In patients aged 15–19 years, thyroid cancer and melanoma account for more than 14% of the malignancies seen in this age group.

About 90% of thyroid carcinomas are papillary carcinomas, and the *BRAFV600E* mutation seen in adults is rare in children.¹³⁸ These tumors are treated by surgical resection and radioactive iodine ablation with 10-year survival rates exceeding 90%.¹³⁹ Patients require lifelong thyroid hormone replacement. Medullary carcinoma is usually familial (multiple endocrine neoplasia II) and is particularly aggressive.¹⁴⁰ Patients may be candidates for inhibitors of RET kinase. Most patients (90%) with melanoma have localized disease at initial evaluation, the most common site being the trunk, although patients younger than 20 years are more likely than adults to have disease primarily in the head and neck.¹⁴¹ Like their adult counterpart, the majority of pediatric melanomas contain the *BRAFV600E* mutation. Survival rates are similar for patients younger than 20 and older than 20 years of age, and the prognosis appears to be stage dependent.¹⁴² In the 15- to 19-year-old age group, the incidence of cutaneous melanoma increased at a rate of 2% per year between 1973 and 2006, but more recent reports show a decreasing trend among children.¹

Late effects and quality of survivorship

With the use of multimodal and risk-based treatment, the overall 5-year survival rate of more than 12,500 children and adolescents (age 0–19) diagnosed with cancer each year in the United States is approaching 80% (SEER). The improvement in survival has resulted in about 1 in 810 individuals under the age of 20 and 1 in 640 individuals between the ages 20 and 39 years representing childhood cancer survivors.

The late sequelae of cancer treatment can cause chronic medical problems and involve all organ systems. Overall mortality among childhood cancer survivors has been described to be 10-fold that of the general population. The Childhood Cancer Survivor Study (CCSS) assessed overall and cause-specific mortality in a retrospective cohort of 20,227 five-year survivors and demonstrated a 10.8-fold excess in overall mortality.¹⁴³ Risk of death was statistically significantly higher in females, individuals diagnosed with cancer before the age of 5 years, and those with an initial diagnosis of leukemia or brain tumor. The excess mortality was due to death from primary cancer, second cancer, cardiotoxicity, and noncancer death, and existing up to 25 years after the initial cancer diagnosis.

The more commonly reported second primary cancers are breast, bone, and thyroid cancers, therapy-related myelodysplasia, and acute myeloid leukemia. Female survivors who were treated with chest or mantle radiation for a pediatric malignancy face a significantly increased risk of breast cancer.

Genetic predisposition was first noted to have a substantial impact on the risk of secondary sarcomas among patients with the genetic form of RB. This risk is further increased by radiation treatment and

increases with the total dose of radiation delivered. Patients with a family history of early onset cancers have also been shown to be at an increased risk of developing a second cancer. Members of families with Li–Fraumeni syndrome have been reported to be at increased risk of multiple subsequent cancers, with the highest risk observed among survivors of childhood cancer.¹⁴⁴ The subsequent cancers reported in this population were characteristic of Li–Fraumeni syndrome. It therefore appears that germline mutations in tumor suppressor genes, as occurring in Li–Fraumeni syndrome, might interact with therapeutic exposures to result in an increased risk of second cancers.

Several genetic polymorphisms of enzymes capable of metabolic activation or detoxification of anticancer drugs, such as NAD(P) H:quinone oxidoreductase (NQO1), glutathione S-transferase (GST)-M1 and -T1, and CYP3A4, have been examined for their role in the development of therapy-related leukemia or myelodysplasia. These studies indicate that NQO1 polymorphism is significantly associated with the genetic risk of therapy-related acute leukemia and myelodysplasia. In addition, individuals with CYP3A4-W genotype may be at increased risk of treatment-related leukemia, presumably by increasing the production of reactive intermediates that damage DNA.^{145, 146}

Because subsequent malignancies remain a significant threat to the health of survivors treated for cancer during childhood, vigilant screening is important for those at risk. Risk of secondary acute myeloid leukemia is associated with exposure to topoisomerase II inhibitors (i.e., epipodophyllotoxins and anthracyclines) for up to 10 years and with alkylating agents for up to 15 years. In addition, there is a significant risk of breast cancer (females) and other solid tumors for survivors of Hodgkin disease who were treated with radiation therapy.

Neurocognitive sequelae of treatment of childhood cancer occur because of radiation to the whole brain, systemic therapy with high-dose methotrexate or cytarabine, or with intrathecal methotrexate and other agents. Children with a history of brain tumors, ALL, or NHL are most likely to be affected. Risk factors include increasing radiation dose, young age at the time of treatment, treatment with both cranial radiation and systemic or intrathecal chemotherapy, and female gender.^{147–149} Severe deficits are most frequently noted in children with brain tumors treated with radiation therapy and in children who were less than 5 years of age at the time of treatment.

Chronic cardiotoxicity usually manifests itself as cardiomyopathy, pericarditis, and congestive heart failure. Childhood cancer survivors in the CCSS who were treated with chest or spinal radiation had a more than twofold increased risk of death related to cardiac disease in comparison with the standard US population.¹⁵⁰ The anthracyclines, doxorubicin and daunomycin, are well-known causes of cardiomyopathy.^{151, 152} The incidence of cardiomyopathy is dose-dependent and may exceed 30% among patients who received cumulative doses of anthracyclines in excess of 300 mg/m². A cumulative dose of anthracyclines greater than 300 mg/m² was associated with an increased risk of clinical heart failure (relative risk 11.8) compared to a cumulative dose lower than 300 mg/m². The estimated risk of clinical heart failure increased with time and approached 5% after 15 years. These studies and others emphasize that cardiomyopathy can occur many years after completion of therapy (15–20 years) and that the onset may be spontaneous or coincide with exertion or pregnancy.

Pulmonary fibrosis and pneumonitis can result from pulmonary radiation. Thus, these problems are seen most often in patients with thoracic malignancies, notably Hodgkin disease. In addition to radiation therapy, a growing list of chemotherapeutic agents appears to be responsible for pulmonary disease in long-term survivors. Bleomycin toxicity is the prototype for chemotherapy-related lung injury. Although interstitial pneumonitis and pulmonary fibrosis have been reported in children, clinically apparent bleomycin pneumonopathy is most frequent in older adults. The chronic lung toxicity usually follows

persistence or progression of abnormalities developing within 3 months of therapy. Alkylating agents also are believed to cause chronic lung injury. Following HSCT, both restrictive and obstructive lung disease, including bronchiolitis obliterans are well described.¹⁵³

Chronic fibrosis of the liver is associated with radiation. Chemotherapy, even in the absence of radiation therapy, may be a cause of chronic hepatopathy. Viral hepatitis, most often related to transfusion of blood products prior to 1992, is another cause of chronic liver disease in long-term survivors.¹⁵⁴

Damage to the proximal renal tubule from chemotherapy can cause Fanconi renal syndrome (hypokalemia, hypophosphatemia, glucosuria, proteinuria, renal tubular acidosis, and rickets). Children at particular risk include those who received treatment with more than one nephrotoxic agent and those with concomitant renal damage related to surgery or radiation.¹⁵⁵ Electrolyte wasting associated with ifosfamide therapy and hypomagnesemia associated with cisplatin therapy appear to persist in some children. Cyclophosphamide and ifosfamide are both capable of inducing hemorrhagic cystitis as a result of accumulation of acrolein in the bladder. Radiation to the pelvis or bladder can result in fibrosis and scarring, with resultant decreased bladder capacity and predisposition to urinary tract infections. Bladder cancer has developed in some patients who received bladder-toxic agents during treatment of childhood cancer. Yearly urinalysis should be done in these patients to evaluate for the presence of microscopic hematuria.

Decreased linear growth is a common problem during therapy in children with cancer. Although catch-up growth may occur, such that the premorbid growth status is regained, in some instances, short stature is permanent or even progressive. Severe growth retardation, defined as a standing height below the fifth percentile, has been observed in as many as 30–35% of survivors of childhood brain tumors¹⁵⁶ and in 10–15% of patients treated with some antileukemia regimens.¹⁵⁷ Whole-brain irradiation is a major risk factor for short stature, especially in doses exceeding 18 Gy.

Observational studies indicate that obesity as measured by weight or body mass index (BMI) has been reported in children with ALL and brain tumors treated with conventional therapy or BMT.¹⁵⁸ This problem has its onset either during therapy or within the first year after discontinuation of therapy and may either progress or stabilize. In addition, hypothyroidism is a common late effect and usually is due to radiation to the neck for a nonthyroid malignancy, which contributes to obesity.

All therapeutic modalities (radiation, surgery, or chemotherapy) cause both germ cell depletion and abnormalities of gonadal endocrine function among male cancer survivors.¹⁵⁹ Radiation to the testes is known to result in germinal loss with decrease in testicular volume and sperm production, and increases in follicle-stimulating hormone (FSH). Effects are dose-dependent, following fractionated exposures of 0.1–6 Gy. All males treated with inverted-Y radiation for HD at a cumulative testicular dose of 1.4–3.0 Gy become azoospermic without recovery after 2–40 months of follow-up, despite lead shielding of the scrotum. At doses of 4–6 Gy, azoospermia may persist for at least 3–5 years, and at doses above 6 Gy, usually appears to be irreversible. Alkylating agents decrease spermatogenesis in long-term survivors of cancer, and the effects are dose-dependent. Gonadal damage following cumulative doses lower than 7.5 mg/m² of mechlorethamine or 200 mg/kg of cyclophosphamide as used in HSCT has been shown to be reversible in up to 70% of patients after therapy-free intervals of several years.

The gonadal toxicities are of serious concern to patients and their families. This concern has popularized pretreatment sperm banking. Unlike the males, germ cell failure and loss of ovarian endocrine function usually occur concomitantly in females. Following radiation therapy, manifestations are both age-dependent and dose-dependent. Prepubertal ovaries are relatively radioresistant because of the higher number of primordial follicles. Ovarian failure has also been associated with chemotherapy, such as

single alkylating agents (cyclophosphamide, busulfan, nitrogen mustard) or as combination therapy. A report from the CCSS of 4029 pregnancies in 1915 female 5-year survivors of childhood cancer did not identify excess adverse outcomes for chemotherapeutic agents.¹⁶⁰ A companion study of 2323 pregnancies in partners of 1427 male survivors reported 69% live births, 1% stillbirths, 13% miscarriages, and 13% abortions (5% of outcomes were not accounted for).¹⁶¹ The probability of a pregnancy ending in a live birth was significantly less than that for partners of male sibling controls (RR 0.8, $p = 0.007$).

Patients who desire to have children after completion of therapy may require care in high-risk obstetrical clinics, especially those who have a discussion of sperm banking storage received abdominal or pelvic irradiation. Because much remains unknown about the problems of children born to survivors of childhood cancer, long-term general follow-up should be emphasized.

Several potentially ototoxic agents are commonly used in the treatment of children with malignancies, including platinum-based chemotherapy, aminoglycoside antibiotics, loop diuretics, and RT. These agents are all capable of causing sensorineural hearing loss. Very young children who received ototoxic agents during their cancer treatment and whose speech has not yet developed should undergo audiologic evaluations to determine whether they require intervention. Interventions to assist children experiencing hearing loss because of cancer treatment include the use of hearing aids and other assistive devices, along with preferential seating in the front of the classroom. Musculoskeletal problems after childhood cancer involve bony abnormalities, such as scoliosis, atrophy, or hypoplasia; avascular necrosis (AVN); and osteoporosis (bone density ≥ 2.5 SD below mean)/osteopenia (bone density 1–2.5 SD below mean), especially with the use of steroids in ALL treatment.

Providing appropriate health care for survivors of cancer is emerging as one of the major challenges in medicine. Childhood cancer survivors, an especially high-risk population, seek and receive care from a wide variety of health care professionals, including oncologists, medical and pediatric specialists, surgeons, primary care physicians, gynecologists, nurses, psychologists, and social workers. The challenge arises from the heterogeneity of this patient population treated with numerous therapeutic modalities in an era of rapidly advancing understanding of late effects. The COG has recently updated risk-based, exposure-related guidelines [Long-Term Follow-Up Guidelines for Survivors of Childhood, Adolescent, and Young-adult Cancers, (version 4.0, 2013)] specifically designed to direct follow-up care for patients who were diagnosed and treated for pediatric malignancies. These guidelines represent a set of comprehensive screening recommendations that are clinically relevant and can be used to standardize and direct the follow-up care for this group of cancer survivors with specialized health care needs. <www-survivorshipguidelines.org>.

Chapter 72

Cancer and pregnancy

Jennifer K. Litton, MD

Overview

The diagnosis of cancer during pregnancy is a clinical and emotional challenge for both the patient and the caregivers. A multidisciplinary approach including medical oncologists, surgeons, radiation oncologists, and obstetrics is vital to coordinate the treatment of the mother and the monitoring of the fetus. The available data regarding the treatment of cancer during pregnancy, including staging, surgery, radiation, and systemic therapy as well as outcomes for the patients and the children exposed to chemotherapy *in utero* is reviewed.

The diagnosis of cancer during pregnancy presents a complex set of challenges for the patient, family members, and physicians. The welfare of the mother may be perceived to be threatened by the pregnancy owing to concerns regarding the disease, diagnostic and therapeutic procedures required for treatment, and a desire to avoid harm to the fetus during treatment for the mother's malignancy. Many have perceived that treatment may require compromise of the wellbeing of either the mother or the fetus. However, in some circumstances, fetal death may be an unavoidable consequence of cancer treatment. Frequently, however, judicious decision making not only can provide appropriate cancer care for the pregnant woman but also will preserve the pregnancy through successful labor and delivery.

Many issues arise in the realm of concurrent cancer and pregnancy ([Table 1](#)). The data for specific tumor types, diagnostic procedures, therapeutic interventions, and long-term cancer outcomes have been derived primarily from case reports, small case series, and retrospective reviews. Controlled studies are rare, and prospective data is even rarer. Data on labor and delivery outcomes for patients completing pregnancy remains scarce, as are long-term data on growth and development of children exposed to cancer treatment *in utero*. Over the past decade, the treatment for cancer during pregnancy has evolved and is now within guidelines of care for several tumor types as cohort descriptions and prospective case series have been reported.¹ With that, there is emerging data on outcomes of patients as well as small, but emerging data on the children exposed to chemotherapy *in utero*.

Table 1 Issues related to cancer and pregnancy

Impact of cancer on pregnancy

Cancer and pregnancy epidemiology

The diagnosis of cancer during pregnancy is rare and tracking the true incidence remains challenging. Much of the data includes pregnancy-associated breast cancers, defined as those cancers diagnosed both during pregnancy and within the 1-year period after delivery. With emerging data that biology and outcomes may be influenced by the timing of diagnosis, evaluating and reporting these incidences separately may be important. Smith et al.² used the California Cancer Registry, evaluating 4,846,505 women of whom 4539 had an identified invasive malignancy either during pregnancy or within 12 months after delivery. In this analysis, cancer occurred in approximately 1 in 1000 deliveries from 1991 through 1999. However, 64% of these cases occurred within the 12 months after delivery. Per 1000 live singleton births, the most common tumor types were breast (0.19), thyroid (0.14), cervix (0.12), melanoma (0.09), Hodgkin's disease (0.05), ovarian leukemia (0.05), and acute leukemia (0.04). In an Australian linkage study between 1994 and 2008, 1798 pregnancy-associated cancers, encompassing diagnoses both during and within 1 year from delivery, were identified in 1,309,501 deliveries.³ Four hundred and ninety five of these cancers were identified during pregnancy. During pregnancy, the most common cancer identified in this cohort was melanoma (15.1/100,00), breast (7.3/100,000), thyroid (3.2/100,000), and gynecological (3.9/100,000). However, cancer from nearly any anatomic location can occur with pregnancy.

Interestingly, in this study from Australia, and others, the incidence of pregnancy-associated breast cancer has been increasing. This may be secondary to increasing maternal age as well as other changes in epidemiological risk factors. In the Australian cohort, from 1994 to 2007, the incidence of pregnancy-associated breast cancer increased from 112.3 to 191.5/100,000 deliveries. A Swedish registry also showed a trend to increasing incidence that may be partially explained by advancing maternal age, with an increase of 16.0 to 37.4 cases per 100,000 deliveries from the beginning to the end of cohorts collected from 1963 to 2002.⁴ This may also be influenced as further advances in reproductive technologies are making pregnancies more accessible to older women.

Diagnosis and staging

A biopsy, with review of cytologic and histologic materials, is required for the diagnosis of any

malignancy during pregnancy. The type of biopsy is determined by the accessibility of the disease site and the quantity of material required.

If a surgical biopsy is required, the anatomic location of the biopsy and the gestational age of the fetus are factors to be considered before proceeding. A surgical biopsy can be performed safely.^{1, 5, 6} It is imperative that adequate material for pathologic diagnosis and required studies be obtained; for example, hormone receptors and HER-2/neu status are necessary for the proper evaluation of breast cancer, and morphologic and immuno-phenotyping of lymphomas and leukemias is essential to their optimal assessment and treatment.

Staging provides guidance for discussions regarding cancer prognosis, recommended loco-regional and/or systemic therapies, and potential risks of treatment in relation to benefit and outcome for the patient. Frequently, staging assessment in the non-pregnant patient involves exposure to ionizing radiation, which is to be avoided whenever possible during pregnancy. The impact of radiation upon the fetus varies with respect to fetal gestational age. Pre-implantation and fetal organogenesis are most sensitive to the negative effects of radiation exposure.⁷ Fetal exposures of < 5 cGy are not thought to be harmful.⁸ With abdominal computerized tomography, exposure may be as high as 30 mSv. As a consequence of known fetal toxicity associated with exposure to ionizing radiation during pregnancy, abdominal shielding and non-ionizing techniques should be used whenever possible during these imaging procedures.⁸ Ultrasonography (US) for breast, liver, and other abdominal organ imaging can also contribute to the staging evaluation without ionizing radiation. Magnetic resonance imaging (MRI) can be used to assess for bone and liver diseases, as well as fetal abnormalities, if required.^{9, 10} The use of gadolinium as a contrast agent for MRI during pregnancy remains controversial. Although multiple case reports have not demonstrated an increase in adverse effects to the fetus, gadolinium is often avoided if possible owing to lack of toxicity information.^{11–13} Accurate determination of disease stage is essential in ensuring accurate cancer treatment decisions, and findings during the staging process also may influence the woman's decision regarding the maintenance of her pregnancy.

The use of PET/CT scanning has become standard in the treatment and evaluation of lymphomas and has had an increase in use in evaluation of metastatic disease in solid tumors as well. There is very limited data regarding the use of PET/CT in the pregnant breast cancer patient. Evidence that FDG crosses the placenta and can accumulate in fetal brain, bladder, and cardiac tissue has been demonstrated in animal studies.¹⁴ Zanotti-Fregonara et al.¹⁵ estimated that the FDG uptake by embryo tissues in early pregnancy is at least 3.3E-2mGy/MBq in a patient found to be pregnant at the time of scanning. Few other case reports exist. Hove et al.¹⁶ describe an 18-year-old woman with Hodgkin's disease who underwent PET/CT. There was significant uptake in the fetal myocardium. The patient developed HELLP syndrome and the child was delivered at 31 weeks by caesarian section. Therefore, there is insufficient safety data to support the use of PET/CT scanning during pregnancy and should be delayed until after delivery whenever possible.

Cancer treatment during pregnancy

The optimal treatment of cancer during pregnancy requires a meticulously coordinated multidisciplinary approach. Careful and repeated consultations with the obstetrician and/or maternal fetal medicine specialist are essential during the course of the pregnancy. Accurate assessment of fetal age, maturation, and the expected delivery date must be performed before treatment planning. The therapeutic options for the pregnant patient do not differ from those of the non-pregnant patient with cancer, but the application of treatment may be more complex. When evaluating multiple tumor types during pregnancy, Stensheim et

al.¹⁷ described 516 women from Norwegian health registries with no difference identified in cause-specific death. However, it is interesting to note that when diagnosed instead during lactation, there was an increase in both breast and ovarian death rates. Outcomes in large cohorts are otherwise described with cancer-specific sites and the timing and treatment are important in relation to the outcomes of the patient.

Surgery

Surgery remains the mainstay for treatment of solid tumors, and pregnancy is not a contraindication for cancer surgery. Mazze and Kallen⁶ have reported on a registry series of 5405 pregnant patients on whom emergency surgery was performed. They did not observe an increased incidence of congenital malformations or stillbirths in women who had surgical procedures while pregnant. An increased frequency of low- and very low birth-weight infants was noted and attributed to prematurity and intrauterine growth retardation and may have been influenced by the underlying reason behind the necessary surgery. No specific type of surgical procedure or anesthesia was associated with an increase in adverse reproductive outcomes. In a case-control study, Duncan et al.¹⁸ did not observe an increase in congenital anomalies in 2565 pregnant women who had surgery while pregnant, when compared to control patients who did not have surgery. If warranted by tumor type and disease stage, surgery should proceed and should be coordinated with the obstetrician, anesthesiologist, and neonatal specialist.

Radiation

Pregnancy has been considered an absolute contraindication to radiation therapy for cancer. Radiation therapy for cervical cancer during pregnancy usually leads to fetal death and spontaneous abortion.¹⁹ The fetus is most sensitive to malformation from radiation exposure 2 to 8 weeks after conception, whereas exposure from 8 to 25 weeks of gestation may have a greater risk of mental retardation.⁷ Nevertheless, successful radiation therapy of pregnant women with Hodgkin's disease has been reported.²⁰ If radiation is warranted, appropriate fetal shielding, careful dosimetry calculations, and estimates of fetal dose exposure are necessary. However, owing to the very limited safety, data should be considered only in very select cases.^{21–25} Radiation therapy for breast cancer, following mastectomy or breast conservation surgery, can usually be delayed until the postpartum period, especially if chemotherapy is administered.

Systemic therapy

Many different agents have been reported to have been used in pregnancy. Representative chemotherapeutic, hormone, and biologic agents are listed in [Table 2](#).

Table 2 Drugs reported to have been used during pregnancy

Regimens	Systemic therapies	
MACOP-B	Hydroxyurea	α -Interferon
MOPP-ABVD	All-trans retinoic acid	Rituximab
FAC	Methotrexate	Trastuzumab
CMF	Doxorubicin/epirubicin	Lapatinib
AC	Cyclophosphamide and nitrogen mustard	Imatinib
VACOP-B	Vincristine and triethylene melamine	Prednisone
CHOP	Bleomycin	Tamoxifen
BEP	Cisplatin	Erythropoietin
	Vinorelbine, vinblastine, and vincristine	Filgrastim
	Paclitaxel	Dasatinib
	Docetaxel	
	Etoposide	
	Idarubicin and daunorubicin	
	Cytosine-arabinosine	
	5-Fluorouracil, busulfan	
	Teniposide	
	6-Mercaptopurine	
	Dacarbazine	
	Aminopterin	
	Actinomycin D	
	Procarbazine	
	Amsacrine	
	L-asparaginase	

ABVD, Adriamycin (doxorubicin), bleomycin, vinblastine, and dacarbazine; AC, Adriamycin (doxorubicin) and cyclophosphamide; CMF, cyclophosphamide, methotrexate, and 5-fluorouracil; FAC, 5-fluorouracil, Adriamycin (doxorubicin), and cyclophosphamide; MACOP-B, methotrexate, Adriamycin (doxorubicin), cyclophosphamide, Oncovin (vincristine), prednisone, and bleomycin; MOPP, mechlorethamine, Oncovin (vincristine) procarbazine, and prednisone; and VACOP-B, VePesid (etoposide), Adriamycin (doxorubicin), cyclophosphamide, Oncovin (vincristine), prednisone, and bleomycin.

Systemic therapy is of concern because of the potential deleterious effects on the fetus. Physiologic changes associated with pregnancy (elevated blood volume, increased cardiac output, amplified glomerular filtration rate, and changes in circulating protein levels) make predictions about drug pharmacokinetics uncertain at best.²⁶ In addition, systemic agents are designed to be anti-proliferative compounds, and their administration during pregnancy poses genuine risk to the developing fetus. Potential concerns include stillbirth, spontaneous abortion, fetal malformations/teratogenesis, organ-specific toxicities, intrauterine growth retardation with low birth weight, and premature delivery.²⁷

In addition to cytotoxic therapy, there are also reports regarding supportive medications. Erythropoietin use during pregnancy was reported by Scott et al.²⁸ as well as others. No maternal or fetal toxicities have

been noted. FDA Black Box warnings about the use of erythropoietin in breast cancer patients would apply to the pregnant patient as well, even in the absence of specific risk data in these patients. Dale et al.²⁹ found that the use of filgrastim during pregnancy was not associated with a change in neonatal outcome, when compared to untreated patients. There have been limited case reports of the safe use of pegfilgrastim during pregnancy after dose-dense chemotherapy for breast cancer.³⁰ Dexamethasone and lorazepam have also been reported as premedications without significant toxicity.⁹

Outcomes in the children exposed to chemotherapy *in utero*

The fetal risks related to chemotherapy appear to be greatest during the first trimester of pregnancy. Doll et al.²⁷ reviewed antineoplastic agents and fetal malformations in relation to the trimester of pregnancy. They reported that *in utero* exposure to systemic agents was associated fetal malformation risks of 14% and 19% for alkylating agents and antimetabolites, respectively. A similar review of second- and third-trimester exposure demonstrated a 1.3% incidence of fetal malformation. Thus, they concluded that single-agent or combination chemotherapy could be given during the second and third trimesters with low risk of fetal malformation, but these agents should be avoided during the first trimester of pregnancy. Similarly, in a review of cytotoxic agents used during pregnancy, Ebert et al.²⁶ collected 217 cases from the literature published between 1983 and 1995. They classified the use of the agents by disease category and analyzed outcome of pregnancy in relation to agent, dose, and gestational age at exposure. There were 94 cases of leukemia, 57 cases of lymphoma, 26 cases of breast or ovarian cancer, 16 cases of cytotoxic therapy used for rheumatic diseases, and the remainder of the malignancies. Eighteen newborns were reported to have congenital developmental abnormalities. Of these 18 newborns, 15 neonates had been exposed to cytotoxic drugs during the first trimester. Chromosomal abnormalities were noted in two neonates who had experienced exposure to cytotoxic agents during the first trimester.²⁶ Antimetabolite use was found in 50% of the neonates with congenital abnormalities following first trimester exposure to chemotherapy. Of the reviewed cases, 82.3% of leukemia patients, 75.4% of lymphoma patients, and 75% of breast or ovary cancer patients with associated pregnancies were reported to have live births with normally developed neonates. Germann et al.³¹ collected data involving 160 patients who received anthracyclines during pregnancy. In this group, five cases of fetal malformations (3%) were found, with three cases occurring with the use of chemotherapy in the first trimester. The remaining two cases of fetal malformation occurred after chemotherapy administration in the second trimester; one involved Down's syndrome unrelated to chemotherapy, and the other involved a congenital adherence of the iris to the cornea that demonstrated no clinical consequence. The combination chemotherapy regimens associated with fetal malformations included cytosine arabinoside or cyclophosphamide. As these initial reports that there have been multiple case studies showing safety of systemic therapy with anthracyclines and taxanes as well as limited information regarding platinum when treated in the second and third trimesters.³²⁻³⁴ Systemic treatment, especially with antimetabolites such as methotrexate, should be avoided during the first trimester of pregnancy except in circumstances in which delay in cancer treatment would jeopardize the life of the patient, such as acute leukemia.

A long-term report on children exposed to chemotherapy *in utero* during treatment of mothers for a variety of hematologic malignancies has been presented by Aviles and Neri.³⁵ They described 84 children followed a median of 18.7 years. Thirty-eight had been exposed to chemotherapy *in utero* during the first trimester of pregnancy. Fertility was reported to be preserved, some of the chemotherapy-exposed children having become parents. No learning, neurologic, or psychological problems were reported for any of the *in utero* chemotherapy-exposed subjects. Van Calsteren et al.³⁶ report on ten children from nine pregnancies exposed to chemotherapy *in utero* for differing primary cancers. The children who were born

prematurely had multiple abnormalities ranging from speech delay to mental and motor retardation. These were children born at less than 33 weeks gestation. Echocardiograms were also obtained demonstrating a tendency towards a thinner ventricular wall. Abdel-Hady et al.³⁷ describe 118 children born to mothers who received chemotherapy during pregnancy with no significant difference when compared to a control group of children.

Much of the data in the children exposed to chemotherapy has come from studies of breast cancer diagnosed and treated during pregnancy. Murthy et al.³⁸ have updated on the outcomes of the children exposed to chemotherapy *in utero*. Complications for the neonate included prematurity, neutropenia, tachypnea of the newborn, and respiratory distress syndrome. One case of spontaneous cryptogenic intracranial hemorrhage occurred which all resolved. There were three congenital abnormalities reported which included Down syndrome (1), congenital ureteral reflux (1), and clubfoot (1).³⁸ Cardonick et al.³⁹ also described a voluntary registry of outcomes in children exposed to chemotherapy demonstrating a 3.8% rate of congenital malformations which is similar to the national average of pregnant patients without cancer. Loibl et al.⁴⁰ reviewed a registry of patients diagnosed with breast cancer during pregnancy from multiple different European sites. Of the 447 patients followed, 197 received chemotherapy during pregnancy from 2003 to 2011. Of these, 22 babies had reported complications and were delivered before the 37th week with four congenital malformations (trisomy 18, rectal atresia, polydactyly, and craniosynostosis). Nine of these babies were delivered after the 37th week with three malformations (asymmetric head, polydactyly, and Moebius syndrome). When evaluating for longer term outcomes in children exposed to chemotherapy *in utero*, Amant et al.⁴¹ described 70 children and evaluated that for neurocognitive and cardiac outcomes as well as general health, there was no significant finding except for those children who were born prematurely. Both of these studies highlight the need for to avoid iatrogenic preterm delivery whenever possible, with holding treatment past the 35th week of pregnancy in order to avoid blood nadirs and allowing the children to proceed full term.

Specific cancers

Breast cancer

The diagnosis of breast cancer during pregnancy is often delayed, presumably due to the anatomical and physiologic changes in the pregnant breast.⁴² However, women with breast cancer during pregnancy have demonstrated the same survival rates, stage for stage, as non-pregnant patients with breast cancer.^{34, 43, 44} Imaging, local, and systemic therapies have been well described in the successful treatment of breast cancer diagnosed during pregnancy.

Imaging of the breast in women with a palpable mass or thickening is warranted, especially if it persists for 2 weeks or longer. Mammography and US may confirm the presence of a malignant mass. Although Max and Kliner reported normal mammograms in six of eight women with breast cancer during pregnancy, others have reported abnormal mammograms in the majority of women with pregnancy and breast cancer (18 of 23 and 5 of 8).^{45–47} There are limited data on US; Liberman reported positive findings in six of six patients, and Samuels found positive findings in two of four patients.^{46, 47} Yang et al.⁴⁸ diagnosed 100% of the masses as well as axillary metastases in 18 of 20 women. US was also shown to be effective for restaging to evaluate response to pre-operative chemotherapy in the pregnant breast.⁴⁸ US may be useful for guiding either fine needle aspiration (FNA) or core biopsy in order to confirm a diagnosis of malignancy.^{49–51} Chest radiography, liver US, and MRI of the thoracic/lumbar spine can be used to assess for extant organ metastasis.^{1, 9}

Lymph node evaluations can be tailored to clinical findings. If clinically suspicious regional nodes are identified on physical examination or by imaging techniques, an FNA that is guided by palpation or US can be utilized to confirm metastases. The theoretical dosage of radiation that would be absorbed by the fetus following sentinel lymph node biopsy has been calculated to be less than 5 cGy.^{52, 53} Khera et al.⁵⁴ have reported their experience with sentinel node procedures in the pregnant patient. Ten patients had sentinel node procedures, six with blue dye and Tc99m, two with Tc99m alone, and two with blue dye alone. No adverse sequelae were reported for nine neonates. One woman chose elective termination of pregnancy. Gropper et al.⁵⁵ have published their series of 25 women who underwent sentinel lymph node dissections during pregnancy with no procedure complications. Gentilini et al. have performed the technique on 12 patients with one child born with a ventricular septal defect.¹⁰

Breast-conserving surgery is possible with postpartum breast irradiation. Pre- or postoperative chemotherapy is used with the same criteria for selection of therapy as in the non-pregnant patient. However, breast-conserving therapy should be considered only when radiation can be given in a timely manner after delivery. Often, given the timing of chemotherapy, this will allow for postpartum radiation. Dominici et al.⁴⁹ have described a single institution experience of mastectomy versus breast-conserving surgery as well as biopsy procedures with no significant difference in wound complications or complications from FNA or core biopsies.

Other agents have been described in the literature to treat breast cancer and include vinorelbine, paclitaxel, docetaxel, and cisplatin.^{56, 57} The use of taxanes, both paclitaxel and docetaxel, has been described also in the second and third trimesters^{56, 58–65} with all available follow-up data reported healthy children.⁵⁶ Vinorelbine has been reported to be used in both adjuvant and metastatic settings, with five of the six children reported healthy at 6–35 months of follow-up. Information on one of the children was not available in the literature. Neonatal complications included one episode of grade 4 neutropenia and transient cytopenia at day 6 of life.^{63, 66–68} Multiple case reports of trastuzumab administered during pregnancy have been identified. This has been associated with oligo- and anhydramnios with its use was described in case reports.^{62, 66, 69–73} One case was of reversible heart failure in the mother with no anhydramnios in the fetus was reported.⁷¹ One of the children born developed respiratory failure, capillary leak syndrome, infections, and necrotizing enterocolitis, dying from multiple organ failure 21 weeks after delivery.⁷³ In addition, Bader et al.⁶² described a case of reversible renal failure in the fetus. One report of the use of lapatinib was recently described in a patient who conceived while on lapatinib. Despite approximately 11 weeks of exposure, the pregnancy was otherwise uncomplicated with the delivery of a healthy baby.⁷⁴ Routine administration of biologic agents is not recommended during pregnancy and trastuzumab now has an FDA Category D rating.

Tamoxifen is a standard treatment for hormone receptor positive tumors in pre-menopausal women. Although some case reports of tamoxifen fetal exposure demonstrated no effect on the newborn, there are other reports including Goldenhar syndrome (microtia, preauricular skin tags, and hemifacial microsomia),⁷⁵ ambiguous genitalia, and other birth defects. In addition, vaginal bleeding and spontaneous abortion have also been reported.^{75–79} Braems et al.⁸⁰ described 11 babies with congenital malformations out of 44 live births and 3 stillbirths. Aromatase inhibitors are not indicated as a single agent in pre-menopausal women and should not be used in conjunction with ovarian suppression in a pregnant patient. Endocrine therapy should be delayed until after delivery.

Outcomes of pregnant breast cancer patients appear to be similar to non-pregnant cancer patients when treated with appropriate therapies in the second and third trimesters. Litton et al.⁸¹ have described the outcomes of a single institution cohort treated at the University of Texas MD Anderson Cancer Center

since 1989 where all women presented for early-stage breast cancer and received chemotherapy with 5-fluoruracil, doxorubicin, and cyclophosphamide (FAC) in the second and third trimesters of pregnancy. There were all live births. Rouzier et al.⁸² reviewed 48 patients with pregnancy-associated breast cancer and have concluded that chemosensitivity and pathological response rates were modeled to be similar in pregnant and non-pregnant breast cancer patients. Amant et al. compared 311 women to 865 non-pregnant breast cancer patients with no statistically significant difference in OS.

Azim et al.³³ performed a meta-analysis of 30 studies of PABC which did show a higher risk of relapse and death. However, this did not hold true for the diagnosis during pregnancy which may further emphasize the importance of separating the situations of being diagnosed during versus after pregnancy. This analysis also included multiple older studies that either delayed or gave substandard therapy to pregnant patients that may also have affected survival outcomes.

Thyroid cancer

In pregnant women, thyroid cancer presents most often as an asymptomatic nodule in the neck. Ultrasound evaluation can confirm the size and solid character of the nodule. FNA biopsy is the most reliable diagnostic test and is safe and accurate during pregnancy.^{83–85} Most often, pregnancy-associated thyroid cancers are differentiated thyroid cancers (DTC). Radioiodine scans and therapeutic radioiodine should not be given during pregnancy and can be safely delayed until after delivery.⁸⁶ Thyroid surgery can be delayed until after delivery for many patients, especially if the diagnosis is made during the third trimester of pregnancy.^{86, 87} If warranted, thyroid resection can be done under local anesthesia.⁸⁸ Moosa and Mazzaferi⁸⁹ reported on 61 pregnant patients with thyroid cancer and 528 age-matched non-pregnant controls. They reviewed diagnosis, treatment, and outcome for the two cohorts. Seventy-four percent of the pregnant patients had been discovered to possess an asymptomatic thyroid nodule during routine examinations. Twenty percent of the pregnant patients underwent thyroid surgery during the second trimester, while 77% of patients underwent surgery following delivery. Thirty percent of the patients received postoperative iodine-131 therapy; all of these treatments were administered postpartum. The presence of pregnancy or delayed surgery did not result in differences in cancer recurrence, distant recurrence, or death. On the basis of these findings, Moosa and Mazzaferi⁸⁹ concluded that treatment for thyroid cancer during pregnancy may be delayed until after delivery in most patients. In addition, Yasmeen et al.⁹⁰ reviewed data from the California Cancer Registry of 595 women diagnosed with thyroid cancer within 9 months antepartum to 12 months postpartum, compared to matched non-pregnant counterparts, and no significant differences were found in overall survival, maternal, or fetal outcomes. Alves et al.⁹¹ performed a systematic review of four studies in total, including the two mentioned earlier, and there was no change in long-term survival outcomes between pregnant and non-pregnant DTC patients.

Cervical cancer

Evaluation of extent of disease for diagnosed cervical cancer includes physical examination and assessment of pelvic anatomic structures by MRI. Laparoscopic lymph node surgery has been reported.⁹² Treatment options vary with disease stage, gestational age at diagnosis, and the desires of the patient. For stage I disease, Sorosky et al.⁹³ have reported a favorable outcome with only planned follow-up observation until the third trimester. They followed eight women with stage I disease, <2.5 cm in dimension, for a mean interval of 109 days. All patients underwent delivery via caesarean delivery, followed by radical hysterectomy. Serial MRIs was used to follow the disease for two patients, and no

clinical disease progression was noted. After treatment, all patients were alive and free of disease at a mean follow-up of 37 months.

In a review of 22 patients with cervical cancer diagnosed during pregnancy or within 12 months postpartum, Allen et al.⁹⁴ noted 20 live deliveries and only one disease recurrence. Nine of eleven patients with microinvasive disease were treated with cone biopsy only. Ten patients with stage IB or IIA disease were treated with radical hysterectomy, and one patient with stage IIIB disease received chemotherapy, radiation therapy, and simple hysterectomy as treatment. Allen recommended all pregnant women undergo cervical cytologic evaluation. Cone biopsy is safe in pregnancy and may be adequate treatment for microinvasive disease.⁹⁴

Outcome and recurrence risk have been assessed in relation to method of delivery for women diagnosed with cervix cancer during pregnancy or within 6 months postpartum. Sood et al.⁹⁵ followed 83 pregnant women with cervical cancer; 56 of these patients were diagnosed with during pregnancy, and 27 patients were diagnosed postpartum. As the risk of recurrence was increased in those diagnosed postpartum who delivered vaginally, Sood et al. concluded that women with cervical cancer should be delivered by caesarean. However, van der Vange et al.,⁹⁶ in a case-control study, reported that mode of delivery had no effect on survival. Overall, they noted no difference in survival of pregnant patients with cervical cancer compared to the non-pregnant group. Systemic chemotherapy for cervical cancer can be effective when given during pregnancy. Most of the reported therapies have been platinum based and administered with several other agents such as vincristine and bleomycin.⁹⁷ However, neoadjuvant chemotherapy regimens have been described and include paclitaxel plus either cisplatin or carboplatin.^{97–99} There are several case reports describing the use of neoadjuvant cisplatin-based regimens with either taxane or vinorelbine used in order to preserve the pregnancy until the fetus is viable with good maternal and fetal outcomes.^{100–102}

Treatment of the pregnant patient with cervical cancer requires careful consideration of disease stage and gestational age. Early in pregnancy with early stage disease, pregnancy termination followed by cancer treatment may be appropriate. Alternatively, planned delay in cancer treatment with careful monitoring of disease may allow for successful completion of the pregnancy.⁹³ Radiation therapy will likely cause fetal death and usually results in spontaneous abortion.¹⁹

As a significant population of patients is diagnosed with cervical cancer while in childbearing age, the concern for preservation of fertility has led to the utilization of radical vaginal trachelectomy with pelvic lymphadenectomy, instead of radical hysterectomy, in select patients with Stage I cervical cancer. Burnett et al.¹⁰³ made this procedure available to 21 patients over a period of 6 years with 18 of 21 patients received radical trachelectomy in order to preserve fertility. Within this group, one patient gave birth to healthy twins, delivered at 24 weeks, following superovulation treatment. One patient delivered a singleton term infant via caesarean hysterectomy; no residual disease was found in the cervix. The last patient most likely became pregnant in the week before the radical vaginal trachelectomy. She had spontaneous rupture of membranes at 20 weeks gestation, requiring hysterotomy for evacuation of the uterus with subsequent neonatal demise. Multiple other groups have described success in this procedure for fertility preservation.^{104, 105} There are only a few case reports of this procedure done during pregnancy and therefore its use remains controversial.^{98, 106}

There remain limitations on survival outcome in women diagnosed with cervical cancer diagnosed during pregnancy. Nguyen et al.¹⁰⁷ concluded that tumor characteristics and maternal survival were not adversely affected by pregnancy, nor was pregnancy adversely affected by cervical cancer. Similar conclusions were reached by van der Vange and colleagues in a case-control study. They reported on 23 patients

diagnosed during pregnancy and 24 patients diagnosed within 6 months postpartum. Thirty-nine patients had early stage disease. No difference in survival was noted for cases compared to controls. They noted that the delivery method had no effect on survival, thus concluding that prognosis for early stage cervical cancer is similar in pregnant and non-pregnant women.^{96, 108} Zemlickis et al.¹⁰⁹ reported on a long-term follow-up of cervical cancer outcome in a case-control study of pregnant women. No survival differences were observed. When compared to matched controls, patients with invasive cervical cancer were more likely to give birth to children who had lower birth weights. No adverse impact of pregnancy on cervix cancer outcome could be demonstrated.

Hodgkin's disease and non-Hodgkin's lymphoma

The presentation of Hodgkin's disease during pregnancy does not differ from that of the non-pregnant patient, with lymphadenopathy being the most common method of presentation.¹¹⁰ The diagnosis is established by lymph node biopsy, with sufficient material to confirm specific type of disease.¹¹¹ Staging assessment, in addition to medical history and physical examination, can include an abdominal shielded chest radiograph, abdominal US, and MRI to document disease location and extent in order to assist treatment planning. For supradiaphragmatic disease, radiation therapy can be completed successfully while maintaining the pregnancy with uterine/fetal shielding.^{20, 22, 111–113} Radiation therapy during pregnancy for stage IA and IIA Hodgkin's disease has been reported by Woo et al.²⁰ Sixteen patients received radiation to the neck (2), neck and mediastinum (3), or mantle.¹¹⁴ Fetal radiation dose estimates were determined for nine patients. Reported doses ranged from 1.4 to 5.5 cGy for photon therapy and 10 to 13.6 cGy for cobalt therapy. There were 16 normal full-term infants, and the 10-year patient survival rate was 71%.²⁰ This outcome is similar to an earlier report by Jacobs et al.,¹¹³ who reported on the use of radiation therapy involving the neck and mediastinum during the second and third trimesters of pregnancy. Supradiaphragmatic radiation therapy can be accomplished while maintaining a viable pregnancy. There are limited data regarding the impact of Hodgkin's disease on pregnancy and the effects of pregnancy upon disease prognosis. Anselmo et al.¹¹⁵ concluded that the prognosis of Hodgkin's disease was not affected by pregnancy. Tawil et al.,¹¹² reporting on their experience with 12 patients with Hodgkin's disease and pregnancy, concluded that pregnancy did not significantly affect the course of the malignancy, and the presence of this malignancy did not affect pregnancy outcome. Examining pregnancy outcome, Zuazu et al.¹¹⁶ found no increase in the complication rate of pregnancy in 56 patients with leukemia or lymphoma. In those patients treated with systemic chemotherapy, there was no increase in incidence of fetal malformations. In the Gelb series, patients were treated with a variety of systemic chemotherapy agent combinations, including MOPP (mechlorethamine, vincristine, procarbazine, prednisone), ABV (doxorubicin, bleomycin, vinblastine), COP (cyclophosphamide, vincristine, prednisone), and CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone).¹¹⁰ No fetal malformations were reported. Fifteen patients were alive and disease free. Gelb and colleagues concluded that otherwise indicated systemic therapy should not be delayed because of pregnancy.

Non-Hodgkin's lymphoma during pregnancy presents at more advanced stage and has more aggressive biologic behavior than Hodgkin's disease during pregnancy.^{110, 117, 118} The clinical behavior of non-Hodgkin's lymphoma appears to be the same with or without pregnancy.¹¹⁰ Because the majority of patients present with advanced stage disease, systemic chemotherapy is warranted. Combination chemotherapy has been reported to be used with some success. Agents used have included epirubicin, vincristine, prednisone, etoposide, cyclophosphamide, doxorubicin, and bleomycin in various combinations (VACOP-B and MACOP-B).^{119–121} There have been several reports of the use of rituximab during pregnancy. Herold et al.¹²² utilized a combination of rituximab, doxorubicin, vincristine, and

prednisolone to treat a female with bulky stage IIA NHL. At the time of initiation of therapy, the patient was in her 21st week of pregnancy. She responded well to therapy and delivered a healthy infant at 35 weeks via caesarean section; the child demonstrated a normal B cell population. Kimby et al.¹²³ treated a patient with Stage IIB NHL with weekly rituximab for four cycles. The patient reported conception occurrence between the first and second infusions of rituximab. She delivered a healthy baby girl at 40 weeks. The infant demonstrated a low granulocyte count at birth, but her hematologic parameters had recovered by 18 months of age. Since that time, there have been multiple reports of rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) during pregnancy for diffuse large B cell lymphoma with reports of fetal leukopenia but with only preterm birth complicating the pregnancy.^{124, 125}

In one of the largest reported multicenter, retrospective analyses, Evens et al.¹²⁵ identified 90 patients diagnosed with either Hodgkin's or non-Hodgkin's lymphoma during pregnancy. Six of the women terminated their pregnancy. Fifty-six women received chemotherapy during pregnancy that included R-CHOP as well as other modified regimens that included etoposide, bleomycin, dacarbazine, cytarabine, and cisplatin. Pretreatment also included steroids and growth factor support. One child was born with a malformation with microcephaly. There was an increase in induction of labor and therefore also c-sections and NICU admissions. The authors reported that the survival was in line with expected outcomes of similar lymphoma patients. Aviles et al.¹²⁶ reported the outcome of 16 patients treated for non-Hodgkin's lymphoma during pregnancy, including eight during the first trimester. No congenital malformations were noted, and normal deliveries were reported. They concluded that pregnancy was not a contraindication to treating non-Hodgkin's lymphoma and that long-term remission was possible. Burkitt's lymphoma, anaplastic large cell lymphoma, and T-cell lymphoma have also all been reported in association with pregnancy.^{127–131}

Ovarian cancer

In a review of adnexal masses during pregnancy, one ovarian cancer was found in 125 patients. There were 40 dermoids, 15 endometriomas, 14 cysts, 13 cystadenomas, 9 tubal cysts, and 4 fibroids, a 0.8% malignancy rate.¹³² In a retrospective review, Sayedur et al.¹³³ identified nine cases of ovarian cancer and pregnancy over 24 years, an incidence of 0.08/1000 pregnant women. For pregnant women, adnexal masses are more frequent, likely to be benign and management decisions are becoming more complex. US, percutaneous aspiration, and surgical intervention are possible.

In a study by Platek et al.,¹³⁴ 31 patients of 43,372 deliveries were found to have adnexal masses > 6 cm persistent beyond 16 weeks of gestation. No ovarian cancers were diagnosed. When malignancies have been found, germ cell tumors and epithelial cancers of low malignant potential were most common.¹³⁵ The pathology of ovarian cancer during pregnancy was reviewed by Dgani et al.¹³⁶ They recorded data on 23 patients over a 24-year period. Borderline carcinomas were most frequent (35%), followed by invasive epithelial tumors (30%), dysgerminomas (17%), and granulosa cell tumors (13%). Early stage disease was common; 74% of patients were stage I.

In the series of Sayedur et al.,¹³³ seven of the nine patients had stage I epithelial tumors. Five patients were treated with salpingo-oophorectomy, three with total abdominal hysterectomy and bilateral salpingo-oophorectomy with omentectomy. They reported 100% survival for stage I disease and 78% 5-year survival overall. Conservative surgery for early stage disease and low malignant potential tumors may preserve fertility. In the Dgani series, 14 of the 23 patients delivered live neonates.¹³⁶ Dgani concluded that the overall prognosis for ovarian cancer during pregnancy is better than ovarian tumors in

general because of early stage at diagnosis and tumors of low malignant potential.

Chemotherapy for more advanced-stage disease has been reported primarily as case reports. Cisplatin, carboplatin, doxorubicin, bleomycin, cyclophosphamide, and, most recently, paclitaxel have all been given for treatment of ovarian cancer during pregnancy.^{99, 137–139}

Acute and chronic leukemia

Acute leukemia

Acute leukemia occurring during pregnancy presents unique circumstances because of bone marrow failure and the attendant cytopenias that may occur. Myeloid leukemias are more common than lymphoid. The presenting signs and symptoms are not different from those of the non-pregnant patient. The diagnosis is made by bone marrow aspiration, and standard classification is used for sub-typing. In a series from the Mayo Clinic, 17 pregnant patients with acute leukemia were seen in a 37-year period. Fifteen of the seventeen patients were diagnosed with acute myeloid disease. The majority of these individuals presented during the first or second trimester of pregnancy. Five of nine patients treated with chemotherapy during pregnancy had long-term complete remissions, whereas three of four patients who delayed treatment until after delivery died of disease. No fetal malformations were noted in those treated with chemotherapy during pregnancy.¹⁴⁰

Cardonick and Iacobucci¹⁴¹ performed an analysis of 152 patients who were treated for acute lymphoblastic leukemia (63 cases) or acute myelogenous leukemia (89 cases). They found that 6 neonates developed congenital abnormalities and 12 neonates demonstrated intrauterine growth retardation. There were 11 cases of intrauterine fetal death and two neonatal deaths. All cases of abnormalities occurred in association with first trimester usage of cytarabine or thioguanine, as monotherapy or in combination with an anthracycline. However, combinations of vincristine, mercaptopurine, doxorubicin or daunorubicin, cyclophosphamide, prednisone, and methotrexate were used in all trimesters.

Acute promyelocytic leukemia (APL) is of special interest because of the use of all-trans retinoic acid (ATRA) in the treatment program. Retinoids have known teratogenic effects.¹⁴² However, a number of case reports have documented fetal safety and favorable patient outcome with the use of ATRA for APL.^{143, 144}

Chronic leukemia

Pregnancy and chronic lymphocytic leukemia (CLL) is extraordinarily rare.^{145, 146} Welsh et al.¹⁴⁶ reported a case of CLL with pregnancy and noted a substantial decrease in white blood cells after delivery. They noted that this apparent hematologic remission was not accompanied by clonal remission. Gurman described a case of a patient who became pregnant shortly after her diagnosis of CLL. She received no cytotoxic therapy, and she delivered a healthy infant at 39 weeks gestation.³¹ Her third trimester was complicated by gestational diabetes and preeclampsia. Unlike the Welsh report, which demonstrated elevated numbers of lymphocytes in the intervillous space, the latter case demonstrated no lymphocytic infiltration of the placenta. Ali et al.¹⁴⁷ treated a patient who was diagnosed with CLL during her 17th week of gestation. She received three courses of leukapheresis at the 25th, 30th, and 38th week of gestation in order to maintain her WBC count below $100 \times 10^9/L$. She delivered a normal infant at 39 weeks of gestation.

Chronic myeloid leukemia has been treated during pregnancy with interferon α , hydroxyurea and

leukapheresis, and leukapheresis alone.^{148–151} No untoward effects of treatment on fetal growth, nor development or complications of labor and delivery have been reported.

Sustaining the pregnancy until delivery is feasible. Limited data suggest that pregnancy has no effect on CML long-term outcome; however, there are no case-control studies. Although limited data from animal studies suggest that imatinib may have teratogenic properties, there is increasing, but conflicting data on imatinib use during pregnancy. Yilmaz et al.¹⁵² described three patients exposed to imatinib during pregnancy, all with healthy neonates at delivery. Prabhash et al.¹⁵³ described two cases of normal births after imatinib exposure and continuation of imatinib therapy throughout the pregnancy. Ault et al. described 19 pregnancies involving 18 patients who conceived while receiving imatinib. All female patients discontinued therapy at the time the pregnancy was discovered. Three pregnancies ended in spontaneous abortion and one with an elective abortion. Two of the 16 babies had abnormalities; one with hypospadias and another with rotation of the small intestine. The authors concluded that patients should use contraception as the discontinuation of imatinib may lead to loss of disease response. Another case report describes the development of a meningocele and death of the fetus exposed to imatinib.¹⁵⁴ Yadav et al.¹⁵⁵ described another woman who received hydroxyurea and imatinib during the third trimester with fetal complications of IUGR and oligohydramnios. However, the child developed normally after delivery. Alizadeh et al.¹⁵⁶ described 22 pregnancies in 14 patients or in the partner of a male patient exposed to tyrosine kinases for CML with only 1 with an atrial septal defect. Therefore, patients should be encouraged to continue with contraception while on imatinib given these scant and conflicting reports; however, some patients have maintained imatinib therapy during pregnancy. This may be an option for some women, only after detailed and deliberative discussion with the treating team regarding risks and the limits of available information.

Melanoma

Surgical management remains the mainstay of treatment for newly diagnosed melanoma during pregnancy. There have been multiple reports of melanoma diagnosed during pregnancy. Johansson et al.¹⁵⁷ described the Swedish registry of 1019 women with pregnancy-associated melanoma. Of these there was no difference in cause-specific mortality in pregnant versus non-pregnant patients. However, Bannister-Tyrell et al.¹⁵⁸ have described an Australian experience of 577 pregnancy-associated melanomas, of which 195 were diagnosed during pregnancy. However, in this group, there was an association with detection of the melanoma at more advanced stages.

Transplacental malignancy and placental metastasis

A number of case reports have noted transplacental passage of malignancy from mother to neonate.^{159–167} Catlin et al.¹⁵⁹ reported a neonatal death related to the transplacental passage of maternal natural killer cell lymphoma. Successful treatment of maternal transplacental small-cell lung cancer has been noted.¹⁶⁶ Teksam presented a striking case of a 33-week neonate who was emergently delivered after her mother was diagnosed with lung cancer. Owing to the presence of placental metastases, the infant underwent initial screening with brain MRI and chest/abdomen CT, both of which were apparently normal. Unfortunately, serial examinations demonstrated development of a cerebellar tumor that significantly improved after chemotherapy, but the mass progressed a few months afterward. Biopsy and resection confirmed that the neoplasm was metastatic lung cancer. Additional metastatic lesions were identified in the frontal and temporal lobes on follow-up MRI.¹⁶⁷

Leukemia cell identification in circulation in a neonate born to a mother with ALL has also been reported. However, leukemic cell engraftment and neonatal disease were not observed.¹⁶⁴ Acute monocytic leukemia transmission from mother to fetus has been documented.¹⁶²

Alexander et al.¹⁶³ reviewed 87 cases of fetal or placental metastases; they found that malignant melanoma affected 31% of these patients, making melanoma the most common malignancy to involve both the fetus and placenta.

Dildy and colleagues reviewed placental metastases and reported 52 cases in 1989. Solid tumors and hematologic malignancies have been noted to involve the placenta ([Table 3](#)).^{129, 168–176} Systematic evaluation of the placenta at the time of delivery of the pregnant woman with cancer has not been routine. However, new technologies are being evaluated for easier identification of possible transplacental transfer of malignancies.

Table 3 Placental metastases

Tumor type
Small-cell lung cancer ¹⁶⁶
Melanoma ¹⁶⁶
Pancreas ¹⁶⁸
Breast ¹⁶⁹
Medulloblastoma ¹⁷⁰
Large cell lung cancer ¹⁷¹
B-cell lymphoma ¹⁷²
T-cell lymphoma ¹⁷³
Non-Hodgkin's lymphoma ¹⁷⁴
Large cell lymphoma ¹²⁹

Conclusion

Cancer and pregnancy presents a unique opportunity for multispecialty oncologic and prenatal care. The gathering and discussion of data to be utilized in treatment planning requires careful coordination with obstetrical, surgical, and anesthesiology colleagues. Given the concern for the well being of both the mother and the fetus, support for and reassurance of the patient during the decision process becomes a paramount duty for physicians. It is possible to have a favorable outcome for mother and child. An outline of a sequential approach to multispecialty management for cancer and pregnancy is presented in [Table 4](#).

Table 4 Multidisciplinary approach to the pregnant patient with cancer

Diagnosis and treatment planning	Considerations
Confirm diagnosis	Cytology and histology
Assess extent of disease	Staging, physical exam, organ function, and metastatic disease
Disease-related prognosis independent of pregnancy	
Assess pregnancy	Comorbidities—age, diabetes, and cardiac function Gestational age Expected delivery date
Review treatment options	<i>For Patient:</i> Anticipated benefits for the patient “Cure,” prolongation of life, improve or delay symptoms
	<i>For Fetus:</i> Anticipated outcome Maintaining pregnancy Anticipated risks for fetus
Plan and implement treatment plan	
Reevaluate patient and fetus at frequent intervals	
Multidisciplinary treatment team members	Patient Obstetrician Oncologists-surgical, radiation, medical, gynecologist, and radiation physicist Nurses Ethicists Social service Pastoral care

Chapter 73

Cancer and aging

Arti Hurria, MD ■ Hyman B. Muss, MD ■ Harvey J. Cohen, MD

Overview

Cancer is a disease of aging. Approximately sixty percent of all cancers and seventy percent of cancer mortality occurs in people \geq age 65. The number of older adults with cancer is on the rise as the US population is aging. However, there is great heterogeneity in the health status of older adults which may impact cancer treatment decisions and outcomes. This chapter will review the principles of geriatric assessment and frailty, the biology of cancer and aging, as well as the unique issues and considerations in caring for older patients with cancer during treatment and into the survivorship years.

Cancer is a disease that disproportionately affects older patients. Almost 60% of all cancers occur in people \geq age 65. People aged 65 and older have a ninefold increase in the incidence of cancer and an 18-fold increase in cancer mortality in comparison to people younger than age 65 ([Table 1](#)).² The number of older people with cancer is continuously growing as the population is aging. In the United States, in 1900, 3.1 million people were of age 65 and older. Over the century, this number increased approximately 10-fold, so that in the year 2000 there were 35 million people aged 65 and older. This number is expected to double yet again, thus in 2030, it is projected that there will be 71.5 million people over the age of 65, accounting for 20% of the population^{3, 4} ([Table 2](#)).

Table 1 Ninefold increase in cancer incidence and 18-fold increase in cancer mortality with age $<$ 65

	Incidence	Mortality
Age	(per 100,000)	(per 100,000)
<age 65	223.8	56.1
\geq age 65	2095.8	1008.4

Source: Data derived from SEER for 1975–2011 Incidence and 1975–2010 for Mortality.¹

Table 2 The growing US population aged 65 and older 1.2

Year	Million	Percentage of population
1900	3.1	4.1
2000	35.0	12.4
2030	71.5	19.7

Among those over the age 65, there has been an age shift over time, leading to an increase in the older segment of the population. For example, during the 1990s the number aged 85 and older increased by 38%, the number aged 75 to 84 increased by 23%, and the number aged 65 to 74 increased by less than 2%. By 2030, the number \geq age 85 is expected to double.³ Those who live to age 100 and beyond, the

“centenarians,” are the fastest growing segment of the older population. On the basis of these statistics, oncologists inevitably care for a large number of older patients. There is no standard chronological age at which a person is considered “older.” Historically, aged ≥ 65 was used for two reasons:

- 1. this was the traditional age for retirement and
- 2. people in the United States become eligible for entitlement programs (Social Security, Medicare).

As our population ages, we see much heterogeneity in the aged ≥ 65 population, with many individuals continuing to work and function similarly to younger counterparts. Therefore, this chapter focuses on defining characteristics to understand “functional age,” rather than “chronological age” to distinguish the “older” patient. This chapter is also dedicated to discussing the unique issues and considerations in caring for an older patient with cancer.

Life expectancy and aging

Statistics regarding average life expectancy are useful to consider when caring for an older patient. The average life expectancy at birth is 76.5 years. As an individual ages, the average projected life expectancy increases. For example, a person who lives to 65 years of age has an average life expectancy of 19.1 years, placing their projected age of death at 84.1 years. A person who lives to 80 years of age has an average projected life expectancy of 9.1 years, placing the projected age of death at 89.1 years. Even the 100-year-old person has an average life expectancy of 2.3 years, placing their average projected age of death at 102.3 years. One may think of this as a “survival of the fittest” phenomenon, in which the absolute life expectancy increases as one ages ([Table 3](#)).⁵

Table 3 Average life expectancy

Age now	Life expectancy	Age of death
65	19.1	84.1
70	15.5	85.5
75	12.1	87.1
80	9.1	89.1
85	6.6	91.6
90	4.7	94.7
95	3.3	98.3
100	2.3	102.3

The biology of cancer and aging

Aging can be defined as “the process that converts healthy adults into frail ones with diminished reserves in most physiologic systems and an exponentially increasing vulnerability to disease and death”.⁶ Despite the universality of this definition, aging is clearly a heterogeneous process. Each individual ages at a unique pace and demonstrates varying manifestations of vulnerability. Although much progress has been made, the mechanisms of both aging and neoplasia are incompletely understood and therefore theories about the association of these two processes are an area of active research.^{7, 8} It has been suggested that cancer and aging are two sides of the same coin with the control of tissue renewal and repair being a

pivotal point with excess proliferation leading to neoplasia and decline in cell growth and function resulting in senescence.^{9, 10} P16^{INK} expression may play a key role in this branch point as may metabolic stress resistance pathways and waste management controls via autophagy pathways.^{11, 12}

Other theories of the association with aging and neoplasia^{13, 14} include longer duration of exposure (time) and possibly increased susceptibility to oxidative stress and carcinogens; age-induced increase in DNA instability resulting in higher mutation potential that could result in both oncogene activation or amplification or tumor suppressor gene defects; a decrease in DNA repair with age, which might enhance the predisposition to the genetic defects; age-related telomere shortening, which might increase the above-mentioned DNA instability; immune dysregulation, which may decrease immune surveillance and allow the emergence of malignant clones but may also create a pro-inflammatory environment favoring the growth of malignant cells; and finally an altered microenvironment, including the presence of senescent cells that may secrete proinflammatory and carcinogenic cytokines.^{14–16} These theories do not explain why there is a decrease in cancer incidence in the older segment of the population. In a autopsy study of 507 patients over 75 years of age, the prevalence of cancer at the time of autopsy decreased with increasing age (35% age 75 to 79, 20% age 95 to 99, and 16% in centenarians). This has been confirmed in a detailed demographic study and suggests that research into the cause of this phenomenon may be enlightening regarding the overall relationship of aging and cancer.¹⁷

Source: Data derived from the National Vital Statistics Report 5.

Physiologic changes with aging

Physiologic changes occur in each organ system with aging, independent of disease. Most organ systems show a linear physiological decline beginning at 30 years of age. This decline occurs at variable rates between individuals and across organ systems. The consequence of these changes during normal activity is minimal; however, during times of stress the decreased reserve becomes more apparent.¹⁸

As the cardiovascular system ages, there is a decrease in cardiac output, decrease in maximal heart rate, and prolonged recovery following exertion. During times of stress, there is a decreased response to catecholamines. As the pulmonary system ages, there is a decreased response to hypoxemia or hypercapnia, decreased elasticity in the lung tissue, increased ventilation–perfusion mismatch, and decreased forced expiratory volume. Endocrine changes with aging include a decrease in certain hormone levels and an increase in others. For example, there is a decrease in insulin-like growth factor, growth hormone, renin, aldosterone, dehydroepiandrosterone, and sex steroids and increase in insulin, norepinephrine, parathyroid hormone, vasopressin, and atrial natriuretic peptide. Changes to the neurological system with aging include neuronal loss, decrease in brain weight, decreased vision, loss in high frequency and low frequency hearing, and alterations in both taste and smell. Changes in the immune system manifest as decrease in thymic mass, decreased production of thymic hormones, decrease in naive lymphocytes, and a decrease in antibody response.¹⁸

There is a decrease in hepatic and renal mass with aging. Autopsy studies demonstrate a decrease in liver volume with aging by approximately 25% to 50%. In addition, there is decreased hepatic blood flow, estimated at a 10% to 15% decrease in liver perfusion, even after taking into account the decrease in liver volume.^{19–21} Renal mass decreases by 25% to 30% over the lifespan, leading to a decreased number of functional nephrons. Renal blood flow decreases by 1% per year after 50 years of age and glomerular filtration decreases by 1 mL/min/year after the age of 40.^{19, 21}

Hematopoietic changes with aging include a decrease in bone marrow mass and increase in bone marrow

fat. Despite this, peripheral blood cell concentrations in healthy older patients are similar to those of younger patients.²²

The frail older patient

The term “frail” is used to describe a subset of older patients with a critically reduced functional reserve that places them at risk for dependency, institutionalization, illness, hospitalization, and mortality.²³ A proposed definition of frailty is “a state of age-related physiologic vulnerability resulting from impaired homeostatic reserve and reduced capacity of the organism to withstand stress.” Therefore, the clinical syndrome of frailty is proposed to be a dynamic consequence of a negative energy balance; for example, starting with undernutrition that leads to loss of muscle and bone mass and contributes to further decline in activity level and strength. This, in combination with decreased reserve, contributes to the increased vulnerability of the frail patient. The end result is failure to thrive, which is a syndrome of unexplained weight loss, decreased muscle mass, and metabolic abnormalities including a decrease in albumin, creatinine, cholesterol, and hemoglobin. Immune dysfunction and chronic inflammation may play a role in frailty. Markers of inflammation are associated with aging and frailty including the cytokine interleukin 6 (IL 6) and the acute phase reactant, C-reactive protein (CRP).^{24–26} In addition, elevations in plasma D dimer have been associated with age. Both IL 6 and D dimer have been predictive of mortality and functional decline.^{23, 27, 28}

A phenotype for frailty was developed in a prospective observational study of 5317 community-dwelling men and women age ≥ 65 . The “frailty phenotype” was defined as a clinical syndrome in which three or more of the following criteria are present: (1) unintentional weight loss ≥ 10 lbs in past year, (2) self-reported exhaustion, (3) weakness defined as the lowest twentieth percentile in grip strength adjusted for gender and body mass index, (4) slow walking speed defined as the lowest twentieth percentile on a timed walk of 15 feet, and (5) low physical activity defined as the lowest quintile of kilocalories per week. Individuals with one or two of the criteria were categorized as an “intermediate or prefrail phenotype.” Patients defined as frail or prefrail, compared with nonfrail, had a higher incidence of 3- and 7-year mortality, hospitalization, incident falls, progressive decline in ability to complete activities of daily living (ADL), and decreased mobility. On the basis of these criteria, 7% of community-dwelling individuals age 65 and older were frail and 47% were prefrail. The prevalence of frailty and prefrailty was greater in women than men and increased with age.²⁹ Frailty is also associated with an increased risk of recurrent falls, hip fracture, and any nonspine fractures.³⁰

Another method of measuring frailty was developed by Rockwood and colleagues in which frailty is viewed as an accumulation of deficits.³¹ This frailty index is based on the premise that while individual deficit may not have a discernible threat to mortality (or other outcomes), the accumulation of these individual deficits will add up to poorer outcomes in the geriatric population. For example, in general populations of older people, the accumulation of deficits has been demonstrated to predict hospitalization, institutionalization, and death.^{32, 33} In comparison to the phenotype model developed by Fried and colleagues, which requires the knowledge of specific parameters, the deficits accumulation method can be used for virtually any data set which captures geriatric assessment variables if enough variables are collected. Future research is needed to identify the utility of these different methods of measuring frailty in predicting outcomes in older adults with cancer.

Frail older patients with cancer represent a unique subset of patients that pose challenging therapeutic decisions. The aforementioned geriatric measures of frailty have not been widely studied in older adults with cancer, where there may be additional outcomes of interest. For example, a consensus statement on

research recommendations for older adults with cancer proposed that an oncologic definition of frailty should assess the risk for toxicity to cancer treatment.³⁴ An important initial step in evaluation of the frail patient is to determine whether the cancer is likely to decrease the patient's life expectancy. In a model proposed by Balducci and Stanta,³⁵ one would consider treatment of the cancer if it was impacting the patient's life expectancy or if it was causing a compromise in quality of life. The goal of treatment must be determined: life prolonging versus palliation. Treatment decisions involve weighing the risks and benefits with the patient and caregiver. As the nation is aging, there will be a rise in the number of frail older patients with cancer. Clinical trials focusing on efficacy and tolerability of treatment within this patient population are needed.³⁶

Evaluation of the older patient: geriatric assessment

The term “geriatric assessment” was defined at a consensus conference in 1989 as “a multi-dimensional inter-disciplinary patient evaluation that leads to the identification of patient's problems.”³⁷ The assessment includes an evaluation of the older person's functional status (ability to live independently at home and in the community), comorbid medical conditions, cognition, psychological status, social functioning and support, medication review, and nutritional status ([Table 4](#)). This comprehensive assessment allows for identification of areas of vulnerability and a multidisciplinary plan to address these areas. In addition, geriatric assessment provides valuable information regarding prognostic factors for morbidity and mortality in the older patient.³⁸ Each domain of a geriatric assessment is reviewed in the following section.

Table 4 Key components of a comprehensive geriatric assessment

Functional status
Comorbid (co-existing) medical conditions
Cognition
Psychological status
Social functioning and support
Socioeconomic issues
Medication review
Nutritional status

Functional status

Assessment of functional status includes an evaluation of an individual's ability to live independently at home and in the community. Traditional assessment measures are “ADL” and “instrumental activities of daily living” (IADL) ([Table 5](#)). ADL are basic self-care skills, such as ability to bathe, dress, toilet, transfer, maintain continence, and feed oneself. These activities are essential in order for one to maintain independence in the home. The need for assistance with ADL has been predictive of cognitive impairment and greater resource requirement,³⁹ nursing home placement,⁴⁰ prolonged hospital stay, and worsening of function in the hospital.⁴¹

Table 5 Functional status assessment

Activities of daily living	Instrumental activities of daily living
Bathing	Telephone
Dressing	Traveling
Toileting	Shopping
Transfer	Preparing meals
Continence	Housework
Eating	Medication management
	Money management

IADL include those self-care skills that allow one to live independently in the community. These include ability to telephone, shop, travel, prepare meals, do housework, take medications, and manage one's finances. In a study by Reuben and colleagues of 282 patients aged 64 and older, dependence in IADL (such as housework, shopping, and driving, scored as a continuous variables) was an independent predictor of mortality ($p < 0.0001$).⁴² The need for assistance with IADL is predictive of risk of cognitive impairment.⁴³ Individuals who require assistance with IADL often need assistance to maintain independence in the community.

Cancer in an older patient is associated with an increased need for assistance in daily activities. In a large study of older patients, individuals with cancer had more limitations in ADL and IADL than individuals without cancer and required more healthcare use.^{44, 45} The need for assistance with IADLs has been associated with poorer overall survival^{46, 47} and increased risk of chemotherapy toxicity in older adults with cancer.^{48–50} For example, the need for assistance with IADL and poorer quality of life are associated with poorer overall survival among older adults with lung cancer.⁴⁷ In a study of older adults with ovarian cancer, predictors of chemotherapy toxicity included a poor performance status (Eastern Cooperative Oncology Group performance status of <2) and functional dependence (defined as living at home with assistance or living with assistance in a specialized institution).⁵¹

Comorbid medical conditions

Comorbidity is defined as a concurrent medical problem that is a competing source of morbidity or mortality. In a study by Yancik and colleagues, summary data on comorbidity were collected on 7600 patients aged ≥ 55 years. The most common concurrent medical problems included hypertension (42.9%), heart-related conditions (39.1%), and arthritis (34.9%). The number of comorbid conditions increased with age. Patients aged 55 to 64 had an average of 2.9 comorbid conditions, patients aged 65 to 74 had 3.6 comorbid conditions, and those 75 and older had 4.2 medical conditions ([Table 6](#)).³ The association between comorbidity and survival in patients with cancer is independent of a patient's functional status.⁵² Therefore, each is an important domain to assess. The potential impact of a new disease as a competing cause of mortality decreases with increasing age secondary to the decrease in absolute projected life expectancy.⁵³ For example, consider the impact of a disease with a projected 50% mortality over 5 years in a 65-year-old person in comparison to an 85-year-old person. This disease will decrease the 65-year-old person's average life expectancy by approximately 10 years, whereas because the absolute projected life expectancy of an 85-year-old person is less than that of a 65-year-old person, it will decrease an 85-year-old person's average life expectancy by only about 2 years.⁵³ A study by Piccirillo et al.⁵⁴ with

evaluative data of over 27,000 patients demonstrated that among individuals with cancer, the mean number of comorbid conditions and the severity of the comorbid conditions increase with age.

Table 6 Rank order of major condition, >10% of study sample

Condition	Percent
Hypertension	42.9
Heart-related conditions	39.1
Arthritis	34.9
Gastrointestinal problems	31.0
Anemia	22.6
Eye problems	19.0
Urinary tract	18.0
Previous cancers	15.4
Gallbladder problems	14.9
Chronic obstructive pulmonary disease	14.5
Diabetes	12.8
Fracture	10.8
Gland disorders	10.6

The level of comorbidity has been shown to affect functional recovery following surgical treatment for breast cancer. In a study of older women with breast cancer, women with >2 comorbid conditions were less likely following surgery to become independent in completing IADL and more likely to experience difficulty completing tasks requiring upper body strength.⁵⁵

Comorbid medical conditions also impact the likelihood of receipt and tolerance of chemotherapy. Data from the Surveillance, Epidemiology, and End Results-Medicare database demonstrates that older patients with colon cancer who have a history of heart failure, diabetes, or chronic obstructive pulmonary disease are less likely to receive adjuvant chemotherapy.⁵⁶ In a clinical trial of older adults with lung cancer, patients with higher levels of comorbidity were more likely to discontinue chemotherapy.⁵⁷

Nutrition

Poor nutritional status is an independent predictor of functional dependency and survival. In a prospective cohort study of 214 older community-dwelling adults, a low body mass index defined as a body mass index < 22 kg/m² was associated with dependency in ADL [odds ratio 1.21; 95% confidence interval (CI) 1.01–1.45]. After adjusting for potential confounding factors including age, gender, mental status, comorbidity, and functional dependency, body mass index < 22 kg/m² was associated with decreased 1-year survival [relative risk (RR) 0.85, 95% CI 0.74–0.97].⁵⁸ However, conflicting data has shown that among hospitalized old adults, a BMI ≥ 30 was associated with better 4-year all-cause mortality, while lower BMI was not associated with increased risk of mortality.⁵⁹

Weight change over a 3-year period was recorded in a study of 4714 community-dwelling adults, aged 65 and older. Weight change, defined as a 5% or greater loss or gain in weight over a 3-year period,

occurred in 34.6% of women and 27.3% of men. A higher proportion of participants lost weight than gained weight. Weight loss, and not weight gain, was associated with an increased risk of mortality (Hazard ratio = 1.67, 95% CI = 1.29–2.15).⁶⁰

The prognostic effect of unintentional weight loss in patients with cancer was evaluated in a study of 3047 patients enrolled in Eastern Cooperative Oncology Group chemotherapy trials. Weight loss during the 6 months before chemotherapy was associated with poorer survival (statistically significant in 9 out of 12 tumor types). In addition, weight loss was associated with lower chemotherapy response rates (significant only in patients with breast cancer). Decreasing weight correlated with decreased performance status in all tumor types except pancreatic and gastric cancer.⁶¹

Cognition

The presence of dementia is an independent prognostic indicator of survival.^{62, 63} In a study by Wolfson and colleagues, 10,263 people aged 65 and older were screened for dementia. Of these, 821 people had a diagnosis of probable Alzheimer's disease, possible Alzheimer's disease, or vascular dementia. The median survival of these patients was 3.3 years (3.1 years if a diagnosis of probable Alzheimer's disease, 3.5 years if possible Alzheimer's disease, and 3.3 years if vascular dementia).⁶³

A baseline assessment of cognition in an older patient with cancer is important for several reasons. First, if a person has a rapid change in memory or new cognitive deficits, metastatic disease to the brain should be excluded. Second, the degree of cognitive impairment will need to be considered when devising a treatment plan. For example, all oral medications and especially chemotherapy drugs should be used with caution in patients with cognitive impairment. Correct dosing for oral chemotherapy is as important as with intravenous chemotherapy, so that if the patient takes an incorrect dose, the side effects could be serious or even fatal. The role of the patient's family or caregiver is critical in maintaining safety. A patient with cognitive impairment will need assistance in remembering instructions regarding use of supportive medications such as antiemetics. A caregiver will need to be aware of potential side effects of treatment that would necessitate medical attention. The presence of cognitive impairment is associated with increased risk of hospitalization and poorer chemotherapy tolerance.^{49, 64}

Psychological state and social support

Older patients with cancer often demonstrate better psychological functioning in comparison to younger patients. Following a diagnosis of breast cancer, older women demonstrate better mental health and well-being in comparison to younger patients.⁶⁵ In women < age 65, a recent diagnosis of breast cancer produced a marked increase in anxiety and depression and decreased morale in comparison to people of the same age who had a diagnosis over 5 years prior. In comparison, for women ≥ 65 years of age, a more recent diagnosis did not affect their level of anxiety, depression, or morale in comparison to age counterparts with a diagnosis greater than 5 years ago.^{66, 67}

The presence of social support plays an important role in the psychological functioning of the older patient. Significant predictors of severe psychological distress in women of breast cancer of any age include being divorced or separated and having less social support.⁶⁸ Social support can serve as a buffer against the psychological impact of a stressful life event.

In addition, social isolation is an independent predictor of mortality. This was demonstrated in a study by Seeman and colleagues in which they examined the importance of four measures of social support: (1) marital status, (2) close contact with two or more close friends/relatives, (3) regular church attendance,

and (4) membership in other types of groups. The presence of social ties was related to survival, independent of age. The relative hazard for increased 5-year mortality among men and women in three community-based cohorts ranged from 1.97 to 3.06 for participants with no social ties in comparison to those with all four social ties.⁶⁸ In another study of 282 patients aged 65 and older, living alone was independently predictive of risk of death.⁴²

Medication review: evaluation for polypharmacy

A review of the patient's medication list is an important part of the geriatric assessment. In addition, one must consider whether newly prescribed medications may cause an adverse effect or drug interaction. Older patients are more vulnerable to adverse drug events than younger patients. Approximately one-fifth of hospital admissions in older patients are secondary to adverse drug events.¹⁹ This is partly because older patients use more medications than younger patients. The average number of medications taken by an older patient with cancer is 5 ± 4 drugs.⁶⁹

Contributing to the risk of adverse drug events are the changes in pharmacokinetics and pharmacodynamics that occur with aging. These changes should be considered with the dosing of any medication, including chemotherapy. There are age-related changes in the gastrointestinal tract such as decreased acid secretion and fewer villi in mucosal surfaces. There are significant changes in volume of distribution including increased body fat (leading to slower metabolism of lipid soluble drugs), decrease in total body water (leading to an increase in the plasma level of water-soluble drugs), decrease in lean body mass, decrease in serum albumin, and decrease in hemoglobin.²⁰ Hepatic metabolism changes with aging, secondary to decreased liver volume and decreased hepatic blood flow. Phase I hepatic reactions (oxidation, deamination, hydroxylation) decrease with aging. These include reactions mediated via cytochrome P-450, decreasing by approximately 30% in older patients. There is no significant change in phase II hepatic reactions (conjugation: acetylation, glucuronidation, sulfation) with aging.^{19–21} Renal mass decreases by 25–30% over the lifespan, leading to a decreased number of functional nephrons. Consequently, there is a decrease in glomerular filtration, tubular secretion, and reabsorption with aging. Therefore, drugs dependent on renal clearance have a longer half-life in older patients and drug dosing may need to be adjusted based on creatinine clearance.

Comprehensive geriatric assessment

Geriatric assessment is a comprehensive approach to the evaluation of the older patient, with an evaluation of the domains described above: functional status, comorbidity, cognition, nutritional status, psychological state and social support, and medication review. Studies regarding the value of this assessment have been conflicting; however, a meta-analysis of the controlled trials by Stuck and colleagues suggests a benefit to geriatric assessment. This meta-analysis of 28 controlled trials comprising 4959 participants and 4912 controls randomized to one of five comprehensive geriatric assessment programs demonstrated that a geriatric evaluation and management unit (inpatient unit for geriatric assessment and rehabilitation) reduced mortality by 35% at 6 months and a home assessment service (in-home geriatric assessment) reduced mortality by 14% at 36 months via early identification and treatment of problems.⁷⁰ A more recently published multisite randomized, controlled trial of inpatient and outpatient geriatric evaluation and management demonstrated that geriatric evaluation and management reduced functional decline and improved mental health but had no effect on survival.⁷¹

The role of geriatric assessment in care of the older cancer patient is an area under active research. A systematic review of geriatric assessment studies in older adults with cancer confirmed that performing a

geriatric assessment is feasible in oncology practice and can identify older adults at risk for adverse outcomes; however, additional studies are needed regarding the impact of geriatric assessment results on oncology decision-making and interventions to improve outcomes.^{72, 73} Balducci⁷⁴ studied geriatric assessment in the evaluation of the older patient with cancer and found that this assessment helped to characterize patients of the same chronological age by identifying impairment in the following areas: dependency in functional status (18% ADL, 72% IADL), serious comorbidity (36% by Charlson scale, 94% by Cumulative Illness Rating Scale—Geriatrics), memory impairment (22%), poor nutrition (19%), and polypharmacy (41%). Garman et al.⁷⁵ performed a retrospective chart review of older patients with cancer admitted to an inpatient Geriatric Evaluation and Management Unit, in which a comprehensive geriatric assessment was used to identify goals of care. These goals were accomplished in over 75% of cases: 73% in symptom management, 79% in functional improvement, and 100% in disposition and caregiver support. Other studies have demonstrated that domains of a geriatric assessment can predict survival and toxicity to chemotherapy in older adults with cancer.^{47, 51} Geriatric assessment and intervention can lead to improve pain control, mental health, and emotional well-being among older adults with cancer.⁷⁶

The information derived from a geriatric assessment could be potentially valuable to oncologists for several reasons. First, it would help the clinician get a sense of the “functional age” of the patient. Second, it would identify patients at high risk for functional decline or toxicity to treatment, for whom targeted intervention may be beneficial. Third, it would provide valuable information regarding older patients in clinical trials, allowing us to standardize patient characteristics across studies and to control for possible confounding factors contributing to mortality.

A traditional comprehensive geriatric assessment is a multidisciplinary assessment that can take 2 h to perform. Because of the time-intensive nature, it is often not feasible in a busy oncology practice. Therefore, other means of performing geriatric assessment are under study. The Cancer and Leukemia Group B (CALGB) is developing a short geriatric assessment tool. Pilot data demonstrated that this brief but comprehensive, mainly self-administered geriatric assessment questionnaire is feasible in the setting of an outpatient oncology clinic⁷⁷ and cooperative group.⁷⁸ This geriatric assessment will be collected as baseline information in subsequent clinical trials. Other authors have reported on the feasibility of a geriatric assessment that is mailed to the patient to complete before the office visit.^{79, 80} There are several abbreviated geriatric assessment screening tools that are available; however, there is no consensus regarding the optimal screening tool to identify patients who would benefit from a more detailed geriatric assessment.³⁴

A proposed framework depicting the factors to consider in decision-making for an older patient with cancer is described in the Comprehensive Geriatric Model, developed by Cohen and DeMaria.⁸¹ This model summarizes the key aspects critical to the care of the older patient including social, psychological, and biological factors that may impact on the host, the disease, and the outcomes from treatment. In this model, chronological age plays a role by defining the decreased functional reserve that can occur with aging, but subsequent factors including biological, social, and psychological factors unique to the individual patient are factored into decision-making. This is a dynamic process in which alterations in one domain can subsequently impact upon the other domains within the model.

Knowledge about older cancer patients: underrepresentation on clinical trials

Despite the aging population and the association of cancer with aging, data regarding the benefits and risks of treatment of the older cancer patient are limited. This is secondary to limited involvement of older patients on clinical trials. The Southwest Oncology Group analyzed 164 clinical trials from 1993 to 1996 and comprised of 16,396 patients. They found that only 25% of the patients on clinical trial were aged 65 and older. This underrepresentation was across 15 cancer types, except lymphoma. Older patients with breast cancer were the least represented, with only 9% of patients over the age of 65.⁸²

Similar data regarding the underrepresentation of the older patient are seen in Canadian trials. Enrollment on clinical trials by age was analyzed from 1993 to 1996. Fifty-eight percent of the Canadian population with cancer is \geq age of 65, whereas only 22% of patients enrolled on trial were \geq age of 65.⁸³

The representation on clinical trials worsens with increasing age. The National Cancer Institute analyzed enrollment of patients \geq age of 65 and patients \geq age of 75. Data from 23,000 patients across 500 therapeutic trials were analyzed. They found an underrepresentation of patients over the age of 65 on clinical trial; however, this was even more pronounced for patients \geq age of 75. Only 11% of men on clinical trial were over the age of 75 and only 5% of women were over the age of 75. There was a striking underrepresentation of older patients with breast cancer, with only 2.7% being over the age of 75. This study demonstrated that with increasing age, there is even less representation on clinical trial.⁸⁴ A review of enrollment on NCI adult cooperative group clinical trials from 2001 to 2011 shows continued underrepresentation of older adults.³⁶

Understanding barriers to clinical trial enrollment

The CALGB Committee on Cancer in the Elderly developed a study to understand barriers to participation of older patients on cancer treatment trials. Women with breast cancer, $<$ age of 65 and \geq age of 65, were paired by physician and stage. The trial sought to determine the frequency with which each group was offered enrollment on clinical trial and likelihood of accepting treatment on trial. The results demonstrated that older women were less likely to be offered enrollment onto clinical trial than younger women (51% $<$ age 65 vs 35% \geq age 65; $p = 0.06$): however, if offered, older women would be as likely to accept enrollment on trial as younger women (56% $<$ age 65 vs 50% \geq age 65; $p = 0.67$). Physicians did not offer a clinical trial to older patients because (1) physicians were concerned about the toxicity of treatment in older patients and (2) physicians were concerned regarding the impact of comorbid diseases.⁸⁵ The most common physician recommendations of ways to improve accrual of older patients to clinical trials include providing clinic personnel to explain trials to older patients and their families, providing educational materials about clinical trials for patients and families, and providing transportation to make it easier for older patients to participate in clinical trials.^{86, 87}

Cancer screening in the elderly

National organizations publish screening recommendations for the public as a whole; however, few provide guidelines for cancer screening in the elderly. Moreover, randomized trials of screening interventions have rarely included meaningful sample sizes of older persons. The American Geriatrics Society (AGS) recommends that cancer screening be individualized, rather than setting guidelines strictly by age, taking into account the patient's preferences, life expectancy, and the risks and benefits of the screening test. In their recent recommendations as part of the "Choosing Wisely" campaign, they recommend no routine screening for prostate, colon, or breast cancer in patients with an estimated life expectancy less than 10 years.⁸⁸ General guidelines to help steer these discussions with patients at

average risk for developing these cancers are summarized in the following section.

Breast cancer

Breast cancer screening traditionally consists of mammography, clinical breast exam, and breast self-exam. The American Cancer Society (ACS) recommends continuing breast cancer screening as long as a woman is in good health and is a candidate for treatment.⁸⁹ The AGS suggests to not screen women with estimated life expectancies less than 10 years. In a recent review of mammographic screening in older women, it was recommended that screening mammography be stopped for women with a less than 10 year life expectancy.⁹⁰ We suggest annual or biennial screening only for older women with estimated survival of at least 10 years.

Cervical cancer

The ACS guidelines for cervical cancer screening recommend that women aged 65 and older may cease screening with the Papanicolaou (Pap) smear if there are three or more documented, consecutive, normal Pap smears or two or more consecutive Pap and HPV tests within the past 10 years (with the most recent test in last 5 years).⁹¹ The US Preventative Service Task Force recommends discontinuing cytologic screening for women aged 65 and older who have had adequate screening with normal results.⁸⁹

Prostate cancer

Screening for prostate cancer consists of a digital rectal exam and prostate specific antigen (PSA) test. The ACS recommends offering annual screening for prostate cancer, with digital rectal exam and PSA test, beginning at the age of 50 in patients at average risk and continued in men who have a life expectancy of at least 10 years. The benefits and limitations of testing should be discussed with the patient so that an informed decision regarding screening is made.⁹¹ The US Preventative Service Task Force 2012 updated guidelines recommend against PSA screening for prostate cancer regardless of age.⁹² We agree with the AGS and suggest that the risks and benefits of screening be discussed only in men with life expectancies greater than 10 years.⁹³

Colon cancer

The ACS recommends that adults at average risk begin screening for colorectal cancer at 50 years of age. There are many options for colon cancer screening including annual fecal occult blood testing, flexible sigmoidoscopy every 5 years, annual fecal occult blood testing plus flexible sigmoidoscopy every 5 years, colonoscopy every 10 years, or double contrast barium enema every 5 years.⁸⁹ The US Preventative Services Task Force acknowledges the appropriate age at which to discontinue colorectal cancer screening is unknown, because screening studies have generally been restricted to patients younger than the age of 80.⁹⁴ They recommend discontinuing screening in patients whose age or comorbid conditions limit life expectancy.⁹⁵ We side with the AGS and do not recommend screening patients with life expectancies of less than 10 years.⁹³

Lung cancer

The ACS recommends lung cancer screening in current and former smokers aged 55–74 in good health and with a 30 pack-year history.⁹¹ The risks and benefits of screening need to be carefully explained in this population⁹⁶ and smoking cessation should be the highest priority. The American Association for

Thoracic surgery and the USPSTF increased the upper age limit for screening to age 79 and age 80, respectively.^{97, 98} We concur with extending the upper age limit to 80 years of age.

Treatment tolerance of the older patient

Surgery

Surgery is the primary treatment for the majority of solid tumors. Failure to obtain definitive surgical treatment is associated with an increased mortality from disease regardless of age. For example, in a study performed by the Cancer Research UK Breast Cancer Trials Group, 455 women older than 70 years of age, with operable breast cancer, were randomized to treatment with tamoxifen alone versus tamoxifen plus surgery. At 12.7 years of follow-up, women who did not undergo surgery had an increase in breast cancer mortality (Hazard ratio 1.68; 95% CI 1.15–2.47).⁹⁹ Therefore, if possible, older women should undergo primary surgical removal of breast cancer in order to decrease their risk of breast cancer mortality.

Several studies have demonstrated that advanced age alone should not be a reason to deny surgical treatment for colorectal cancer.^{100–103} Risk of surgical morbidity and mortality is increased with intra-abdominal surgery or those performed under an emergency situation; however, even in these high-risk situations, older patients benefit from surgical management. In a study of emergency colorectal surgery, older and younger patients had a similar primary resection rate (95% > age 70, 89% ≤ age 70; $p = 0.70$) and primary anastomosis rate (84% > age 70, 78% ≤ age 70; $p = 0.64$). Older patients had a higher incidence of postoperative cardiopulmonary complications but no statistically significant difference in mortality (9% > age 70, 5% ≤ age 70; $p = 0.48$).¹⁰⁰ The PACE tool utilizes geriatric assessment items to identify older adults with cancer at risk for surgical complications.^{104, 105}

Radiation therapy

Radiation therapy is commonly used for both curative and palliative intent in the older patient. Studies have demonstrated that treatment tolerance in younger and older patients is similar.^{106, 107} In a study of 1208 patients receiving thoracic irradiation, age had no impact on the acute or late radiation toxicities. Patients were divided into 6 age groups, ranging from <50 to >70. There was no significant difference in acute toxicities such as nausea, dyspnea, esophagitis, or weakness and there was no significant difference in survival between age groups ($p = 0.82$). Older patients were more likely to experience weight loss than younger patients ($p = 0.002$).¹⁰⁷ Therefore, close attention should be paid to nutritional status in older patients receiving radiation.

Treatment tolerance to radiation and efficacy of radiation therapy in the “oldest old” patient has also been demonstrated. In a retrospective review of 191 patients ≥ age of 80, 94% were able to complete treatment without complications. A response to treatment was seen in 77% of patients treated for curative intent and 81% of patients treated for palliative intent. Six percent of patients required treatment interruption, secondary to weight loss from diarrhea, dysphagia, or progressive disease. This occurred more commonly in patients who were treated with large treatment fields. Of patients receiving treatment for aero-digestive tract cancer, 20% of patients had grade 3 mucositis and 2% of patients had grade 4 mucositis, reinforcing the need for careful attention to nutritional status and weight loss in older patients.¹⁰⁸

Other studies have sought to determine whether there is a subgroup of older patients with low risk disease

in which radiation therapy can be eliminated. A study performed by the CALGB randomized 636 women aged 70 and older with clinical stage I, estrogen-receptor-positive breast cancer who underwent a lumpectomy to treatment with radiation to the affected breast and tamoxifen, or tamoxifen alone. The women treated with tamoxifen alone had more locoregional recurrences at 5 years of follow-up: 4% in the tamoxifen alone arm versus 1% in the tamoxifen and radiation arm ($p < 0.001$); however, there was no difference in breast cancer-specific mortality or 5-year rates of overall survival.¹⁰⁹

Chemotherapy

Several studies have sought to determine whether treatment on chemotherapy trials is more toxic for older patients.¹¹⁰ A study by the Piedmont Oncology Association was a case control study of women with metastatic breast cancer enrolled on clinical trials. The women were divided into three groups, by age: <50, 50 to 69, and >70. The study demonstrated that older women receiving treatment on clinical trial had no significant difference in the incidence of toxic effects, dose delivery, or dose delays in comparison to younger women. In addition, there was no difference in response, time to disease progression, or survival. Therefore, older women who received treatment on clinical trial not only tolerated the treatment but also equally benefited from this treatment.¹¹¹ An analysis of phase II trials at Illinois Cancer Center found similar results. Older and younger patients had no difference in toxic effects, need for dose reduction, or need for treatment interruption or delay. In addition, there was no difference in response to treatment.¹¹² In contrast, an analysis of three CALGB clinical trials for the adjuvant treatment of patient with node-positive breast cancer demonstrated that older adults were more likely to experience a grade 4 hematologic toxicity and were more likely to discontinue therapy because of toxicity. In addition, older adults were more likely to die of acute myelogenous leukemia or myelodysplastic syndrome.¹¹³

A limitation in interpreting these studies is that geriatric assessment information was not collected. Therefore, it is not clear whether the older patients who enrolled on these clinical trials are representative of the patients cared for in everyday practice. As so few older patients are offered entry on clinical trial, the older patients represented on clinical trials may have a younger “functional age.” Therefore, incorporating geriatric assessment into clinical trials would be a valuable way of standardizing possible confounding factors across patients of the same chronological age, helping to determine the “functional age” of the patients represented. Clinical trials focusing on the older patient are needed in order to optimize care of this patient population. Developing a registry of older patients with selected diseases (breast cancer, colon cancer, intermediate grade lymphoma, etc.) and treated with chemotherapy with curative intent would provide a database with which to evaluate patterns of care and outcomes.

Survivorship

Accompanying the increasing number of older people with cancer and improvements in treatment, the number of older cancer survivors is also increasing. It is estimated that by 2020 two-thirds of cancer survivors will be over the age of 65. The aging cancer survivor is dealing with the simultaneous and often interacting impact of their aging physiology, the accumulation of multiple chronic conditions, geriatric syndromes, the after effects of cancer, and the late effects of cancer treatment.¹¹⁴ The latter's impact on multiple organ systems may to an extent mimic the aging phenotype.¹¹⁴ The management of this challenging situation requires a coordinated effort among oncologists and primary care providers with effective information exchange. A shared geriatrics-oriented survivorship care plan, fueled by a comprehensive geriatric assessment, may be the most effective way to accomplish this.^{115, 116} The patient has a role to play as well and using the cancer survivorship status as a teachable moment, improved outcomes can be

Conclusions

Cancer is a disease that disproportionately affects older patients. Data regarding the care of these patients are limited secondary to the underrepresentation of older patients on clinical trials. In moving forward, an effort should be made to include older patients on clinical trial, in order to increase our understanding about the optimal way to care for this growing population. Incorporation of geriatric assessment in the care of the older patient will provide information regarding prognostic factors that distinguish two individuals of the same chronological age, thereby helping us understand “functional age” and risk of chemotherapy side effects. Brief, comprehensive geriatric assessment screening tools for older oncology patients have been developed.

Chapter 74

Disparities in cancer care

Otis W. Brawley, MD, MACP

Overview

Differences in healthcare outcome have become increasingly apparent over the past 50 years. It is especially apparent in cancer, a discipline that has had tremendous advancement. Ironically, the more progress that is made, the greater the disparities become. There are populations that do not enjoy the progress usually because of socioeconomic differences. The field of health disparities has grown into its own discipline within epidemiology. It involves population categorization by race, area of geographic origin, socioeconomic status, and so on. The discipline looks at differences in risk of cancer, risk of death, survival, and the survival experience.

A number of well-designed studies show that equal treatment yields equal outcome among equal patients whether one categorizes population by race, socioeconomic status, or other major factors. If people with the same genetic markers are compared, race for example is not a factor in outcome unless it is allowed to be. Numerous patterns of care studies demonstrate that there is not equal treatment by race in the United States. The discipline of health disparities has progressed to include assessment of interventions to reduce disparities.

The advent of precision medicine and tailored therapy will make categorization using genes and polymorphisms more important. The crude categories of race and ethnicity and even socioeconomic status will only be important in terms of social issues such as access to care and equality of treatment.

Social interventions to overcome disparities and bring about equity include efforts to (1) increase cultural competence and understanding of the patient among healthcare providers; (2) increase access to care; and (3) improve communications and educate those needing service.

Introduction

Over the past 50 years, there has been tremendous progress in healthcare and especially in the prevention and treatment of cancer. This progress has led to an increasing appreciation of the differences in outcomes among populations. The first studies to discuss the fact that some populations had higher rates of death from certain cancers were conducted in the late 1960s and published in the early 1970s.^{1, 2} These studies noted that Black-Americans have higher death rates than Whites. The area has grown to encompass other racial groups and the poor. As the issue became more broadly understood and the discipline matured, health disparities and health equity became a political issue. Indeed, the discipline was an influence on healthcare reform legislation, as well as legislation on the design and recruitment to US government funded clinical trials.

Reporting and understanding population differences in cancer incidence and outcome is important. The causes of cancer are both genetic and environmental. When the populations and the differences between

them are truly understood, reasonable hypothesis can be generated about the factors that cause or prevent cancer, as well as the factors that make cancers more or less aggressive. With rigorous careful study of the well-defined populations, one can also increase knowledge about the efficacy and effectiveness of preventive and treatment interventions.

The birth of a discipline

The US National Cancer Institute established the Surveillance, Epidemiology, and End Results (SEER) program in the early 1970s as part of the implementation of the National Cancer Act. This program collects cancer incidence and mortality data from a number of population-based registries around the United States. Before SEER, there was extremely limited cancer incidence data. Even today SEER does not provide a fully representative sample of the country for calculation of incidence rates. SEER publishes cancer incidence and mortality data as well as 5-year survival rates by race and gender annually. This data is publically available at www.cancer.gov/statistics.

Through its “Black–White Studies” in the 1980s and 1990s, SEER clearly documented Black–White racial disparities in cancer incidence, mortality, and survival. The SEER studies also demonstrated differences in treatment patterns with a higher proportion of Blacks getting inappropriate cancer care.

Interest in other diseases also contributed to the birth of the academic discipline. As cancer disparities were studied, disparities in cardiovascular disease, especially hypertension was also being defined. Interest in the genetic blood disorder known as sickle cell anemia was also increasing.

The discipline was first called “minority health research” and later “special populations' research.” It has now evolved into the field of “health disparities” and some are now even referring to it as “health equity.” As the field has matured, the questions have become better defined and some of the solutions better elucidated. It has remained the study of the underserved, those who do not receive adequate preventive and treatment services. Today, the field of health disparities is far more than cultural competence among healthcare providers and developing specific interventions to overcome health disparities. It is transdisciplinary integrating basic science, clinical science, epidemiology, and social science.

Defining health disparities

The National Cancer Institute (NCI) defines “cancer health disparities” as adverse differences in cancer incidence, cancer prevalence, cancer mortality, cancer survivorship, and burden of cancer or related health conditions that exist among specific population groups in the United States. Translated, disparities in health are the concept that some populations do worse than others.

Factors measured

Health disparities are differences between populations. A number of outcomes can be measured and compared. Most common are as follows:

Incidence—usually expressed as the number diagnosed with the disease in a given year per 100,000 in the population. Incidence rates are the equivalent of the population's risk of developing a disease. Individuals from groups with a higher incidence of a disease have a higher risk of getting that disease.

Mortality—usually expressed as the number dying due to the disease in a given year per 100,000 in the

population. Mortality rates are the equivalent of the population's risk of death from the disease. Individuals from groups with a higher mortality from a disease have a higher risk of dying from that disease.

Incidence and mortality are often “age adjusted” to a standard population to remove the effects of two populations having different age distributions. Age adjustment is also used to remove the effect of a population aging over time. Age is a risk factor for many cancers. A population having a higher age-adjusted incidence in 1990 compared to 1960 is not because there are more older people alive in that population in 1990 compared to 1960.

Survival rates—the median time from diagnosis to death for a cohort or the percent alive 5 years after diagnosis.

Prevalence—the proportion of a population that has a disease or risk factor for a disease.

Differences in patterns of care (screening and treatment) are also measured. This refers to the proportion of two or more groups getting a treatment standard to the condition. In more sophisticated analyses, it can be the proportion of a group getting high-quality treatment compared to another group.

Less commonly, and not in the NCI definition, disparities in morbidity, comorbid disease, and quality of life are measured outcomes.

Population categorization

While the field started by looking at Black and White race, it has evolved to the point that “populations” can be defined by race, ethnicity and culture, area of geographic origin, socioeconomic status (SES), and other factors. Clearly defining populations is extremely important in doing good health disparities research.

Race is a concept first put forth about 350 years ago. The initial categories were Caucasian, Negroid or African, and Mongoloid or Asian.³ These categories had to do with skin color, facial traits, and presumed geographic area of origin. Distinct racial groups do not exist. Based purely on visible traits, racial groups are overlapping populations. The anthropology community has never accepted race as a biologic categorization.

The US Office of Management and Budget (OMB) defines race for use in government collection of data. The OMB definition is used most importantly in the decennial census, but, by legislation, is also used to describe the populations enrolled in federally funded clinical trials.

The OMB directive specifically states that its racial categories reflect a social definition of race as recognized in the United States and that the definition is not an attempt to define race biologically, anthropologically, or genetically. The OMB racial definition has changed over time. A person from the Indian subcontinent of Asia who migrated to the United States before the 1950 census has been considered three different races over the past 65 years. The current definition was published in 1997 ([Table 1](#)).

Table 1 US Government definitions of race and ethnicity year 2000 census

White	A person having origins in any of the original peoples of Europe, the Middle East, or North Africa. It includes people who indicate their race as “White” or report entries such as Irish, German, Italian, Lebanese, Arab, Moroccan, or Caucasian
Black or African American	A person having origins in any of the Black racial groups of Africa. It includes people who indicate their race as “Black, African Am., or Negro”; or report entries such as African American, Kenyan, Nigerian, or Haitian
American Indian and Alaska Native	A person having origins in any of the original peoples of North and South America (including Central America) and who maintains tribal affiliation or community attachment. This category includes people who indicate their race as “American Indian or Alaska Native” or report entries such as Navajo, Blackfeet, Inupiat, Yup'ik, or Central American Indian groups or South American Indian groups
Asian	A person having origins in any of the original peoples of the Far East, Southeast Asia, or the Indian subcontinent including, for example, Cambodia, China, India, Japan, Korea, Malaysia, Pakistan, the Philippine Islands, Thailand, and Vietnam. It includes people who indicate their race as “Asian Indian,” “Chinese,” “Filipino,” “Korean,” “Japanese,” “Vietnamese,” and “Other Asian” or provide other detailed Asian responses
Native Hawaiian and Other Pacific Islander	A person having origins in any of the original peoples of Hawaii, Guam, Samoa, or other Pacific Islands. It includes people who indicate their race as “Native Hawaiian,” “Guamanian or Chamorro,” “Samoan,” and “Other Pacific Islander” or provide other detailed Pacific Islander responses

In collecting race data, the OMB has one “ethnicity” question. Ethnicity is defined by the OMB for government data as simply “Hispanic” or “non-Hispanic.”

The National Cancer Institute SEER Program and the National Center for Health Statistics of the Centers for Disease Control and Prevention publish health data using OMB definitions. They are dependent on US Census data for the denominators to calculate incidence and mortality rates. Mortality trends by OMB Race/Ethnicity Criteria as published by the NCI SEER are plotted in [Figure 1](#). This plot uses the definition used in the 1990 census.

Figure 1 Age-Adjusted Cancer Mortality Rate 1990–2010 by 1990 OMB racial/ethnic category. Note: Age-adjusted mortality rates have declined significantly over the past 20 years for all but Native American/Alaskan Natives. The Native American/Alaskan Native (NA/AN), Hispanic and Asian-Islander (API) death rates are lower rates compared to Whites who have lower rates than Blacks. This graph uses the category Asian-Pacific Islander, which was the category used until 2000. Native Hawaiians are included in the Native American/Alaskan Native Category.

Race is a useful category to collect data if viewed as a social definition. Some populations do bear an unequal burden. There are civil rights issues such as discrimination and differences in access to care that determine outcomes.

Ethnicity and culture as used in academic study is a very broad term that encompasses human identity. It is not static or mutually exclusive. It is fluid and without definite boundaries. In social research, ethnic groups are distinguished by specifying the nature and source of human variation (e.g., behavior, lifestyle habits, and other environmental influences) and their relationship to health. When used appropriately, populations of one nationality can have a number of ethnicities.

This is a more scientific categorization than race as it relates to environmental influences such as diet and other extrinsic influences that may increase or decrease the likelihood of an illness. Even such habits as how one smokes cigarettes or engages in sexual activity are influenced by ethnicity and culture.

While ethnicity and culture is related to factors that cause cancer, there are also ethnic and cultural influences on one's acceptance of a disease and in how one seeks and accepts therapy.

Area of geographic origin is more scientific than race. Many confuse race and area of geographic origin and there is some overlap. Many people have several areas of geographic origin because of the commingling of populations over the centuries.

A number of genetic traits correlate with area of geographic origin. For example, sickle cell disease is a genetic disease of people from the Mediterranean basin and sub-Saharan Africa. There are people from Spain, Italy, Greece, Syria, Turkey, and Lebanon with Sickle cell disease. Natives of southern Africa do not have sickle cell disease. There are people who we consider White who get sickle cell disease and people who we consider Black who do not.

While a genetic trait can have a higher prevalence among people from a specific geographic area, it's important to realize while the prevalence can be higher, the people of that area likely do not monopolize that trait. For example, cystic fibrosis is more common among, but not exclusive to those originating in northern Europe and alcohol dehydrogenase deficiency is common, but not exclusive to those from Japan.

Ancestry is yet another way of categorizing populations. Ancestry is of course linked to race and area of geographic origin. Use of race can be especially problematic as people transcend racial boundaries. When one considers ancestry, it may be a bit easier to appreciate the effect of family and admixture. Genetic influences often parallel ancestry.

Some of the Black–White differences in breast and prostate cancer might be due to differences in genetics that better parallels ancestry or area of geographic origin more so than race.

SES is defined by education, income, and occupation. While the social determinants of health are extremely important, there is controversy over how well SES can be used to define the human condition. The European literature uses a concept called “deprivation.” The “deprivation index,” calculated during the decennial census in Scotland, takes a number of markers of wealth, education, and social status into account.⁴

SES or social deprivation determines where we live, birthing habits, diet, and even how or if we consume healthcare. Education is particularly important, Americans with the least education are more than twice as likely to die of cancer as compared to the most educated.^{5–7}

There can also be population differences in stage at diagnosis and differences in the distribution of pathologies by SES. Differences in the uptake of screening by SES can lead to a higher proportion of the wealthy being diagnosed with early-stage disease when compared to lower SES cohorts. A group of people who participate in screening and indeed are more likely to get high quality screening are more likely to do well. In a disease with substantial overdiagnosis, the differences can be even more dramatic.

Relationships among population categories

Race is perhaps better seen as a characteristic and not a category or subtype. Much emphasis is placed on racial groups and differences in outcome among racial groups. The emphasis is partly due to the American obsession with race and the fact that most American data on population differences is collected based on the US government definition of race. Outcomes data based on ethnicity, SES, or ancestry is not easily obtainable. While the racial categories are not based in biology, they do have some relevance for what they are, a sociopolitical construct that can be related to ethnicity, area of geographic origin and SES.

Unfortunately, the medical literature is filled with the “medicalization of race.” There are a number of papers to suggest that genetics defines differences among the races and these differences are the cause of a number of disparities.⁸ Some of these papers should be discussing ancestry, which is different from race, and others often ignore the fact that there are clear correlations between race and SES. Low SES can be a cause of disparity. Race can also correlate with ethnicity and culture, which leads to behavior. Some behaviors increase risk of disease.

While there can be a correlation between race and cancer outcomes, it is important to remember that correlation does not necessarily mean causation. Racial differences are often due to social issues such as discrimination in education and in the provision of healthcare. Many in medicine falsely consider race a biologic categorization, thinking of race to be defined by genes. Sickle cell disease is a genetic, inherited

condition. In the United States, it was and is still wrongly viewed as a “Black disease.” This helped reinforce many of the views regarding race, genetics, and risk of disease. We often hear about race as a biologic category influencing disease in the discussion of prostate cancer incidence and mortality or in the discussion of the higher prevalence of triple negative breast cancer in Black women compared to Whites.

There is a lack of well-defined universal terminology in describing the above-mentioned categories making it difficult to assemble information on disparate/underserved populations. SES often includes education and income and even measures of wealth, but neglects to capture status in the social hierarchy. The European social science concept, deprivation and the deprivation index, takes social hierarchy and SES into account. It is a more precise tool than SES for measuring social situation.

Even using the crude measure of SES, there are clear correlations between race and SES. As a result, the effect of SES on risk of a bad health outcome is often and can easily be misattributed to race. Indeed, researchers often toss a SES measure into a model without considering the potential cause or contributory role or conclude that a racial/ethnic difference must be genetic or cultural after one or two SES measures are controlled for.

SES is often correlated with a higher risk of certain cancers because the poor have a higher prevalence of habits associated with disease risk. These habits are often due to poverty. For example:

- High caloric intake, lack of physical activity, and obesity are habits causally associated with more than a dozen cancers.⁹ It is estimated that this triad is responsible for nearly a third of all cancers in the United States and it is a growing problem internationally. Those with lower SES in the United States have a higher prevalence of obesity.¹⁰ The less educated and poor do tend to consume more calories per day. Processed calorie dense high-carbohydrate foods are less expensive than low calorie protein-rich foods.¹¹
- Lung cancer and a number of smoking-related cancers are more common in the poor versus the middle class. Adults living below the poverty line are more likely to smoke compared to adults in America's middle class (30% prevalence vs 6% of Americans with a college degree).¹²
- The poor or those of lower SES are less likely to engage in medical preventive services. Surveys show that they are less likely to receive commonly accepted screening for breast or colon cancer.¹³

SES, ethnicity, and culture can come together to increase cancer risk. It can lead to a cancer causing infectious disease to be endemic within a group of people, however defined. This can lead to increased risk of a cancer in that group. This has been seen in cervical cancer owing to human papilloma virus, especially in people lacking access to preventive services. The increased risk of hepatoma among people from southeast Asia is another example. It is linked to hepatitis B that has a high prevalence in that population.¹⁴ There are also studies to show that migration of cohorts from areas of low cancer risk in Asia to and acculturation in the United States increases risk of cancer within two generations.¹⁵

Disparities in treatment patterns

Many of the early health disparities studies focused on the fact that there are significant disparities in the quality of treatment received. In the initial studies, a higher proportion of Whites receive high-quality treatment compared to Blacks. Studies suggested that a number of factors lead to differences in treatment received.^{16, 17} Poverty, lack of insurance, or social disenfranchisement puts a patient at higher risk of receiving poor-quality healthcare or being underserved.¹⁸

Some patients:

- Decline therapy due to their culture discouraging acceptance or cultural differences with the healthcare provider.
- Do not adhere to prescribed regimens due to illiteracy or lack of medical sophistication.
- Do not adhere to prescribed therapy due to inconvenience of getting care.
- Cannot receive preferred more aggressive therapies due to comorbid diseases more common in disparate populations.
- Are not offered needed care due to racism or discrimination based on SES.

Awareness of these issues is extremely important and the biggest hurdle to overcoming them. Healthcare providers sensitive to these issues are often able to provide better service.¹⁹ There has been a move toward training physicians to provide “culturally competent” care.²⁰ The American Society of Clinical Oncology and others offer courses on communicating to patients from backgrounds different from the provider www.university.asco.org/cultural-competence-oncology-practice.

The fact that some groups are more likely to receive poor quality of treatment has been most rigorously studied in breast cancer. Lund et al.²¹ studied treatment patterns in metropolitan Atlanta over a 2-year period (2000 and 2001). Assessing women diagnosed with a localized breast cancer, they found that 7% of Black and 2% of White received no therapy within the first year after diagnosis.

Others have demonstrated that minority race, lack of education, lack of insurance, and lower SES are variables predicting for patients more likely to get inadequate care.^{17, 22} When these studies are assessed with logistic regression, regardless of race, less educated breast cancer patients are more likely to receive nonstandard breast cancer treatment regimens and less likely to receive adequate chemotherapy dosing.^{10, 23} Obese breast cancer patients are also less likely to receive adequate dosing of chemotherapy.

Disparities in quality of care lead to disparities in prognosis and treatment

While race does not appear to be the direct cause of these disparities in care given, race does translate into a higher proportion of Black or African-American Women receiving poor cancer treatment. This is because compared to Whites, a higher proportion of Black or African-American women have less than a high school education, and a higher proportion are obese. Approximately, 50% of Black women are obese compared to 34% of Whites. The disparate treatment of the less educated, the poor and the obese translates into a higher proportion of Blacks receiving less than optimal care compared to Whites. Again, the difference between correlation and causation is important.

Variable access to quality care by race can lead to differences in outcome in unsuspecting ways and lead to erroneous assumptions. For example, there is a Black–White disparity in American colorectal cancer death rates. Blacks have higher mortality rates and inferior 5-year survival rates when compared to Whites at each stage. This has led some to suggest that colorectal cancer is more aggressive in Blacks. It should be noted that Black–White colorectal mortality rates were very similar in the 1970s and the disparity in death rate has increased every year since 1981. The mortality disparity is greater in 2011 than at anytime despite the decline in mortality rates for both races.

Patterns of care studies suggest that Blacks with stage 3 disease are less likely to receive adjuvant

chemotherapy and part of the disparity in stage 3 disease might be due to disparities in treatment. One might be tempted to stop here, but looking further, there are studies to show that Blacks tend to be treated in hospitals that are overcrowded and resource limited.²⁴ They are more likely to get fewer lymph nodes resected at surgery and they are less likely to have a thorough pathologic examination of those nodes. Translated, a proportion of the Blacks diagnosed with stage 1 and 2 cancer would have been diagnosed with stage 3 colorectal if they had received appropriate surgery and pathologic evaluation. These true stage 3 patients would improve the survival rates of Black stage 3 patients by their inclusion and improve the survival of Black stage 1 and 2 patients by their exclusion.

This is a classic Will Rogers' phenomenon.²⁵ Blacks of each stage have inferior 5-year survival because of disparities in treatment and staging. When assessed in an equal access system, racial differences in outcome decrease dramatically.²⁶

Genetic expression—race, ancestry, ethnicity, and culture

Still within colorectal stage with good treatment, there are disparities in outcome. Black survival is slightly inferior to White survival. EMAST, a marker of microsatellite instability, confers a poorer prognosis and is more common among Blacks or African-Americans. EMAST appears to be an acquired defect associated with inflammation.²⁷ The role of diet, microbiome, and accumulation of EMAST is an important issue when studying Black–White colon cancer disparities. This is an example of diet, an element of ethnicity and culture, paralleling race or ancestry and affecting the genetic expression and biologic behavior of a tumor.

Some extrinsic influences associated with race, ethnicity, and culture and even socioeconomics can affect genetic expression within a malignancy. A higher proportion of American White women are middle class and college educated. Middle class, college educated women often delay childbirth to establish a career. Having a first term pregnancy after the age of thirty is a risk factor, not just for breast cancer, but estrogen receptor positive breast cancer. Indeed, this is likely the reason that White American women have a higher incidence of breast cancer compared to Black American women. This is also the reason that White women have a higher incidence of estrogen receptor positive disease.²⁸

Studies of White breast cancer patients in the United States and Scotland suggest that middle class social status in childhood is associated with a higher risk of estrogen receptor positive breast cancer in adulthood. Poverty in childhood is associated with estrogen receptor negative disease in later life.^{29, 30} Differences in diet and patterns of weight gain in childhood are thought to be causal. Duration of breast feeding, number of children breast-fed, and length of breast feeding have all been correlated with a lowered risk of basal-like breast cancer, but not a reduced risk of better prognosis luminal A disease.³¹

In the United States, the Black and Hispanic female population has disproportionately high number who are overweight and obese. This may be due to ethnicity and culture as well as SES. Obesity, or more specifically weight gain in adulthood, is thought a risk factor for postmenopausal breast cancer.³² Differing pathologic trends seen in Black and White American women may be due to these influences.³¹

The understanding of the environmental influences associated with SES, ethnicity, and culture in the groups being compared can be especially useful. An understanding of the genetic polymorphisms and mutations (markers) that are associated with area of geographic origin and conserved because of ethnicity and culture is also helpful. As the field of epigenetics progresses, the affect of extrinsic influences will be even better appreciated.

Population and genetic differences

While evidence suggests that differences among broad ill-defined population categories have been overemphasized, there are intrinsic genetic differences between well-defined populations. Race is not the appropriate way to define those populations. Intrinsic genetics markers better correlate with ancestry, area of geographic origin, and sometimes with ethnicity and culture. Genetic differences correlated or associated with race should most often be considered familial or ancestral. A gene or series of genes can be conserved among families. Even then, the prevalence of a polymorphism or gene may be higher in a specific population, but that population is unlikely to monopolize that gene.³³

A closed society will conserve genetic traits within that society. Segregation on the basis of race, ethnicity and culture, area of geographic origin, or other factors can lead to preservation of a specific gene or series of genes in the segregated population. This is demonstrated in several genetic diseases such as Tay Sachs disease, cystic fibrosis, and sickle cell disease.³⁴ Each of these diseases has a higher prevalence in, but is not exclusive to, a specific group.

Perhaps the best example is that of BRCA mutations. Women with certain mutations of the BRCA-1 and BRCA-2 genes are at higher risk than average risk for the development of breast and ovarian cancer. Mutations of BRCA-1 and BRCA-2 have been found in women of all races, but three specific mutations are common, but not exclusive, to people who identify themselves as being of Ashkenazi Jewish ancestry.^{33, 35} Population modeling suggests that these specific mutations are linked to a small number of individuals living about 1000–1200 years ago. These mutations are considered ancestral and are common among Jewish families owing to ethnic segregation among families.

Pharmacogenomics

There is clinically relevant variability in drug response due to differences in the enzymes that metabolize drugs. These differences can vary by populations as categorized by race, ethnicity, ancestry, and area of geographic origin or even at times SES. Extrinsic factors such as diet and use of some medicines can up or down regulate hepatic enzyme expression. The same pathways through which drugs are metabolized are often involved in the detoxification of environmental toxins and carcinogens, and thus variations in detoxification enzymes may lead to variations in cancer risk.

The physician is, of course, interested in how his or her individual patient metabolizes drugs to be prescribed. One can sometimes use a form of “population profiling” to assess an individual for certain common drug treatment issues. For example, approximately 10% of persons from certain areas of Asia develop severe cutaneous adverse reactions such as Stevens–Johnson Syndrome, when administered carbamazepine.³⁶ This might be a reasonable justification for avoiding use of carbamazepine in people whose ancestry includes an area of geographic origin in Malaysia, Singapore, Thailand, or India. If carbamazepine must be used, careful monitoring or testing for certain allele frequencies of HLA-B*1502 might be in order.

Tacrolimus has been well studied in renal transplant patients. This drug, which is structurally related to several anticancer drugs, is metabolized by CYP3A. In clinical use, some Black or African-American kidney transplant patients require higher tacrolimus doses to reach trough concentrations similar to those observed in White patients. This is due to differences in polymorphisms of CYP3A. Even within a specific group, there can be substantial variability in pharmacology. Within Blacks, there is a three to fivefold range in 12-h postdose tacrolimus concentrations.³⁷ Special attention to pharmacokinetics is

needed in all patients treated with this drug.

Among cancer drugs, population differences of polymorphisms of UGT1A1 affect the dosing and efficacy of irinotecan.³⁸ Indeed, some suggest pharmacogenetic testing before use of this drug. Differences in ABCG2 affect the dosing and efficacy of topotecan, irinotecan, mitoxantrone, doxorubicin, and methotrexate.³⁶

This is not a new concept, indeed in the genomic age, it is an old concept reapplied. For decades, we have appreciated that glucose-6-phosphate dehydrogenase (G6PD) deficiency is more common among people whose ancestry includes people of Mediterranean or Africa origin. Indeed, it is the most common human enzyme defect. Those with the deficiency are at risk of hemolysis when taking sulfa antibiotics, antimalarial, or certain other drugs.

US Government rules on minority inclusion in clinical trials

The US Government rules are the result of concerns that “racial minorities and women do not benefit from federally sponsored research because they do not participate in it.”

The clinical trialist doing research with funding from the US National Institute of Health must report the race and gender of patients accrued to trials on an annual basis. While the NIH is legally obligated to require this information for all phase 3 clinical trials, NIH and other government agencies often require this information for all their trials involving human subjects.

The NIH revitalization of 1993, Public Law 103-43, mandates inclusion of women and minorities in clinical research. Specifically, it states, “the Director of the NIH shall ensure that trials are designed and carried out in a manner sufficient to provide valid analysis of whether the variables being studied in the trial effect women or members of minority groups as the case may be differently than other subjects in the trial.” The stated goal of the legislation is to increase the opportunities for obtaining critically important information with which to enhance health and treat disease among all Americans and to detect and account for significant differences between genders or racial and ethnic groups where they exist and to identify more subtle differences that might warrant further exploration in targeted studies.³⁹

The Revitalization Act is interpreted as demanding diverse representation on Federally sponsored trials, especially phase III trials. The funded researcher must make a good faith effort to accrue minorities and women proportionate to the US population.³⁹

The legislation is controversial in that it is scientifically flawed. It calls for subset analysis to assess racial and ethnic differences. It uses race and ethnicity as if they define biological categories.³⁹ An additional issue is the legislation calls for subset analysis. A cardinal rule of clinical trialist is subset analyses are often wrong and should only be used to establish a hypothesis to be tested in a more rigorous study. A subset analysis is post hoc, retrospective, and underpowered. Power could be increased by oversampling minorities, but this creates ethical concerns in that a disproportionately greater number of minorities would be subjected to the risk of the study compared to majority Whites.

Interestingly, the law was written after a subset analysis of a study suggested that zidovudine was less effective among the Black or African population.^{40, 41} The result is many Blacks with HIV stopped taking or refused to start antiviral therapies. It was not widely appreciated that later studies showed that equal treatment yielded equal outcome among equal patients. A higher proportion of Black participants in the original study started therapy with more advanced HIV disease and were less likely to adhere to the prescribed regimen for social reasons.⁴² Factors associated with SES again causing a difference in

outcome which some interpreted as due to an inherent racial-biologic difference.

The lawmakers who wrote the NIH Revitalization assumed that disparities exist because the drugs and therapies used in the treatment of major diseases have not been tested in minorities and women. Some actually believed that disease like cancer are different in the different races. Other believed that drugs or therapies have different affects in Blacks versus Whites.⁴³ Ignored is an important fact; many of the racial differences are because minority and poor patients do not get the treatment that is known beneficial to them and treatments not administered certainly do not work.

If health disparities are to be overcome and we are to have equity, it is best to embed good disparities related research questions into cancer treatment, prevention, screening, and control trials. This can provide more robust statistical power to address important questions.

Diverse enrollment in clinical trials is important. In the study of interventions and outcomes, there is the concept of efficacy and effectiveness. Efficacy is how well an intervention works in an ideal clinical environment. Effectiveness is how well that intervention works in a “real-world” situation. It is important that persons from all communities participate in clinical trials. An effort to do research in the community where the majority of cancer care is provided is an effort to make results more broadly pertinent. Study of accrual to NCI funded treatment studies has for some time shown relative racial/ethnic balance in clinical trial enrollment and refusal rates.^{44, 45} Indeed, there is interest in inclusion of the elderly, people with comorbid diseases in clinical trials to get more realistic findings.⁴⁶

Summary

Health disparities or health equity research and programs are important. It is paramount that we carefully define our measures of outcome and the populations being compared. There are differences in disease incidence and outcome by population, however defined.

An important fact is a number of well-designed studies and meta-analysis of studies show that equal treatment yields equal outcome among equal patients.²⁶ If people with the same genetic markers are compared, race is not a factor in outcome unless it is allowed to be. Rarely discussed is the fact that numerous patterns of care studies demonstrate that there is not equal treatment. Often find the discussion focuses on is a particular breast cancer drug is as effective in Blacks as it is in Whites, but it is forgotten that a substantial proportion of Blacks do not get adequate treatment to include surgery as well as chemotherapy and radiation.

With scientific progress, our understanding of cancer improves. We better appreciate its causes, biologic behaviors, and treatments. We are quickly moving into an era of personalized medicine in which genetics and genomics become very relevant. The advent of precision medicine and tailored therapy will make categorization using genes and polymorphisms more important. The crude categories of race and ethnicity and even SES will only be important in terms of social issues such as access to care and equality of treatment.

Social interventions to overcome disparities and bring about equity include efforts to:

- Increase cultural competence and understanding of the patient among healthcare providers
- Increase access to care

Provision of insurance

Staffing community health centers

Attention to the patients social situation

- Improve communications and educate those needing service

Targeted messaging

Patient navigation

Chapter 75

Neoplasms in acquired immunodeficiency syndrome

Jeremy S. Abramson, MD, MMSc ■ David T. Scadden, MD

Overview

Immunodeficiency of multiple etiologies is associated with an increased risk of malignancy, particularly lymphoma. The risk is variable, depending on the severity and extent of the immunologic abnormality. In the setting of the acquired immunodeficiency syndrome (AIDS) secondary to human immunodeficiency virus type 1 (HIV-1) infection, the range of tumor types is more extensive. Yet, the tumors are generally associated with oncogenic viruses and may be considered secondary, opportunistic neoplasms. Etiologic factors contributing to them include poor control of oncogenic viruses, altered cytokine regulation owing to HIV effects on immune cells and tissue stimulation from other AIDS-associated events. The interplay of immunity, infection, and oncogenesis is central to AIDS-related malignancies.

The spectrum of the tumor types seen in the context of immunodeficiency extends beyond that of lymphoma, but is quite limited. There appears to be little interaction between the conditions that predispose to the emergence of epithelial malignancies seen in the general population and immunodeficiency. Rather, immunodeficiency tumors represent a narrow subset of neoplasms, some of which are seen with only very low incidence in the general population. For example, primary central nervous system (PCNS) lymphoma and Kaposi sarcoma (KS) are extremely rare entities in all but the immunodeficient population, where they compose a large proportion of tumors. In addition, the incidence of specific tumor types varies according to the immunodeficient state. Non-Hodgkin lymphoma (NHL) is a common theme among all of the immunodeficiencies, yet in AIDS there is a broader spectrum of histologic subtypes than are seen in other immunodeficient states. KS is increased in subgroups of patients with HIV-related and pharmacologically induced immunodeficiency. Cutaneous tumors are common in many immunodeficient states, but the increase in squamous cell tumors of the skin is higher in the post solid-organ-transplantation population than in those with HIV-related immunodeficiency. In the latter, papillomavirus-related squamous cell neoplasia of the anogenital region predominates ([Table 1](#)).

Table 1 Tumor types with increased incidence in HIV disease

Kaposi sarcoma
Non-Hodgkin lymphoma
Diffuse large B-cell lymphoma
Burkitt lymphoma
Plasmablastic lymphoma
Primary effusion lymphoma
Primary CNS lymphoma
Squamous cell neoplasia
Hodgkin lymphoma
Leiomyosarcoma (in children)
Plasmacytoma
Seminoma
Skin cancers
Lung cancer
Oropharyngeal cancer
Liver cancer
Prostate cancer

Shared among the tumors related to immunodeficient states is the frequent association with an infectious pathogen. The presence of Epstein–Barr virus (EBV) in immunodeficiency-related lymphomas is well known and likely a result of the direct stimulation that the virus provides to B-cell proliferation. In the absence of effective immunologic targeting of cells expressing EBV latency gene products, the overgrowth of cells may proceed unchecked, with the subsequent emergence of a transformed cell. This model for the direct ability of viruses to induce cell proliferation is a paradigm that may be applied to human papilloma virus (HPV)-related tumors as well. However, the model is less easily applied to the KS-associated herpesvirus/human herpesvirus-8 (KSHV/HHV8)-related tumors. The tumors associated with KSHV/HHV8 are more varied and are of less clear pathophysiologic relationship to viral gene products issues that are discussed in greater depth in sections that follow. In general, the tumors that do emerge in immunodeficiency are those in which a secondary pathogen can be implicated ([Table 2](#)). Immunodeficiency further leads to a failure of innate host tumor surveillance. In essence, the concept of inadequate immunologic control provides a unifying mechanism, and these tumors may be considered opportunistic malignancies, much the way in which specific infections are considered opportunistic infections. Indeed, the opportunistic malignancies of the immunocompromised patient represent the overlap between infectious diseases and oncology and provide unique insight into the intersection of immune function and tumor development.

Table 2 Secondary virus infections associated with AIDS-related malignancies

Virus	Tumor
EBV	NHL (PCNSL; most systemic DLBCL; PBL)
	HL
	Leiomyosarcoma (children)
KSHV/HHV8	KS
	NHL (PEL)
	Multicentric Castleman disease (premalignant)
HPV	Squamous cell neoplasia

Abbreviations: ARL, AIDS-related lymphoma; EBV, Epstein–Barr virus HL, Hodgkin lymphoma; HPV, human papillomavirus; KS, Kaposi sarcoma; KSHV, Kaposi sarcoma herpesvirus; NHL, non-Hodgkin lymphoma; PCNS, primary central nervous system; PBL, plasmablastic lymphoma; PEL, primary effusion lymphoma; DLBCL, diffuse large B-cell lymphoma.

Epidemiology

The spectrum of tumors in the context of HIV-1 infection varies on the basis of risk group and is substantially affected by the use of modern combination antiretroviral therapy (cART).

Pre-cART

cART did not become available until 1996, with the introduction of the protease-inhibitor class of anti-HIV medications. Widespread use of protease inhibitors occurred rapidly in the United States, Western Europe, and Australia, altering the death rate and complication rate of HIV disease. The spectrum of opportunistic diseases also changed,^{1, 2} with an impact on malignant disease, discussed in the section “Post-cART.” Given the ongoing lack of access to cART in much of the developing world, and the number of patients unable to take or having failed cART, the profile of AIDS-related malignancies in the pre-cART era is still of considerable importance.

One of the first manifestations of the AIDS epidemic was the cluster of cases of a rare malignancy among men who have sex with men in the coastal cities of the United States. That tumor, KS, was identified as an AIDS-defining illness with the first attempt at classifying the immunodeficiency syndrome by the Centers for Disease Control and Prevention (CDC).³ The prevalence of KS among HIV-infected patients was approximately 20% early in the AIDS epidemic, but clearly was noted to be highest among patients whose risk factor for HIV transmission was men having sex with men.⁴ KS prevalence was substantially lower in the groups infected by blood products or through parenteral drug use.⁵ Subsequent behavioral studies indicated that specific types of sexual practice, including promiscuity and oral–fecal contact,⁶ had the highest risk and substantiated the impression that KS might be a manifestation of a secondary, transmissible pathogen. Indeed, it was strong epidemiologic data that galvanized efforts to identify a pathogen and that led to the molecular cloning of the KSHV, also known as HHV8.⁷

The second most common malignancy, which was recognized in 1984 to be increased among young men who have sex with men, was NHL. This disease was added to the list of AIDS-defining complications in the first revision of the CDC criteria for AIDS. It was noted that lymphomas that occurred in this population were generally of high-grade histology and followed extremely aggressive clinical courses.

Unlike KS, this complication was much more broadly based in the risk groups for HIV infection. All groups had a high relative risk, estimated to be approximately 60-fold above that of the general population.^{6, 8–10} Subsets of infected individuals have been noted to have somewhat greater or lesser risk, such as the hemophiliac population, in which at least one study has noted an increased risk.^{6, 10} Similarly, it has been noted that risk among intravenous drug users or those from the Caribbean basin may be lower, but concern about confounding issues of care and surveillance complicate that analysis. However, the potential for important cofactors of lymphomagenesis within these subsets remains, and attention to this possibility may yield important information about the process of lymphocyte transformation.

The third most common malignancy occurring in the setting of HIV disease are anogenital squamous cell neoplasms, which are invariably associated with HPV infection of oncogenic serotypes. The majority, however, appear to be *in situ* carcinomas or high-grade intraepithelial neoplasia, while an increased incidence of invasive cancer remains controversial.^{11, 12} HPV-associated head and neck cancers may also be increasing in prevalence, related to the high seroprevalence of HPV, as well as additional concomitant risk factors for head and neck cancers including immunosuppression, tobacco, and alcohol use.

Post-cART

The introduction of cART has resulted in profound and dramatic changes in the nature of HIV disease. The inexorable decline in immune function and its attendant ravaging secondary infections and tumors in many cases is stopped, and indeed reversed, when combination therapy with protease inhibitors is introduced. The improvement in those patients with advanced disease has led to widespread use of the agents, including among those individuals who have recently acquired HIV-1 infection. The result has been a precipitous decline in the rate of death from AIDS in populations with access to the medications. Although death and debility from AIDS has decreased dramatically, there has not been a similar decline in new cases of HIV infection. Therefore, the total population with HIV infection in the West is rising, and those infected are living longer; globally, the epidemic goes unabated. Some changes in the epidemiology of malignancies in HIV infection have been immediately evident since cART was introduced, but the impact of longer periods of more modest immune dysfunction or even of the antiretroviral drugs themselves is only now becoming understood.

An observation immediately evident in the clinical care of patients with advanced HIV disease was the regression of KS following successful HIV suppression on cART. The impact on new cases of KS was also rapidly noticeable, and epidemiologic data have substantiated the magnitude of those clinically apparent effects. Multiple studies from sites in the United States, Europe, and Australia indicate the widespread decline in KS, with estimates of decline in incidence as high as 80-fold.^{13–16} The risk for development of KS, both pre- and post-cART, correlates directly with the depth of CD4 count suppression,¹⁷ though cases of KS in patients with increased CD4 counts are being increasingly reported in the post-cART era,^{18, 19} where the disease may be more localized to the skin of the lower extremities with less visceral dissemination, more akin to endemic KS seen in non-HIV-infected individuals in the Mediterranean basin.

As with KS, changes in the incidence of primary central nervous system lymphoma (PCNSL) are dramatic. Although this complication of advanced HIV disease was much less common than KS, and its decline was therefore less well documented, the impact in clinical terms has been comparable in magnitude. Cases are rarely seen except among those who have failed or have not been receiving antiretroviral therapy. This is a complication of severe immune suppression that, like the post-transplantation setting, is virtually uniformly associated with EBV detectable in tumor tissue. In general,

the EBV latency genes expressed in these tumors are type III or those of lymphoproliferative disease (EBNA1-6, LMP1, and LMP2).²⁰ These and other features distinguish PCNS lymphoma from other AIDS-related lymphomas (ARL) and may be the basis for clear differences in the impact of cART.

The incidence of systemic AIDS-related NHL has also decreased in the cART era, and the pattern of lymphoma subtypes in this population has also evolved.^{21–24} Early in the cART era, it became clear that there was significant variability in the impact of cART among lymphoma subtypes, with the greatest risk reduction seen in PCNSL and immunoblastic diffuse large B-cell lymphoma (DLBCL), while the incidence of Burkitt lymphoma (BL) and Hodgkin lymphoma (HL) did not decline.^{22, 25} One recent study of a cohort of 23,050 HIV-positive individuals in the United States found that 476 (2%) developed lymphoma between 1996 and 2010, among which 83% were NHLs and 17% were HL.²⁶ The most common subtype in the cART era is DLBCL, accounting for 42% of cases, and it is also the most common type of NHL in non-HIV-infected individuals. BL accounted for 12% of cases, which is a significantly greater proportion compared to the general population. PCNSL has declined the most dramatically in incidence compared to the pre-cART era, accounting for only 11% of NHLs in this cohort. The risk for most HIV-related lymphomas correlates directly with decline in CD4 count, though less so for BL and HL than other histologies.¹⁷ Median CD4 counts in DLBCL and BL in this modern cohort were 68 and 118 cells/ μ L, respectively. Reflecting the HIV-infected patient population in the pre-cART era, the median CD4 count was lowest in PCNSL in this modern analysis with a median of 14 cells/ μ L.

The differential impact of cART within lymphoma subsets highlights biologic differences between these tumor types and suggests differential immune participation in tumor development.

Kaposi sarcoma (KS)

It was the announcement of clustered cases of KS in Los Angeles and New York that made headlines and first brought the AIDS epidemic to public awareness in 1981.²⁷ Having originally been described by the Hungarian dermatologist Moritz Kaposi in 1872,²⁸ KS was regarded as a tumor that generally had an indolent course in elderly men of Mediterranean extraction, but which could be problematic in the context of immunosuppressive medication for organ transplantation. It was this latter association that helped focus attention on an immune alteration spreading among subcommunities in urban centers. Recognized as a common entity among HIV-positive men who have sex with men, but not among groups with other risk factors for HIV infection (such as blood product exposure),^{5, 25} it was long suspected as being related to a second cofactor.²⁹ A number of potential culprits were examined; none proved tenable until the identification of KSHV/HHV8. This virus was first recognized through the use of a genetic comparison of tissues from individuals with and without KS. A deoxyribonucleic acid (DNA) fragment that had partial homology with other members of the gamma-herpesvirus family was consistently noted.⁷ This subset of the herpesviruses includes several viruses with oncogenic potential, such as EBV, associated with a number of tumors and *herpesvirus saimiri* (HVS), associated with the ability to transform T cells. Because of the company KSHV/HHV8 kept and the high frequency of detectable signature DNA sequences in KS lesions, this virus rapidly and justifiably became the focus of investigation for a pathophysiologic basis of KS.

Viral epidemiology

KSHV/HHV8 is a 165-kilobase (kb) double-stranded DNA virus with features strongly supporting its causative role in clinical KS. There are data indicating that KSHV/HHV8 infection precedes tumor

formation,^{29, 30} that populations with high seroprevalence for KSHV/HHV8 are also those with a high incidence of KS,²⁵ and that the virus infects cell types within tumors.²⁹

The definition of prior exposure to KSHV/HHV8 depends on documentation of antibodies specifically reactive against the virus. There have been a number of assays that have been tested with variable results. Data indicate seropositivity estimated at 3.5% in North America, up to 25% in the peoples of the Mediterranean basin, and up to 89% in sub-Saharan African populations.^{31–33}

The much-suspected role of sexual transmission has been convincingly demonstrated in a longitudinal study of men in San Francisco over a 10-year period. Among exclusively heterosexual men, no KSHV/HHV8 seropositivity was detected; however, among men who have sex with men, the incidence of seroconversion was linearly related to the number of male sexual-intercourse contacts.³⁴ Men who had more than 250 sexual partners in the preceding 2 years had a seropositivity rate of 65%. Yet, sexual transmission is not the exclusive basis of virus spread. KSHV/HHV8 can be identified in saliva, and it is thought that oral transmission can rarely occur.³⁵ The higher incidence of KSHV/HHV8 seropositivity among family members in areas of endemic KS and given that children are often infected in sub-Saharan Africa indicate that nonsexual means of transmission do occur, but the specific basis is still to be fully defined.

Clinical manifestations

KS characteristically appears as pigmented macular-papular lesions on mucocutaneous surfaces ([Figures 1](#) and [2](#)). It is typically violaceous or erythematous in hue and may be associated with an ecchymotic halo. Typically, the lesions are multifocal and do not have a predictable order or pace of progression. Lesions may present as solitary nodules or plaques, but may also occur in clusters or simultaneously in multiple well-segregated sites. Although classic or endemic KS often favors the lower extremities, the pattern of involvement is much less predictable in the setting of HIV infection. Virtually any mucocutaneous site may be involved. On the face, the ears and nose are often affected, resulting in profound disfigurement. In addition to the disabling cosmetic effects of KS, lesions do occasionally become thick, uncomfortable plaques and can ulcerate with possible superinfection. Lesions are not generally destructive, however. The integument or mucous membrane overlying a lesion is most often intact, and deep invasion into muscle or bone generally does not occur.

Figure 1 Cutaneous Kaposi sarcoma in a white patient with advanced HIV disease. The violaceous plaques on the chest are of characteristic appearance. These lesions entirely resolved on paclitaxel chemotherapy and antiretroviral medication.

Figure 2 Kaposi sarcoma in an African American male with HIV-1 infection. Skin tone can make the lesions less readily distinguishable from other cutaneous processes and quite distinct from the appearance in lighter skinned individuals.

Edema often accompanies KS either locally or at a dependent site distal to KS lesions ([Figure 3](#)). The edema can be marked, with profound compromise of extremity mobility or occasionally with periorbital, peripubic, or genital edema. Two mechanisms are thought to contribute to the development of edema. One is the involvement of lymphatic vessels or lymph nodes with KS, thereby causing a mechanical obstruction to lymphatic flow. The other is the elaboration of permeability factors by KS lesions. The vessels that compose a KS lesion are themselves leaky, with extravasation of plasma proteins and cells into surrounding soft tissue. In addition, the vascular endothelial growth factor (VEGF) produced by KS

lesions can alter the integrity of surrounding otherwise-normal vessels, increasing their permeability, and, thus, their contribution of fluid to interstitial fluid. The increased demand on lymphatic drainage and the compromised egress of lymph results in thickened skin locally and frank edema distally.

Figure 3 Lower extremity involvement by Kaposi sarcoma can result in marked edema and limited mobility. This patient had pedal edema that had limited response to chemotherapy despite marked improvement in the circumferential Kaposi sarcoma.

Involvement of organs other than lymph nodes and skin occurs frequently. The most common site is the gastrointestinal (GI) tract, where mucosal-based lesions are commonly observed in the course of endoscopic examination. The physiologic significance of these lesions is often minimal, however. Most patients will be unaware of GI involvement, and serendipitous observation of a mucosal KS lesion should not trigger a reflex to undertake aggressive therapy. However, there are some individuals for whom GI KS can be a symptomatic and even life-threatening complication. Massive bleeding has been observed, as has intussusception.

Pulmonary involvement may take several forms. Pleural-surface studding with KS lesions can result in pleural effusions, which are often bloody, but which do not have a characteristic set of diagnostic findings or cytologic abnormalities. Bronchial mucosa may be involved and, like GI mucosal surfaces, may be incidentally noted during bronchoscopic examination. The lesions are generally not destructive; but depending on location, they may be responsible for bronchial irritation, coughing, and hemoptysis. Involvement of the parenchyma of the lung occurs and is arguably the most serious complication of KS, because it is associated with life-threatening respiratory compromise and a high mortality rate if unsatisfactorily treated.³⁶ Radiographically, involvement often takes the appearance of peribronchiolar cuffing on computed tomography (CT). Pathologically, this infiltration may extend into fine interstitial tissue and affect airspace function. This results in either a patchy or diffuse reticulonodular appearance on X-rays. The diagnosis of KS involvement of the lung is often difficult to firmly establish short of parenchymal thoracoscopic or open biopsy. Bronchoscopy is useful in assessing alternative infectious explanations for clinical findings and may identify mucosal lesions. However, mucosal lesions do not necessarily coincide with parenchymal infiltration, and transbronchial biopsy is often unrevealing. Notably, KS of the bronchial mucosa may coexist with opportunistic infections of the lung parenchyma, such as *Pneumocystis jiroveci* (*P. jiroveci*), cytomegalovirus (CMV) and others, so clinicians must maintain a broad differential diagnosis regarding lung findings in HIV patients, particularly with low CD4 counts. In some circumstances, the use of a therapeutic trial may also be helpful in establishing a presumptive diagnosis. If thorough microbiologic evaluation has been unrevealing, the chemotherapeutic agents discussed below have been well tolerated and associated with high rates of response, such that their use in select patients may be justified as a test for chemotherapy responsiveness of a parenchymal

infiltrate. Such a strategy is generally reserved for those patients in whom (1) there is a diagnosis of KS already established from involvement of other sites, (2) there are no symptoms suggesting infection, or (3) aggressive assessment for infection is negative and there are no other contraindications to cytotoxic chemotherapy.

In addition to lung, GI tract, and lymph nodes, special sites of concern are areas of the upper airway. Involvement of the mucosa of the mouth, sinuses, pharynx, and larynx can result in distortion of soft tissues such that airway compromise or alteration of food ingestion can occur. These are lesions that generally respond rapidly to therapy and do not invade deeper structures. Therapeutic approaches are discussed in the section “Treatment.”

Given the common involvement beyond the readily apparent skin or oral mucous membranes, extensive staging evaluations are often considered. Although the bulk of tumor does influence prognosis, other characteristics of the patient's immune and general health were incorporated into a KS staging system by the AIDS Clinical Trials Group (ACTG), based on pre-cART data on KS patients (Table 3).³⁸ In the cART era, tumor extent and concomitant systemic illness appear to be the most powerful predictors of prognosis in this model, with limited tumor involvement and lack of opportunistic infections predicting a 3-year overall survival of approximately 90%, compared to only 50% with extensive or visceral disease and presence of other HIV-related complications.³⁹ An alternative prognostic model has been proposed in the cART era based on multivariate analysis in 326 AIDS-associated KS patients, which identified four favorable prognostic variables by multivariate analysis: (1) having KS as the AIDS-defining illness, (2) increasing CD4 count, (3) age <50 years, and (4) absence of another AIDS-associated illness.⁴⁰ These variables generated risk scores predicting for 5-year overall survival ranging from 98% in the most favorable cohort, to only 8% in the least.

Table 3 Staging classification for AIDS-related Kaposi sarcoma

	Good risk^a	Poor risk (1)^b
Tumor (T)	Small tumor burden with limited involvement of one or more	Large tumor burden
		Oral
	Lymph nodes	Gastrointestinal
	Skin	Pulmonary
	Other ^c	Other visceral with involvement of tumor associated edema or ulceration
Immune system (I)	CD ⁴⁺ cells >200 mm ³	CD ⁴⁺ cells <200 mm ³
Systematic illness (S)	No opportunistic infection (including thrush), or B symptoms ^d	History of opportunistic infection or thrush B symptoms ^d
		Other HIV-related illness (e.g., NHL or other malignancy, neurologic disease, wasting syndrome)

^a All the parameters listed.

^b Any of the parameters listed.

^c Limited oral disease is confined to the palate and is not nodular.

^d B symptoms are unexplained fever, night sweats, weight loss of more than 10% of body weight, or diarrhea persisting for more than 2

weeks.

Abbreviations: HIV, human immunodeficiency virus; NHL, non-Hodgkin lymphoma.

Source: Krown 1989.³⁷

The staging performed at diagnosis is often based on clinical presentation, with radiographic studies limited to a chest x-ray unless symptoms dictate otherwise. Testing of stool for fecal occult blood is a reasonable screening test for GI involvement, though specificity is poor. If localizing symptoms do suggest organ involvement, then more extensive radiographic and procedural interventions are appropriate, but they cannot be recommended routinely. Criteria for staging do include assessment of the underlying HIV infection, and all patients should have a careful history regarding medications, other complications of HIV infections, and documentation of the CD4 count in the blood.

Establishing the diagnosis of KS generally depends on simple punch biopsy of the skin or a snip biopsy of mucosal surfaces. The CDC criteria for an AIDS-defining diagnosis of KS do not require histologic confirmation if assessment is by an experienced clinician. However, biopsy is strongly recommended, given the broad differential diagnosis for nonblanching lesions resembling KS,³⁸ including bacillary angiomatosis (usually caused by *Bartonella* infection, with increased frequency in advanced HIV-infection patients); hematoma; purpura; sarcoid plaques; lichen planus; pyogenic granuloma; mycosis fungoides; secondary syphilis; pityriasis rosea; drug-related erythema multiforme; prurigo nodularis; nevi; vascular lesions of the phakomatoses; epithelioid hemangioendothelioma; angiosarcoma; melanoma; and basal cell carcinoma.

Pathology and pathogenesis

The histologic appearance of KS belies its unclear association with the term “sarcoma.” No monomorphic array of mesenchymally derived cells is seen. Rather, the lesions are composed of endothelial cells lining ectatic vascular spaces surrounded by spindle cells of variable extent admixed with mononuclear immune cells and extravasated red blood cells. It is the red blood cells that provide the pigment to KS lesions and their breakdown that leads to the ecchymotic halo seen in actively growing lesions. The hemosiderin deposited locally yields a pigmented lesion that may remain even after effective therapy reverses the proliferative spindle and endothelial cell components. Cutaneous lesions are generally within the dermis and deep invasion to muscle is generally not seen.

The origins of the endothelial and spindle cell components remain controversial. The endothelial cells of KS lesions express the VEGF-C receptor characteristic of lymphatic endothelium and do not have detectable nitric oxide synthase, generally present in vascular endothelium.^{41, 42} The finding that the spindle cell expresses the mannose-binding receptor and CD68 suggests that the origin may be a macrophage-like cell type, perhaps emanating from the sinuses of secondary lymphoid organs and circulating in the blood before ultimately assuming its role in a KS lesion.⁴³

The difficulty in defining the cell of origin emanates from its complex histology and the limitations of the available *in vitro* or *in vivo* models. *In vitro* culture has been established for some cell types, and outgrowth of cell lines has been documented, although the relationship to the primary disease process is unclear. *In vivo* transplantation of KS tissue into immunodeficient mice has resulted in tumors, but these are of murine origin. The potential for cytokine elaboration driving lesion development was hypothesized, and studies have extensively characterized cytokine production by KS lesions.^{44–46} The cytokines, particularly VEGF and basic fibroblast growth factor (bFGF), may play a role in the paracrine or autocrine sustenance of KS. Antibodies to bFGF block the proliferation of KS cells and prevent them from entering the S-phase of the cell cycle, even in the presence of exogenous growth factors like the

interleukin (IL)-6–IL-6R complex, IL-10, tumor necrosis factor (TNF)- α , and oncostatin M.⁴⁷ But exogenous growth factors do not completely explain the phenotype and growth potential of KS cells, which overexpress the antiapoptotic *bcl-2* gene independently of any factors contained in conditioned medium from these cells.⁴⁸

KSHV/HHV8 appears necessary for the induction of KS and is found in KS lesions regardless of whether the underlying context is HIV disease, organ transplantation, or endemic KS. However, the specific mechanism by which the virus participates in the oncogenic process is unclear and does not readily fit into paradigms established by other virus-related neoplastic disease. The latent genes implicated in EBV-induced transformation do not have homologs in KSHV/HHV8. The genes of HVS, which are known to transform cells, have homology only in the genome of a KSHV/HHV8 gene, *K1*, that is capable of transforming an immortalized cell line.⁴⁹ However, this gene is not expressed in the latent phase of the KSHV/HHV8 life cycle. Similarly, a chemokine receptor-like KSHV/HHV8 gene product, open reading frame (ORF 74), is constitutively activated and is capable of transforming cells when transduced as a single gene; but it is also a lytic-phase gene.⁵⁰ The encoded viral G-protein-coupled receptor activates multiple signaling pathways including the phosphatidylinositol-3 kinase (PI3K)/AKT, mitogen-activated protein kinase (MAPK), and Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathways.^{51–53} These pathways exert protean antiapoptotic and proliferative effects that promote tumorigenesis. Two other gene products, K9 (a homolog of the interferon regulatory factor family) and K12 (with no clear gene family homology), are capable of transforming cell lines when transduced but are not expressed in latent phase.^{54–57} The lack of clear association with the latent phase would suggest that these gene products are not transforming in *cis*, but whether they may transform in *trans* cannot be excluded. A number of other mechanisms, including those that may be capable of acting at a distance, have been raised as possibilities for KSHV/HHV8. These include the chemokine-related gene products, vMIP-I (K6) and vMIP-II (K4), or the IL-6 homolog, K2. Each is capable of interacting with cognate receptors on target cells, either acting as agonists (K2 and K6) or antagonists (K4).^{58, 59} Finally, there are KSHV/HHV8 gene products that have antiapoptotic effects and that may enhance tumorigenicity. ORF 16 encodes a *bcl-2*-related gene product,⁶⁰ and ORF 71 (K131) encodes a functional member of the Fas-associated death domain-like IL-10-converting enzyme-inhibitory protein (FLIP) family of antiapoptotic genes.⁶¹ The vFLIP of KSHV/HHV8 protects cells from Fas-mediated cell death and can enhance tumor progression of cell lines transplanted *in vivo*. KSHV/HHV8 further induces transcription of hypoxia-induced factor 1 alpha (HIF1alpha) and HIF2alpha resulting in upregulation of the proangiogenic factor, VEGF, as well as other proangiogenic and antiapoptotic factors.^{62, 63} VEGF and VEGF receptors are richly expressed within KS lesions and appear to play a critical role in pathogenesis.^{64, 65} KSHV/HHV8 has further been shown to encode a microRNA that downregulates thrombospondin 1, a negative regulator of angiogenesis and tumor suppressor.⁶⁶ Thus, KSHV/HHV8 encodes a range of gene products with potential for altering the growth, death, and immunologic characteristics of infected cells. It is not clear which of these mechanisms will be seen to play a dominant role in oncogenesis; further investigations into the process will certainly lead to new insights into viral-induced tumors and open new avenues for therapeutic attack.

The prevalence of KS in populations, (1) that are HIV infected, (2) that have undergone solid organ transplantation, (3) that are aged, and (4) that are of Mediterranean extraction, or live in economically disadvantaged parts of tropical Africa, suggests that expression of a KS disease phenotype requires a degree of immunosuppression. The advent of cART for HIV infection treatment offers dramatic support to a central role for immune suppression: Complete remissions of cutaneous and pulmonary KS are well recognized in the context of increases in CD4 count and declines in HIV load induced by cART.^{67, 68}

Although HIV-induced immunodeficiency is only one type of immune abnormality that may predispose to KS, the relative risk among the population co-infected with HIV and KSHV/HHV8 is strikingly high, suggesting the potential for interaction between the two viruses in the pathogenesis of tumor. The HIV gene product, *tat*, affects KSHV/HHV8 replication itself,⁶⁹ alters cytokine and cytokine receptor expression in target cells, and leads to proangiogenic effects.^{70, 71} Expression of *tat* may induce the lytic phase of KSHV/HHV8, resulting in increased viral transcripts, IL6 production, and stimulation of the JAK/STAT proliferation pathway, which offers a pathophysiologic rationale for the preferential occurrence of KS in HIV-infected patients versus solid-organ transplant recipients and other immunosuppressed populations.⁵¹ Retrospective analysis of the incidence of KS among HIV-infected patients receiving antiherpesvirus medications has suggested a direct role of replicating KSHV/HHV8 in the pathologic process. In several studies, there was a decreased incidence of KS in patients treated with ganciclovir or foscarnet.^{72–75} Therefore, suppression of replicating virus appears to lower the risk of KS. A randomized controlled clinical trial of valganciclovir in HHV8 seropositive individuals has also been shown to significantly decrease HHV8 replication,⁷⁶ though benefits on clinically meaningful endpoints has yet to be established. Although transformation is generally associated with the latent phase of herpesvirus infection, control of the lytic phase (the only time at which the anti-herpesvirus medications have known activity) may limit the potential for transformation.

Control of virus by immunologic means also appears to be highly relevant to the risk of developing KS. It has long been known that there is an increased risk of KS in the context of multiple types of immunologic deficiency. The definition of epitopes of the virus that are recognized by cytotoxic T lymphocytes (CTLs) will allow for further definition of this important point and potentially lead to vaccine strategies.

Treatment

Treatment of KS should be guided by the impact of the tumor on the patient. The goals of treating this disease are to palliate symptoms, alleviate organ compromise, reduce edema, and improve quality of life and ultimately overall survival in affected patients. The variability in the course of HIV-infected patients with KS and the lack of clear association of tumor control with mortality suggests that aggressive therapy may not always be an appropriate response to the diagnosis of KS. This is particularly true among patients with advanced HIV disease or untreated HIV disease. In that setting, the toxicity of cytotoxic therapy may be daunting, and the potential therapeutic effect of anti-HIV medications is considerable. Suppressing HIV replication is associated with a rise in CD4 count, with attendant improvement in immunologic function, and also reduction in whatever the direct contribution of HIV to the pathophysiology of KS might be. The net result is a high frequency of clinical improvement among patients with established KS and, occasionally, complete eradication, simply by the introduction of cART. Therefore, for patients in whom the impact of KS is not organ threatening or profoundly symptomatic, a therapeutic trial of antiretroviral therapy alone is appropriate first-line therapy ([Figure 4](#)). This strategy was validated in a phase III placebo-controlled trial in sub-Saharan Africa, where 59 subjects were randomly assigned to cART alone or cART plus combination chemotherapy.⁷⁷ Subjects treated with chemotherapy had a higher overall response rate at 1 year (66% vs. 39%), but no difference in overall survival. CD4 count and quality of life improved in both arms, without a statistically significant difference.

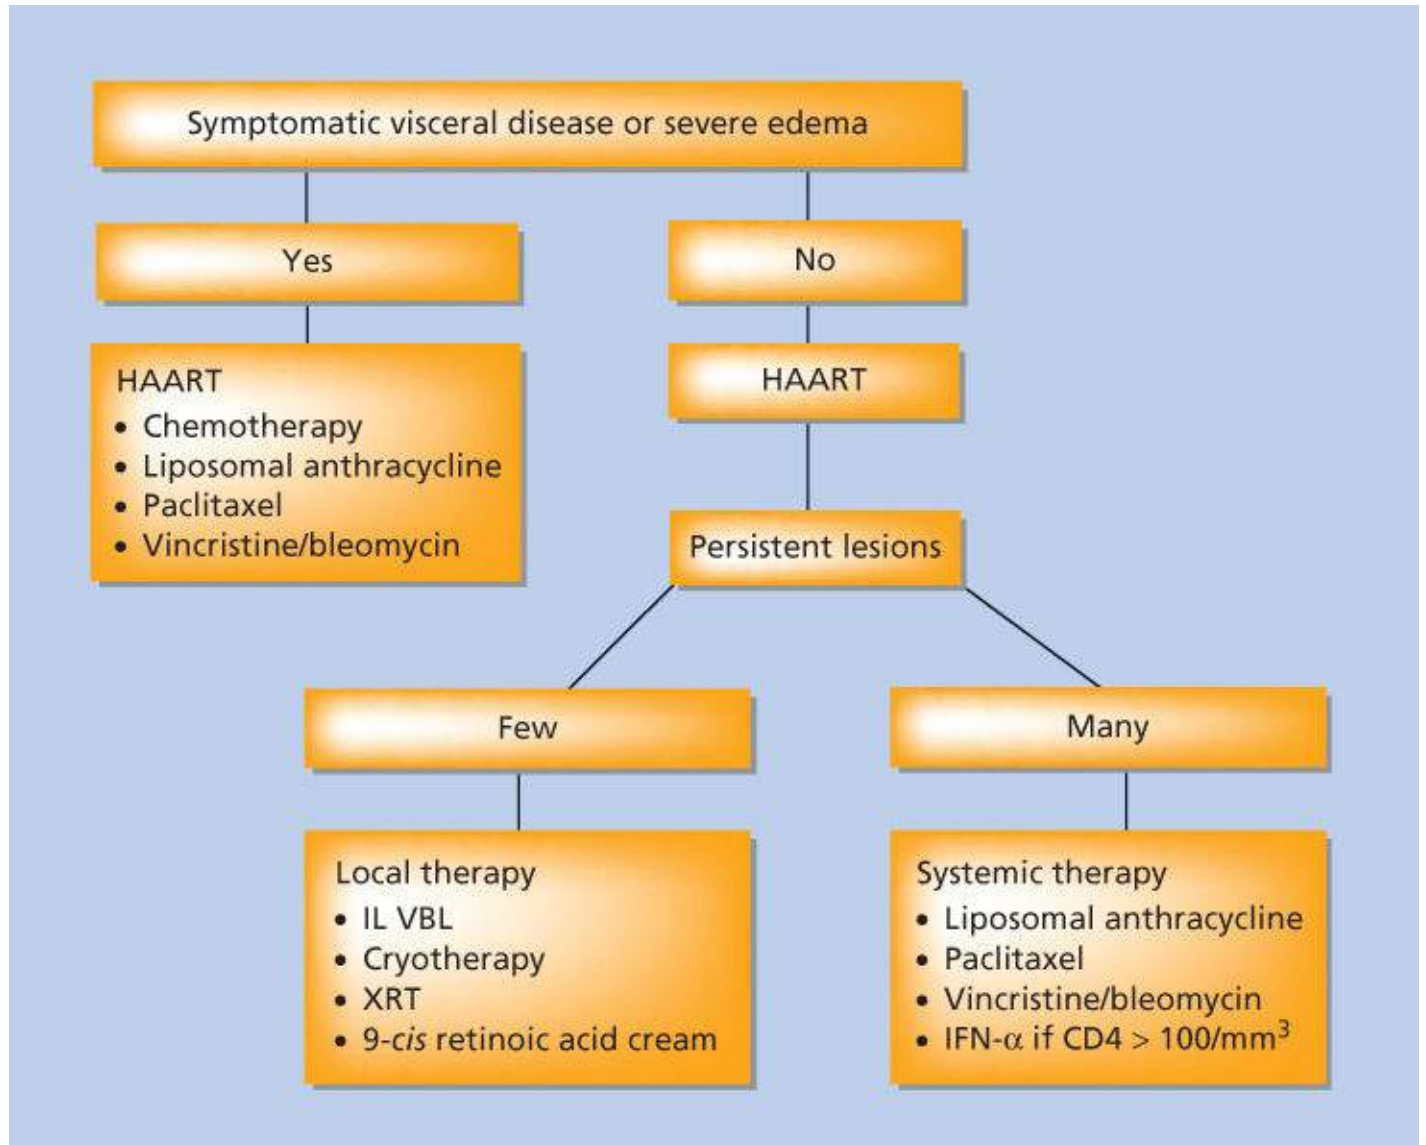

Figure 4 Treatment schema for patients with Kaposi sarcoma. *Abbreviations:* HAART, highly active antiretroviral therapy; IFN- α , interferon- α ; IL, interleukin; VBL, vinblastine; XRT, radiation therapy.

In patients with highly symptomatic or organ-threatening disease, a more aggressive approach is warranted, concurrent with cART. Though anti-HIV therapy is an important component in the treatment of HIV-related KS, it should be recognized that not all patients will experience an improvement in their KS with antiretroviral therapy, and that improvement, when it occurs, may only be noted only after 4–8 weeks of therapy. If the patients do not show an improvement in KS by 12 weeks of initiation of anti-HIV therapy, it is unlikely that their disease will be controlled by that intervention alone; additional treatment options must then be considered. Another important phenomenon is that some patients will experience a flare of their KS shortly after beginning cART, evidenced by a rapid increase in size and number of KS lesions. Such flares may be self-limited and can regress with ongoing cART; however, this warrants close attention by treating physicians and consideration of additional KS-directed therapy if a flare becomes clinically significant. In contrast to antiretroviral drugs for HIV, anti-herpesvirus medications do not appear to have a therapeutic role in the management of active KS, where objective responses to ganciclovir and valganciclovir have not been observed. Anti-herpesvirus agents currently available, therefore, cannot be recommended as anti-KS therapy at this time.

Local antitumor chemotherapy

Therapies directed at KS tumors can be divided into either local or systemic therapies. Local therapies

offer the benefit of deferring systemic chemotherapies and their attendant risks of increased immunosuppression in an already vulnerable patient population. The selection of a local therapy may be influenced by certain factors, such as the extent and location of the lesions (e.g., small, singular lesions on the trunk or on an extremity) and the rapidity of clinical change (e.g., indolent development of new lesions over months rather than weeks). Options for local therapy include intralesional injection of vinblastine, topical retinoid, radiotherapy and cryotherapy, among others.

For patients who have a small number of lesions that are unresponsive to anti-HIV medications, or who require more rapid improvement than the anti-HIV medications may offer, intralesional injection of vinblastine is a reasonable first-line approach. In particular, palatal or buccal mucosa lesions respond promptly to intralesional vinblastine.⁷⁸ Practitioners most commonly use vinblastine at 0.1–0.4 mg/mL, injecting approximately 0.1–0.2 mL into a 1 cm² lesion. Local discomfort may be considerable, and so the vinblastine may be admixed 1 : 1 with lidocaine to improve tolerability. Local reaction is generally modest, but skin breakdown can occur. Unfortunately, responses are usually short-lived, with most lesions progressing after a few months.

Topical 9-cis-retinoic acid (alitretinoin) gel has also been approved for treatment of cutaneous KS based on a randomized placebo-controlled trial in 139 patients, which demonstrated a sixfold higher response rate in the retinoic acid-treated group, as compared with the placebo-treated group.⁷⁹ The difficulty with this medication is its potential for inducing an irritating local reaction when applied to normal skin. Consequently, patients must be counseled to be fastidious in their application of the compound exclusively to affected skin. Even with such care, some patients develop local reactions that may be troubling. Responses are not immediate, and may not be observed for 1–2 months after initiation of treatment, so patience is required. Of note, the same compound appears to have activity when given systemically. In two open-label multicenter trials, the tumor response rate was nearly 40%.⁸⁰ Headache, dry skin, hyperlipidemia, and pancreatitis were notable toxicities.

Radiation therapy

Radiation therapy using either orthovoltage or electron beam may provide highly effective locoregional control of KS, even at relatively low doses. The great majority of treated patients will experience an objective response, many of which will be complete. A French study of 643 patients with AIDS-associated KS found a complete response rate of 92% when 20 Gy was delivered over 2 weeks, followed 2 weeks later with 10 Gy over 1 week.⁸¹ Modifications in dose schedule may reduce the complexity for patients. A 36-person study administered a total of 21 Gy in thrice weekly fractions for 2 weeks, achieving an overall response rate of 91% with complete response rate of 80%.⁸² Treatment with as little as one 8 Gy fraction has been reported to achieve a response in approximately three-quarters of patients.^{83, 84} Tolerance of therapy is generally good, though acute and late toxicities may occur including increased edema, ulceration, and chronic skin injury. Caution must be used when targeting mucous membranes, as the sensitivity of patients with AIDS to mucositis from radiation therapy appears to be heightened, and debilitating complications can occur.

Photodynamic therapy is an experimental modality employing light activation photosensitizing drugs to result in local tumor necrosis. A study of the photosensitizer photophrin in nearly 350 KS lesions yielded a 96% response rate, one-third of which were complete.⁸⁵

Cryotherapy

Liquid nitrogen cryotherapy has been evaluated in a phase II clinical trial for local control of cutaneous

KS.⁸⁶ Twenty patients had 2–4 lesions and could be treated every 3 weeks until achievement of maximal response. Complete responses were observed in 80% of lesions with an average of three treatments per lesion (range 1–8). A subsequent retrospective analysis of 30 patients reported a complete response rate in 63% of patients with a mean of 3 sessions required per patient, and many of the remissions were sustained.⁸⁷ Blistering occurs frequently with this technique, but bleeding, pain, and infection are uncommon. Liquid nitrogen cryotherapy can therefore be considered an effective and well-tolerated local therapy for discrete symptomatic KS lesions. Cosmetic effects of treating lesions in highly visible sites should be considered, however, as the blistering can be unsightly for days to weeks.

Systemic antitumor chemotherapy

Systemic therapy for KS is appropriate for advanced symptomatic disease, particularly for those patients with edema, extensive mucocutaneous disease, and pulmonary or symptomatic GI involvement. Type 1 interferons have demonstrated efficacy owing to their antiviral, antiproliferative, antiangiogenic, and pro-immunologic activities, though this treatment is rarely employed due to the slow onset of action and poor tolerability.⁸⁸ Single-agent and combination cytotoxic chemotherapies are most commonly employed for those patients with symptomatic or organ threatening disease who are not candidates for local therapy or cART alone. Effective agents in this disease include doxorubicin, bleomycin, etoposide, taxanes, the vinca alkaloids, and gemcitabine. Combination strategies with either bleomycin and vincristine (BV) or doxorubicin (adriamycin), bleomycin, and vincristine (ABV) initially demonstrated tumor response rates of 57–88%.^{89, 90} The definition of response to chemotherapy in KS has historically been more ambiguous than with most other tumors because of the limitations of the bidimensional measurement in cutaneous, mucosal, and visceral lesions. KS can undergo complete regression of identifiable tumor on histology, yet the region of hyperpigmentation may not change in size. What does change is the nodularity of the lesion, the color characteristics (from a violaceous or salmon color to a gray-brown hemosiderin stain), and, when present initially, associated edema. Responses in the early literature are difficult to assess due to lack of uniform response criteria, while more recent studies have benefited by the introduction of standard response criteria initially defined within the ACTG and refined by a joint effort of the AIDS Malignancy Consortium, the National Cancer Institute, and the US Food and Drug Administration (FDA).

Combination cytotoxic therapy with ABV has served as a standard for comparison with newer treatment regimens. Although this regimen produces a substantial response rate, side effects are common, most prominently nausea, alopecia, fatigue, peripheral neuropathy, acral cyanosis, Raynaud phenomenon, cytopenias, and infection.⁹¹ These toxicities can be quite debilitating in a patient population on numerous other medications and often dealing with numerous other medical problems. The impetus for an active, but more easily tolerated, treatment program has therefore been particularly acute in KS. The liposomal encapsulated anthracyclines have provided that option and have emerged as a highly effective and tolerable treatment option. The leaky vasculature composing KS lesions predisposes to deposition of the drug, and lesion concentrations of drug have been shown to be almost an order of magnitude higher than in noninvolved tissue.⁹² Furthermore, the side effect profiles of these agents are more favorable. Two phase III studies with approximately 250 HIV-related KS patients in each found liposomal doxorubicin monotherapy superior to traditional cytotoxic combinations of either ABV or BV. Liposomal doxorubicin achieved responses in 46–58% of patients, compared to 25% with the traditional two- and three-drug combinations.^{93, 94} Time to response and tolerability were both improved in the liposomal doxorubicin-treated patients, as was health-related quality of life,⁹⁵ though survival differences were observed. A large randomized study comparing the traditional ABV combination with liposomal daunorubicin found the liposomal drug to have less toxicity, but the tumor response rate was equivalent and not as high as that

found for liposomal doxorubicin.⁹⁶ A small trial compared the liposomal formulations of doxorubicin and daunorubicin, with the liposomal doxorubicin appearing superior, but the trial was too small to draw definitive conclusions.⁹⁷ The overall body of evidence supports the use of liposomal doxorubicin as an initial chemotherapy of choice in advanced symptomatic KS; standard dosing is 20 mg/m² every 2–3 weeks until maximal response or unacceptable toxicity.

Taxanes act upon neoplastic cells by stabilizing microtubules, and have emerged as highly active, well-tolerated agents for KS. After showing encouraging activity and safety in a phase I trial,⁹⁸ phase II studies in previously treated patients with KS showed response rates of 56–71% with median durations of response of 9–10 months, longer than has been seen with any other therapy.⁹⁹ Responses are seen in anthracycline-treated patients, and patients can tolerate low-dose paclitaxel (100 mg/m² every 2 weeks) extremely well. Given the excellent efficacy and tolerability of paclitaxel, this was compared to liposomal doxorubicin in a randomized controlled trial as initial therapy.¹⁰⁰ Seventy-three patients were enrolled, three-quarters of whom were on concurrent cART. The overall response rates for paclitaxel and liposomal doxorubicin were 56% and 46%, respectively, which was not a statistically significant difference. The majority of patients in both arms who presented with pain or KS-associated edema had clinical improvement with their respective therapy. The median progression-free survival was 18 months for paclitaxel and 12 months for liposomal doxorubicin ($p = 0.66$). Overall survival was identical in both arms, and both agents were well tolerated overall. Based on the aggregated data, either liposomal doxorubicin or paclitaxel can be considered an appropriate frontline systemic therapy for KS, with the alternate agent reserved for therapy at relapse if required. At our center, we typically employ liposomal doxorubicin as frontline therapy if there are not contraindications to anthracycline use, and reserve paclitaxel for relapsed disease. For patients who quickly progress off therapy, paclitaxel can be continued as ongoing maintenance therapy; and some patients have received this therapy for over 2 years at our center, with ongoing excellent tumor control. The newer taxane, docetaxel, also has demonstrated efficacy in advanced KS, including patients who have previously received anthracyclines or even paclitaxel, though neutropenia has been a problem.^{101, 102} We currently would not recommend docetaxel outside of a clinical trial.

Novel therapies

The highly vascular nature of KS lesions and their ready accessibility to study have made KS a candidate disease for assessment of anti-angiogenesis agents. A number of clinical trials involving a range of different agents have occurred or are under way. Bevacizumab is a monoclonal antibody against VEGF-A that was evaluated in a phase II clinical trial of HIV-associated KS patients who did not respond to cART alone.¹⁰³ This was an overall high-risk population and the majority of patients had previously been treated with chemotherapy (most commonly liposomal doxorubicin), with a median time since last chemotherapy of 3 months. Bevacizumab was administered intravenously at 15 mg/kg on a 21-day cycle to a total of 17 subjects. The overall response rate was 31%, with 3 patients achieving a complete response. The median number of cycles administered was 10 (range 1–37), and the median time to progression was 8 months. Given the high-risk and pretreated nature of the study population, these results suggest encouraging activity of bevacizumab in HIV-associated KS. Studies combining bevacizumab with other agents are ongoing. The agent thalidomide has a number of properties, including inhibiting angiogenesis, and has been assessed in early-phase studies in patients with KS. A phase II study with 20 patients demonstrated partial responses in 8 patients and a median time to progression of 7 months.¹⁰⁴ Neutropenia, depression, somnolence, and neuropathy were notable toxicities. The next-generation agent lenalidomide has shown responses in case reports, and a prospective trial for lenalidomide in KS is

Membrane metalloproteinases (MMPs) are overexpressed in KS cells and may facilitate tumor invasion and metastasis.¹⁰⁷ The MMP inhibitor COL-3 demonstrated efficacy and safety in a 75-patient randomized phase II trial of low-dose and high-dose oral COL-3.¹⁰⁸ The overall response rate was 41% in the low-dose and 29% in the high-dose group, with responses correlating with decline in plasma MMP levels. Rashes and photosensitivity were the most frequent adverse events.

KSHV/HHV8 induces the PI3K/AKT/mTOR pathway, resulting in pro-proliferative and anti-apoptotic effects which contribute to KS pathogenesis.⁵³ Targeting of the mTOR pathway has therefore garnered attention as a rational therapeutic target in this disease. Enthusiasm for this strategy was generated by a report of 15 patients with KS post renal transplantation who had a striking 100% complete response rate when immunosuppression was changed from cyclosporine to sirolimus.¹⁰⁹ A small study by the AIDS Malignancy Consortium of seven subjects with HIV-associated KS on cART showed responses in three subjects, all of whom were on protease-inhibitor-containing therapy which resulted in higher sirolimus exposure.¹¹⁰ The drug was well tolerated and did not result in significant changes in HIV viral load or a significant decrease in CD4 counts. Additional data will hopefully further inform the role of this agent in HIV-associated KS.

Tyrosine kinase inhibitors have attracted attention as a possible treatment strategy in KS due to the role of platelet-derived growth factor (PDGF) and c-KIT activation in KS biology.^{111, 112} The AIDS Malignancy Consortium conducted a 30-person phase II trial of imatinib mesylate in HIV-associated KS.¹¹³ Seventy-seven percent of patients had prior cART, and 57% had prior chemotherapy for KS. The overall response rate was 33%, all partial responses, with a median time to response of 21 weeks. Among responders, the median duration of response was 9 months.

The viral process underlying KS and the relationship of the disease to immune function also suggests that immunologic approaches may ultimately have therapeutic value. KSHV/HHV8 can alter both macrophage and CTL function. Macrophage inhibitory chemokines are encoded by the virus and produced in KSHV/HHV8-infected cells. The cells also produce an OX-2 homolog termed K-14. OX-2 receptors are present on monocyte/macrophages and stimulation dampens the ability of macrophages to be activated by other stimuli. K14 is capable of reducing activated macrophage production of inflammatory cytokines, possibly restricting host response to KSHV/HHV8.¹¹⁴ In addition, KSHV/HHV8 encodes genes that alter the ability of infected cells to be targeted by CTLs. The K3 and K5 viral gene products limit CTL engagement of MHC class I molecules, and K5 also inhibits interaction with the coreceptor (B7) complex necessary for CTL activation.¹¹⁵ However, a number of reports have defined epitopes within KSHV/HHV8 gene products that are recognized by CTLs.^{116, 117} Definition of whether reactivity to certain epitopes associates with protection from disease and whether immune inhibitory pathways may be further considered if a vaccine or adoptive cell therapies become of interest in this disease.

Non-Hodgkin lymphoma (NHL)

Lymphoproliferation occurs in the context of immunodeficiency of many different types. It is a common complication in individuals born with congenital abnormalities of T-cell function, individuals receiving immunosuppressive medications for organ transplantation, and in individuals with HIV infection. The common theme among these is the role of EBV going unchecked in its ability to induce B-cell proliferation. However, only a minority of ARL resembles the lymphoproliferative disease of the congenital or post-transplantation setting. ARL comprises a complex set of tumors with challenging

clinical scenarios. It has been, and remains, the most lethal complication of HIV infection, demanding new approaches and new understanding of the pathophysiology underlying it. The most common ARL is DLBCL, followed by BL, PCNSL, primary effusion lymphoma (PEL) plasmablastic lymphoma (PBL), and rarely peripheral T-cell lymphomas (PTCL). These entities show significant variation in incidence based on the depth of HIV-related immunosuppression.

Epidemiology

The association of NHL with HIV infection was evident within the first half-decade of the AIDS epidemic, when an unusual number of lymphomas among young men became evident in cancer registries in California. The first revision of the definition of AIDS by the CDC, in 1987, included NHL, and it has remained an important and devastating manifestation of HIV infection. Unlike KS, in which select subsets of HIV-infected individuals have a unique risk, NHL is more uniformly distributed among risk groups for HIV, with little variation. What variation is present may be attributable partly to issues of care.

The risk of NHL among HIV-infected individuals is in part determined by the level of immunosuppression, with higher risk noted among those with low CD4 cell counts; however, specific subsets of lymphoma have a stronger association with severe immunosuppression than others. The occurrence of PCNSL is restricted to those with very advanced immunodeficiency, as are the PEL and PBL subsets of systemic ARLs. These manifestations of profound immune dysfunction have significantly decreased in incidence since the advent of cART. Among the other ARLs, DLBCL has declined in incidence due to cART, but continues to be the most common ARL. Unlike other subtypes of ARL, BL occurs most commonly in the setting of preserved immune function, and constitutes an increasing proportion of ARLs over time as individuals enjoy longer lives with well-controlled HIV.^{26, 118} The median CD4 counts in most treatment reports of ARLs are in the range of 50–100 cells/mm³, with the BL group often having a CD4 count >200 cells/mm³. In contrast, reports of patients with PCNSL demonstrate profound CD4 count depression).^{26, 119} Thus, NHL may occur across a broad range of contexts in HIV disease, including those with virtually no other manifestations of immunosuppression, and may be the presenting illness of HIV infection. Possible unrecognized HIV infection should therefore be considered in any person presenting with an NHL histology that may occur in the context of HIV infection. The duration and severity of persistent immunosuppression is important in determining risk for developing an ARL, with a relative hazard of approximately 1.4 for each 50% decline in CD4 count. Reassuringly, as the CD4 count responds to cART, the risk of lymphoma reduces, but there is a lag time of approximately 1 year, somewhat longer than for other opportunistic diseases.²¹ Interestingly, the reduction in risk appears to proceed with longer time on cART in parallel and likely reflects the gradual repair in immune function seen over long periods of time on cART. Immune function is accompanied by HIV ribonucleic acid (RNA) level as a predictor of ARL risk. In the EuroSIDA study, each log of HIV RNA was associated with a relative hazard of 1.51.²¹ Therefore, controlling HIV is a critical determinant of ARL, presumably because of the immunologic alterations it engenders, though other pathophysiologic mechanisms may also participate.

Pathology and pathogenesis

The development of lymphoma among HIV-infected individuals is virtually always associated with transformation of a B cell, a cell type that HIV itself is unable to infect. Thus, HIV does not play a direct role in the development of most ARL; rather, it provides the background immunosuppression either for transforming viruses or for proliferative triggers for B cells to go unabated. The rare exception to this is a small subset of tumors of T-cell origin (PTCL).

HIV-associated PTCL is distinctly uncommon, but includes a spectrum of clinicopathologic entities.^{24, 120–122} In one subset, the HIV genome has been identified either in the T cells or in tumor-associated macrophages. Definition of the HIV chromosomal integration site revealed a preferential localization to a region upstream of the *c-fes* proto-oncogene, a finding that suggests a direct role for HIV in tumor pathogenesis.¹²³

Although HIV may not be present in any but the rare PTCL, other viruses are often present and play a crucial pathogenetic role in lymphomagenesis. Most notably, EBV is common in certain systemic ARLs and virtually all cases of PCNSL. The biology by which this gamma-herpesvirus exerts its effects is being unraveled through molecular analyses and perhaps is most clearly defined for the PCNS lymphomas and post-transplantation lymphoproliferative diseases (PTLDs). In that context, specific expression of latent virus genes is characteristic of a so-called type III pattern. These genes include the *LMP1*, *LMP2*, and *EBNA1* through *EBNA6*. The *LMP1* gene has been extensively studied as a potentially direct mediator of B-cell proliferation and has been shown to interact with the tumor necrosis factor receptor (TNFR)-signaling pathway.^{124, 125} *LMP1* is expressed in primary tumor tissue from patients with PTLD and ARL and is associated with activation of NFκB, a critical regulator of survival in normal and malignant B cells.¹²⁶ *LMP1* is a six-transmembrane-spanning molecule with a cytoplasmic carboxy terminus capable of interacting with the TNFR II-associated factors (TRAFs) that mediate downstream transcription factor activation.^{125, 127, 128} Aggregation of the cytoplasmic domains of *LMP1* mimic activated TNFR II, thereby providing a stimulus resembling constitutively activated receptor.¹²⁹ The activated pathways are similar to those of the TNFR family member CD30, involving the transcriptional regulators NFκB and cjun.^{129, 130} Potential downstream targets of these regulators are the pro-proliferative cytokines, IL-6 and IL-10.

A number of mutations within the carboxy terminus of *LMP1* have been noted, and there are some data to support the possibility that these are associated with HIV-associated NHL and HL.^{129, 131–133} However, other studies have indicated that the frequency of such mutations is no greater among those with lymphoproliferative disease than it is among patients in an unaffected control group.¹³² The concept that molecular evolution of persistent EBV infection may lead to alteration in the malignant potential of select latently infected B cells is an appealing hypothesis that remains speculative at this time.

The proportion of tumors associated with EBV varies by histologic subtype. EBV is present in virtually all cases of PCNSL and PBL, and in approximately 80% and 30% of HIV-related DLBCL and BL, respectively.^{134–137} This finding leaves a large fraction of systemic ARLs without a clear association with an oncogenic virus; among these, however, a small proportion is linked to KSHV/HHV8. PEL is a unique ARL subtype typically seen in patients with profound immunosuppression, and presents as a fluid collection without tumor mass in the involved body cavity, which may be the pleural space, peritoneum, or pericardium.¹³⁸ The tumor cells generally do not express most B-, T-, or even hematopoietic-cell surface markers (they are CD45, CD3, and CD19 negative). Molecular analysis of the cells demonstrates that they have undergone immunoglobulin gene rearrangement consistent with an origin in the B-cell lineage. All such tumors identified to date include the KSHV/HHV8 genome, and most have evidence of EBV co-infection. Notably, nearly all cases of PEL express the CD30 surface antigen. CD30 is the target of brentuximab vedotin, and anti-CD30 monoclonal antibody covalently bound to the microtubule toxin monomethyl auristatin E (MMAE). This drug is FDA approved for other relapsed CD30-expressing lymphomas, HL, and anaplastic large cell lymphoma. Based on the CD30 expression in PEL, brentuximab vedotin was evaluated in PEL cell lines where it resulted in decreased proliferation and apoptosis.¹³⁹ *In vivo* evaluation in mouse xenografts with PEL cell lines resulted in tumor progression and prolonged survival. These intriguing *in vivo* and xenograft data warrant clinical evaluation of brentuximab vedotin in

this rare but currently unmet medical need.

The ability of KSHV/HHV8 to infect B cells *in vitro* has been shown, whereas the impact of that infection has been difficult to discern *in vitro*. No clear association of virus infection with altered B-cell growth kinetics, as with EBV, has been noted with KSHV/HHV8. However, the close clinical and pathologic relationship of KSHV/HHV8 to PEL is compelling evidence for a direct relationship between KSHV/HHV8 and B-cell oncogenesis. PEL cells are latently infected with KSHV/HHV8, and so latent gene products likely play a dominant role in disease pathogenesis. Specifically, LANA-1, LANA-2, v-cyclin, v-FLIP, and viral IL6 are all transcribed from a common promoter and are constitutively expressed in PEL cells, where they promote cellular proliferation and survival through various mechanisms.¹⁴⁰

Among the possible contributions of viruses to malignant transformation is alteration in the immunologic reactivity to neoplastic cells. Mechanisms include the ability of EBV EBNA1 to alter antigen-processing pathways and thereby potentially mask EBV-infected cells from CTL reactivity.¹⁴¹ Although the specific details of the mechanism remain to be elucidated, it appears that KSHV/HHV8 exerts a similar effect on infected transformed cells. In addition, viral gene products may be elaborated by infected cells and may impact immune effector cells. For example, EBV encodes a viral IL-10 homolog (BRCF-1) with biologic activity, mimicking that of endogenous IL-10.¹⁴² Cell lines and tumors from AIDS patients and animal models of ARL indicate that IL-10 is produced,^{142–145} and that it potentially exerts an inhibitory influence on the T-helper cell (TH1) response. IL-10 potently suppresses interferon- α and IL-2 production by effector cells of the TH1 response and is a B-cell mitogen.

Other cytokines potentially participating in altered reactivity to malignant cells include IL-6, which, in addition to serving as a proliferative stimulus to B cells, may act to alter cell sensitivity to immune killing. Specifically, IL-6 has been shown to reduce the ability of EBV-positive cells to be lysed by antigen-specific CTL from HIV-1–positive individuals.¹⁴⁶ IL-6 levels have been noted to be elevated in the serum of patients with AIDS and may be associated with the development of NHL.¹⁴⁷ The CD40 and CD40 ligand (CD40L) interaction has also been hypothesized to participate in the development of HIV-related lymphomas. Activation of this TNFR family pathway alters the proliferation, differentiation, and survival of B cells that serve as a key mechanism of interaction of the B- and T-cell-mediated immune mechanisms. The infection of microvascular endothelial cells from the bone marrow and CNS has been shown to result in altered CD40 signaling that upregulates adhesive interactions with B cells and possibly explains the potential for extranodal lymphoma in HIV-infected individuals.¹⁴⁸

Chemokine pathways may also contribute to the unique susceptibility of HIV-infected patients for lymphomagenesis. Patients with a genetic variant in the CXC chemokine, stroma-derived growth factor-1 (SDF-1), have an excess risk of developing the BL subtype of ARL.¹⁴⁹ This chemokine is a known B-cell mitogen and by exerting chemokinetic effects, may contribute to a proliferative stimulus for patients with the genetic variant. The presence of this variant has been suggested to possibly provide a method of identifying those patients with increased risk of lymphoma, although the potential for this risk factor remains speculative at this time.

Genetic mutations in the tumor cells have been well characterized and are related to the specific histologic subtype. DLBCLs exhibit a *Bcl-6* rearrangement in approximately 33% of cases, a *c-myc* rearrangement in as high as 40%, and a TP53 mutation in approximately 25%.^{150, 151} In contrast, BLs seen in AIDS have *c-myc* rearrangements but not *Bcl-6*, and rarely have TP53 mutations.^{152–154} The presence of EBV is variably associated with either the *c-myc* or *Bcl-6* rearrangements in BL and DLBCL, respectively. The finding that rearranged *c-myc* gene juxtaposes with the immunoglobulin gene heavy

chain switch region suggests that the malignant event is occurring proximate to the time of immunoglobulin class switching. This relatively late event in B-cell ontogeny is indicative of transformation in a relatively mature germinal center B cell.

Clinical manifestations

ARLs are generally extremely aggressive, high-grade lymphomas. The presenting clinical features of systemic ARLs are similar to those of aggressive NHLs in the immunocompetent host, though HIV-infected patients are likelier to present with advanced-stage disease and frequent involvement of extranodal sites. Extranodal involvement occurs in the majority of patients,¹⁵⁵ and lymphoma restricted to extranodal sites may be seen in approximately half of the patients. Particular sites of involvement are favored by specific histologic types. Among those patients with BL, bone marrow and leptomeningeal disease occur in approximately one-quarter, while DLBCL favors the GI tract and liver as well as brain parenchyma and leptomeninges, though no extranodal site is immune from lymphoma involvement.

Systemic “B” symptoms of significant weight loss, fevers, and drenching night sweats are common. Given the immunosuppressed nature of these patients, a thorough microbiologic evaluation is required to exclude concomitant bacterial, mycobacterial, viral, fungal, or parasitic disease. KSHV/HHV8-associated multicentric Castleman disease (MCD) should also be considered in the differential diagnosis, as discussed below.

PEL is usually an end-stage complication of HIV-induced immunosuppression occurring generally with a CD4 count of <50 cells/mm³ and has occasionally been observed in other types of immunosuppression, including that associated with organ transplantation. The common sites of involvement with this tumor are the peritoneal cavity, pleural space, and pericardium.¹⁵⁶ Involvement of the bone marrow has been observed with progressive disease, and rare cases of extracavitary PEL do occur, usually involving other extranodal locations.^{157–159} The approach to this patient population is similar to any other systemic ARL, including evaluation of the CNS.

Plasma cell disorders are increased in the setting of HIV infection and are also fairly heterogeneous. Rare cases of highly aggressive PBL of the jaw and oral cavity occurs most frequently in severely immunosuppressed patients, usually with CD4 counts below 50 cells/mm³, but may occur in patients with less profound immune dysfunction.¹³⁶ Histopathology has indicated that these tumors mark as plasma cells with MUM1, CD138, and CD38 and are often negative for typical lymphoid markers, such as CD45 (leukocyte common antigen) and CD20. EBV is uniformly present with a lower frequency of KSHV/HHV8. PBL is a highly aggressive disease. The Ki67 proliferation fraction is usually $>90\%$, and MYC translocations are detected in approximately half of the patients.¹⁶⁰ Extramedullary plasmacytomas and overt multiple myeloma with paraprotein specific for HIV antigens have also been reported. Treatment of plasmacytoma and multiple myeloma should be based on standard guidelines for these diseases outside the context of HIV infection. The optimal care for PBL remains undefined, but CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), as would be used for DLBCL, has produced very poor results. Given the rapid disease kinetics and often MYC translocation, therapies typically directed at BL are often used in patients who can tolerate such therapy.

PCNSL represents 15–20% of all HIV-related lymphomas, and is generally a manifestation of severe immunosuppression. Mean CD4 counts are <30 cells/mm³, there is commonly a previous history of an AIDS-defining complication, and the EBV genome is invariably present in the tumor.¹⁶¹ Histologically, these tumors have an immunoblastic diffuse large B-cell appearance and express a type III pattern of EBV latent gene products.¹⁶² The clinical approach to these patients is detailed in a later section.

MCD, or angiofollicular lymph node hyperplasia, may occur in patients with advanced HIV disease and mimic the presentation of an ARL or infectious disease.¹⁶³ MCD is a polyclonal disease that is uniformly associated with KSHV/HHV8 in the HIV-infected patient and may exhibit a rapidly progressive, lethal course. Both the hyaline-vascular and plasma cell subtypes of MCD have been reported in AIDS, but the plasma cell histology type is far more common. KSHV/HHV8 is found in the involved nodes, and there is a high prevalence of co-incident or subsequent KS.¹⁶³ Fever, lymphadenopathy, hepatosplenomegaly, and anemia are present in virtually all patients; and IL-6 is abundantly produced in MCD and plays a critical role in the pathophysiology, via activation of the JAK/STAT pathway, and promotion of angiogenesis and proliferation.^{164–166} A monoclonal antibody against IL-6 has shown clinical efficacy in the treatment of HIV-negative HHV8-negative MCD,¹⁶⁷ but clinical efficacy in HIV-associated MCD has yet to be established. Patients with MCD may present with a synchronous ARL, and an ARL may occur subsequent to the diagnosis of MCD; so diagnostic vigilance is required with a low threshold for repeat biopsy in the setting of progression or relapse, or based on a change in clinical behavior.

Clinical approach

Evaluation of patients with ARL follows staging procedures for other types of NHL, with several caveats specific to the HIV-infected population. First, the frequent involvement of the CNS mandates a more thorough assessment of the CNS than in HIV-negative counterparts, including sampling of the cerebrospinal fluid (CSF) in the majority of patients at diagnosis, and consideration of neuroimaging, particularly in the presence of neurologic signs or symptoms. CSF sampling can be omitted in selected patients with no neurologic symptoms and low-risk features including limited stage disease, absence of extranodal disease, and normal LDH. Second, the potential for co-incident opportunistic infection must be kept in mind when evaluating a patient with “B” symptoms or suspicious radiographic findings.

Microbiologic evaluation is particularly important for that population with CD4 counts <200 cells/mm³ in whom the risk of opportunistic disease is increased, and is a necessity for those with <50 cells/mm³. Depending on the clinical scenario, particular concern should be paid to the possible presence of active *P. jiroveci* (formerly *Pneumocystis carinii*), CMV, *Toxoplasma gondii*, *Mycobacterium avium* complex, *Mycobacterium tuberculosis*, and *Cryptococcus*. Hepatitis B and C serologies should be evaluated in all patients since co-infection may occur. Third, assessment of the status of the HIV disease is critical in defining the therapeutic approach. CD4 cells should be measured as well as plasma HIV RNA, and a detailed history of previous antiretroviral therapy and opportunistic disease should be obtained. Those patients for whom NHL represents a manifestation of end-stage, treatment-refractory HIV disease should be considered for palliative intent. For the majority of patients, however, viral suppression on cART offers an open-ended prognosis from HIV-1 infection, and the emphasis should be on curing the lymphoma—a concept not realistically considered in the pre-cART era, but of substantial importance since the availability of cART in 1996. Selecting a cART regimen appropriate for the patient involves weighing where the patient may lie in the continuum of HIV disease as well as consideration of drug–drug interactions, and should be performed collaboratively with an infectious disease specialist.

Prognostic factors

Prognosis in patients with ARL has generally been poor; but with the advent of cART, the improved prognosis from HIV-1 itself, as well as the improved tolerance of chemotherapy, long-term outcome in patients with ARL has substantially improved. Prior to the advent of cART, the median survival for patients with HIV-associated DLBCL was 8 months compared to 43 months in the setting of cART.¹⁶⁸ Poor prognostic factors in ARL prior to the introduction of cART included age >35 years, intravenous

drug use, and stages III/IV disease, which predicted overall survival ranging from 46 weeks in the most favorable subgroup to 18 weeks in the least.¹⁶⁹ The International Prognostic Index (IPI) is the most commonly used risk stratification tool in the setting of non-HIV-related aggressive lymphoma,¹⁷⁰ and has been evaluated in ARL. In the pre-cART era, outcome was poor in all IPI subgroups; however, since the advent of cART, the IPI separates three risk groups with risk scores of 0–2, 3, and 4–5 predicting 3-year overall survivals of 64%, 50%, and 13%, respectively.¹⁷¹ None of these patients, however, received rituximab, which is now included in the therapy for the majority of patients with CD20+ lymphomas, as discussed below. A prognostic score has been developed in the cART and rituximab era based on an analysis of 487 ARL patients treated on prospective clinical trials with rituximab-containing chemotherapy.¹⁷² The majority of patients had DLBCL (70%), with most remaining patients having BL. The median CD4 was 174 cells/ μ L and 40% had a prior diagnosis of AIDS. The most common chemotherapy regimen administered was R-CHOP (49%), followed by EPOCH-R (19%), the GMALL regimen (16%), and CDE (cyclophosphamide, doxorubicin, etoposide, 15%). Based on significant prognostic factors on multivariable analysis, a prognostic model was developed incorporating the traditional age-adjusted IPI risk factors (advanced stage, poor performance status, and elevated LDH), with the addition of CD4 count, HIV viral load, history of AIDS, and number of extranodal sites. These prognostic factors generated three risk groups with 5-year overall survival in the low, intermediate, and high-risk groups of 78%, 60%, and 50%, respectively, which appeared to be a superior predictor than the traditional IPI. These data demonstrate the high curability of ARLs using modern therapies and concurrent cART. Additional studies have also non-center marker expression (BCL-6 and CD10 negative, MUM1/IRF4, or CD138 positive) to be associated with a shorter disease-free survival, analogous to HIV-negative DLBCL.¹⁷³ BL demonstrates an extremely poor outcome when treated with traditional DLBCL-type regimens like CHOP, but modern data demonstrate that HIV-related BL patients fare just as well as their HIV-negative counterparts when treated with combination regimens typically used in adults with non-HIV-associated BL.^{171, 174–176} In considering prognosis of ARL patients, the status of HIV disease itself must always be carefully considered given that tolerance of therapy is significantly poorer in patients with advanced AIDS failing antiretroviral therapy.

Treatment

Early in the AIDS epidemic, the aggressive nature of the lymphomas observed was met with an aggressive clinical approach to therapy. The result was severe toxicity and frequent treatment-related death. Since that time, however, prophylactic therapy for opportunistic infections has improved, as has supportive care with hematopoietic growth factors, thus easing the tolerability of chemotherapy. Low-dose chemotherapy regimens were developed with the goal of minimizing treatment-associated toxicity in the setting of AIDS, but demonstrated uniformly poor results in the pre-cART era. With cART and supportive care, however, it became clear that patients with ARL could then be treated with the same standard dose chemotherapy regimens administered to their HIV-negative counterparts, with much improved outcomes compared to the pre-cART era. Accordingly, reduced dose regimens rarely have a role in modern ARL therapy.

The most commonly employed regimens for ARL in the modern era are CHOP and EPOCH, with the addition of rituximab for CD20+ cases (see further discussion below) ([Table 4](#)).

Table 4 Commonly used therapy regimens for AIDS-related lymphoma

Therapy regimen	Dose and schedule
CHOP (+/– Rituximab based on CD20 expression) ^a	
Cyclophosphamide	750 mg/m ² , IVPB, day 1
Doxorubicin	50 mg/m ² , IVPB day 1
Vincristine	1.4 mg/m ² (not to exceed 2 mg), IVPB, day 1
Prednisone (each cycle q 21–28 d)	100 mg, po, days 1–5
Rituximab (if included)	375 mg/m ² , day 1
Supportive care includes concurrent cART and prophylaxis against <i>P. jiroveci</i> and herpesviruses	
EPOCH regimen (+/– Rituximab based on CD20 expression) ^a	
Etoposide	50/m ² , CI, days 1–4
Vincristine	0.4 mg/m ² , CI, days 1–4
Doxorubicin	10 mg/m ² , CI, days 1–4
Prednisone	60 mg/m ² , po, days 1–5
Cyclophosphamide	375 mg/m ² , IV, day 5
Rituximab (if included)	375 mg/m ² , day 1 (or on day 1 and day 5 if administering as SC-EPOCH-RR
Supportive care includes concurrent cART in most patients and prophylaxis against <i>P. jiroveci</i> and herpesviruses, and a proton-pump inhibitor	

Abbreviations: CHOP, cyclophosphamide, hydroxydaunomycin (doxorubicin, adriamycin), Oncovin (vincristine), prednisone; CNS, central nervous system; EPOCH, etoposide, prednisone, Oncovin (vincristine), cyclophosphamide, hydroxyldaunomycin (doxorubicin, adriamycin); G-CSF, granulocyte stimulating factor; IV, intravenously; po, per os (orally); SC-EPOCH-RR, short-course-EPOCH with 2 doses of rituximab per cycle.

^a CNS prophylaxis with intrathecal methotrexate should be included for the majority of patients, but may be omitted in selected low-risk patients with limited-stage disease, normal LDH, and absence of extranodal disease.

Standard cytotoxic chemotherapy plus antiretroviral therapy

Early in the ART era, combination of antiviral therapy with chemotherapy proved difficult due to drug–drug interactions and overlapping toxicities including bone marrow suppression and peripheral neuropathy, among others. This led to some early debate on whether ART should be administered concurrently with chemotherapy or be held during cancer therapy. Given the advances in modern cART, however, the toxicities and drug–drug interactions are reduced and highly manageable. It has also become clear that concurrent cART decreases complications of AIDS during therapy and improves the ability to administer full-dose chemotherapy with curative intent. Accordingly, concurrent administration of cART with chemotherapy in ARL is the modern standard of care.

This approach was validated by a trial of CHOP plus indinavir, d4T, and 3TC conducted by the AIDS Malignancy Consortium and involved a cohort of patients receiving low-dose CHOP and a subsequent cohort receiving full-dose CHOP plus the same antiretroviral regimen.¹⁷⁷ This study indicated that the

combination did not result in unexpected severe or more frequent toxicities. Pharmacologic analysis tested the possibility both of antineoplastic drugs affecting protease inhibitor levels and of antiviral therapies altering cytotoxic drug metabolism. No alterations in levels of indinavir or doxorubicin were noted, although a reduction in cyclophosphamide clearance of approximately 50% was observed.

The United States National Cancer Institute tested infusional dose-adjusted EPOCH without concomitant cART.¹⁷⁸ The etoposide, vincristine, and doxorubicin were given as a 96-h continuous infusion, followed by bolus cyclophosphamide on day 5; the cyclophosphamide dose was modified based on baseline CD4 count and neutropenia during the prior cycle. Intrathecal methotrexate was administered with each cycle for CNS prophylaxis. Holding antiviral therapy resulted in a rise in HIV RNA during cancer chemotherapy that reverted to entry levels when antivirals were resumed following completion of chemotherapy. Clinical outcome was the best reported to date in ARL patients with 74% of patients achieving a complete response and 5-year disease-free and overall survivals of 92% and 60%, respectively. Continuous-infusion regimens have also been combined with antiviral therapy as initial treatment of ARL. The CDE regimen (cyclophosphamide 800 mg/m², doxorubicin 50 mg/m², etoposide 240 mg/m², by continuous 96-h infusion) was tested in 98 patients with concomitant cART (dideoxyinosine [ddi] monotherapy was used in the first 43 patients) resulted in a complete response rate of 45%, with 43% of patients alive after 2 years.¹⁷⁹ Patients treated with concomitant cART versus ddi had an improved overall survival owing to decreased hematologic toxicity and treatment-associated death. These trials support that combining antivirals and antitumor therapy appears safe and effective. The short-term consequences of holding antiretroviral therapy appear to be acceptable in selected low-risk patients with reasonable immune function; but this should be done cautiously, with initiation of cART once feasible.

BL patients have traditionally been included in trials with other ARLs and have not clearly had a worse outcome from HIV-related DLBCL, though the majority of these trials were conducted prior to cART when outcomes were uniformly poor. Modern evidence suggests that patients with HIV-related BL experience similarly encouraging outcomes to non-HIV-infected patients when treated with intensive multiagent chemotherapy.^{174, 175}

Monoclonal antibody therapy

Efforts to improve the outcome for patients with ARL have included the addition of the humanized anti-CD20 antibody rituximab, which has shown a survival benefit when combined with CHOP chemotherapy in HIV-negative DLBCL.¹⁸⁰ A multicenter randomized phase III trial testing CHOP versus CHOP plus rituximab (R-CHOP), however, demonstrated that in the setting of AIDS, patients did not have an improvement in overall outcome with the addition of rituximab.¹⁸¹ There was a trend toward improved response (58% vs. 47%) with rituximab that did not reach statistical significance; however, this was outweighed by an increased rate of infection-related death (14% vs. 2%). Most deaths in the rituximab arm were in patients with CD4 counts <100 cells/mm³, with 60% of deaths occurring at a CD4 count <50 cells/mm³. Further complicating analysis of this trial is a 3-month maintenance rituximab period following initial R-CHOP, during which time 40% of infection-related deaths occurred. Subsequent phase II studies, however, showed that rituximab could be added to standard chemotherapy for ARL with the suggestion of improved clinical outcomes,^{175, 182–185} and a meta-analysis of 1060 ARL patients treated on prospective clinical trials with rituximab plus chemotherapy or chemotherapy alone demonstrated an improved survival in rituximab-treated patients.¹⁸⁶ Accordingly, inclusion of rituximab is considered standard for patients with ARL in the modern era, but patients with low CD4 counts continue to be at increased risk for treatment-associated complications and must be followed up closely and receive

maximal supportive care including prophylactic antibiotics and growth factor support.

The optimal chemoimmunotherapy strategy remains a subject of debate. R-CHOP and EPOCH-R are both considered standard regimens for HIV-associated DLBCL. A pooled analysis of 150 patients with HIV-associated CD20+ NHL treated on AIDS Malignancy Consortium studies found EPOCH-R to be associated with an improved event-free survival (hazard ratio [HR] 0.40; 95% confidence intervals [CI], 0.23, 0.69; $P < 0.001$) and overall survival (HR, 0.38; 95% CI, 0.21, 0.69; $P < 0.01$),¹⁸⁷ making this a preferred regimen for most patients. Studies of EPOCH-R have also shown that concurrent administration of rituximab on day 1 of each chemotherapy cycle appears to offer improved disease control compared to sequential treatment of EPOCH followed by rituximab, and that ARL patients may be treated with fewer chemotherapy cycles if rituximab is administered twice per cycle (short-course EPOCH-RR).^{184, 185} Both standard EPOCH-R and short-course EPOCH-RR can be considered appropriate regimens for CD20+ ARL patients. Though primarily studied without concurrent cART, EPOCH-R can be safely combined with cART and this is recommended as standard practice. Routine prophylaxis on EPOCH-R also includes routine white cell growth factor support, and prophylaxis against *P. jiroveci*, herpesvirus infections, and gastric ulcers with a proton pump inhibitor.

BL patients may be treated with the same intensive chemotherapy regimens plus rituximab, as have been used for non-HIV-infected BL patients.¹⁷⁴ The safety of high-intensity regimens in HIV infection may reflect the generally improved HIV control and CD4 count relative to other ARL subsets. More recently, the short-course EPOCH-RR regimen (rituximab is given twice per cycle) has been evaluated in 11 HIV-associated BL with a 6-year overall survival of 90%.¹⁷⁵ These encouraging data warrant further evaluation in a larger cohort of HIV-associated BL patients. PBL is a highly aggressive lymphoma, often also including an MYC translocation, that is usually treated similarly to BL. Our practice is to use EPOCH in the majority of PBL patients. Rituximab usually has no role as these cases are typically CD20 negative, but rituximab should be included for rare CD20 positive cases. Multiple case reports have demonstrated responses to the proteasome inhibitor bortezomib, so this can be considered an option for relapsed disease.^{188–192} As with other ARLs, concurrent cART is recommended for all patients.

CNS prophylaxis

The role of CNS prophylaxis has been much debated. Although early studies indicated a very high incidence of CNS involvement or relapse, the usefulness of routine CNS prophylaxis has never been rigorously studied in this patient population. The approach to this issue is center dependent, and many centers treat all patients with an intrathecal chemotherapy injection (most commonly methotrexate) with every cycle of systemic chemotherapy. The practice at other centers has been to reserve this treatment for patients with Burkitt histology or bone marrow, testicular, or Waldeyer ring involvement, or for patients with multiple extranodal sites of disease and an elevated LDH. It is our practice to include intrathecal methotrexate as a CNS prophylaxis in the treatment program for the majority of patients with DLBCL, but to omit it in patients with very low-risk features including limited-stage disease, absence of extranodal involvement, and normal LDH. All patients with the highly aggressive BL and PBL histologies require CNS prophylaxis.

Treatment of relapsed or refractory disease

Treatment of relapsed aggressive lymphoma in non-HIV-infected individuals incorporates the use of high-dose chemotherapy with autologous stem cell rescue (ASCT), an approach which has been proved to cure more patients than standard dose chemotherapy alone.¹⁹³ Myeloablative chemotherapy in the setting of HIV infection carries substantially increased risks of morbidity and mortality, though evidence suggests it

can be performed effectively in the cART era. In one study including 50 patients with relapsed ARL, 27 actually proceeded to peripheral blood stem cell transplant with a 4-year progression-free and overall survival of 76% and 75%, respectively. The overall survival for all 50 patients was 50%, reflecting the poor outcomes in patients who did not proceed to transplant.¹⁹⁴ The reasons for not being transplanted were primarily chemotherapy-resistant disease (14), failure of stem cell mobilization (6), and early toxic death (2). Multiple other reported experiences for ASCT in relapsed ARL have similarly reported encouraging rates of cure.^{195, 196} Of note, the modern availability of the CXCR4 antagonist plerixafor to improve stem cell mobilization will likely decrease the risk of mobilization failures, as it has on the non-HIV population.¹⁹⁷ ASCT should therefore be considered the treatment of choice for relapsed ARL patients considered fit enough to undergo high-dose therapy. Such transplants should only be performed at centers experienced in stem cell transplantation for this uniquely high-risk population of patients.

Allogeneic stem cell transplantation (alloSCT) in HIV-infected patients using fully myeloablative conditioning has been reported and carries marked infection-related toxicity in addition to graft versus host disease and progressive lymphoma.^{198–200} Non-myeloablative alloSCT using a reduced intensity conditioning regimen, however, appears feasible in a small series of patients with HIV and relapsed hematologic malignancy, with reduced toxicity.^{201, 202} AlloSCT has also resulted in the only known cure of HIV. This is the remarkable case of Timothy Ray Brown, also known as the Berlin patient, who had HIV and developed acute myelogenous leukemia (AML).²⁰³ He was given an alloSCT with donor stem cells harboring the 32 base pair deletion in CCR5, which confers resistance against HIV infection by preventing viral entry. Mr. Brown remains free of AML as well as without detectable HIV in the blood or tissues, and is off all antiretroviral therapy. Two additional cases of HIV patients treated with alloSCT and concurrent cART for relapsed hematologic malignancies using stem cells from a CCR wild type donor initially found no evidence of persisting HIV infection post transplant, but subsequently identified viral relapse in the two patients at 12 and 32 weeks, respectively.²⁰⁴ These patients demonstrate that alloSCT and cART may significantly reduce the HIV reservoir, but does not eradicate it when using CCR wild-type stem cells, perhaps due to persistence of the virus in tissue reservoirs post transplant. Genetic engineering methods that produce mutant CCR5 in donor stem cells that prevent HIV viral entry in transplanted patients, as was seen in the Berlin patient, warrant investigation.

Supportive care

All patients should be considered for prophylaxis for opportunistic infections. Reduction in CD4 count by approximately half can be expected during chemotherapy, and *P. jiroveci* prophylaxis is recommended even if entry CD4 count exceed 200 cells/mm³. The other prophylactic therapies standardly used in advanced HIV disease are also applied to this population.

Growth factor use is often required, given the noted increased sensitivity to myelotoxic injury in patients with HIV disease. A single randomized trial of CHOP versus CHOP plus GM-CSF found a significant decrease in the incidence of fever and neutropenia and days of hospitalization in the cohort receiving prophylactic growth factor,²⁰⁵ though this trial antedated the use of protease inhibitors, which has generally improved patients' tolerance of chemotherapy. Given the increased incidence of neutropenia and infections on chemotherapy in HIV patients, we recommend routine use of G-CSF support in the majority of patients receiving combination chemotherapy regimens for ARL.

Treatment of malignancy concurrent with HIV also warrants careful attention to possible drug–drug interactions. Many protease inhibitors such as darunavir, indinavir, ritonavir, and saquinavir inhibit CYP3A4, which is responsible for metabolizing vinca alkaloids as well as taxanes. Accordingly, patients

on these antiretroviral drugs will have higher chemotherapy levels and must be monitored for higher risks of marrow toxicity and neuropathy, and the dose reduced accordingly. Similarly, non-nucleoside reverse transcriptase inhibitors like efavirenz and nevirapine will induce CYP3A4 and thus theoretically lead to subtherapeutic levels of substrate chemotherapies. Empiric dose escalation of chemotherapy in this setting, however, is not recommended. In general, zidovudine should be avoided with cART due to myelotoxicity, and caution should also be used with stavudine and didanosine due to peripheral neuropathy.

Primary CNS lymphoma

A brain mass in the context of HIV infection can be caused by a number of infections and neoplastic processes, and thereby poses a substantial diagnostic challenge. Most commonly seen in AIDS patients are *T. gondii* abscess, PCNS lymphoma, mycobacterial or bacterial abscess, and progressive multifocal leukoencephalopathy (PML). Criteria for distinguishing among these entities remain imperfect without tissue sampling, but for those patients in whom biopsy is not possible or is refused, certain parameters can raise or lower the likelihood of a lymphoma diagnosis, and the use of PCR analysis for EBV DNA in the CSF has greatly improved the reliability of a diagnosis without histologic confirmation.

In general, PCNSL, PML, and toxoplasmosis are complications of far advanced immunosuppression with CD4 counts of <50 cells/mm³. This patient population is often on trimethoprim-sulfamethoxazole prophylaxis for *P. jiroveci*, which provides excellent protection against *Toxoplasma*. For those patients in whom a *Toxoplasma* antibody titer is negative and who have been on such prophylaxis, the likelihood of a lymphoma diagnosis in the setting of a CNS mass lesion has been documented to be 74%.²⁰⁶ Additional information can be gained from PCR analysis for the EBV genome in CSF samples. Detection of EBV in the CSF has been reported to have specificity for lymphoma approximating 100%.^{206, 207} Sensitivity may be only 80% and there are rare cases of EBV+ CSF where no lymphoma is diagnosed, but this test has become extremely useful in assessing the patient who is unable or unwilling to undergo a definitive histologically defining procedure.

Radiographic features more suggestive of lymphoma include central location, lack of multifocality, and size >2 cm.²⁰⁸ In addition, a lesion that crosses the midline is highly likely to be a neoplastic process. Single-photon emission computed tomography (SPECT) or positron emission tomography (PET) can also help distinguish lymphoma from abscess. The combination of one of these imaging techniques with a positive DNA PCR for EBV is now often considered sufficient evidence for initiation of therapy. If these tests do not clearly delineate the process and a biopsy is not feasible, empiric anti-Toxoplasma therapy may be used as a diagnostic as well as therapeutic tool. Initiation of sulfadiazine or clindamycin with pyrimethamine generally halts the progression by 5 days and results in clinical or radiographic improvement by 14 days.^{209, 210} For those in whom these milestones are not met, the likelihood of toxoplasmosis is low.

Therapy for PCNSL remains very limited, and with poor outcome. Radiation with or without chemotherapy, has been the mainstay of care, with response rates ranging from 60% to 79%, but durable remissions are uncommon. Outcomes do appear improved in the cART era.^{161, 211–213} High-dose methotrexate-based therapy has been the mainstay of therapy in PCNSL in non-HIV-infected patients, where response rates are high and may result in sustained remissions. Such chemotherapy has been limited in HIV patients based on data from the pre-cART era when outcomes were extremely poor due to high rates of toxicity and infectious complications.²¹³ Even in the cART era, however, PCNSL patients often have advanced HIV and very low CD4 counts, and thus remain at high risk. Among HIV-associated

PCNSL with CD4 counts >100 cells/mm³ and in otherwise good health, methotrexate-based therapy including rituximab should be considered. Combination of cytotoxic chemotherapy and radiation therapy has been tested, with disappointing effect on the tumors and unacceptable toxicity. In spite of the fact that EBV genome is associated with PCNSL, it is generally in the latent phase and therefore unlikely to be sensitive to lytic-phase-specific antiviral agents. Nonetheless, limited experience with the use of ganciclovir in combination with zidovudine and IL-2 has suggested antitumor activity.²¹⁴ The ultimate use of these agents or other EBV-directed genetic or chemical manipulations awaits careful assessment in clinical trial. The relationship of the disease to poor immunologic function does provide the rationale, however, for emphasizing optimization of anti-HIV therapy as a component of antitumor therapy. The overall poor outcome for these patients also strongly advocates the encouragement of patients to participate in clinical protocols testing novel approaches.

The use of steroids in this patient population has engendered concern because of the potential worsening of immunosuppression. There is an absence of data regarding this point, but the opportunity to reduce edema and mass effect should not be avoided out of concern for immunosuppression. Rather, the tapering of steroids should be as rapid as is tolerated, and vigilance regarding the development of concurrent infection should be maintained. In the era preceding cART, death was as commonly caused by secondary events as by tumor.²¹⁵ For those patients who present with PCNSL who have not been receiving cART, initiating antiretroviral therapy should be considered a priority, as anecdotal reports have emerged of long-term survivors among the group gaining control of HIV-1.^{216, 217}

Multicentric Castleman disease

MCD is a lymphoproliferative disorder associated with KSHV/HHV, usually seen in the setting of advanced HIV infection. Patients typically present with a systemic syndrome of fevers, malaise, diffuse lymphadenopathy, hepatosplenomegaly, edema, effusions, and anemia. Though not a clonal process, MCD can transform into DLBCL, so attention to the possibility of a high-grade transformation should be paid both at the time of initial diagnosis and subsequent recurrence. Patients may also present with other concomitant HHV8-associated malignancies, KS or PEL, or with opportunistic infections given the usually low CD4 count at diagnosis. All patients should be treated with cART, though antiretrovirals alone are unlikely to produce remissions. While antiviral therapy against HIV has not been shown to successfully treat MCD, antiviral therapy against HHV8 may be effective given that HHV8 lytic replication is common in MCL and thus may be medically targeted. A prospective trial of high-dose zidovudine plus valganciclovir in 14 patients with symptomatic HIV- and HHV-8 associated MCD found an overall clinical and complete response rate of 86% and 50%, respectively.²¹⁸ Traditional chemotherapy agents alone have proved disappointing historically, though small, have reported efficacy with single-agent alkylators, vinblastine, oral etoposide, thalidomide, or liposomal doxorubicin.^{163, 219–223} Rituximab has been tested in MCD given the robust presence of CD20+ B cells. A prospective trial of rituximab monotherapy in 24 patients with chemotherapy-dependent HIV-associated MCD reported sustained remissions in 71% of patients after 1 year; responses to rituximab in patients previously treated with rituximab have been reported as well.^{224, 225} Of note, patients with MCD and concomitant KS may experience a flare of KS while on rituximab, so this warrants careful attention by the treating clinician. For patients with highly aggressive disease, or disease progressing on rituximab monotherapy, rituximab has been combined with either etoposide or liposomal doxorubicin with encouraging results.^{226, 227} The combination of rituximab and liposomal doxorubicin may be a particularly appealing combination for patients with concurrent KS and MCD. More recently, the anti-IL-6R monoclonal antibody siltuximab has been FDA approved in HIV-negative HHV8-negative MCD based on a randomized trial showing that

34% of patients treated with siltuximab achieved a durable clinical and radiological response, compared to 0% in the placebo arm.¹⁶⁷ This data cannot easily be extrapolated to HIV-associated MCD, however, where viral IL-6 is produced by HHV8, and is not targeted by the siltuximab antibody. IL-6 targeted agents warrant evaluation in HIV patients in the context of a clinical trial.

For initial therapy of MCD, we recommend rituximab along with concurrent cART in the majority of patients. Liposomal doxorubicin or etoposide can be added for rapidly progressive or resistant disease, with more intensive therapy like CHOP²²⁸ reserved for rare fulminantly progressing cases, or those with high-grade transformation. High-dose zidovudine with valganciclovir may also be considered.

Hodgkin lymphoma (HL)

Although not officially an AIDS-defining tumor, HL is increased in frequency in HIV-infected patients and has a number of unique characteristics distinguishing it from HL outside the context of AIDS.

Epidemiology

The risk of HL in patients infected with HIV-1 is estimated to be 2.5- to 8.5-fold above that of the uninfected population.^{9, 229–231} This risk appears to be uniformly increased across the risk groups for HIV infection, independent of age or gender.²³² Notwithstanding the increase in relative risk in the HIV-infected population, the overall magnitude of the problem is still relatively small compared with that of NHL. Unlike most AIDS-associated NHL, the incidence of HL in HIV infection has not decreased in the cART era, and may even be increased.^{123, 233, 234} The cause of this surprising increase is speculative, but it may be due to the critical role host CD4-positive T-cell signaling plays in the microenvironment of HL. Indeed, HL is more likely to occur at moderately decreased CD4 counts than in the setting of severe immunodeficiency.

Pathology and pathogenesis

HL in the context of HIV infection has pathologic features that distinguish it from the seronegative population. In particular, there is a much higher frequency of the mixed-cellularity subtype, with a corresponding reduction in the relative proportion of patients with nodular sclerosis histology. The overall frequency of mixed-cellularity or lymphocyte-depleted histology was found to be two-thirds of the cases in the HIV-1-positive context compared with only 29% in uninfected patients.²³⁵ In addition, the presence of EBV in HL tissue is markedly increased in HIV-infected individuals. Estimates ranged from 80% to 100% in contrast to the HIV-negative population.^{234, 236} Of note, expression of the EBV LMP1, but not EBNA2, latency genes is in a type 2 pattern. Thus, the EBV genome is identified with high-frequency in HIV-infected HL and is considered likely to play an etiologic role.

In addition to the presence of EBV, there are other molecular characteristics of HL unique to the HIV-infected population. The transcription factor Bcl-6 expressed in germinal-center B cells, is present on Reed–Sternberg cells from both HIV-1-infected and uninfected individuals whereas, syndecan-1 (a proteoglycan associated with the post-terminal center) is restricted to the HIV-1-positive population.^{237, 238} Therefore, the postgerminal-center B cell may be the cell of origin in HIV-1-related HL, as opposed to the germinal-center cell of origin presumed to be the source of Reed–Sternberg cells in the uninfected population.

Clinical features

HL in patients with HIV is typically of advanced stage and associated with B symptoms.^{239, 240} Stage III or IV disease has been documented in approximately 80% of patients with HIV-associated HL at the time of diagnosis, as compared with just under half in HL patients without HIV. Like ARL, the location of HL in the setting of HIV-1 infection is often extranodal, involving the bone marrow in up to 50% of patients. Other sites include the tongue, rectum, skin, and lung, and extranodal disease may be the site of presentation. Staging strategies should be the same as those in HL patients outside the context of HIV-1, with particular attention to possible microbiologic explanations for B symptoms.

Treatment

The clinical treatment approach to patients with HL in the setting of HIV infection is similar to that in other contexts; and radiation therapy, chemotherapy, or combined radiation and chemotherapy should be applied as appropriate for stage, similar to guidelines for treatment outside the setting of HIV infection.

Though pre-cART outcomes of AIDS-associated HL were quite poor, with a median survival of <2 years,²⁴¹ modern treatment in the setting of antiretroviral therapy has shown encouraging rates of cure.²⁴⁰ Patients with advanced-stage disease treated with standard Adriamycin (doxorubicin), bleomycin, vinblastine, and dacarbazine (ABVD), and concomitant cART were reported to achieve complete responses in 87% of cases with 5-year event-free and overall survivals of 71% and 76%, respectively.²⁴² Favorable outcomes have also been observed with the bleomycin, etoposide, Adriamycin (doxorubicin), cyclophosphamide, Oncovin (vincristine), procarbazine, and prednisone (BEACOPP), and Stanford V (doxorubicin, vinblastine, mechlorethamine, etoposide, vincristine, bleomycin, prednisone, and radiotherapy) regimens, when given with concomitant cART.^{243, 244}

The underlying level of immunosuppression and overall performance status of the patient must be considered before embarking on these therapies, and, in general, prophylaxis for *P. jiroveci* is recommended for all patients regardless of CD4 count. Treatment complications, including myelosuppression and opportunistic infections, may be expected to be more severe among patients with advanced AIDS; however, cure of HL is a realistic aim in the setting of HIV infection, and antitumor therapy dose reduction should be contemplated only in patients with advanced AIDS who have demonstrated intolerance to the standard-dose regimens. As with the treatment of NHL, treating clinicians must be vigilant for drug–drug interactions between chemotherapy and cART.

Squamous cell neoplasia

The issue of HPV-related disease is an increasing concern in the HIV epidemic for several reasons, including (1) the increasing frequency of women infected by HIV, (2) the rampant progression of HIV disease in parts of the world where there is already a high incidence of cervical cancer and limited screening for cervical disease, and (3) the extension in overall survival of HIV-infected individuals. The nature of the abnormalities is fairly broad in scope and includes anogenital, conjunctival, oropharyngeal, and cutaneous neoplasia.

Epidemiology

The increased frequency of squamous cell neoplasia in HIV-infected individuals has been well documented, and has not decreased since the introduction of cART, may be increasing.^{12, 245, 246} The single AIDS-defining disease among the HPV-related tumors is that of invasive cervical carcinoma, though there is controversy as to whether this malignancy is increased in frequency in the setting of HIV

infection. However, it is very clear that intraepithelial neoplasia of both the uterine cervix and the anus is increased. HIV-infected men who have sex with men have a particularly high incidence of squamous cell abnormalities and a markedly increased risk of high-grade anal intraepithelial neoplasia and anal cancer, which has the most rapidly rising incidence of all malignancies in the cART era.¹² Indirect evidence that immune suppression augments this cancer risk comes from an analysis of AIDS and cancer registries. In a retrospective study of more than 300,000 HIV patients, the incidence of *in situ* and invasive cancers was significantly higher in the 5 years following an AIDS-defining illness than in the 5 years preceding it.²⁴⁵ Among women, cervical, vulvar/vaginal, and anal cancers were increased, while among men, anal, penile, tonsillar, and conjunctival cancers were increased.

Pathology and pathogenesis

The association of specific subtypes of HPV with a potential for epidermal cell transformation has been long established, and the frequency of HPV-16, -18, and -19, is reported to be increased in HIV-infected individuals.²⁴⁷ The frequency of multiple subtypes of HPV has also been assessed and found to be markedly increased in the HIV-infected population (73% of HIV-1-infected men who have sex with men, as compared with 23% of uninfected men).^{247, 248} The incidence of high-grade intraepithelial neoplasia of the anus has been estimated to be as high as 48% among HIV-1-positive men who have sex with men over a 4-year interval and was associated with the presence of multiple HPV subtypes, persistent anal infection, and high-level infection with oncogenic HPV subtypes.²⁴⁹ Screening for intraepithelial neoplasia among HIV-1-infected men who have sex with men has demonstrated a prevalence of high-grade anal intraepithelial neoplasia (or carcinoma *in situ* [CIS]) of 36% compared with 7% of HIV-1-negative men who have sex with men.²⁵⁰ Most often, these lesions on the anus and uterine cervix are not solitary sites but rather represent one of multiple areas of dysplasia and are therefore difficult to satisfactorily treat, particularly on the anus. Patients with a history of high-grade intraepithelial neoplasia may often have recurrence following attempts at excision, cryotherapy, or topical treatment because of the ubiquitous nature of the HPV infection locally and the tendency of that virus to continue to have effects on local tissue.

A critical issue in evaluating the magnitude of this problem is the risk of progression of intraepithelial neoplasia to frank invasive cancer. This issue remains ill defined and highly controversial. If the risk is estimated at 1% or above, cost-benefit analyses have indicated that ongoing screening is justified.²⁵¹ The lack of large increases in the frequency of invasive anogenital cancer among HIV risk groups suggests that the risk is relatively small. However, the potential for frank invasion is not zero, and, therefore, vigilance among patients with HIV disease is warranted.

The risk of some opportunistic neoplasms is clearly diminished in the context of aggressive therapy for HIV and suppression of HIV replication. There have been conflicting reports of whether HPV-related tumors are among those responsive to improved anti-HIV therapy. Some reports have indicated that some individuals may experience improvement in HPV-related neoplasia;²⁵² however, the bulk of data suggests that antiretroviral therapy has little impact on the incidence of dysplasia or invasive anal cancer.²⁵³ At present, the complete suppression of HIV should not be regarded as a fail-safe defense against the development of HPV-related tumors.

Clinical presentation

HPV disease may present anywhere along the continuum of condyloma acuminatum to invasive anal cancer. Patients who have anal dysplasia may or may not have symptoms associated with it. Common

practice with patients with a history of high-grade anal dysplasia is to perform an anoscopic examination and possible biopsy, even if the diagnostic lesion is on the anal verge, to assess for possible invasive disease out of the external examination field. Some centers perform anal Papanicolaou (Pap) evaluation for HIV-infected individuals, where it has been shown to be effective at identifying premalignant lesions. One study in 245 men found that 96% of anal Pap smears were interpretable with two-thirds of men screened having an abnormal cytology.²⁵⁴ High-resolution anoscopy and biopsy demonstrated a positive predictive value of 96% for detection of anal dysplasia by cytologic screening. The clinical relevance of early cytologic detection remains unclear, though early lesions may benefit from local therapy. Given the rising incidence of HPV-associated anal cancer in HIV-infected individuals, anal Pap smears may be considered in high-risk individuals, such as men who have sex with men.

For women with HIV infection, the standard practices and recommendations for cervical screening are to be followed, with increased vigilance for those with severe immunosuppression. For HIV-infected women with CD4 counts of <200 cells/mm³, the recommendation is for Pap smears to be performed semiannually.

HPV vaccination is a vital tool in the prevention of cervical cancer where it has been proved to decrease the incidence of high-grade cervical intraepithelial neoplasia related to HPV,²⁵⁵ and is now considered a standard vaccine in young girls. HPV vaccination of boys has been more controversial, though it may reduce their incidence of HPV-associated neoplasia as well as prevent transmission of HPV to women, thus contributing to a reduced incidence of cervical cancer. A quadrivalent HPV vaccine was administered to 4065 males aged 16–26 in a randomized placebo-controlled trial, and found a reduction in HPV infection as well as in HPV-associated external genital lesions.²⁵⁶ A substudy of MSM also found the vaccine to be effective in this population, and to reduce the incidence of high-grade anal intraepithelial neoplasia. Based on these data, HPV vaccination is now recommended for all males up to age 21 and MSM up until age 26.

Treatment

Treatment guidelines for dysplasia and carcinoma of the uterine cervix are well defined and should be followed in the setting of HIV infection. Management of anal disease is less clear.

High-grade intraepithelial neoplasia or CIS at the anal verge may be treated with topical imiquimod or 5-fluorouracil, while lesions in the anal canal may be treated with surgical excision, cryotherapy, or laser ablation. Given the ambiguity of risk for progression to frank invasive cancer, these lesions may be followed with vigilant monitoring alone, and spontaneous regression of anal intraepithelial neoplasia may occur.²⁵⁷ For patients with invasive carcinoma of the anus, treatment guidelines recommending a combination of chemotherapy and radiation therapy should be followed as in non-HIV-infected individuals; this treatment has been reasonably well tolerated in the HIV-infected population.^{258, 259} There is a distinct increased sensitivity to mucosal injury with radiation in HIV disease, and, therefore, close interaction between the medical and radiation oncologists is essential. If patients have very advanced HIV disease failing antiretrovirals, a conservative approach to management of the malignancy may be warranted, but this requires case-by-case assessment.

Other non-AIDS defining cancers

A number of other non-AIDS defining malignancies occur at a relatively increased risk in HIV-infected individuals, even in the cART era; these include cancers of the lung, oropharynx, liver, prostate, testes,

and skin.^{231, 260–263} Among skin cancers, melanoma, basal cell, and squamous cell cancers all occur at increased rates. Merkel cell carcinoma (MCC) is a very rare neural-crest-derived skin cancer that has also been shown to be increased in the setting of AIDS, as well as in solid organ transplant recipients.^{264, 265} Though generally a disease of the aged, MCC in immunosuppressed patients tends to occur at a significantly younger age and carries an aggressive natural history. The association of this rare skin cancer with immunosuppressed patients prompted a search for an underlying infectious pathogen, which recently resulted in the identification of a previously unknown polyomavirus, now called Merkel cell polyomavirus (MCV).²⁶⁶ MCV DNA was found to be integrated into the tumor cell genome in the majority of MCCs but not in control tissues, and the pattern of integration suggested that infection preceded clonal expansion of the tumor cells. These data suggest a pivotal role for this novel polyomavirus in the pathogenesis of MCC, though the exact nature of this role has yet to be determined. Identification of the MCV highlights the potential role of other undiscovered viruses in immunosuppression-related malignancies where a pathogen has not yet been identified, and remains an area of ongoing investigation.

Chapter 76

Cancer survivorship: new challenge in cancer medicine

Julia H. Rowland, PhD

Overview

As the population of cancer survivors continues to increase, so too has attention to the long-term care needs of these individuals after treatment ends. While most survivors adapt well post-treatment, many experience lingering effects of their illness. In some cases, these effects become permanent and raise challenges to recovery and adaptation. In this chapter, we outline some of the common persistent sequelae of cancer and their management and review the emerging guidelines for survivorship care planning. Models of follow-up care after cancer are discussed, along with the needs and support of informal cancer caregivers in this process. Recommendations for future directions in survivorship research and care are provided.

Introduction

A quick glance through the chapters of the ninth edition of this classic volume reveals how very far we have come in advancing the science and art of cancer medicine. Arguably, the greatest measure of the progress made is the growing population of cancer survivors. While a testament to the many successes achieved, this population is at the same time a reminder that a focus on cure is not enough; we must attend equally to the life to which we return each patient treated. How best to care for patients after primary treatment ends and there is no evidence of disease, is one of the emerging challenges for healthcare providers.

In this chapter, we will review the magnitude of the challenge clinicians—along with cancer survivors themselves and their loved ones—face after cancer. Survivors of childhood cancer have been at the vanguard of the survivorship movement in the United States, in part because of the truly dramatic progress made in curing cancers in this youngest population. The special challenges to and guidelines for their long-term care are well detailed elsewhere.^{1–8} In this chapter, we will restrict our review to the post-treatment recovery and care of individuals diagnosed as adults.

Cancer survivorship: a brief history

Before the 1970s, the picture for most patients diagnosed with cancer was bleak. There were few effective treatment options, and most entailed serious adverse effects that were often poorly controlled.⁹ ¹⁰ In this earlier period, a major focus was on helping people die of their disease, not live with it. The “survivors” in this earlier period were more often grieving family members than patients themselves. As our ability expanded to both cure and control the many diseases we call cancer, this picture changed dramatically.

The origins of the survivorship movement are often attributed to two events. The first was the publication in 1985 in the *New England Journal of Medicine* of a piece by a young physician, Dr. Fitzhugh Mullan,

entitled “Seasons of Survival.”¹¹ In this commentary, Mullan describes his personal experience with cancer and provided, for the first time, language for thinking about an expanded cancer trajectory. The following year, a group of 23 individuals, including Mullan, gathered in Albuquerque, New Mexico, and founded what is now known as the National Coalition for Cancer Survivorship (NCCS). This group proposed a new definition of the term “cancer survivor.” Until then, the term “cancer survivor” referred to someone who had remained disease-free for a minimum of 5 years. The coalition members argued that a “cancer survivor” should refer to anyone with cancer, from the moment of diagnosis and for the balance of his or her life. The intent of the NCCS founders was not to label individuals. Rather, they wanted first to convey a message of hope to those newly diagnosed with cancer that life was not over, and second, to promote a dialogue between patients and their physicians about the impact that different treatment options might have on survivors' future health and functioning (i.e., to foster informed, patient-centered decision making). Although some persons with a cancer history do not consider themselves to be survivors,^{12, 13} the language helped launch a survivorship movement globally.

Since 1986, the field of cancer survivorship has come into its own. The past dozen years in particular have seen national attention paid to the topic of cancer survivorship. This is reflected in the publication of five major reports addressing the status of the research and care of those living with cancer, including two volumes produced by the Institute of Medicine (IOM) on childhood¹ and adult cancer survivorship,¹⁴ a report by the Centers for Disease Control and Prevention (CDC) and the Lance Armstrong Foundation calling for a national action plan around cancer survivorship,¹⁵ and two reports from the President's Cancer Panel.^{16, 17} Major noncancer and cancer scientific journals have devoted special issues to this aspect of the cancer control continuum,^{18–21} texts have appeared summarizing our accomplishments in the field of survivorship research and promoting evidence-based care,^{22, 23} and the field now has a scientific journal dedicated to this burgeoning area of science.²⁴ Importantly, cancer survivorship is recognized to represent a discrete place on the cancer control continuum, bringing its own unique set of concerns and challenges. The key driver behind attention to this field has been the sheer numbers ([Figure 1](#)).

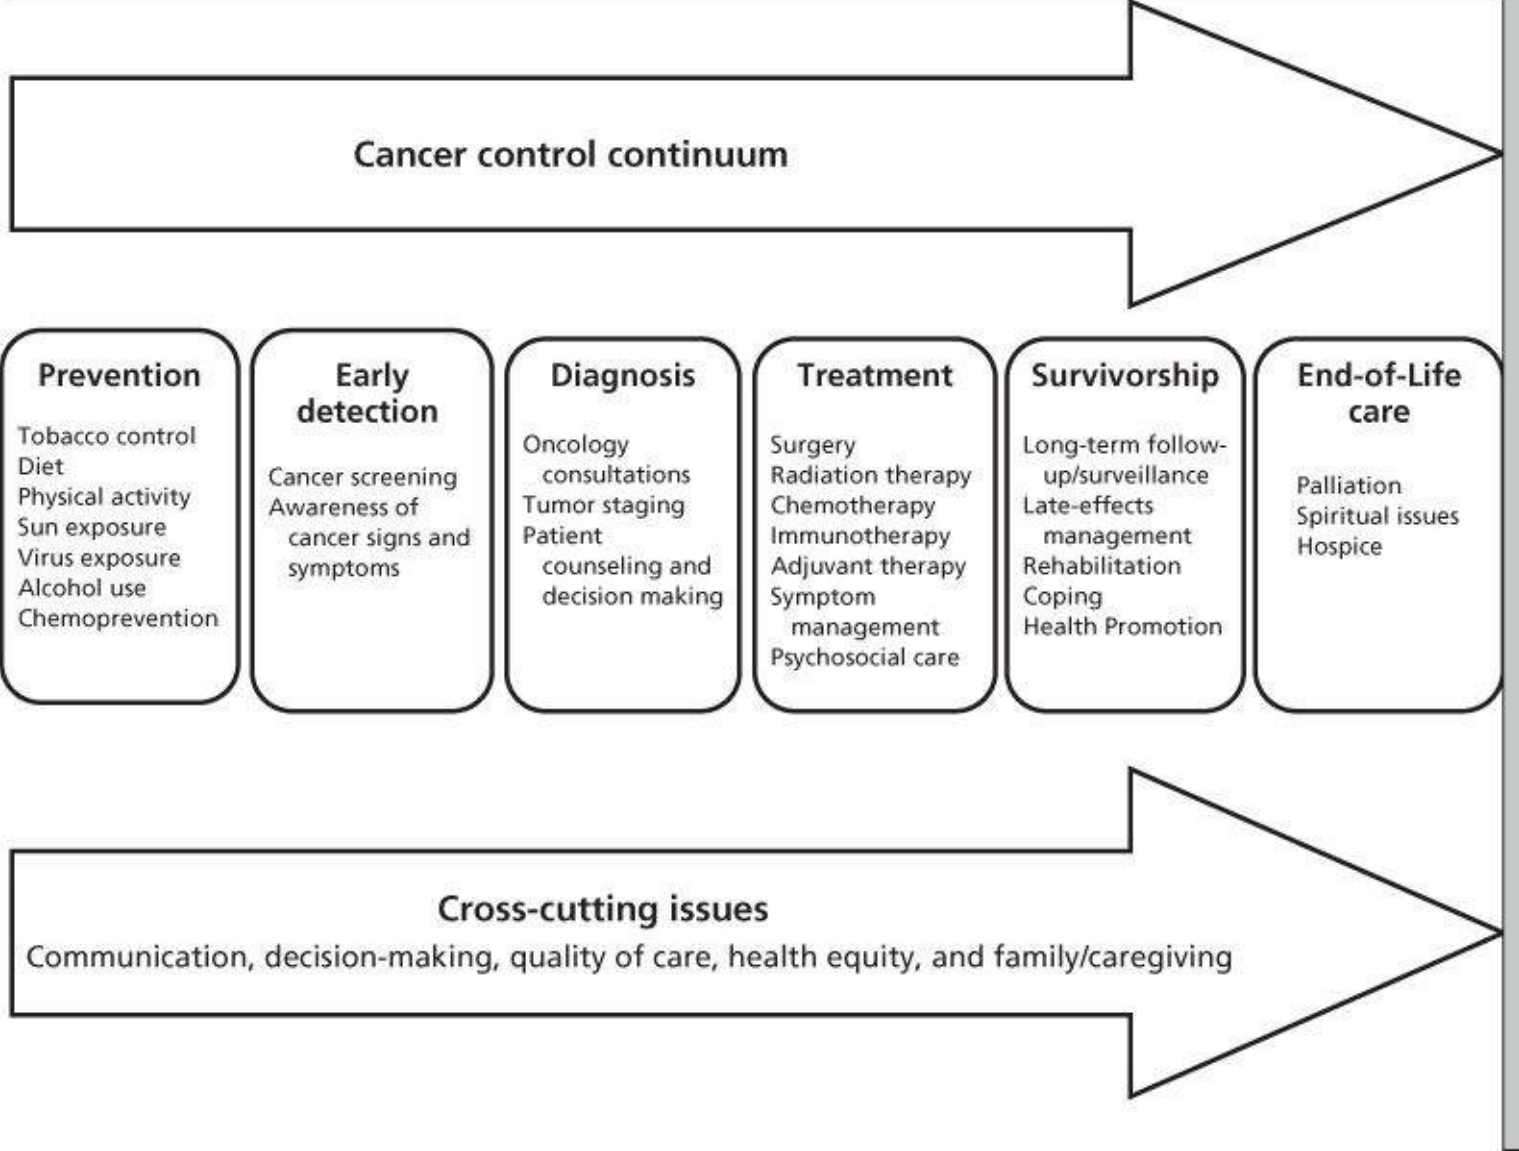

Figure 1 Cancer control continuum—elaborated.

Figure 2 Estimated and projected number of cancer survivors in the United States from 1977 to 2022 by years since diagnosis.

Source: de Moor 2013.²⁷

Magnitude of the problem

Cancer prevalence

As of January 1, 2014, there were an estimated 14.5 million cancer survivors in the United States alone.²⁵ Globally, figures suggest that there are over 32.6 million cancer survivors worldwide, although this represents a minimum count as most countries can only project prevalence up to 5 years post diagnosis.²⁶ As reflected in [Figure 2](#), the number of cancer survivors has increased steadily over the past 45 years. In 1971, when President Nixon signed the National Cancer Act and declared the “war on cancer,” there were an estimated three million survivors. By 2024, this number will climb to 19 million. The increase in numbers is due in part to advances in early detection, treatment efficacy, and supportive care. Breakthrough discoveries notwithstanding, however, the biggest contributor to growth in cancer prevalence in the decade to come will be the aging of the population.²⁸

Today, over 60% of those diagnosed are aged 65 and older. With the Baby Boomer generation turning 65 at a rate of approximately 11,000 a day (since January 2011), it is estimated that 11 million cancer survivors will be older adults by 2020, representing a 42% increase in their numbers in just one decade (2010–2020).²⁹

In addition to their growing numbers, today's cancer survivors are also living longer. In 2014, 41% of survivors were diagnosed 10 or more years ago, and an impressive 15% were diagnosed 20 or more years earlier ([Figure 2](#)).²⁷ *Healthy People 2020* has a target goal to increase the proportion of cancer survivors who are living 5 years or longer after cancer to 72.8%.³⁰ While we have surpassed this figure

for those diagnosed as children (age <15), where 10-year survival is now >77%, this is definitely a challenge goal in adult onset cancers. Approximately 68% of adults diagnosed today can expect to be alive in 5 years. Unknown in all of these figures is the well-being or disease status of this burgeoning population. Beyond estimates for the number of individuals within 1 year of diagnosis, and 1-year from death, our Surveillance Epidemiology and End Results (SEER) registry data provide limited information about the health status of the cancer survivor population. This constitutes an important gap in our knowledge base. Of note, *Healthy People 2020* also has a goal to increase the mental and physical health-related quality of life (HRQOL) of cancer survivors.³⁰ How we are to measure this effect remains unclear.

Cancer's long-term and late effects

Research among long-term cancer survivors has grown in parallel to their growing numbers. Clear from this science and the testimony of survivors themselves is that being told you are cancer-free does not mean you are free of the cancer experience. As one survivor put it, “It's not over when it is over.”

Cancer has the capacity to affect virtually every aspect of an individual's life and function: physical, psychological, social, economic, and existential ([Table 1](#)). Some of these effects are acute and resolve quickly once treatment ends (e.g., nausea and vomiting, and hair loss). Others become more chronic, arising during active treatment and persisting over time (e.g., fatigue, sexual dysfunction, memory problems, bladder, and bowel problems). While some of these latter symptoms may resolve in the longer term, other sequelae of cancer and its treatment can be permanent (e.g., infertility and amputation). Further, as survivors are living longer, they are surviving long enough to experience effects once considered only as “putative” risks secondary to some treatments (e.g., radiation therapy and certain chemotherapeutic agents). A third category of effects are those that are late-occurring, defined as manifesting 6 months or more after treatment. In addition to recurrence or second cancer,^{31, 32} risks for other chronic health conditions (e.g., cardiovascular disease, diabetes, and osteoporosis) is also increased.^{33, 34} Depending on the age of the survivor, these conditions may be of more concern than the cancer itself.³⁵

Table 1 Potential long term and late effects of cancer and its treatment

<i>Physical/Medical</i> (e.g., second cancers/recurrence, cardiac dysfunction, pain, fatigue, memory problems, sleep disturbance, sexual impairment, infertility, and loss of bowel/bladder control)
<i>Psychological</i> (e.g., fear of recurrence, depression, anxiety, lowered self-esteem, and altered body image)
<i>Social</i> (e.g., changes in interpersonal relationships, altered family functioning/dynamics, social isolation, altered intimacy, problems advancing at work/returning to school)
<i>Financial</i> (e.g., concerns regarding health or life insurance access/coverage, financial strain due to cost of care/job loss)
<i>Existential/spiritual issues</i> (e.g., disillusionment, loss of faith, altered sense of purpose or meaning, appreciation of life, benefit finding, and post-traumatic growth)

Overall, most survivors are remarkably resilient, coping well with what at times can be lengthy as well as physically rigorous treatments. Although a significant subset continues to struggle with emotional distress, by a year or more after treatment, most cancer survivors report levels of emotional well-being equivalent to or better than their peers without a cancer history.³⁶ When it comes to physical health, the

picture is different. Compared with those without a cancer history, survivors demonstrate worse physical functioning, higher rates of disability, and more unemployment.^{37–39} Further, research suggests that lingering physical symptoms commonly occur in clusters (e.g., pain, sleep problems, and fatigue) and greater symptom burden is associated with increased risk of poor quality of life.⁴⁰

The provision of detail about each of the lingering effects of cancer is beyond the scope of this chapter (for reviews, see Refs). However, four persistent effects are worth discussing here because they are common across a number of cancers and troubling: fear of recurrence, fatigue, depression, and memory problems. Perhaps the most universal effect of surviving cancer is worry that the disease will return.⁴⁴ Fear of recurrence can be exacerbated by a variety of triggers (e.g., coming for routine follow-up visits, anniversary dates of diagnosis or treatment, death of a fellow or publicly visible cancer survivor, and any unexplained ache or pain),⁴⁵ and healthcare professionals see this response as challenging to manage.⁴⁶ Reassurance that such anxiety is normal and often diminishes over time, along with counsel about what is or, more important, is not a worrisome sign or symptom generally helps to allay concerns. In cases where fear persists and is interfering with daily function and/or recommended follow-up care, referral for brief counseling to see what may be contributing to the anxiety, to learn some relaxation techniques, and to obtain social support can be helpful. Of note, survivors who continue on long-term therapies (e.g., use of adjuvant hormonal therapy among breast cancer survivors) may feel less anxious about the disease coming back. These individuals often report being reassured by the sense that they are doing something active to reduce risk of recurrence.

Fatigue, common during treatment, persists in approximately a quarter to a third of long-term survivors.^{47, 48} The mechanisms of risk for long-term fatigue are not well understood.⁴⁹ The importance of addressing this troubling effect of cancer and its therapy is reflected in the American Society of Clinical Oncology (ASCO) guideline for assessment of this symptom post-treatment.⁵⁰ To date, few interventions appear to mitigate cancer-related fatigue, with the exception of exercise. While seemingly counterintuitive, patients who remain physically active during and after treatment report lower, not higher levels of fatigue.⁵¹ After ruling out possible physiologic causes of fatigue (e.g., anemia, infection), reassurance that fatigue generally abates over time, albeit far more slowly than once thought, can be helpful in reducing distress about this lingering effect.

Prevalence rates of depression or depressive symptoms among cancer survivors are higher than that observed in the general public, particularly in the early 1–2 years post-treatment.⁵² Depression is not only painful, but is also associated with delay in return to work and lower adherence to medical regimens in survivors.⁵³ Younger age, being female, and prior history of depression are all associated with increased risk for depression among cancer survivors, yet many survivors experience depression for the first time after a cancer diagnosis.^{54–56} Survivors and their clinicians need to be aware that cancer treatments can induce depression especially as many people believe that their symptoms are a sign of poor coping or mistakenly assume that depressed mood is expected in the face of cancer.⁵⁵ Because of the risk for higher all-cause mortality associated with depression, routinely screening for symptoms of depression and referring for treatment is important. Excellent algorithms exist for caring for individuals who are found to be depressed; many can benefit from psychotherapy alone without the need for added medications that many cancer survivors report they are reluctant to take.^{57, 58}

Although long dismissed in the clinical setting, growing attention is now being paid to survivors' complaints of chronic difficulties post-treatment with memory and concentration. Neurocognitive dysfunction (i.e., difficulty remembering things, thinking clearly and focusing attention, also referred to as “chemo-brain” or “chemo-fog”) is a real and persistent effect of cancer that, more recent studies suggest,

may affect between 15% and 25% of survivors in the early re-entry period, with a range as high as 61%.⁵⁹ The etiology of cancer-related cognitive impairment is multifactorial and may involve systemic proinflammatory cytokines that cross the blood–brain barrier, exposure to chemotherapy, hormonal and biotherapies, and direct treatment toxicities (e.g., surgery, radiation to the brain).^{60, 61} Both older age and lower cognitive reserve increase risk for cognitive problems after chemotherapy, findings that contribute to the emerging hypothesis that cancer treatments accelerate the aging process.⁶¹ A number of promising interventions have been developed to help childhood cancer survivors manage cognitive problems resulting from cancer,⁶² and more recently, cognitive behavioral therapy interventions are being explored among adult survivors.⁶³

Providing survivorship care

Transitioning to recovery

For many survivors, the relief of completing treatment may be tempered by concerns about what the future holds. The stress associated with transitioning to recovery and life *after* (instead of with) cancer has multiple sources. First and foremost among these is worry that the cancer will return now that therapy has stopped. General levels of anxiety may increase as patients transition off treatment. Fear in the survivor can have an adverse effect on family quality of life; the reverse also is true, with family members' fears negatively influencing the quality of life of the survivor.⁶⁴ When activated, fear may also lead to disruptive behavior such as heightened body monitoring and anxiety well in advance of a doctor visit, and worry about the future. In some instances, severely disabling reactions can occur including hypochondriac-like preoccupation with health at one extreme, or avoidance and denial at the other, along with inability to plan for the future, and despair. Interventions are being developed to help survivors cope successfully with uncertainty.⁶⁵

Survivors can be taken by surprise by what feels like a paradoxical response to ending treatment, a combination of joy and anxiety. Persistent symptoms (e.g., fatigue, memory problems, and pain syndromes) contribute to a sense of diminished well-being and can lead a survivor to feel she is less well than when treatment was initiated. Loss of the supportive therapy environment (including relationships with staff and fellow patients) must be negotiated. All of this generally occurs in a setting in which family and friends, and even survivors themselves, are ready for everything to be back to “normal.”

Key to navigating this transition is acknowledging that it can be stressful. Having a plan of action for the future is also helpful. In this context, the current demand for the development and delivery of survivorship care plans (SCPs) may provide a ready solution to aid smooth coordination of post-treatment care.

Standards for survivorship care

One of the key recommendations in both the President's Cancer Panel report on cancer survivorship¹⁶ and the IOM report, *From Cancer Patient to Cancer Survivor: Lost in Transition* (whose title aptly describes the survivor's dilemma when treatment ends¹⁴), is that clinicians should provide patients with a comprehensive treatment summary and a tailored plan for follow-up care. Together, these documents comprise what is known as a survivorship care plan or SCP. Although there is not yet consensus on a standard SCP format or content, several common elements are recommended for inclusion. The treatment summary should provide details about the specific cancer (e.g., diagnosis, stage, pathology, and genetic markers if relevant), type of treatments received (e.g., chemotherapy, radiotherapy with dosing and target area as appropriate, hormonal therapy, and biologic agent use), toxicities experienced, treatment

response, and risk for late effects, along with the name and contact information for treating physicians. This information is then used to generate a unique plan of post-treatment care. The IOM¹⁴ identified 11 elements as part of this document that can be summarized in four broad categories: (1) surveillance for recurrence or new cancers including the nature and timing of these tests; (2) assessment and treatment of or referral to community resources for help with persistent effects of cancer, encompassing psychosocial as well as physical sequelae, acknowledging that psychosocial effects of survival are often overlooked⁶⁶; (3) recommendations for prevention of future cancer or adverse health conditions, including lifestyle recommendations and potential referral for genetic testing; and (4) specification regarding the components of follow-up care, as well as the contact information for the clinician(s) responsible for delivering follow-up care ([Table 2](#)).

Table 2 Essential elements of survivorship care

<i>Surveillance</i> for recurrence or new cancer (e.g., tests to be performed and their periodicity and changes to be monitored)
<i>Assessment and treatment</i> or referral for persistent effects including medical problems (e.g., depression, lymphedema, sexual dysfunction, and functional impairment), symptoms (e.g., pain and fatigue), psychological distress experienced by cancer survivors and their caregivers; and concerns related to employment, insurance, and disability; use of rehabilitation as indicated
<i>Prevention</i> of late effects (e.g., second cancers, cardiac problems, and osteoporosis) accompanied by use of genetic testing as indicated; including a focus on health promotion (e.g., diet, weight, physical activity, and sun block use), and management of comorbid conditions
<i>Coordination of care</i> (e.g., including frequency of visits, tests and who is performing these) between specialists and primary care providers to ensure that all of the survivor's health needs are met

Source: Adapted from Hewitt 2006.¹⁴

Despite being strongly recommended in two national reports, use of SCPs has been slow to catch on. In their review of the literature on use of SCPs, Mayer et al.⁶⁷ arrive at several overarching conclusions: SCPs are broadly endorsed by both patients and providers, but in practice remain underutilized, with large numbers of clinicians reporting failure to deliver these or patients to receive same; while agreement exists among both providers and patients on preferred SCP content, the timing of delivery and who should deliver these is unclear; and finally, limited data exist on the impact of SCP implementation, raising concern about what, if any, difference these documents will make in care delivery or outcomes. These challenges notwithstanding, pressure to embrace SCP use is growing.

In an important step toward making treatment summaries and care plans a part of quality care, ASCO decided to incorporate relevant measures as part of its Quality Oncology Practice Initiative (QOPI). A voluntary program opened to ASCO members in 2006, QOPI was created to promote excellence in cancer care by helping oncologists create a culture of self-examination and improvement. In 2008, ASCO added three items to its core set of questions inquiring whether a chemotherapy treatment summary was completed, a copy was provided to the patient, and a copy was also sent or communicated to another practitioner, all within 3 months of chemotherapy end. Somewhat complex templates for cancer surveillance for breast, colorectal, and prostate cancer were a regular feature on the ASCO web site. More recently, ASCO released a short SCP template.⁶⁸ An online tool for building SCPs, *Journey Forward*, is also readily available, the result of a collaboration of oncology experts, industry, a health insurer, and advocacy groups (<http://journeyforward.org/>). A number of the key oncology electronic software vendors have begun to develop tools for this purpose as well although lack of interoperability

among platforms creates a barrier to their intent, namely, to share information and maximize coordination of care. Key hurdles to optimal SCP use are the personnel time it takes to generate them, lack of easy IT integration to facilitate data capture and exchange, and limited evidence-based guidelines with which to inform recommended care.⁶⁹ Busy clinicians are hardpressed to use these documents and provide high-quality care because of limited time and budgets. At the same time, SCPs are of limited utility without the intended conversation between patient and provider on their content and use; without these informing dialogues, they are just another piece of paper.

Despite the legitimate concerns about their use, starting in 2015, the American College of Surgeon's Commission on Cancer is including development and delivery of SCPs as an accreditation criterion.⁷⁰ Ideally, this action will stimulate thoughtful research regarding who should create and deliver these documents, what is the best approach to doing this, when in the course of care this process should be initiated, and who will pay for this activity. Importantly, understanding whether or not use of SCPs improves patient, provider and system function will be critical.

Models of survivorship care

While it is increasingly recognized that cancer survivors need to be followed for life after treatment, little consensus exists about how this should be done. Anticipated shortages of oncology providers,⁷¹ coupled with growing pressure for these professionals to see new patients, makes solving the question of who should provide cancer-related follow-up care a paramount concern.

A number of papers have called for consideration of a shared-care model in which primary care physicians (PCPs) have primary responsibility for follow-up with referral back to oncology or other specialists as needed.^{72–74} In this model, it is essential that the oncologist provide the PCP with an SCP to communicate key information about the survivor's illness history, surveillance recommendations, and potential late complications for which to monitor. One large survey suggests that many US PCPs prefer a shared-care model; fewer prefer an oncologist-led model, a PCP-led model, or other specialty survivorship clinics.^{75, 76} This same study reported PCPs' confidence regarding their knowledge of survivorship care may be less than optimal.⁷⁷ However, international studies have found comparable time to recurrence, quality of life, and psychological functioning among survivors followed up by oncology and those followed up in primary care with some element of guidance (e.g., one page of follow-up instructions).^{78, 79}

Other models of follow-up care have also been launched, the most common of these developed at large comprehensive cancer centers, being multidisciplinary, specialized survivorship clinics.⁸⁰ These tend to offer one of two models: (1) a consultative program in which patients can come at any point post-treatment for review of their history, current function and risk for future problems, and leave with recommendations for care of current problems and an outline of proposed future care to share with their providers; or (2) a full-service program in which survivors can come for regular visits for some specified period of time (e.g., 2–5 years) after cancer treatment. A third model involves nurse-led care in which the nurse serves as a conduit between the care team and the survivor.^{81–83} Evolution of a given program often reflects the resources of the clinic or facility, the patient population being served, and more generally, the passion of a key leader or leaders to bring the program together and champion funding support for the enterprise. Sustainability for survivorship care programs is a central concern as there is as yet no clear system for reimbursing this care. Models for financing include fee-for-service, insurance reimbursement, research grants, philanthropy, and dedicated program-specific fund raising. Some larger centers see inclusion of a survivorship clinic as “value added” to their operation and will put resources toward

support of these programs in the expectation that they will bring more new patients (as well as survivors) to their high-quality facility.

Because of the complexity of cancer and its treatment and the wide variation in what patients bring to their cancer experience (e.g., with respect to pre-existing medical history, function and psychosocial resources), it is clear that one size does not fit all when it comes to models of survivorship care. Additional calls have been made to develop risk-stratified approaches to post-treatment care. In this approach, clinician specialty and visit frequency depend on survivor needs and risk for recurrence and late effects.^{84, 85} Low-risk survivors (e.g., early-stage breast or colorectal cancer receiving surgery only) may be transferred right back to primary care shortly after conclusion of treatment. High-risk survivors (e.g., those undergoing stem-cell transplant or with more complex care needs) would be seen regularly by oncology with routine care addressed by the PCP.^{72, 73} A risk-stratified model of care is currently being tested in Great Britain (<http://www.ncsi.org.uk/what-we-are-doing/risk-stratified-pathways-of-care/risk-stratification/>). For this type of care to become more common, evidence-based predictive models are needed for survivors most likely to experience negative sequelae after cancer.

Regardless of the model used, two central tenets of survivorship care remain constant: coordination of care is critical if survivors are to receive optimal post-treatment follow-up, and survivors themselves necessarily play an important role in their healthcare and outcomes. While current survivorship care in the United States involves multiple providers from a variety of specialties,⁸⁶ no system for communication and coordination among these individuals or teams has been established.⁸⁷ Furthermore, until such time as there is consensus about which providers are responsible for, or appropriately skilled in, the essential components of survivorship care,^{77, 88, 89} survivors are at risk of care that is potentially duplicative, inappropriate (e.g., over testing in the absence of proven utility of special scans or tumor markers), or ineffective in reducing cancer-related morbidity. Even some oncologists report incomplete knowledge of the late effects of cancer treatment.⁹⁰ To maximize the efficiency and effectiveness of survivorship care, clear communication is crucial at the end of cancer treatment between patients and their providers, as well as cancer providers and their patients' PCP and other specialists, about who is going to provide what kind of care, and when and where this will be delivered. Increased efforts are needed in training diverse healthcare providers about the long-term and late effects of cancer and developing guidelines for delivery of optimal survivorship care. Toward this latter goal, guidelines released by the National Comprehensive Cancer Network (NCCN),^{91, 92} ASCO,^{68, 93} and the American Cancer Society (ACS)⁹⁴ are already available for advancing survivorship care. Similar efforts are occurring globally.⁹⁵

For their part, survivors may expect that if they continue to see their oncologist years after treatment, he or she is providing primary care.⁹⁶ In addition to serving as a communication vehicle between clinicians, SCPs can facilitate survivors' education about their role in managing post-treatment health. Self-management interventions have been shown to improve survivors' quality of life, psychological functioning, and health behaviors. The care received is also more likely to be consonant with survivors' needs and goals when survivors actively participate in treatment-related decision making.⁹⁷

Rehabilitation and health promotion

As the goal of cancer therapy expands beyond merely curing or controlling disease to optimizing function and quality of life after cancer, two additional aspects of care have emerged as central to these aims: rehabilitation and health promotion. Use of cancer-related rehabilitation in the United States has diminished over time, in part reflecting earlier diagnosis (hence less need for more aggressive treatments)

and broader use of more limb- and tissue-sparing approaches to surgery. Concern about the persistent effects of cancer and its treatment, however, are causing clinicians to rethink use of these services, access to which remain a standard of care in many countries outside the United States.^{98, 99} Survivors report multiple rehabilitative needs after cancer,¹⁰⁰ and research suggests that attending to these, both preventively and after the fact,¹⁰¹ can reduce cancer-related morbidity and mortality. A licensed program designed to meet the rehabilitative needs of cancer survivors has been adopted by several sites across the United States.¹⁰² In 2013, the Commission on Accreditation of Rehabilitative Facilities (CARF) developed certification standards for cancer rehabilitation.¹⁰³ How quickly incorporation of these types of services occurs in large cancer centers remains to be seen.

Interest in health promotion after cancer has grown in the past decade driven by multiple factors, including demand by survivors themselves. Most cancer survivors are older, often present with comorbid conditions that are exacerbated by cancer treatment or are at increased risk for comorbid health problems (e.g., cardiac problems, obesity, and osteoporosis) as a function of treatment, develop poor health habits while in active treatment (sedentary and poor diet), are aging, and could benefit from lifestyle interventions. Importantly, survivors often ask their care team what they can do to reduce the risk of a recurrence and regain health after cancer. Because of these factors, researchers see cancer as a “teachable moment.”¹⁰⁴

The benefits of healthy lifestyle are well known in association with prevention of cancer, covered elsewhere in this volume. Among cancer survivors, observational studies suggest that smoking cessation, increased physical activity, and weight control may reduce the risk of cancer recurrence, cancer specific mortality, and overall mortality,^{105–107} although randomized clinical trials are still needed to support causal statements about the effects of behavior change. The consistency of the data behind the benefits of remaining or becoming more physically active during and after cancer is sufficient for clinicians to recommend their patients strive to be up and about right from the start of treatment. The ACS provides and regularly updates guidelines for cancer survivors about nutrition and physical activity after cancer.¹⁰⁸ While some survivors change their behavior spontaneously,¹⁰⁹ many do not.¹¹⁰ Survivorship care provides an important opportunity for clinicians to support cancer survivors' efforts to make changes in dietary behaviors, levels of physical activity, smoking, and stress management that have the potential to reduce risk of recurrence, second malignancies, and comorbid health conditions, an opportunity currently being missed by many practitioners.^{111, 112} More research is urgently needed on how providers can effectively deliver health promotion assistance and how survivors can successfully implement and sustain beneficial changes.

Families and informal caregivers

Because the advocacy community considers informal caregivers to be cosurvivors, no discussion of survivorship care is complete without consideration of the family caregiver. With the majority of cancer care now delivered in the outpatient setting and many more individuals living long-term after cancer, large numbers of whom will live with cancer as a chronic illness, the burden of cancer on families is rising rapidly. Research suggests that family caregivers frequently feel ill-prepared for the demands of care for their loved one, receive little or no guidance on what to do, and often strain under the demands of competing roles, including holding jobs, managing children, and caring for their own health.¹¹³ One study found that two out of five caregivers experience moderate psychological distress and one out of five desires formal support.¹¹⁴ Caregivers may worry more about recurrence than the survivor.⁶⁴ Unrealistic expectations for a speedy return to life as usual can contribute to anxiety that lingering symptoms may

reflect return of the disease and resentment that recovery is taking too long and lead to disruptions in family functioning.

Providing both cancer survivors and their caregivers with information about what to expect in the first 6 months after treatment ends is vital to reduce distress in both parties. Dyadic studies indicate that health outcomes in both patients and their caregiver partners are mutually dependent.^{115–117} Because family caregivers, like their care recipients, tend to be older adults and at risk of their own comorbid health conditions (including cancer), it is possible that healthy lifestyle education efforts with the survivor may also benefit the caregiver, although this effect remains to be tested. Moreover, involvement of family caregivers can be critical to ensuring survivors' adherence to recommended adjuvant therapies, follow-up visits, and symptom control and reporting. Thus, ensuring that this vital support system is functioning well can provide an enormous asset to providers in effectively managing their patients' care. Already a number of cancer centers are striving to include services for caregivers as part of their comprehensive care.¹¹⁸

Conclusion

The growing population of cancer survivors has taught us several lessons. First, that cancer survivorship—defined as the period that extends from completion of curative therapy until recurrence or death from cancer or another event—represents a distinct phase along the cancer control continuum. It brings its own unique set of challenges and opportunities for recovery and growth. Second, the majority of survivors will live years beyond their initial diagnosis. Those treated as children, adolescents, or young adults have the potential to live a lifetime with a cancer history. However, few of our current therapies are entirely benign; most have some degree of associated toxicity and a number produce considerable adverse physical as well as psychosocial sequelae. Consequently, third, all of these chronic and late effects must be tracked and actively addressed. Fourth, while a subset of survivors continues to struggle after cancer treatment ends, most are remarkably resilient. Nevertheless, the capacity of survivors and their healthcare providers to realize the shared goal of good quality of life and function requires collaboration and communication between both groups. Defining and delivering high-quality survivorship care, albeit a high-end problem, constitutes a significant challenge for cancer medicine. Success, in our efforts to reduce undue suffering and premature death due to cancer, will require continued investment in survivorship research. It will also require enhanced commitment to the training and support of current and future generations of multidisciplinary providers who care long term for those treated for cancer. While a number of questions remain about how to achieve these lofty goals, the resources to do so are evolving rapidly. Further, a number of evidence-based programs have evolved to address survivors' post-treatment needs. Though far from perfect, these are good enough to begin disseminating.¹¹⁹ Increased attention will be needed, nevertheless, to promote tailoring of care to older adult cancer survivors, a surprisingly neglected population.¹²⁰ Along with interest in the field of cancer survivorship more generally, the number of survivorship scientists and practitioners is expanding steadily both in the United States and abroad.^{121, 122} There is broadening public awareness of the importance of managing the care of those with chronic illnesses like cancer, and the advocacy community championing cancer survivorship needs remains strong. The next decade will permit us to promote and measure the impact of collective efforts to enable more survivors and their families to thrive after cancer.

Summary

- The number of individuals in the United States with a cancer history will continue to grow over

the next two decades, driven largely by the aging of the population. By 2022, there will be 18 million cancer survivors, approximately two-thirds of whom will be age 65 or older.

- Cancer survivorship—defined as the period that extends from completion of curative therapy until recurrence or death from cancer or another event—represents a unique place on the cancer control continuum and is accompanied by its own set of health care challenges.
- Cancer and its treatment can cause a variety of persistent (e.g., pain, fatigue, memory problems, and sexual dysfunction) as well as late-occurring (e.g., second cancers, cardiac problems, diabetes, osteoporosis, and depression) adverse sequelae. Often occurring in clusters, these effects can have a negative impact on every aspect of a survivor's life: physical, psychological, social, economic, and existential.
- Most cancer survivors are remarkably resilient and adapt well after cancer. However, a significant subset struggle with the aftermath of their illness. Use of systematic assessment at the end of treatment with early identification and referral of those in need of additional support is important.
- Use of SCPs to improve quality of and communication around post-treatment care is growing. In addition to a treatment summary, essential elements of an SCP include plans for (1) surveillance for recurrent or new cancers; (2) assessment and treatment of persistent effects of cancer; (3) prevention of late consequences, including use of genetic testing and health promotion; and (4) coordination of care.
- No consensus exists on the best model for follow-up care delivery. Currently, multiple models are being examined. Interest is growing in the development of models that (1) involve shared care between oncology and primary care providers and (2) are structured around risk-based algorithms (e.g., survivors with early-stage disease and minimal treatment would return quickly to their PCP, whereas those at high risk of recurrence would remain more closely connected with oncology care teams and centers).
- Survivorship may provide a “teachable moment” for clinicians to help cancer survivors pursue healthy lifestyles and behaviors.
- Attention must be given to the psychological and physical well-being of family caregivers in the recovery process. Viewed as “secondary survivors,” informal caregivers play an important role in survivors' recovery and yet may struggle themselves with this transition to a “new normal.”

Part 11

Disease Sites

Chapter 77

Primary and metastatic neoplasms of the brain in adults

Lisa M. DeAngelis, MD, FAAN

Overview

Primary brain tumors are uncommon but aggressive neoplasms even when histology is low grade. Secondary, or metastatic, tumors are at least 3 times more common than all primary tumors combined. Diagnosis is easily established by magnetic resonance imaging (MRI), and surgical resection provides histologic confirmation and decompression; surgery alone may suffice for low-grade tumors and most extra-axial tumors such as meningiomas. Treatment of parenchymal brain tumors, primary or metastatic, often requires a combination of radiotherapy and chemotherapy, which may improve patient function and control disease but rarely achieves cure.

Introduction

Tumors of the central nervous system (CNS) are a heterogeneous group of both benign and malignant intracranial neoplasms. CNS tumors are classified into two groups: those that grow within the brain (intracerebral) and those that grow outside the brain (extracerebral). Historically, CNS tumors have been intractable to standard therapies of surgical resection, radiotherapy (RT), and chemotherapy. However, over the past several decades, advances in diagnostic imaging, surgical techniques, radiation oncology, and chemotherapy have improved survival and quality of life. Most important, we are acquiring a better understanding of the molecular events associated with the malignant phenotype of a brain tumor, which has led to several novel chemotherapeutic approaches to their treatment.

Epidemiology

Primary intracranial tumors are uncommon. The overall annual incidence of brain tumors, both benign and malignant, in the United States is estimated at 21.03 cases per 100,000 person-years leading to an estimated 63,000 new cases diagnosed each year (Central Brain Tumor Registry of the United States Statistical Report [CBTRUS] 2006–2010).¹ More than 26% are gliomas, and almost three-quarters of these are high grade with a higher incidence in men (7.76 per 100,000 person-years) than in women (5.60 per 100,000 person-years).¹

The incidence and histologic type of intracranial tumor differs by race, gender, and age.¹ The overall incidence of brain tumors (especially gliomas) is greater in Whites than Blacks. However, meningiomas are more frequent in Blacks than Whites. Pituitary adenomas are also more common in Blacks than Whites. Gender differences are apparent. The male to female ratio is 1.3 for oligodendrogliomas, 1.38 for astrocytomas, and 0.77 for malignant meningiomas, and for benign meningiomas, the male to female ratio is 0.44. Lymphomas and germ cell tumors are more common in males, 1.31 and 2.33, respectively.

CNS tumors can occur at any age, but the incidence and histologic type vary by age. There is a small peak before age 10 and a steady rise from age 15. The average age of onset for all primary brain tumors is 54

years. The average age of onset of glioblastoma (GBM) and meningioma is 62 years, whereas for oligodendroglioma the mean age of onset is 16 years. The CBTRUS data show that the highest incidence for all brain tumors occurs in the 75- to 84-year-old age group, with GBMs occurring most frequently in patients older than 65 years. Survival is directly related to patient age and tumor histology. For instance, the 5-year relative survival rate for patients with pilocytic astrocytomas (a common childhood tumor) is 94.4%, compared to 4.7% in patients with GBMs. Other important prognostic factors include extent of disease, extent of resection, and tumor location.

Risk factors

There have been a large number of studies examining the relationship between the environment and the occurrence of brain tumors, but only two unequivocal risk factors have been identified: ionizing radiation and immune suppression ([Table 1](#)). The role of low- and high-dose therapeutic ionizing radiation as a significant risk factor for brain tumors has been confirmed in many studies. Irradiation for intracranial tumors, e.g., medulloblastoma or extracranial head and neck cancers, including prophylactic irradiation for leukemia, increase the incidence of both gliomas and sarcomas sevenfold in those who survive more than 3 years. The cumulative relative risk of secondary brain tumors in patients treated with cranial irradiation ranges from 5.65 to 10.9; approximately two-thirds of the tumors are gliomas and one-third are meningiomas.² High-grade gliomas have a median latency of 9.1 years from cranial RT compared to 19 years for meningiomas. Low-dose radiation such as that used to treat tinea capitis, a fungal infection of the scalp, and skin hemangiomas in children is associated with an increased risk of brain tumors. A relative risk of 18, 10, and 3 have been observed for nerve sheath tumor, malignant meningioma, and glioma, respectively.

Table 1 Risk factors for primary brain tumors of neuroepithelial, meningeal, or lymphocytic origin

Definite risk factors
Ionizing radiation
Hereditary syndromes
Family history of brain tumors
Immunosuppression

Congenital or acquired immune suppression, such as human immunodeficiency virus (HIV) infection, or the use of immunosuppressive drugs after organ transplantation, increases the incidence of primary central nervous system lymphoma (PCNSL).³ HIV infection may also increase the frequency of glioma and intracranial leiomyosarcomas. PCNSL in immunosuppressed patients is driven by a pre-existing latent Epstein–Barr viral infection of B-lymphocytes. When a lymphoma occurs in an immunosuppressed patient, it is twice as likely to occur in the brain as elsewhere in the body.

Other studies of environmental risk factors are less convincing than those of ionizing radiation and immunosuppression, including dietary exposure to N-nitrosourea compounds, occupational exposure to pesticide and fertilizer manufacturing, formaldehyde, synthetic rubber production, vinyl chloride synthesis, and petrochemical industries. Additional research evaluating the association of brain tumors with head trauma, cigarette smoking, seizure history, maternal alcohol use, and infection has been inconclusive.

Exposure to electromagnetic fields (EMF), especially through the use of cellular phones, has been of interest. Most studies have demonstrated no association between cellular phone use and brain tumors, but

there may be a dose relationship to brain tumor risk.^{4, 5} Recent data suggest a history of allergies or atopic disease may be protective against glioma development. In addition, large genome-wide association studies point to eight germline DNA single nucleotide polymorphisms in seven genes that predispose to glioma formation or specific glioma grade or subtypes; the mechanism of this predisposition is unknown.⁶

Molecular genetics

There is evidence that somatic mutations in different molecular pathways may lead to the development of an identically appearing GBM. There appear to be at least four different molecular subclasses of GMB that include (1) *classical* characterized by EGFR amplification/mutation and p53 mutation, (2) *proneural* characterized by alterations in PDGFRA and isocitrate dehydrogenase (*IDH*) mutations, (3) *mesenchymal* characterized by NF1 dysfunction, and (4) *neural* with EGFR overactivity and displaying neural markers.⁷ At the present time, this molecular classification scheme does not drive treatment selection or prognosis. Lower grade gliomas with either astrocytic or oligodendroglial features are characterized by IDH mutations, primarily the *IDHR132H* mutation in 70%.⁸ This mutation leads to the formation of the oncometabolite, 2 hydroxyglutarate (2HG), which has become both a diagnostic and therapeutic target using magnetic resonance (MR) spectroscopy and novel IDH1 inhibitors. *IDH1* mutations are thought to arise early in gliomagenesis, but they are noticeably lacking in primary GBMs, or those that present in older age as *de novo* GBMs.

In addition to oncogene amplification and tumor suppressor gene inactivation, malignant tumors acquire the ability to invade adjacent neural structures and form a new blood supply via angiogenesis. Glial tumors are extremely invasive neoplasms and typically extend well beyond their macroscopic or imaging borders. Angiogenesis leads to vascular hyperplasia, which is the pathologic hallmark of a GBM. Vascular endothelial growth factor (VEGF) is one of the key stimulants to angiogenesis in gliomas. VEGF is not expressed in normal brain endothelium but is upregulated in gliomas by local hypoxia. VEGF also increases vascular permeability and plays a role in the peritumoral edema seen in malignant gliomas.

Familial tumor syndromes of the CNS

Familial brain tumor syndromes are a heterogeneous group of disorders characterized by an association of brain tumors with systemic features, primarily dermatologic ([Table 2](#)).

Table 2 CNS tumor syndromes

Disorders	CNS tumors	Tumors of other organs and tissues	Skin lesions	Genes	Ch
Neurofibromatosis-1	Glioma, neurofibroma	Iris hamartoma, osseous lesions, pheochromocytoma, leukemia	Café au-lait spots, cutaneous axillary freckling, neurofibromas	NF1	17q24
Neurofibromatosis-2	Vestibular Schwannoma, Meningioma	Posterior lens opacities, retinal hamartoma	None	NF2	22q12
von Hippel–Lindau disease	Hemangioblastoma	Retinal hemangioblastoma, renal cell carcinoma, pheochromocytoma,	None	VHL	3p21

		visceral cysts, endolymphatic sac tumor			
Tuberous sclerosis	Subependymal giant cell astrocytoma (SEGA)	Cardiac rhabdomyoma, adenomatous polyps of the duodenum and small intestine, cysts of the lung and kidney, lymphangi leiomyomatosis, renal angiomyolipoma	Cutaneous Angiofibroma ("adenoma sebaceum"), peau de chagrin, subungual fibromas	<i>TSC1, TSC2</i>	9q34 16p11
Li–Fraumeni syndrome	Gliomas (10%)	Breast carcinoma; bone and soft tissue sarcoma; adrenocortical, lung, and GI carcinoma; leukemia	None	<i>P53</i>	17p13
Cowden disease	Cerebellar mass (Lhermitte Duclos disease)	Hamartomatous polyps of the eye, colon, and thyroid; breast carcinoma, thyroid cancer	Multiple trichilemmomas, fibromas	<i>PTEN</i>	10q26
Brain tumor- polyposis syndrome type 1	Malignant glioma	Colorectal adenomas, colon carcinoma, No polyps		<i>MLH1</i> <i>MSH2</i> <i>MSH6</i> <i>PMS2</i>	3p21 2p21 2p16 7p22
Brain tumor- polyposis syndrome type 2	Medulloblastoma	Colon cancer, colonic polyps		<i>APC</i>	5q21
Nevoid basal cell carcinoma syndrome (Gorlin syndrome)	Medulloblastoma (anaplastic)	Jaw cysts, ovarian fibromas, skeletal abnormalities	Multiple basal cell carcinomas, palmar and plantar pits	<i>PTCH</i>	9q24
Retinoblastoma	Pineal tumor	Retinal tumor, osteosarcomas and other tumors	None	<i>RBI</i>	13q14
Bloom syndrome	Medulloblastoma meningioma	Characteristic face and voice, gonadal failure, diabetes, immunodeficiency	Sun sensitivity, patches of hyper- and hypopigmentation	<i>BLM</i>	15q21

PNET, primitive neuroectodermal tumor; AML, acute myelogenous leukemia.

Neurofibromatosis 1

Neurofibromatosis 1 (NF-1), also known as von Recklinghausen disease, is the most common hereditary disease predisposing to CNS cancer, with a prevalence of 1 in 4000. The incidence is equal in men and women. It is an autosomal dominant disorder with 100% penetrance but is highly variable in its expressivity with both minimally and severely affected individuals within the same family. The NF-1 gene has been mapped to chromosome 17q11.2 and encodes a tumor suppressor, neurofibromin.

The predominant CNS tumors in NF-1 are optic pathway and brainstem gliomas. Optic pathway gliomas are usually pilocytic astrocytomas and brainstem gliomas are astrocytomas. The typical peripheral nerve tumor is the plexiform neurofibroma, which often involves the paraspinal and cranial nerves. Other NF-1 related tumors include malignant schwannomas, rhabdomyosarcomas, and GBMs.

Neurofibromatosis 2

Neurofibromatosis 2 (NF-2), known as central neurofibromatosis, is an autosomal dominant disorder that accounts for only 10% of all neurofibromatosis cases. The NF-2 gene is a tumor suppressor gene located on chromosome 22q12.2, which encodes a tumor suppressor, merlin. The predominant CNS tumors in NF-2 are vestibular schwannomas, often bilateral, and meningiomas.

Tuberous sclerosis

Tuberous sclerosis (TS) is an autosomal dominant disorder. It has been mapped to two different loci: TS complex 1 located on chromosome 9q34.14 encodes the protein hamartin and TS complex 2 located on chromosome 16p13.3 encodes the protein tuberlin. The classic clinical triad of mental retardation, seizures, and facial angiofibromas occurs only in the most severe cases. Skin lesions are seen in 96% of patients, including angiofibromas, uncal fibromas, hypomelanotic skin patches known as “ash leaf spots,” and dental pits. The hallmark CNS tumor is the subependymal giant cell astrocytoma (SEGA). Although pathologically benign, SEGAs are driven by mTOR overactivity and recent work has demonstrated the value of mTOR inhibition with drugs such as everolimus causing tumor regression and improved seizure control.⁹

von Hippel–Lindau disease

von Hippel–Lindau (VHL) disease is a tumor syndrome involving multiple organ systems leading to hemangioblastomas in the cerebellum, spinal cord, and retina and pheochromocytomas and renal cell carcinoma. Other less common lesions include pancreatic and renal cysts and endolymphatic sac tumors.

The hemangioblastomas are associated with overexpression of VEGF. VHL is an autosomal dominant disorder mapped to chromosome 3p25-p26. It has a high penetrance but variable expressivity.

Li–Fraumeni syndrome

Li–Fraumeni syndrome is a rare autosomal dominant disorder seen in children and young adults leading to multiple different tumors. It is caused by germ line mutations of p53. However, some families do not have the p53 mutation and their genetic defect is unknown. Overall penetrance of the gene is about 50% by age 30 and 90% by age 60. Common tumors include breast, osteosarcoma, and brain tumors, primarily high-grade gliomas. Some develop medulloblastomas and supratentorial primitive neuroectodermal tumors (PNET). Other less common tumors include soft tissue sarcomas, leukemia, and lung, adrenal, gastric, and colon cancers.

Brain tumor-polypsis/GI cancer syndromes

These hereditary syndromes are characterized by colon carcinoma with or without associated polyposis and malignant brain tumors. The two broad variants of brain tumor-polypsis syndrome vary in their association with malignant brain tumors: type 1 is associated with malignant gliomas and type 2 is associated with medulloblastoma. These syndromes incorporate autosomal dominant and autosomal recessive syndromes. The type 1 brain tumor-polypsis syndrome may not have polyposis and is due to mutations in one of the mismatch repair genes; these syndromes have also been called Turcot, Lynch, Muir-Torres, or Gardner syndrome. The type 2 brain tumor-polypsis syndrome is usually due to a germline mutation in the APC gene which has also been described as Turcot syndrome.

Histological classification of CNS tumors

WHO classifies tumors by their patterns of differentiation and presumed cell of origin. The majority of primary CNS tumors are neuroepithelial and the cell of origin is the glial cell (usually astrocyte) ([Table 3](#)).¹⁰ The remainder arise from meningeal, pituitary, lymphocytic, or germ cells. Neurons constitute less than 10% of brain cells and are an uncommon source of CNS neoplasms.

Table 3 Partial WHO list of common tumors of neuroepithelial tissue

I.	Astrocytic tumors
	1. Diffuse astrocytoma, grade 2
	2. Anaplastic astrocytoma, grade 3
	3. Glioblastoma (giant cell, gliosarcoma variants), grade 4
	4. Pilocytic astrocytoma, grade 1
	5. Pleomorphic xanthoastrocytoma, grade 2
	6. Subependymal giant cell astrocytoma, grade 1
II.	Oligodendroglial tumors
	1. Oligodendroglioma, grade 2
	2. Anaplastic oligodendroglioma, grade 3
	3. Oligoastrocytoma, grade 2
	4. Anaplastic oligoastrocytoma, grade 3

III.	Ependymal tumors <ol style="list-style-type: none"> 1. Ependymoma, grade 2 2. Anaplastic ependymoma, grade 3 3. Myxopapillary ependymoma, grade 1 4. Subependymoma, grade 1
IV.	Choroid plexus tumors <ol style="list-style-type: none"> 1. Choroid plexus papilloma, grade 1 2. Choroid plexus carcinoma, grade 3
V.	Neuronal and mixed neuronal-glial tumors <ol style="list-style-type: none"> 1. Gangliocytoma, grade 2 2. Ganglioglioma, grade 2 3. Anaplastic ganglioglioma, grade 3 4. Dysembryoplastic neuroepithelial tumor (DNET), grade 1 5. Central neurocytoma, grade 2
VI.	Pineal tumors <ol style="list-style-type: none"> 1. Pineocytoma, grade 1 2. Pineal parenchymal tumor of intermediate differentiation, grade 2 3. Pineoblastoma, grade 3
VII.	Embryonal tumors <ol style="list-style-type: none"> 1. Medulloblastoma (desmoplastic, large cell, melanotic, medulloblastoma) 2. CNS primitive neuroectodermal tumors (PNETs) <ol style="list-style-type: none"> a. Neuroblastoma b. Ganglioneuroblastoma c. Ependymblastoma d. Medulloepithelioma

In general, children most frequently develop PNETs, low-grade astrocytomas, and ependymomas; 70% are infratentorial and occur near the midline. In contrast, adults usually present with supratentorial tumors that are off the midline and are higher grade astrocytic tumors. GBM, a WHO grade 4 tumor, is hypercellular with nuclear pleomorphism, mitotic figures, endothelial proliferation, and necrosis. Gliosarcomas display the typical pathologic features of GBM in combination with densely packed spindle-shaped cells in herring bone patterns. Gliosarcomas have the same prognosis as GBM and are treated identically. Anaplastic astrocytomas (AA), WHO grade 3 tumors, also have increased cellularity, nuclear atypia, and mitoses, but necrosis and microvascular proliferation are absent. WHO grade 2 astrocytomas typically comprise a fairly uniform group of astrocytes in a background of fibrillary matrix. There is less cellular pleomorphism, and mitoses are rare; there is an absence of vascular proliferation and necrosis. Grade 2 and 3 tumors with an *IDH* mutation have a better prognosis than tumors matched for

type and grade without an *IDH* mutation.

Glial tumors can be very heterogeneous; there can be different grades and even different histologic features with astrocytic and oligodendroglial appearing regions within the same tumor. This can be challenging diagnostically and highlights the need to get an adequate pathologic sample for examination. The highest grade found within the lesion determines the diagnosis and dictates treatment. Grade 1 tumors, juvenile pilocytic astrocytomas (JPA), occur almost exclusively in children. They are characterized by low cellularity, Rosenthal fibers, and cysts, and they do not infiltrate surrounding tissue extensively. They may contain rare mitoses and hyperchromatic nuclei, although these are not features of malignancy in these tumors. In young children, they occur most commonly in the cerebellar hemispheres where they have a 95% 5-year progression-free survival (PFS) rate after complete resection. The other low-grade glial tumors also tend to be discreet and less infiltrative. These include pleomorphic xanthoastrocytoma (PXA), ganglioglioma, neurocytoma, and dysembryoplastic neuroepithelial tumor (DNET). These tumors usually require an experienced neuropathologist to diagnose.

Oligodendrogliomas are characterized by a relatively uniform array of small round cells with artifactual perinuclear halos in a background of fine capillary (“chicken-wire”) vasculature. They are typically described as having a “fried-egg” appearance. Occasionally, oligodendrogliomas have features of anaplasia, pleomorphism, and necrosis and are classified as grade 3 anaplastic oligodendrogliomas (AO). They have a better clinical prognosis than their astrocytic counterparts. Some oligodendrogliomas have loss of heterozygosity on chromosomes 1p and 19q due to a translocation. Tumors with 1p19q codeletion have a better prognosis and are more responsive to therapy. Tumors containing a mutation in *IDH* and have 1p19q codeletion have the best prognosis.

PNETs are a group of neoplasms characterized by undifferentiated small blue cells with Homer–Wright rosettes (cells arranged around a true lumen). They are usually fast growing and often disseminate along CSF pathways. They are most common in children and are often found in the cerebellum (medulloblastoma) and in the pineal gland (pinealoblastoma). Although these lesions are histologically identical, the medulloblastoma is more amenable to treatment and has a better outcome.

Ependymomas arise from ependymal cells that line the ventricles and spinal canal. They arise wherever ependymal cells are present and have a predilection for the fourth ventricle. They are the most frequent neuroepithelial tumor of the spinal cord, accounting for more than 50% of spinal gliomas in both children and adults. They are histologically characterized by perivascular pseudorosettes (tumor cells arranged radially around blood vessels) and Homer–Wright rosettes. These tumors are usually low grade but can be aggressive and spread along CSF pathways.

Clinical presentation

Patients with brain tumors may present with generalized, nonfocal symptoms and signs or with focal manifestations related to the specific location of the tumor in the brain.¹⁰ Factors that contribute to the presenting symptoms and signs include tumor location, size, and growth rate. Supratentorial tumors are more likely to present with seizure, whereas infratentorial tumors more commonly present with headache, nausea, and vomiting. Superficial cortical tumors are more likely to cause seizure, whereas deeper tumors are more likely to cause personality and cognitive changes. Seizure is the presenting symptom in about 20% of patients with malignant brain tumors, but is the initial manifestation in approximately 90% of those with low-grade tumors. Tumors in eloquent areas of the brain will cause focal symptoms such as aphasia, hemiparesis, or sensory loss. Tumors in the brainstem typically present with cranial nerve deficits such as diplopia or facial weakness. Tumors of the cerebellum may cause ipsilateral ataxia,

unsteady gait, and nystagmus.

Symptoms usually evolve over several weeks; sometimes the symptoms begin acutely, corresponding to a hemorrhage into a metastasis or glial tumor, or a seizure with a prolonged postictal state. GBM and oligodendrogliomas of any grade have a 5–10% risk of hemorrhage. Any intracranial metastatic tumor can hemorrhage, but certain tumors, such as melanoma, thyroid, renal, and choriocarcinoma, have a propensity to bleed; however, lung cancer is the most common source of a hemorrhagic brain metastasis because of its high frequency of CNS metastases. On occasion, focal seizures can cause neurologic signs that do not resolve completely.

Diagnostic neuroimaging

Patients with symptoms and signs suggestive of an intracranial lesion should have a magnetic resonance imaging (MRI) study; it is the modality of choice for CNS tumors and CT should be used only in those patients unable to get an MRI.

High-grade tumors such as GBM disrupt the blood–brain barrier and have the characteristic appearance of a hypointense center surrounded by a hyperintense irregular rim of contrast enhancement ([Figure 1](#)). Almost 95% of GBMs will enhance with gadolinium. Anaplastic gliomas enhance less frequently, particularly in younger adults, and they may be confused with lower grade gliomas radiographically ([Figure 2](#)). GBMs also have a greater tendency to spread along white matter tracts, particularly the corpus callosum, and to cross to the contralateral cerebral hemisphere. In comparison, low-grade tumors have an intact blood–brain barrier and usually do not contrast enhance. An exception is the JPA, a grade 1 tumor that has areas of dense enhancement. Fluid-attenuated inversion recovery (FLAIR) sequences provide rapid distinction between normal brain and brain tumor or edema and provide the best images to delineate the radiographic extent of the lesion ([Figure 3](#)). On FLAIR imaging, however, infiltrative tumor cannot be differentiated from edema. Diffusion-weighted imaging (DWI) assesses the mobility of water molecules and may differentiate between ischemia and tumor. Perfusion images measure blood volume and vascularity and correlate with tumor grade and with ¹⁸fluorodeoxyglucose (FDG) positron emission tomography (PET) studies.

Figure 1 Glioblastoma. This is a postgadolinium T1-weighted MRI of a right posterior frontal glioblastoma. There is irregular contrast enhancement with focal areas of necrosis.

Figure 2 Anaplastic oligodendroglioma. (a) FLAIR image showing extensive tumor infiltrating the right hemisphere. (b) Patchy enhancement is seen throughout the tumor.

Figure 3 Low-grade glioma. (a) FLAIR image demonstrating extensive infiltrative disease predominantly of the left frontal lobe extending across the anterior corpus callosum and involving the deep right frontal white matter. (b) Postcontrast images show no evidence of enhancement of this large lesion.

On MRI, metastases are usually spherical and have more regular margins than primary tumors. They are usually found at gray–white matter junctions in watershed areas of the brain. When small, they uniformly contrast enhance, and when larger, they may ring enhance. The tumor is usually surrounded by substantial edema. Very small metastases may appear as small dots of contrast enhancement with or without hyperintensity on the FLAIR image; they usually lack surrounding edema. Fifty percent of patients have a single identifiable brain metastasis, 20% have two metastases, 13% have three and the remainder have more than three. There are some limitations to MRI, and the differential diagnosis of a brain tumor includes radiation necrosis, ischemic stroke, infection, inflammatory process, and demyelination.

Other imaging techniques

PET has several uses in the diagnosis of brain tumors. PET can help distinguish between recurrent tumor and radiation necrosis, may differentiate low-grade from high-grade lesions, and may guide stereotactic biopsy to the site of high-grade tumor within an apparently low-grade lesion seen on MRI ([Figure 4](#)). PET is performed by injecting substances such as glucose, an amino acid such as methionine, or even a nucleotide labeled with a positron-emitting isotope such as O15, C11, N13, and F18. FDG is the most commonly used isotope for evaluating brain tumors, and defines the metabolic rate of the lesion being examined. Hypermetabolism (increased FDG uptake) is common in high-grade tumors and hypometabolism (low FDG uptake) is common in low-grade tumors. FDG PET may help distinguish radiation necrosis from recurrent tumor. Whereas both may appear similar on MRI, radiation necrosis is typically, but not always, hypometabolic on PET in comparison to recurrent high-grade tumor, which is either isometabolic with normal brain or hypermetabolic on PET.

Figure 4 Low-grade glioma. This is an FDG PET image of a left temporal low-grade glioma showing an area of focal hypermetabolism that corresponded to a focal area of anaplasia.

Functional magnetic resonance imaging (fMRI) maps the functional organization of the brain, particularly the primary motor, sensory, and language cortices. fMRI is based on the concept that increased neuronal activity results in increased cerebral blood flow (CBF), causing a focal change in the oxyhemoglobin to deoxyhemoglobin ratio leading to increased signal on MRI. The fMRI is useful in presurgical planning and allows a surgeon to map eloquent cortex and then plan resection while preserving neurologic function; this facilitates maximal resection without neurologic deficit.

Principles of therapy

Treatment of a brain tumor includes both definitive and supportive therapy. Definitive therapy encompasses surgery, radiation therapy, and chemotherapy. Supportive therapy considers management of tumor symptoms such as treatment of focal and general symptoms with corticosteroids, seizure control with antiepileptic medication, treatment of deep venous thrombosis (DVT) with anticoagulants, and the provision of psychosocial support when needed.

Supportive therapy

In addition to surgery, RT, and chemotherapy, where the goal of treatment is to extend survival, various types of supportive therapy are also required to treat a patient's neurologic symptoms and improve their quality of life.

All seizures from a brain tumor begin as a focal seizure even if the focality is not observed clinically. Patients with brain tumors who have had a seizure either at presentation or during the course of their treatment should be treated with an antiepileptic drug (AED). The optimal AED does not affect the hepatic microsomal system, which can alter the metabolism of chemotherapeutic agents; common choices include levetiracetam, topiramate, or zonisamide. AEDs do not prevent seizures in patients with brain

tumors who have never had a seizure, and they should be avoided in this situation.¹⁰

Corticosteroids dramatically relieve the symptoms from edema caused by brain tumors, thus reducing intracranial pressure. Symptomatic improvement usually takes hours and patients may be symptom free within 24–48 h. Corticosteroids are indicated in all symptomatic patients with brain tumors, except those with presumed PCNSL where corticosteroids may cause tumor necrosis owing to their lympholytic effect, compromising a histologic diagnosis if the steroids are administered before biopsy.

The optimal dose of corticosteroid is unclear. A common starting dose is 16 mg of dexamethasone per day divided in two doses as the drug is long-acting. The dose should be titrated to the lowest dose commensurate with good neurologic function. For patients on steroids longer than 6 weeks, prophylactic treatment for *Pneumocystis jirovecii* infection is indicated.

DVT is a common complication of brain tumors. Factors that contribute to its development include immobility, neurosurgery, the release of thromboplastins from the brain, and hypercoagulability related to cancer and chemotherapy. The use of prophylactic and therapeutic anticoagulation is safe and effective and does not increase the risk of intratumoral hemorrhage.¹¹ Anticoagulants, including low molecular weight heparin and the newer inhibitors of thrombin or factor Xa, are the agents of choice. Vena cava filters should be reserved for those with absolute contraindications to anticoagulation.

Surgery

Surgery is the most important single modality in the treatment of brain tumors. The goals of surgery are multifactorial: establish a tissue diagnosis, decompress the tumor mass, alleviate symptoms, and reduce steroid dose. The ultimate goal of surgery is gross total resection. Biopsy, in particular stereotactic needle biopsy, is indicated for (1) a surgically inaccessible tumor such as those in the brainstem, basal ganglia, or thalamus, (2) multifocal tumors or gliomatosis cerebri, (3) a patient with medical comorbidity resulting in a high surgical/anesthetic risk. Needle biopsies have several limitations. There is a limited tissue sample that can often compromise accurate diagnosis, both with respect to tumor type and grade. Benign tumors or grade 1 gliomas may be cured by complete removal. For tumors that cannot be cured, such as all infiltrative gliomas, extent of resection is a significant prognostic factor, and biopsy alone confers inferior survival compared with more extensive resection. A retrospective analysis of three prospective RTOG randomized trials of 645 GBM patients revealed a statistically significant improvement in survival between GBM patients who had gross total resection (median 11.3 months) vs. those who had biopsy only (median 6.6 months)¹²; comparable data are available for low-grade gliomas (LGGs). Furthermore, resection usually improves neurologic function, not worsen it. In a prospective multi-institutional series, the morbidity among 408 patients undergoing craniotomy for newly diagnosed malignant glioma was 24%; mortality was 1.5%. Fifty-three percent of patients improved neurologically after craniotomy, and only 8% were neurologically worse.¹³ Preoperative fMRI (see earlier text) and awake intraoperative cortical mapping are techniques that facilitate tumor removal without neurologic injury.

Radiation therapy

RT is an effective adjuvant treatment for malignant glioma. For some tumors, such as germinomas, RT is curative. In prospective trials, RT gives better survival than surgery alone, or surgery plus chemotherapy. In the original 1978 Brain Tumor Study Group report of high-grade glioma, the median survival of patients treated by surgery alone was 14 weeks, whereas those receiving postoperative whole-brain radiotherapy (WBRT) of 50–60 Gy was 36 weeks. Improved RT techniques now allow for higher doses to the tumor while sparing normal brain. Focal RT is delivered to the area of abnormal FLAIR signal on MRI scan with a margin of 2–3 cm, followed by a cone down to the enhancing area. Standard fractionated

external beam RT involves delivering the optimum dose of 60 Gy in daily fractions of 1.8–2.0 Gy/day over 6 weeks. Modern techniques involve intensity-modulated radiation therapy (IMRT), which conforms the dose to the shape of the target volume, sparing adjacent critical structures.

Stereotactic radiosurgery (SRS) is another technique used to treat some brain tumors, particularly metastases. SRS delivers highly focal RT to a clearly defined small target, typically in a single dose. SRS can be delivered by a gamma knife (cobalt 60 sources), linear accelerator, or Cyberknife with equivalent results. To maintain a steep dose gradient, the target volume must be small—less than 4 cm. Radiosurgery is primarily used to treat small lesions such as metastatic tumors, meningiomas, acoustic neuromas, and pituitary adenomas. It is rarely used in the treatment of malignant glioma because this infiltrative disease does not lend itself to focused RT.

Protons, neutrons, and heavy charged particles have also been used to treat CNS tumors. Proton beams interact with nuclei of atoms rather than their electrons. Large doses of radiation are deposited in a targeted area sparing adjacent tissue. Charged particles can have an abrupt fall off sparing sensitive structures that could not withstand therapeutic irradiation. This technique is ideal for skull base tumors such as chordomas, meningiomas, and chondrosarcomas, lesions adjacent to the optic nerves, chiasm, and brainstem. Proton therapy is also used to a greater extent in pediatrics to limit RT exposure to developing organs, but its superiority to standard RT has not yet been established.¹⁴

Chemotherapy

Chemotherapeutic drugs have traditionally been unsuccessful in the treatment of most brain tumors. Some exceptions include PCNSL, germinomas, and some oligodendrogliomas. The role of chemotherapy in the treatment of astrocytomas is limited with respect to extending survival compared with surgery and radiation alone. There are no adequate chemotherapeutic agents for acoustic neuromas and meningiomas.

There are several problems specific to the chemotherapy of brain tumors. These include the role of the blood–brain barrier, the paucity of lymphatics in the brain, the heterogeneity of gliomas, the intrinsic resistance of gliomas, and a low therapeutic/toxic ratio. Many chemotherapy agents cannot penetrate a tumor in the brain owing to an intact blood–brain barrier. In tumors such as metastases and high-grade gliomas, there is disruption of the blood–brain barrier allowing variable penetration of water-soluble chemotherapeutic agents to the tumor. However, in certain tumors such as LGGs, the blood–brain barrier is intact and water-soluble chemotherapeutic agents cannot reach the disease. In high-grade gliomas, the blood–brain barrier is intact at the infiltrative margin of the tumor, where the cells are most viable. Many attempts have been made to disrupt the blood–brain barrier in the treatment of brain tumors, such as opening the blood–brain barrier with a hyperosmolar agent such as intraarterial mannitol. Other attempts include intraarterial infusions, intratumoral injections via catheters, implanting drug-impregnated wafers, and drugs altered to cross the blood–brain barrier. None has yet proved to be more effective, and many are more toxic than conventional routes.

In addition to the blood–brain barrier, most brain tumors have intrinsic resistance to conventional chemotherapeutic agents, and therefore, most are ineffective even if they achieve adequate concentrations in tumor tissue. The exception to this is the growing role of systemic chemotherapy to treat brain metastases. When RT or chemotherapy does succeed in killing tumor cells, the deficiency of a lymphatic system in the brain prevents the easy removal of detritus caused by treatment. Thus, necrotic tissue may serve as a nidus for edema and worsening neurologic function. Specific drugs will be discussed by tumor type.

Glioblastoma and anaplastic astrocytoma

GBM is a disease of advancing age where the mean age is 54 years, compared with a mean age of 45 years for AA. The median survival for AA ranges between 3 and 5 years and for GBM is about 18 months. Favorable prognostic factors include younger age, a high Karnofsky performance score (KPS), AA vs. GBM histology, and surgical resection vs. biopsy alone.¹⁰

For newly diagnosed GBM, the standard treatment following surgical resection is RT (60 Gy in 1.8–2.0 fractions) with concurrent daily temozolomide followed by at least six cycles of adjuvant temozolomide. A prospective randomized trial of 573 patients aged ≤ 70 years with newly diagnosed GBM showed that patients treated with RT plus continuous daily temozolomide (75 mg/m²/day) followed by 6 months of adjuvant temozolomide (150–200 mg/m²/day for 5 days of a 28-day cycle) had a median survival of 14.6 months compared with 12.1 months in patients treated with RT alone. More importantly, the 2-year survival rate was 26.5% compared with 10.4%.¹⁵ There was minimal toxicity in the combined RT/chemotherapy group. The significance of the DNA repair enzyme, MGMT, was also demonstrated. Hegi et al.¹⁶ analyzed the methylation status of the *MGMT* promotor in approximately one-half of the subjects from the phase III study. There was a distinct survival advantage for any patient whose promotor was methylated and therefore less active. Median survival of patients treated with RT plus temozolomide was 21.7 months for those with a methylated *MGMT* promotor and 15.3 months for those without ($p = 0.007$). Although patients whose tumors have a methylated promotor benefitted the most from the addition of temozolomide, there was some benefit with the addition of temozolomide even in patients whose tumor had an unmethylated *MGMT* promoter.

Elderly patients (>70 years of age) treated with surgery and RT survive longer than those treated with surgery alone, but the prognosis still remains poor.¹⁷ Reducing the dose and duration of RT for patients over 70 years (45 Gy/25 fractions) has comparable efficacy to the more protracted regimens. Alternatively, temozolomide alone may be equally efficacious. There are no definitive data for chemoradiation in the elderly.

Despite standard therapy, almost all patients will recur, usually at the original location. Treatment options at relapse include re-resection, rarely re-irradiation with highly focused RT such as SRS with or without bevacizumab, and a change in systemic chemotherapy. Bevacizumab is FDA approved for recurrent GBM as a single agent based on a randomized phase II trial demonstrating a 6-month PFS rate of 30% and a median survival of 9 months, which was identical to the combination of bevacizumab and irinotecan.¹⁸ These preliminary data led to two large randomized phase III trials of standard chemoradiation with or without bevacizumab for newly diagnosed GBM.^{19, 20} Both studies demonstrated a statistically significant prolongation of PFS (median 6–7 months to 10.7 months), but no effect on overall survival (median 15–16 months). However, the two studies differed in their quality of life data with one study showing better maintenance of quality of life with bevacizumab, and the second showing an increase in symptom burden and a worse quality of life with bevacizumab. On the basis of these data, incorporation of bevacizumab into initial therapy is not recommended. In addition, preliminary data from a randomized European trial suggest that bevacizumab plus lomustine is superior to bevacizumab alone for recurrent GBM, suggesting that single agent bevacizumab is inadequate at progression; final results of this study are not yet available. The molecular profiling of malignant gliomas has led to the targeting of specific pathways in tumor growth. There are several ongoing trials for recurrent GBM looking at the role of EGFR inhibitors, mTOR inhibitors, PKC inhibitors, and interruptions in RAS signaling.²¹

Immunotherapy has emerged as a novel treatment strategy for gliomas given its recent success in other

solid tumors.²² This has taken a variety of approaches including vaccine development using processed tumor antigens, often from the patient's own tumor. Immunotherapy using dendritic cells or a peptide vaccine is capable of producing an antiglioma response. Early results from a randomized phase III trial of a vaccine targeting EGFRvIII suggest a survival benefit when added to the standard treatment at diagnosis; unfortunately, this is applicable to only approximately 20% of patients. Dendritic cell vaccinations may increase the sensitivity of tumor cells to chemotherapy and improve survival. Other immunotherapeutic approaches, such as immune checkpoint inhibitors, including anti-CTLA4, anti-PD1, and anti-PDL1 agents, are also being explored in ongoing trials.

While tumor progression is inevitable and median survival for GBM remains at 18 months, there is a growing minority of patients surviving several years with excellent functional status who are benefitting from many of these new approaches.

Anaplastic gliomas

AA is much rarer than GBM and consequently there have been few trials studying grade III tumors exclusively. An ongoing randomized trial evaluating the role of adding temozolomide to RT will provide guidance in the future, but off-study most have adopted a treatment approach identical to GBM for newly diagnosed patients. A phase III trial of all types of grade III gliomas demonstrated that outcome was unaffected by whether a patient started with RT alone or even chemotherapy alone when the other modality is employed at progression.²³ However, most use RT plus temozolomide at diagnosis.

Low-grade gliomas and oligodendrogliomas

LGGs include astrocytomas, oligodendrogliomas, and mixed oligoastrocytomas.¹ There is great histologic diversity to LGGs that makes generalizations about their treatment and prognosis difficult. In general, they are slow-growing tumors that may not require immediate therapeutic intervention. However, their major risk lies in their tendency to transform to a higher grade glioma at which time their prognosis is dictated by the new histology.

LGGs constitute approximately 10% of all primary brain tumors.¹ The median age at diagnosis is 37 years, and young age is an important positive prognostic factor. Oligodendrogliomas have a tendency to arise in the white matter of the frontal (40%), parietal (30%), and temporal (20%) lobes of young adults. They represent 10% of all LGGs in adults and 5% of LGGs in children.

Seizure is the initial symptom in 60–80% of patients, and the majority of seizures are focal. Most patients are neurologically well at presentation with 90% having a KPS of 90–100 at diagnosis. Patients with LGGs have a better prognosis than those with malignant gliomas, but almost all will die from their disease. The median survival for a low-grade oligodendroglioma is 9.8 years compared with 4.7 years for a low-grade astrocytoma.

At present, the only agreed upon intervention in the management of LGGs is obtaining tissue for histologic diagnosis. There is growing evidence to suggest that a complete resection at diagnosis is a favorable prognostic factor. A recent review of 216 patients with LGG who underwent surgical resection demonstrated that after adjusting for age, KPS, tumor location, and histology, the extent of resection remained a significant factor in overall survival and PFS.²⁴ In addition, there was no association between extent of resection and postoperative neurologic deficit. Most series report 80% or greater 5-year survival rates in patients who undergo gross total resection based on review of immediate postoperative

MRIs. These data strongly argue for achieving a maximal resection in LGGs.

The timing of RT in the treatment of LGG is also controversial. The European Organization for Research and Treatment of Cancer (EORTC) conducted a prospective phase III trial in adults with supratentorial LGGs, randomizing them to observation only or to initial treatment with radiation alone.²⁵ The median PFS was 5.3 years in the treated group compared with 3.4 years in the observation arm ($p < 0.0001$). However, the overall survival rate was similar (median 7.4 and 7.2 years, respectively). Two-thirds of patients in the observation arm eventually received RT. Therefore, observation and deferral of RT may be justified without compromising overall survival depending upon the clinical situation. However, there is growing consensus that high-risk patients, variably defined as those with poorly controlled seizures or serious neurologic deficits, residual tumor volume >4 – 6 cm and older age, need immediate treatment.

The dose of RT was examined in two prospective randomized trials comparing low-dose radiation (45–50 Gy) to a higher dose (59.4–64 Gy).^{26, 27} There was no difference in PFS or overall survival between low- and high-dose groups, but higher RT doses were associated with greater toxicity, so lower doses are standard. Importantly, the role of adjuvant chemotherapy has been clarified recently. In a large prospective trial (RTOG 9802), patients were stratified based on risk factors (age and extent of resection) into favorable and unfavorable patients. Favorable patients were observed (group 1) and unfavorable patients were randomized to RT \pm procarbazine, CCNU, and vincristine (PCV) (groups 2 and 3). The addition of PCV to RT significantly prolonged median survival from 7.8 years to 13.3 years in high-risk patients.²⁸

Several series have shown that temozolomide has activity in patients with LGGs who have had progression after radiation.²⁹ Among these patients, 47–67% had tumor shrinkage ($>25\%$) with a median PFS of 10–22 months. Several small studies have explored the use of temozolomide as the initial postsurgical therapy for LGGs.³⁰ Response rates, when minor responses are included, range from 31 to 61%, and median time to progression was 31–36 months. Many have used these data to suggest that temozolomide can replace PCV when used together with RT for the initial treatment of LGGs because of its markedly lower toxicity profile.

LGGs with 1p and 19q chromosomal deletions respond better to chemotherapy and those with both an *IDH* mutation and 1p19q codeletion respond best and have the longest survival. Increasingly diagnostic classification of the grade II and III tumors is relying upon their molecular profile and not their histologic appearance, which is subject to variable interpretation. Codeletion of 1p19q was first recognized in oligodendrogliomas and was appreciated as both a prognostic and predictive factor in the uncommon AO. The median overall survival in AO without 1p19q loss is 2 to 3 years, but greater than 6 to 7 years in patients with tumors with combined 1p19q loss. One study showed that 100% of AO patients with 1p or combined 1p19q loss had an objective response to PCV chemotherapy in contrast to a 25–31% response rate when these alleles were retained.³¹ The 5-year survival rate for patients with tumors with 1p19q loss is 95% as opposed to 25% for those whose tumor retained these alleles. No formal comparison between PCV and temozolomide is available, although some retrospective data suggest PCV may be superior.³²

There have been two large randomized trials of patients with AO at initial diagnosis.^{33, 34} Both examined the administration of RT \pm PCV chemotherapy; one trial used PCV in the neoadjuvant setting and the second used it following RT. Both trials demonstrated that chemotherapy significantly prolonged PFS and overall survival was prolonged for the entire group in one study. However, both studies demonstrated dramatic prolongation of median overall survival with RT and PCV in the 1p19q codeleted group (e.g., median 14.7 vs. 7.3 years). Therefore, the standard of care is to treat such patients with RT and chemotherapy. Whether PCV must be the regimen of choice is unknown as temozolomide is clearly

effective and better tolerated. The chemosensitivity of AO has made upfront chemotherapy attractive in an effort to defer radiation and its potential toxicity in long-term survivors. A few small studies using temozolomide exist. One trial of upfront temozolomide alone shows a short time to progression (8 months) in patients who did not have 1p loss, in contrast to patients with 1p loss who were free from progression at 24 months.³⁵ In a phase II trial of 69 patients with newly diagnosed AO, an intensive PCV regimen was followed by high-dose thiotepa with autologous stem cell rescue, without RT.³⁶ The median PFS in the 39 patients who received the stem cell procedure was 78 months and the overall survival has not been reached. These data provide conflicting information regarding the optimal approach to patients with AO, but a clear standard is RT plus chemotherapy.

Ependymoma

Ependymomas account for approximately 2% of all intracranial tumors in adults and 5% in children. Ependymomas are derived from ependymal cells that tend to occur along the surfaces of the ventricles. They may also occur in the brain parenchyma adjacent to the ventricles or anywhere along the spinal canal. More than 60% of ependymomas occur in the posterior fossa and arise from the caudal floor of the fourth ventricle. Supratentorial ependymomas are typically parenchymal rather than intraventricular in location and most common in the frontal and parietal lobes. They can extend along the subarachnoid space and seed the CSF.

The WHO divides ependymomas into ependymomas (WHO grade II), anaplastic ependymomas (WHO grade III), subependymomas, and myxopapillary ependymomas (both WHO grade I). Although histologically identical, the molecular profile of ependymomas varies with location: supratentorial, posterior, and spinal. Supratentorial ependymomas are characterized by an oncogenic fusion of *RELA* and an unknown gene, *C11orf95*, which spontaneously drives NF- κ B signaling.³⁷ Good molecular prognostic factors in intracranial ependymomas, which include both supra- and infratentorial lesions, include gains in chromosomes 9, 15q, and 18 and loss of 6, whereas gain of 1q or homozygous deletion of *CDKN2A* is associated with significantly shorter PFS and overall survival.³⁸

Clinical findings depend on the tumor location. Infratentorial ependymomas most commonly cause brainstem compression or CSF obstruction leading to headache, nausea, and vomiting. Supratentorial tumors may present with seizure or focal deficits. MR scan demonstrates a tumor that is heterogeneously hypo- and isointense on T1 and hyperintense on T2 and may or may not enhance. Calcification is present in 60% of infratentorial tumors and areas of necrosis and cysts are seen in 80% of tumors.

The initial treatment of ependymomas is surgical. A gross total resection will prolong survival but may not always be possible depending upon the tumor location. A complete resection of a grade II tumor does not require additional treatment. However, subtotal resection of a grade II lesion or identification of an anaplastic ependymoma (grade III), regardless of extent of resection, should be followed by focal RT.

Radiotherapy is delivered to the tumor bed and not to the entire neuraxis unless CSF spread is documented at diagnosis on spine MRI or CSF cytology, which should be done in all patients for staging. Ependymomas are primarily chemoresistant tumors, and there is no role for routine adjuvant chemotherapy. At recurrence, some investigators have reported response rates of up to 65% with platinum drugs; others have reported responses with nitrosoureas, etoposide, or even bevacizumab, but temozolomide is not the agent of choice.³⁹

Primary central nervous system lymphoma

PCNSL is a non-Hodgkin lymphoma typically of the diffuse large B-cell subtype, restricted to the brain, CSF, spinal cord, or eyes. It accounts for 2% of all brain tumors.¹ It is more common in the immunosuppressed patient where it is usually associated with the Epstein–Barr virus.

The median age at PCNSL diagnosis is 60 although immunocompromised patients are younger. Older age and poor performance status are associated with shorter survival. Multiple lesions occur in 30–40% of sporadic cases. PCNSL grows rapidly, so symptoms are usually present for only a few weeks before diagnosis. The most common presenting symptoms are cognitive deficits or personality changes that can be attributed to the tumor's predilection for the frontal lobe and its tendency for multifocality ([Figure 5](#)). Ocular involvement of PCNSL is common. It may be the initial manifestation of the disease, or occur at relapse. Patients who develop ocular lymphoma first have a 50–80% chance of developing cerebral lymphoma. The diagnosis of isolated ocular lymphoma can be difficult because symptoms often mimic benign inflammatory conditions such as uveitis. Diagnosis is made from slit lamp exam, ocular ultrasound, and often vitreal biopsy. Staging evaluation should include an ocular exam and lumbar puncture for cytologic evaluation in every patient with cerebral PCNSL as well as a systemic evaluation.

Figure 5 PCNSL. Pre-gadolinium (a) and postgadolinium (b) images of a right frontal diffusely enhancing PCNSL. Note the edema that surrounds the enhancing mass.

PCNSL is a highly treatable disease. It is very chemo- and radiosensitive, similar to systemic non-Hodgkin lymphoma. Despite this sensitivity to treatment, PCNSL has a high recurrence rate with a 5-year survival of 25–50%. There are differing reports on the therapeutic value of surgical resection, but most patients are diagnosed by biopsy alone as resection is usually not feasible. Owing to their oncolytic effect on malignant lymphocytes, steroids should be held before surgical biopsy so as not to interfere with the pathologic diagnosis.

Modern treatment of PCNSL is based on high-dose methotrexate regimens. Standard chemotherapy regimens for systemic lymphoma such as CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) are not beneficial and should be avoided. Methotrexate is the most effective and commonly used drug for the treatment of PCNSL. High-dose methotrexate (doses of 3–8 gm/M²) with leucovorin rescue produces response rates of 60–90% when used as a single agent or in combination with other

drugs. A wide range of high-dose methotrexate regimens are reported in the literature, and they can achieve a median overall survival of 30–60 months. Other drugs commonly employed with methotrexate include cytarabine, procarbazine, and temozolomide. Methotrexate-based regimens have been consolidated using various approaches including autologous stem cell transplantation (highly selected patients), low-dose WBRT of 2340 cGy (theoretic potential for neurotoxicity), and continuous infusion of etoposide and high-dose cytarabine (severe systemic toxicity).^{40–42} Rituximab has been added to most regimens despite its poor penetration into the CNS; efficacy has been observed. The optimal approach will be clarified by the completion of multiple ongoing randomized studies. A large phase III trial failed to demonstrate a survival benefit when full dose WBRT radiotherapy of 4500 cGy was added to methotrexate and this approach has largely been abandoned owing to the enhanced neurotoxicity seen in long-term survivors, especially among older patients.⁴³

Meningioma

Meningiomas account for approximately 25% of intracranial tumors. They are extra-axial and arise from arachnoidal cap cells rather than the dura itself. They are more common in women than in men.¹ Approximately 85% of meningiomas are supratentorial, and multiple meningiomas occur in 10% of sporadic cases. Ionizing radiation is the only established risk factor for meningioma. Both low- and high-dose radiation have been associated with the development of meningiomas. These meningiomas are more often atypical or malignant and are often multifocal.

Recent molecular profiling work demonstrates that the tumor suppressor NF2 is inactivated in about one-half of patients. Approximately 25% have *TRAF7* mutations with co-occurrence of the K409Q mutation in *KLF4*, a transcription factor. Approximately 20% had an E17K mutation in *AKT1*, which often co-occurred with *TRAF7* mutations. Finally, about 5% had mutations in *SMO*, which activated the Hedgehog signaling pathway. Each of the mutations conferred geographic localization of the tumor at the skull base, usually anterior, and distinct from the NF2 mutations, which had no genetic overlap and occurred in the posterior skull base.^{44, 45} These interesting biologic insights do not yet provide a therapeutic pathway but they may in the future.

The prognosis after treatment of meningiomas depends on the histology of the tumor and the extent of resection. Age at diagnosis and tumor size may also play a role. Younger patients fare better than the elderly. The recurrence rate for a completely resected typical meningioma is 20% at 5 years and 25% at 10 years. Tumors that are incompletely resected have about a 60% chance of recurrence without RT. McCarthy et al.⁴⁶ published a survey of more than 9000 patients with meningiomas treated in the United States and included in the National Cancer Data Base. The 5-year overall survival was 60%, 81% for patients < 65 years, and 56% for patients > 65 years. The estimated 5-year survival for benign tumors was 75% and 55% for malignant tumors. Population-based studies reported a 5-year survival rate near 90%.

Typically, meningiomas compress rather than invade adjacent brain. However, they may invade venous structures such as the superior sagittal sinus. The histologic appearance of meningiomas may vary, but only those with rhabdoid or clear cell features are more aggressive and carry a worse prognosis. Atypical meningiomas have a higher mitotic index as well as increased cellularity, a high nucleus/cytoplasm ratio, prominent nucleoli, necrosis, and patternless growth. A malignant meningioma must have at least 20 mitoses per 10 high-power fields or histology resembling carcinoma or sarcoma. Whereas only 1% of meningiomas metastasize, about one-half of malignant meningiomas metastasize, usually to liver, bone, and lung.

Most meningiomas are very slow growing and may be asymptomatic; many are found incidentally on imaging done for other reasons. Meningiomas produce symptoms and signs by compressing brain structures and causing edema or hydrocephalus. Although most meningiomas do not cause significant brain edema, secretory meningiomas may cause edema resulting in significant neurologic symptoms. Convexity meningiomas may cause seizure. Meningiomas in particular locations may have typical clinical syndromes, such as cavernous sinus meningiomas that cause diplopia, proptosis, and other oculomotor abnormalities.

CT and MRI readily diagnose meningiomas. On CT, meningiomas are hyperdense extra-axial masses. Calcification is present in 25%. Meningiomas demonstrate dense uniform contrast enhancement. Atypical, malignant, and large meningiomas more commonly cause surrounding brain edema. On T1- and T2-weighted MRI images, most meningiomas have signal intensity similar to surrounding grey matter. They enhance diffusely and a dural tail seen on contrast-enhanced images is characteristic ([Figure 6](#)). Some tumors may have flow voids indicating marked vascularity. The first step in the management of a patient with a meningioma is to decide whether treatment is necessary. Many meningiomas may be followed for years if they do not exhibit growth or cause neurologic symptoms. If seizures are the only symptom and are well controlled with medication, surgical resection may not be necessary. Some meningiomas are not resected because tumor removal may be dangerous. This is usually the case for lesions located at the skull base and cavernous sinus. These meningiomas may encase portions of the intracavernous carotid artery as well as multiple cranial nerves.

Figure 6 Meningioma. A coronal postgadolinium MRI of a multilobulated meningioma extending below and above the tentorium. There is a second lesion in the left occipito-parietal cortex.

Surgery is definitive and if the tumor can be removed completely, a cure may be achieved. Meningiomas with the best potential for complete removal are those located along the convexity. Preoperative

embolization may be done to reduce the size and vascularity of the tumor, making resection easier. Even in those patients in whom a complete removal has been accomplished, approximately 15–20% of these tumors will recur and may require additional surgery or RT.

RT is used in the treatment of inoperable meningiomas in partially resected tumors in some patients at recurrence, and in all malignant tumors regardless of resection.⁴⁷ The role of RT in atypical meningiomas is unclear. Recent data suggest that RT can be effective, particularly in prolonging PFS for patients with atypical tumors, but this is true for a minority of patients and the effect on overall survival is less clear. In addition, new 3D planning techniques and stereotactically guided conformational RT allow for reductions in the volume of normal tissue irradiated and less neurotoxicity. The use of protons in the treatment of some meningiomas has also been of benefit in reducing toxicity and delaying recurrence.

Stereotactic RT is an important treatment option for atypical, malignant, and recurrent meningioma. Radiosurgery has also become an option for small typical meningiomas less than 3 cm. In a retrospective comparison of 198 adult patients who underwent either surgical resection or radiosurgery as initial treatment of their meningioma, both modalities had equivalent tumor control. Tumor control rates with SRS are higher than 90% in most series with complication rates less than 5%.

There is a small group of patients in whom, despite multiple surgical resections and RT, the meningioma recurs. In these patients, medical therapy may be considered but is generally ineffective.⁴⁸ The progesterone antagonist, mifepristone, initially appeared effective, but this was not sustained with further testing. To date, no effective chemotherapy has been found to treat meningioma. There have been some attempts with anthracyclines, cisplatin, and irinotecan but without definite success. There are several small series of patients with recurrent meningioma that report a response to hydroxyurea, but most patients do not appear to benefit. Sunitinib has been reported effective.⁴⁹ Pasireotide may be helpful in those patients whose tumors express somatostatin receptor.⁵⁰ Bevacizumab has been helpful in reducing edema or in treating radionecrosis of underlying brain if present, but does not shrink the tumor, regardless of grade.

Brain metastasis

Metastasis is the most common tumor affecting the brain with approximately 70,000 patients diagnosed with symptomatic intracranial metastases annually. Most brain metastases present late during the course of a widely metastatic cancer, but in a smaller percentage of patients, a brain metastasis may be the first evidence that the patient has cancer; alternatively, a patient with cancer believed to be localized may have an asymptomatic brain metastasis found on screening neuroimaging. With more effective systemic therapy, brain metastases are increasingly emerging as the sole site of relapse in patients with otherwise controlled cancer.^{51, 52}

The most common sources of brain metastases are lung and breast carcinoma and melanoma ([Table 4](#)). However, any malignant neoplasm can metastasize to the brain and it is likely that there will be an increasing number of metastases from what are believed to be uncommon sites, e.g., ovary or prostate.^{51, 52} In as many as 10% of patients with brain metastases, no primary tumor is found on initial search although immunocytochemical analysis of the brain metastasis may help identify the primary site. On rare occasions, the primary tumor is not identifiable even at autopsy.

Table 4 Source of brain metastases in 729 patients

Primary tumor	Total (%)	Single	Multiple
Lung cancer	288 (39)	137	151
nonsmall cell	178	89	89
small cell	110	48	62
Breast	121 (17)	59	62
Melanoma	80 (11)	39	41

Data from Ref. 53.

Pathophysiology of the metastatic process

To reach the brain, a systemic cancer must develop its own blood supply, invade local tissues, and enter the circulation either by invading venules or lymph channels that eventually reach the venous circulation ([Figure 7](#)).^{52, 54} Because systemic tumors enter the venous circulation and, ultimately, the right side of the heart, the first capillary bed they encounter is in the lung. Accordingly, the majority of patients with brain metastases have either primary lung tumors or lung metastases at the time the brain lesions become symptomatic. To reach the arterial circulation, the tumor must (1) grow in the lung and seed the pulmonary venous circulation,¹⁴ (2) traverse the lung capillary bed to enter the left side of the heart, or (3) cross a patent foramen ovale to enter the left heart directly. Some have proposed that tumor reaches the brain via the vertebral venous system (Batson's plexus) to explain the absence of lung metastases.

Figure 7 Pathophysiology of the metastatic process. Metastasis is a multistep process. In this illustration: (A) malignant neoplasm arises in an organ distant from the central nervous system and, as it grows, it develops its own vascular supply. (B) Clone(s) of malignant cells with metastatic potential enter blood or lymph channels and eventually reach the venous circulation. (C) The malignant cells enter the right heart with the venous circulation and either exit through the pulmonary artery to the lung (D), or cross a patent foramen ovale (D), to enter the systemic circulation. Most tumors that enter the lung either arrest in the pulmonary capillary bed, grow as pulmonary metastases and subsequently seed the pulmonary venous circulation, or, alternately, (E), transverse the pulmonary vascular bed without arresting (E), to enter the pulmonary venous circulation. Malignant clones in the pulmonary venous circulation then enter the left heart and exit into the systemic circulation (F), along with those cells that may have crossed a patent foramen ovale (F). Once in the systemic circulation, the likelihood of entering the cerebral circulation is high because, in the resting state, 15–20% of cardiac output supplies the central nervous system. Tumor cells entering the cerebral circulation must then arrest in brain capillaries or venules, cross the vessel wall, and grow within the brain (G, H).

Source: DeAngelis and Posner, 2008.⁵² Reproduced with permission from Oxford University Press.

Two factors promote intracranial metastases: (1) In the resting state, the brain receives 15–20% of the body's blood flow, enhancing the probability that circulating tumor cells will reach the brain. (2) Certain tumor cells find the brain a propitious place for arrest and growth, such as small-cell lung carcinoma. Once in the intracranial cavity, the tumor must arrest within the capillary bed, cross the endothelium and vessel wall, grow within the organ, vascularize itself through the process of angiogenesis, and then grow

large enough to cause symptoms. At each step in the metastatic process, the tumor cells may fail, so that only a fraction of cells that reach the circulation ever become metastases.

Tumors may metastasize to virtually any portion of the intracranial cavity, but the overall distribution of brain metastasis is also determined by the size of the region and its vasculature. Thus, about 85% of brain metastases are found in the cerebral hemispheres, 10–15% in the cerebellum, and only approximately 3% are found in the brainstem, comparable to the distribution of blood flow to these areas.

In patients whose systemic tumor is otherwise controlled, the brain is often a site for isolated metastatic disease. Neither blood flow nor the nature of the CNS microenvironment fully explains this phenomenon, but the blood–brain barrier may. The CNS as a sanctuary site of microscopic disease may apply to breast, small-cell lung, and perhaps other cancers with effective systemic treatment using water-soluble agents unable to penetrate an intact blood–brain barrier. When a chemosensitive tumor has relapsed in the CNS, it does not necessarily mean that the CNS disease is resistant to the chemotherapeutic agents that controlled the systemic tumor. The blood–brain barrier may have prevented those tumor cells from ever seeing a significant concentration of the drug, thus preserving the tumor cells' intrinsic chemosensitivity to that agent, which may then be demonstrated by changing the dose or schedule to achieve higher drug concentration in the brain.

Treatment

The therapeutic approach to patients with brain metastases depends on the number and location of metastases, on the biology of the primary tumor, and on the extent of systemic disease.

Surgery

Two controlled trials clearly indicate that for patients with a single brain metastasis, surgical removal followed by WBRT is superior to WBRT alone, both in preventing brain relapse and in improving quality of life.^{55, 56} A third trial found no benefit, but many of the patients randomized to radiotherapy alone underwent resection at relapse.⁵⁷ In patients whose systemic disease is quiescent or controllable, surgical removal of a single brain metastasis substantially improves survival; 2-year survivals are 15–20%, depending on the primary tumor, and 5-year survival rates are approximately 10%. Retrospective analysis supports the resection of two or even three metastases, with an outcome comparable to a surgically treated single brain metastasis.

A randomized controlled trial indicates that patients with a single resected metastasis who receive postoperative WBRT have fewer recurrences in the brain and are less likely to die of neurologic causes than are similar patients treated with surgery alone.⁵⁸ However, overall survival was comparable between the two groups because patients with controlled cerebral disease died of progressive systemic tumor. These data suggest that an appropriate patient with a single, surgically accessible brain metastasis should have that metastasis removed and receive postoperative WBRT. However, because of the toxicity of WBRT, particularly in the over 60 age group, many physicians do not use it in the immediate postoperative period, but reserve radiation until relapse, even though RT may be less effective once a tumor has recurred.

Radiation therapy

The time-honored treatment of brain metastases has been WBRT, delivering 3000 cGy in 10 fractions. For patients with extensive systemic disease or multiple brain metastases, this remains the best option. Most patients improve with steroids and RT ([Figure 8](#)) and are less likely to die of their neurologic disease

than are patients who do not receive this treatment. However, survival is short, with a median of 4–6 months, because most patients die of uncontrolled systemic tumor. In occasional patients, RT actually sterilizes the brain metastases and they do not recur. Because of late-delayed radiation toxicity in those patients whose systemic prognosis is more than a year, we recommend a dose of 4000–5000 cGy given in 180–200 cGy fractions. The lower dose per fraction reduces the risk of radiation toxicity but cognitive dysfunction may occur even with small fractions, especially if the patient is elderly. Cognitive deficits from RT are more severe in adults over 60 years of age, and in those who receive extensive chemotherapy. Nevertheless, even young adults often complain of memory loss after WBRT.

Figure 8 Metastatic small-cell lung cancer before and after radiation therapy. (a) The T1-weighted image before radiation shows two of the multiple contrast enhancing metastases; the larger is surrounded by hypointense brain edema. (b) The T2-weighted image before radiation shows hyperintense edema surrounding the relatively hypointense tumor. (c, d) MRI scans after radiation show an excellent response to radiation therapy.

Radiosurgery

Radiosurgery is increasingly employed instead of surgery for the treatment of single or even multiple

brain metastases that are <3–4 cm in diameter.^{52, 59–61} SRS can be delivered either using the gamma knife, linear accelerator, or Cyberknife, all with equal efficacy. It is usually given as a single dose but it can be fractionated. The treatment appears to be most effective against those tumors that are relatively resistant to conventional external beam RT, such as melanoma and renal cell carcinoma. Most report approximately 80% tumor control defined as disappearance, decrease in size, or stability of the treated lesion. Postradiosurgery MRI may show a transient increase in tumor size because of radiation injury or tumor necrosis. This can resolve over a few months and, therefore, an increase in lesion size a few weeks to months after SRS does not necessarily indicate tumor progression. Local control may be maintained over 2 years in 60% of patients, but with increasing survival, symptomatic recurrence becomes increasingly likely. Radiosurgery has advantages over surgery in that it is relatively noninvasive, does not require hospitalization, and can often reach areas that are surgically inaccessible. SRS has the disadvantage that it is not useful for tumors larger than 3–4 cm and should be avoided for lesions with extensive uncontrolled edema.

A randomized, prospective trial comparing WBRT and WBRT followed by a SRS boost in 331 patients with one to three newly diagnosed brain metastases showed no survival advantage with the addition of radiosurgery to WBRT.⁶² A separate randomized controlled trial examined SRS with and without WBRT in patients with 1–4 brain metastases. Similar to the findings in the postoperative WBRT study, WBRT significantly reduced brain recurrence but had no effect on survival.⁶³ Furthermore, these authors demonstrated that cognitive function was better when CNS disease was controlled even when WBRT was necessary to achieve that control; they did observe that WBRT could contribute to impaired neurocognitive function in some long-term survivors.⁶⁴ Thus, the decision to use postoperative or post-SRS WBRT should be individualized.

There have been no randomized, prospective studies comparing neurosurgery and radiosurgery as treatment of solitary brain metastasis, and retrospective studies have shown conflicting results. However, most agree that they achieve comparable degrees of local control. At this time, we use surgery to resect lesions from accessible locations if they are >3–4 cm, are associated with significant vasogenic edema or hemorrhage, arise from a radioresistant primary, or cause obstruction of CSF flow. SRS is an excellent option for smaller lesions or those in a surgically inaccessible location; we rarely treat more than three lesions in a patient and usually do not administer WBRT concurrently.

Chemotherapy

Chemotherapy is increasingly recognized as efficacious for brain metastases from chemosensitive systemic cancers. These include germ cell tumors, breast cancer, small-cell lung cancer, and others.^{52, 59, 65, 66} Chemotherapy is often reserved for patients whose brain metastases have recurred after surgery or WBRT, but chemotherapy may also be considered in asymptomatic patients with brain metastases discovered on a screening MRI who are scheduled to receive chemotherapy for their systemic disease.

There are several reasons for administering chemotherapy before radiation: (1) It is useful to judge tumor response to chemotherapy before initiating RT. If the tumor is responsive, the chemotherapy can be continued. (2) RT decreases the blood supply to the tumor, but may increase it to the brain, and thus may decrease the amount of chemotherapeutic agent that reaches the metastases but enhance exposure of normal brain to chemotherapy toxicity. (3) Some evidence suggests that chemotherapy delivered before radiation is less neurotoxic than the converse because RT may open the blood–brain barrier and allow entry of potentially toxic agents that are given post-RT. The evidence is best for methotrexate but may apply to other drugs as well.

In addition to standard chemotherapeutic agents, small-molecule inhibitors may be effective against brain metastases. This has been best observed with erlotinib in non-small cell lung cancer, sunitinib for renal cancer, and vemurafenib for melanoma.^{67, 68} Furthermore, changing the dosing schedule to a weekly high-dose regimen that enhances CNS drug penetration improves CNS tumor response. Initial reports of lapatinib's efficacy against brain metastases from breast cancer failed to meet the expected response rate in a phase II trial.⁶⁹

Prognosis

Patients treated with WBRT have a median survival of 4–6 months, and those treated by surgery followed by WBRT have a median survival of about 9 months. Patients with controlled systemic disease treated by surgery and radiation have a 10–15% 5-year survival. Prolonged survival can also be seen after SRS.⁵²

Prognostic factors include mental status, response to steroids, activity of the systemic tumor, and treatment modality. In one series, site of the primary tumor, age, and the number of brain metastases were prognostic factors, although with lesser importance than those indicated above. In patients with lung primaries, male sex was a significant adverse factor. In patients with breast primaries, the interval between the primary tumor and the development of brain metastases was also significant, with a longer interval correlating with better survival. The RTOG performed a recursive partitioning analysis of prognostic factors in 1200 patients with brain metastases treated with WBRT in three RTOG trials.⁷⁰ They segregated patients into three classes based only on KPS, age, and the presence of extracranial metastases. Class 1 patients had a KPS \geq 70, were <65 years of age, and had a controlled primary and no extracranial metastasis; median survival was 7.1 months. Class 3 patients had a KPS < 70 and a median survival of 2.3 months. Class 2 included all other patients and had a median survival of 4.2 months. This classification scheme may apply to patients treated with surgery and radiosurgery.⁷¹

Chapter 78

Neoplasms of the eye

Jasmine H. Francis, MD ■ Amy C. Scheffler, MD, FACS ■ David H. Abramson, MD

Overview

Cancers involving the eye are less common compared to lung, prostate and breast cancer. However, they pose a special challenge because they can influence both life and vision. The field of ophthalmic oncology focuses on these two elements: improving efficacy to treat the disease and save life, and limiting the consequence of treatment to maintain vision. The eye itself is composed of a variety of distinct tissues and ophthalmic malignancies can affect a number of these anatomical areas. This makes the topic of neoplasms of the eye heterogeneous in origin, pathogenesis, prognosis, and treatment.

Introduction

This chapter reviews benign and malignant ocular, orbital, and lid tumors in both children and adults. The most common of these are listed in [Table 1](#).

Table 1 Most common ophthalmic neoplasms, benign and malignant

	Benign	Malignant	
		Primary	Secondary
Children			
Ocular	—	Retinoblastoma	Leukemia
Orbital	Capillary hemangioma	Rhabdomyosarcoma	Leukemia
Adult			
Ocular	Choroid nevus	Uveal melanoma	Metastasis (lung, breast)
Orbital	Cavernous hemangioma	Lymphoma	Sinus cancer
Lids	Chalazion	Basal cell carcinoma	Lymphoma

Pediatric ophthalmic oncology: ocular diseases

Benign disease

Benign pediatric ocular lesions are very rare. Choroidal nevi, which are present in more than 10% of the adult population, are rare before puberty and are never seen in the infant. Conjunctival and iris nevi are also extremely rare in prepubertal children. Iris nevi detected in children often represent Lisch nodules, a manifestation of neurofibromatosis type 1.

Benign retinal tumors are also rare. When found they are usually astrocytic hamartomas and are frequently

part of the tuberous sclerosis syndrome. When viewed with indirect ophthalmoscopy, astrocytic hamartomas usually have a thin, transparent membrane overlying the retina and typically obscure retinal blood vessels. They may enlarge and calcify with time. They may be confused with myelinated nerve fibers, which are white, follow the distribution of the nerve fiber layer, and obscure retinal vessels.

Hamartomas of the retinal pigment epithelium are rare in children. They are frequently near the optic disc and are pigmented, with distortion of retinal vessels and a slightly opaque appearance. They have no malignant potential.

Primary malignant disease (retinoblastoma)

Introduction to retinoblastoma

The most common primary ocular malignancy of childhood is retinoblastoma.¹ Retinoblastoma arises from a cone precursor cell.² Although retinoblastoma is relatively rare, it has been the subject of great interest because of its well-studied genetic inheritance pattern and molecular biology.

Retinoblastoma has an incidence rate of 1 in 18,000–30,000 live births worldwide. Surveys suggest a relatively constant occurrence in this century. The incidence in the United States is relatively low, at 3.58 cases for each million children under the age of 15 years, and decreases with advancing age. The overall median age at diagnosis in the United States is 18 months, with the median age of diagnosis of bilateral cases occurring at 12 months and of unilateral cases at 24 months. In rare instances, retinoblastoma is detected prenatally via ultrasound or during adulthood.

Survival rates for retinoblastoma patients in the developed world have increased dramatically over the past century. The mortality of retinoblastoma was reported as 83% in 1897 in children who were treated with enucleation, and as 43% in all children in 1916.³ In contrast, cancer registry reports in Europe and the United States have demonstrated 5-year survival rates of 90% and 98%, respectively. The improved survival rate is due to earlier detection of the tumor and improved techniques for local tumor control. In contrast to developed countries, however, developing nations report dramatically low survival rates, as patients in these countries typically present with widespread metastatic disease. Worldwide approximately 50% of patients still die of metastatic retinoblastoma.

There are no differences in incidence by sex, race, or right versus left eye. Some data suggest geographic clustering, but convincing evidence is lacking. Retinoblastoma does appear to occur more commonly in poor patients worldwide.

Molecular biology of retinoblastoma

The traditional view of retinoblastoma genetics, widely held until recently, was that the disease occurs in two forms, germinal and nongermlinal. Both forms occur as a result of loss or mutation of both alleles of the retinoblastoma gene (*rb1*). In nongermlinal cases, both *rb1* alleles are inactivated somatically in a single developing retinal progenitor cell, whereas in germinal cases, the first mutation occurs in the germline and only the second mutation is somatic. Nongermlinal retinoblastoma is always unilateral and unifocal, although the tumor may break apart resulting in hundreds of tiny intraocular seeds. Recent evidence has indicated that nearly all retinoblastoma patients probably demonstrate a degree of mosaicism for the *rb1* mutation. Furthermore, evidence suggests that genomic instability, microsatellite instability, defects of the DNA mismatch repair system, and alterations in DNA methylation and acetylation/deacetylation may also be necessary for the malignant transformation of retinoblastoma after the loss of pRB.⁴

The proposed retinoblastoma gene was localized to chromosome 13q14 through deletion studies and linkage analysis. The protein is a regulator at the cell cycle checkpoint between G₁ and entry into the S-phase ([Figure 1](#)). Loss of normal *rb1* function, as in the case of the tumors, allows for uncontrolled entry into the S-phase and more rapid cell division. Recently, it was discovered that *Rb1* wild-type tumors may occur in the context of MYCN oncogene amplification.⁵

Figure 1 Artistic rendition of molecular mechanism of retinoblastoma gene action.

Rb1 was the first tumor suppressor gene to be identified. The tumor-suppressive function of the *rb1* gene was confirmed in studies that demonstrated the loss of both alleles of the gene in tumor tissue specimens. Later studies showed that a germinal *rb1* mutation was present in virtually all retinoblastoma kindreds and that inheritance of the mutant *rb1* allele predicted disease.⁶ The tumor-suppressive function of the gene has furthermore been demonstrated in transfection studies showing that the introduction of wild-type expression in pRB-defective cell lines partially reverses the malignant phenotype.

Genetic testing

Both population data gathered from families and our current understanding of the molecular mechanisms of inheritance of the disease have enabled us to predict the likelihood that new offspring in families affected by retinoblastoma will develop the disease ([Table 2](#)). Karyotypic studies, which analyze the morphology of entire chromosomes, are generally not useful for the clinical diagnosis of retinoblastoma because they can only identify deletions spanning 2–5 million base pairs and only 3–5% of retinoblastoma patients carry deletions this large.⁷ Instead, more sophisticated indirect and direct techniques that detect smaller mutations are used. At the present time, a single genetic test is unlikely to detect all germline RB gene mutations in patients with retinoblastoma because of the variety of types and locations of mutations that occur. However, adaptation of a routine clinical protocol including a series of complementary tests based on the observation that most mutations alter the protein size and disrupt the large pocket domain may be able to rapidly detect the majority of mutations.⁸

Table 2 Genetic counseling for retinoblastoma

If parent was	Bilateral				Unilateral				Unaffected			
Chance of offspring having retinoblastoma	45% affected		55% unaffected		7–15% affected		85–93% unaffected		<<1% affected		99% unaffected	
Laterality	85% bilateral		15% unilateral		0%	85% bilateral	15% unilateral	0%	33% bilateral	67% unilateral	0%	0%
Focality	100% multifocal	96% multifocal	4% unifocal	0%	100% multifocal	96% multifocal	4% unifocal	0%	100% multifocal	15% multifocal	85% unifocal	0%
Chance of next sibling having retinoblastoma	45%	45%	45%	45%	45%	45%	45%	7–15% ^a	~6% ^a	~6% ^a	~6% ^a	<1%

^a If parent is a carrier, then the chance of next sibling having retinoblastoma is 45%.

Presenting signs and symptoms of retinoblastoma

The most common presenting signs and symptoms of retinoblastoma vary depending on the socioeconomic conditions in which the patient presents. In developing countries, children have often developed extraocular disease before they are diagnosed and frequently present with proptosis and an orbital mass (Figure 2). These children are older at diagnosis (age 4–6 years) compared patients in the United States and few survive. Many large retrospective studies over the past quarter-century have examined the most common presentations of retinoblastoma in large developed nations.⁸ In the United States, the most common presenting sign (60% of cases) is leukocoria, a white pupillary reflex (Figure 3). The reflex is caused either by the reflection of incoming light off the tumor or by the retinal detachment caused by the underlying tumor.

Figure 2 Advanced orbital presentation of retinoblastoma.

Source: Courtesy of A. Wachtel, M.D., Lima, Peru.

Figure 3 Leukocoria (white pupillary reflex) caused by retinoblastoma. The tumor can be seen in the vitreous. There are seeds in the anterior chamber, anterior to the iris.

Presenting signs in the United States that occur less commonly include strabismus (misalignment of the eyes), inflammatory signs (mimicking orbital cellulitis), anisocoria (different sized pupils), heterochromia (different colored irides), hyphema (blood in the anterior chamber), tumor hypopyon (tumor in the anterior chamber), and nystagmus. Two large retrospective studies on large populations of retinoblastoma patients have recently examined the patterns of detection of retinoblastoma in the United States. The vast majority of patients' disease was discovered by a family member (80%) rather than by a pediatrician (8%) or an ophthalmologist (10%).⁸

Diagnostic testing

The differential diagnosis of retinoblastoma includes lesions that can simulate a solitary ocular tumor such as astrocytic hamartomas and toxocara canis and lesions that can cause a total retinal detachment such as Coats' disease, retinopathy of prematurity, and persistent hyperplastic primary vitreous [persistent fetal vasculature (PFV) syndrome] (Table 3). Patients suspected of having retinoblastoma should undergo indirect ophthalmoscopy and fundus photography as well as ophthalmic ultrasonography. Ultrasonography is useful as it demonstrates masses with high reflectivity that block sound, causing characteristic shadowing behind the tumor. Needle biopsies are rarely performed for suspected retinoblastoma, as puncturing the eye and aspiration can lead to tumor seeding with orbital invasion and even death from metastatic disease.

Table 3 Lesions simulating retinoblastoma

Solitary ocular tumor
Astrocytic hamartoma
<i>Toxocara canis</i>
Total retinal detachment
Coats' disease
Retinopathy of prematurity
Persistent fetal vasculature (PFV)

Staging of intraocular retinoblastoma

The Reese–Ellsworth classification scheme was the worldwide gold standard for describing intraocular tumors (Table 4a).⁹ It is not a true staging scheme (for untreated patients do not progress from group I to higher groups), but it has served as an excellent ocular reference for comparison of different series and treatment schemes. A higher numeric classification signified that a tumor was more anterior and that there was a decreased success rate in treating the lesion with lateral port external-beam radiation. Its usefulness has been questioned by many ophthalmic oncologists, who feel that it is no longer appropriate given the current trend away from the use of external-beam radiation. An alternate classification system was developed and has been used clinically by several centers in a collaborative study (Table 4b).¹⁰ It has been shown to correlate with the response to treatment of intraocular disease with systemic chemotherapy combined with focal therapy. As with the Reese–Ellsworth classification, this system may also become antiquated as treatment trends inevitably change in the future.

Table 4 (a) Reese–Ellsworth scheme for intraocular retinoblastoma. (b) New international classification for retinoblastoma

(a)	
Group I	<ul style="list-style-type: none">• Solitary tumor, <4 disc diameters in size, at or behind the equator• Multiple tumors, none over 4 disc diameters in size, all at or behind the equator
Group II	<ul style="list-style-type: none">• Solitary tumor, 4–10 disc diameters in size, at or behind the equator• Multiple tumors, 4–10 disc diameters in size, behind the equator

Group III	<ul style="list-style-type: none"> Any lesion anterior to the equator Solitary tumors larger than 10 disc diameters behind the equator
Group IV	<ul style="list-style-type: none"> Multiple tumors, some larger than 10 disc diameters Any lesion extending anteriorly to the ora serrata
Group V	<ul style="list-style-type: none"> Massive tumors involving over half the retina Vitreous seeding
(b)	
Group A	$Rb \leq 3$ mm in basal dimension or thickness
Group B	$Rb > 3$ mm or with one or more of the following: <ul style="list-style-type: none"> Macular location (≤ 3 mm to foveola) Juxtapapillary location (≤ 1.5 mm to optic nerve) Additional subretinal fluid (≤ 3 mm from margin)
Group C	Retinoblastoma tumor with one of the following: <ul style="list-style-type: none"> Subretinal seeds ≤ 3 mm Vitreous seeds ≤ 3 mm Both subretinal and vitreous seeds ≤ 3 mm
Group D	Retinoblastoma tumor with one of the following: <ul style="list-style-type: none"> Subretinal seeds > 3 mm Vitreous seeds > 3 mm Both subretinal and vitreous seeds > 3 mm
Group E	Extensive retinoblastoma occupying $> 50\%$ of globe or any of the following: <ul style="list-style-type: none"> Neovascular glaucoma Opaque media from vitreous hemorrhage in anterior chamber, vitreous, or subretinal space Invasion of postlaminar optic nerve, choroid (> 2 mm), sclera, orbit, or anterior chamber

Treatment of intraocular retinoblastoma

Survival rates in excess of 95% are currently achieved for most patients treated at major centers in developed countries with a multimodal treatment approach that may include enucleation, external-beam radiation, brachytherapy, transpupillary thermotherapy (TTT), cryotherapy, and chemotherapy (systemic, intra-arterial, periocular, and intravitreal). The treatment strategy for each patient depends on several factors: involvement of one or both eyes, heredity of the disease, age of the patient, tumor volume and localization, stage of disease (including Reese–Ellsworth classification), and presence of extraocular disease.¹

Enucleation

Enucleation is surgical removal of the eye without resecting the lids or extraocular muscles.¹ Patients considered for enucleation include those with advanced retinoblastoma in one or both eyes, active tumor in a blind eye, and painful glaucoma from tumor invasion.

External-beam radiation

External-beam radiation, once employed in many patients with intraocular retinoblastoma, has fallen out of favor due to its contribution to the development of second nonocular cancers in germinal retinoblastoma patients.¹ When radiation is given, it is often used as a last resort salvage therapy after other therapies have failed.

Transpupillary thermotherapy (TTT)

TTT is a treatment modality for retinoblastoma that is delivered using modifications to the hardware and software of the infrared diode laser.¹ TTT is used to treat selected small retinoblastomas, typically those located in the posterior aspect of the globe. A study examining the use of TTT as single modality therapy for small tumors found that 92% of tumors 1.5 disc diameters or less in base diameter were successfully cured with TTT alone.

Cryotherapy

Cryotherapy is used as a primary treatment for small peripheral retinoblastomas or as adjuvant or secondary treatment for tumors treated by other modalities.¹ Rapid freezing (-90°C per minute) results in intracellular ice crystal formation, protein denaturation, pH changes, and finally cell membrane rupture. All studies examining the use of cryotherapy alone have demonstrated 90–100% cure rates in tumors that are <3 mm in diameter and <1 mm in thickness with minimal complications.

Brachytherapy

Episcleral brachytherapy was pioneered in 1933 by the British ophthalmologist Henry Stallard. Radioactive plaques can be used as primary therapy and their relative indications include tumors that are classified as Reese–Ellsworth stage IVa or less and tumors that are between 4 and 10 disc diameters in size. Brachytherapy can also be used as a salvage technique in eyes that have failed other types of therapy including intra-arterial chemotherapy, external-beam radiation, photocoagulation, or cryotherapy. ¹²⁵Iodine is currently the most commonly used isotope in brachytherapy for retinoblastoma. This isotope is advantageous because the radioactive seeds can be placed into a custom-built plaque designed to match the size of the lesion.

Systemic chemotherapy

Chemoreduction can be used to shrink these tumors so that focal treatments such as cryotherapy, thermotherapy, or radioactive plaques can be administered afterward.¹ Most studies of chemoreduction for retinoblastoma since 1996 have utilized vincristine, carboplatin, and an epipodophyllotoxin, either etoposide or teniposide. The addition of cyclosporine as a P-glycoprotein inhibitor has also been suggested to decrease multidrug resistance.¹¹ Choice of agents and number and frequency of cycles vary currently at different institutions.

For patients with Reese–Ellsworth groups I–III eyes patients, many authors have demonstrated that enucleation can be successfully avoided almost 100% of the time. Results for patients with Reese–

Ellsworth groups IV and V eyes have been more discouraging. In a meta-analysis of patients treated with chemoreduction, 37% of eyes avoided *both* external-beam radiation and enucleation. Forty-one percent of eyes required radiation but avoided enucleation, and 40% of eyes required enucleation (with or without prior radiation).¹² Owing to concerns of short- and long-term toxicity, many centers have abandoned systemic chemotherapy as primary treatment of retinoblastoma in favor of more focal chemotherapy techniques.

Intra-arterial chemotherapy

Clinicians in Japan were the first to postulate that another method of local drug delivery, intra-arterial infusions of chemotherapy, may increase penetration of the drug into small intraocular tumors and decrease systemic side effects.¹³ Our group introduced a technique in which the ophthalmic artery is selectively cannulated and a combination of up to three drugs (melphalan, topotecan, and carboplatin) are injected at the ostium.¹ Other techniques to access the ophthalmic artery include catheterization of the middle meningeal artery or the use of a balloon. Treatment typically consists of monthly infusions given an average of three times. This technique has been adopted by many centers worldwide and is our primary method of treatment for both unilateral and bilateral retinoblastoma. It can be used to treat eyes of all classifications, whether naïve or prior treated, and bilateral cases can be infused in the same session with tandem therapy. In children <3 months of age or 6 kg, bridge therapy is employed: single-agent carboplatin is given until the child reaches an adequate age and weight for intra-arterial chemotherapy. Two-year Kaplan–Meier estimates of ocular event-free survival are estimated at 82% for naïve eyes and 60% for prior treated eyes,¹⁴ although with the recent adoption of intravitreal chemotherapy, these numbers are likely higher ([Figure 4](#)).

(a)

(b)

(c)

Figure 4 (a) An example of the typical patient undergoing intra-arterial chemotherapy. The globe is full of retinoblastoma with a total retinal detachment visible behind the lens. (b) Fundus photograph before intra-arterial chemotherapy. Note that the large tumor is obscuring the optic nerve head. (c) Fundus photograph after intra-arterial chemotherapy. The tumor has become calcified and there are no vitreous seeds visible. The optic nerve head can now be visualized above the tumor. The retina is flat.

Ocular side effects are minimal and may include periocular inflammation, medial forehead erythema, and chorioretinal changes.¹⁴ Electroretinogram monitoring of retinal function demonstrates that carboplatin and topotecan have no impact on retinal function; and while melphalan may have an effect, these changes are minimal and likely clinically irrelevant. Approximately 30% of children have at least one episode of grade 3 or 4 hematotoxicity during their treatment course (particularly when melphalan dose exceeds 0.4 mg/kg) and therefore monitoring of blood counts is advised. Vascular complication is a rare complication and no death has been reported from this procedure.

Periocular chemotherapy

Periocular injections of carboplatin or topotecan have been used, particularly as salvage or adjuvant treatment. However, side effects, particularly with carboplatin, include scarring and loss of vision. Furthermore, its long-term efficacy of this delivery method has been questioned.

Intravitreal chemotherapy

Injections through the wall of the eye and into the vitreous were historically avoided owing to concerns of extraocular extension of tumor through the needle tract. However, the adoption of safety-enhanced techniques and an exceedingly low calculated risk of extraocular extension have lessened these fears. Intravitreal injections of chemotherapy typically consist of melphalan, but have included carboplatin and topotecan, given weekly up to eight times. This modality is rapidly becoming the optimal method for treating vitreous seeding with ocular survival rates reportedly as high as 83–100%. However, electroretinogram recordings have revealed that for every 30 µg injection of melphalan, the retina function decreases by 5% and future work may mitigate this toxicity either with other drugs or alterations to the delivery method.¹⁵

Treatment of extraocular retinoblastoma

In the most developed nations, extraocular disease occurs only in a small minority of patients. For more complete information on the treatment of extraocular retinoblastoma, the reader is encouraged to consult more extensive sources.^{16, 17}

Second malignancies

In 1949, it was first recognized that some retinoblastoma patients develop second nonocular neoplasms years after the successful treatment of the eye cancer. Since then, the incidence of additional nonocular cancers in survivors of retinoblastoma who carry the *rb1* mutation has been reviewed extensively.¹⁸ Previous analyses have also shown that additional nonocular cancers are the leading cause of death in survivors of germinal retinoblastoma in the United States. Of the survivors of germinal retinoblastoma, cumulative incidence reports of second malignancies vary, but most large studies with adequate long-term follow-up have reported yearly incidence rates of approximately 0.5–1% per year.^{18, 19}

Several clinical risk factors and treatment-related exposures have been shown to have an association with the development of second nonocular cancers in retinoblastoma survivors ([Table 5](#)). For instance, external-beam radiation increases the risk of development of second cancers in a dose-dependent manner. Secondary acute myeloblastic leukemia (AML) has been linked to the use of etoposide (an epipodophyllotoxin) in systemic chemotherapy regimens for retinoblastoma.

Table 5 Risk factors for second nonocular cancer development in retinoblastoma survivors

Factor	Strength of association with incidence of second cancers
Presence of germinal mutation in <i>rb1</i> gene	Definite causation (necessary risk factor)
Dose of external-beam radiation	Dose-dependent causation
External-beam radiation given at <1 year of age	Very likely association
Presence of lipomas	Definite association (noncausative)
Smoking	Definite association
Chemotherapy	Possible association
Sun exposure	Possible association
Growth hormone	Possible association

Second malignancies observed in retinoblastoma survivors in the United States include, in order from most common to least, osteogenic sarcomas of the skull and long bones, soft tissue sarcomas, pineoblastomas, cutaneous melanomas, brain tumors, Hodgkin's disease, lung cancer, breast cancer, salivary gland, and oral cancers. This reflects a cohort who historically received large doses of external-beam radiation. In the United Kingdom, a study published several years ago offers unique insight into the types of malignancies that develop in patients not treated with external-beam radiation.²⁰ Patients in the study, who were all over 25 years of age at follow-up, had a much higher risk of developing epithelial cancers (notably lung, bladder, and probably breast) than of developing sarcomas and other early onset cancers compared to patients in the United States who received radiation.

Secondary malignant disease (leukemia)

Childhood acute lymphocytic leukemia (ALL) is the most common malignant tumor that involves the eyes of children. Leukemia primarily involves the uveal tract: the iris, ciliary body, and/or choroid. It can also involve the retina, optic nerve, and orbit.

Leukemic iris infiltrates can appear as creamy clusters of cells floating on the surface of the iris. When iris infiltrates are present, they can manifest as heterochromia (different color irides), cells in the anterior chamber (tumor hypopyon mimicking idiopathic iritis), or bleeding in the anterior chamber (hyphema). Hyphema can be associated with glaucoma and a painful, photophobic, red, sensitive eye. In contrast to iris involvement, leukemic infiltration is virtually impossible to detect ophthalmoscopically in the ciliary body or choroid because ALL diffusely invades the choroidal blood vessels. This subtle thickening is often detectable only by B-scan ultrasound.²¹ Leukemic infiltration in the choroid has been identified in 90% of eyes at autopsy after death from leukemia. Retinal involvement is rare.

Leukemic infiltration of the eye can present in different time sequences in relation to the overall presentation of the disease. Most commonly, the infiltration presents simultaneously with the initial presentation of the leukemia. The majority of patients with ALL demonstrate ultrasonic ocular findings at presentation. When the leukemia is treated, the choroidal involvement usually disappears within days. Leukemic infiltration of the eye can also present as an isolated site of relapse following induction treatment and CNS (central nervous system) radiation prophylaxis. In these children, the CNS has often been treated with radiation but the eye has escaped treatment, functioning as a sanctuary site. Treatment of the eye alone in such cases may be justified. Finally, leukemic infiltration can present as a sign of CNS recurrence with or without evidence of a gross mass in the CNS. These patients frequently have leukemic cells near the posterior pole and in the vitreous. In these cases, the tumor cells enter the eye via the optic nerve, which has been seeded directly from the CNS. In these cases, treatment to the brain with chemotherapy or external-beam radiation is generally considered.

Pediatric ophthalmic oncology: orbital diseases

Benign disease

Capillary hemangiomas

Benign tumors of the orbit in children are frequently incidental problems detected on CT (computed tomography) scan or observed because of lid or orbital asymmetry. Many require no treatment. The most common benign orbital tumor of childhood is the capillary hemangioma.²² On CT, capillary hemangiomas are usually associated with congenitally enlarged orbits while rhabdomyosarcomas are not.

Treatment of these hemangiomas is frustrating. The tumors respond to low-dose radiation and we have used fractionated doses up to 800 cGy with success. There have also been several reports of treatment with recombinant interferon alpha.²³ Local injections of short- and long-acting steroids are probably the treatment of choice when mandated by visual or overwhelming cosmetic reasons. When capillary hemangiomas occur on the skin, they can be treated with a topical β -blocker.

Dermoid cysts

Dermoid cysts are benign and represent congenital ectodermal rests. Treatment is surgical, but utmost care must be taken because some have bilobed posterior orbital extensions that can extend intracranially.

Lymphangioma

Despite the fact that lymphatics do not exist in the orbit, benign lymphangiomas do.²⁴ These tumors are thought to be congenital and have no malignant potential, but in contrast to hemangiomas are rarely present at birth. They are most commonly seen at around age 6 with explosive proptosis caused by bleeding of the tumor into the cystic spaces referred to as *chocolate cysts*. Treatment is difficult. They do not respond to steroids or radiation. Surgery with electrocautery laser is the treatment of choice. Satisfactory cosmetic results are difficult to attain.

Malignant disease

Rhabdomyosarcoma

The most common primary malignant orbital tumor of childhood is rhabdomyosarcoma. The average age at diagnosis is 6–10 years with equal incidence in both sexes and both orbits. Although the hallmark presentation of an orbital rhabdomyosarcoma is rapid, progressive, painless proptosis, patients can present with a less dramatic course with slow, progressive proptosis or with ptosis, strabismus, or a subconjunctival fleshy mass. The diagnosis of rhabdomyosarcoma should be considered whenever rapid progressive proptosis occurs in the first 20 years of life. The most common location in the orbit is superonasal. CT or MRI (magnetic resonance imaging) scans can help define the extent of the tumor.

Urgent biopsy is mandatory. All attempts should be made to biopsy the lesion directly without going through the sinuses or skull because of the possibility of causing metastatic disease by tracking tumor cells along the biopsy path. The most common histologic type is an embryonal rhabdomyosarcoma. When rhabdomyosarcomas present in the inferior orbit they are usually histologically alveolar type. These malignancies do not originate from extraocular muscles but from undifferentiated pluripotential mesenchymal elements in the orbital soft issues.

External-beam radiation was first utilized in the mid-1960s and later combined with chemotherapy producing excellent local cures and better than 90% long-term survival. The Intergroup Rhabdomyosarcoma studies in the 1980s demonstrated that the most effective combination for disease localized to the orbit was vincristine, actinomycin-D and radiation. In giving radiation, the eye was not spared or shielded. Long-term follow-up demonstrated that after a median of 7 years, only 14% of such eyes were enucleated, but vision was impaired in 70% of them.²⁵ A meta-analysis completed by four international collaborative groups found no significant difference in survival for those patients treated with chemotherapy alone versus chemotherapy plus radiation.²⁶

Adult ophthalmic oncology: ocular diseases

Benign disease

Benign tumors of the lid, conjunctiva, iris, and choroid are common while those of the retina and cornea are rare. Benign tumors of the lens and vitreous do not occur. The most important benign tumors of the eye in adults are the choroidal nevi.

Choroidal nevi

Choroidal nevi are never present at birth, but generally present around puberty. In the United States, 10–13% of the adult population have choroidal nevi. They are racially related; choroidal nevi in blacks are very rare.

Choroidal nevi are flat, pigmented benign lesions with edges that can be feathered and irregular or rounded ([Figure 5](#)). They are usually slate-gray to light chocolate in color. Over time (months to years), there can be associated changes visible by ophthalmoscopy. Many demonstrate changes on their surface such as drusen or have associated findings such as subretinal fluid or neovascular membranes. They may also cause visual field defects. As 10% of the adult population has choroidal nevi and there are only 1500 choroidal melanomas in the United States yearly, it is assumed that the chance of a choroidal nevus becoming a melanoma is <1 in 6000. A number of studies have now demonstrated which nevi are more likely to undergo malignant transformation. The predictive factors are shown in [Table 6](#).

[Figure 5](#) Choroidal nevus located inferior to the macula. Note the yellow drusen indicating benign status.

Table 6 Predictive factors: nevus to melanoma transformation

- *Size*: The greater the thickness of a choroidal nevus, the greater the chance of it becoming a melanoma. Of nevi 2.5 mm in thickness, approximately 1% per month become melanomas.
- *Location*: Nevi at the posterior portion of the eye more commonly become melanomas than those situated anteriorly.
- *Orange Pigment*: When choroidal nevi develop orange pigment on their surface, the chance of a melanoma developing greatly increases.
- *Serous Fluid*: Serous fluid in the form of an overlying retinal detachment can be seen with nevi, but such nevi more likely become melanomas.
- *Absence of Drusen*: Drusen are a strong indicator of chronicity and benignity and lesions with drusen rarely transform.
- *Hot Spots* on fluorescein angiography
- *Symptoms* (decreased vision or visual field defect)

A melanocytoma is a special type of choroidal nevus often observed in darker-skinned Caucasians of Mediterranean origin. Melanocytomas are brown-black lesions that most commonly originate from the optic nerve head, but can evolve from the choroid, ciliary body, or iris. The lesions may be several millimeters high, can grow slowly, and can affect the visual field or visual acuity. Pathologically, the lesion is a magnocellular nevus with jet black pigmentation. While the lesions are benign, rare cases of transformation to malignancy have been recorded although no deaths have been documented.

The differential diagnosis of a choroidal nevus includes congenital hyperplasia of the retinal pigment epithelium (CHRPE), hamartomas of the retinal pigment epithelium, and hemorrhages within the retina, especially hemorrhages beneath the retinal pigment epithelium (most commonly associated with age-related macular degeneration). Ophthalmoscopic appearance and results of a fluorescein angiogram and ultrasonography are used to distinguish these lesions from each other.

Iris nevi and melanomas

Iris nevi are benign lesions of the iris that appear on slit lamp examination as pigmented flat areas. They are common, may be multiple, and occur more often in blue-eyed patients. Like choroidal nevi, iris nevi are rarely present at birth and present around puberty. Rarely, they can appear elevated and can grow and shed pigmented cells into the anterior chamber angle, clogging the trabecular meshwork and causing a severe secondary glaucoma that can blind the eye. These lesions have often been referred to as iris melanomas. Widespread metastases, however, are seen rarely if ever. Many clinicians have theorized that the reason for the less aggressive behavior observed in iris melanomas versus choroidal melanomas is simply the smaller size of these lesions. However, studies suggest that they are distinctly different from choroidal lesions in that a significant percentage demonstrate an activating mutation in exon 15 of the BRAF gene, which is common in cutaneous melanoma, but almost never seen in choroidal lesions. Management of iris melanoma is based on the presence or absence of glaucoma and should not be guided by a need to prevent metastases. Melanomas that originate in the ciliary body and extend into the iris, however, often demonstrate very aggressive behavior and can metastasize.

Malignant disease

Introduction to choroidal melanoma

Choroidal melanoma is the most common primary ocular malignant tumor in adults in the United States but the second most common worldwide (after retinoblastoma). There are about 1500 new cases per year of choroidal malignant melanoma in the United States. The average age at diagnosis is 55–65 years with men and women equally affected and no predilection for right versus left eye. In the United States, 99% of choroidal melanomas occur in Caucasians. The most common way in which the tumor is detected is on routine exam (41%). Men more often present with symptoms and when there are symptoms, the right eye is more often found to have the tumor. The most common symptom is a perceived deficit in the peripheral visual field followed by decreased vision. The lesion is not painful, unlike metastatic tumors to the eye in which pain is not unusual.

Melanomas of the choroid originate in melanocytes that normally lie within the choroid. The choroid, the layer between the sclera and retina is a rich, high-flow syncytium of vascular lobules that not only supply blood to the photoreceptors (rods and cones) of the retina but also serve as a heat sink to dissipate heat energy liberated by absorbed visible light.

Whether all melanomas of the choroid originate from choroidal nevi is not known, but patients with flat, pigmented, untreated nevi followed for more than 20 years have developed melanomas arising from the previously dormant lesion. The cause of choroidal melanomas is unknown but predisposing medical conditions include melanosis oculi (nevus of Ota) and dysplastic nevus syndrome. Medications that have been shown to cause increased growth of the tumors include estrogen replacement therapy and levodopa. Occupational associations include agriculture and farming work and several industrial operations, including welding. Mutually exclusive mutations in GNAQ/GNA11 occur in almost all choroidal nevi and melanomas, and the addition of a BAP1 mutation is believed to be a genetic event that is associated with malignant transformation of these lesions.²⁷

Diagnosis of choroidal melanoma

The diagnosis of choroidal melanoma can usually be made on the basis of ophthalmoscopic examination alone. The lesions most often appear as elevated, dome-shaped masses that can rupture Bruch's membrane ([Figure 6](#)). When Bruch's membrane is ruptured, the tumors are referred to as mushroom shaped or collar button because of their characteristic shape. The lesions can also be multilobed or flat and diffuse. Lesion color varies from patient to patient and from area to area within the tumor. As many as 40% of the tumors have no pigment clinically. When pigmented, the tumors are frequently a dusky gray to charcoal in color but occasionally they are deep brown.

Figure 6 Malignant melanoma of the choroid.

Ocular ultrasonography and sometimes fluorescein angiography can also aid in diagnosis. All choroidal melanomas have associated retinal detachments. In some cases, it may be difficult to detect the detachments ophthalmoscopically, while in others the retinal detachment may be so extensive that the melanoma is not seen clinically. Typically, the B-scan ultrasound demonstrates an elevated solid tumor and the A-scan demonstrates medium to low reflectivity. With the use of rigorous and standardized ophthalmic and systemic examinations, a diagnostic accuracy of 99.7% was reached in the Collaborative Ocular Melanoma Study (COMS).²⁸ As clinical accuracy is so high, needle biopsy for diagnosis is rarely needed.

As there are no lymphatics in the eye or within the orbit, melanomas of the choroid metastasize through vascular channels. Approximately 68% of single-site metastases occur within the liver. The median survival has been reported as 6 months to 1 year.²⁹

Clinical and pathologic risk factors

A number of clinical and pathological features have been shown to correlate with patient survival.³⁰ First, larger tumors, measured clinically using the height and/or greatest base diameter to volume, are more likely to metastasize. Second, location of the melanoma affects prognosis. Patients with melanomas originating in the iris have the best outcome. Ciliary body melanomas have a threefold mortality compared with choroidal melanomas. Third, patients younger than 60 have better survival than those older than 60. Fourth, patients with extraocular extension have higher mortality rates than those who do not. Finally, many pathologic features (only available in cases where the eye has been removed) correlate with survival and are covered extensively elsewhere. The best known of these is cell type. Epithelioid cells, which are larger and more pleomorphic, are more likely to be contained in large tumors and carry a worse prognosis.

The COMS group, which included 44 institutions across the United States, was a series of prospective, randomized clinical trials and other reports on the prognosis and treatment of small, medium, and large choroidal melanomas. The COMS size classification scheme is shown in [Table 7](#) and the results of the studies are detailed in [Table 8](#).

Table 7 Final size classifications of choroidal melanomas in the collaborative ocular melanoma studies (COMS)

	Small	Medium	Large
	melanomas	melanomas	melanomas
	(mm)		
Apical height	1–2.5	2.5–10 mm AND	>10 mm OR
Largest basal diameter	5–16	<16 mm	Greater than 16 mm (when 2 mm or greater in height)

Table 8 Results of the collaborative ocular melanoma study (COMS)

	Small	Medium	Large
Reference	<i>Arch Ophthalmol.</i> December 1997; 115(12):1537–1544	<i>Arch Ophthalmol.</i> July 2001; 119(7):969–982	<i>Am J Ophthalmol.</i> June 1998; 125(6):779–796
Type of study	Nonrandomized, prospective follow-up	Prospective randomized clinical trial	Prospective randomized clinical trial
Number of patients in study	204	1317	1003
Size of melanomas included in study	Apical height: 1.0–2.5 mm	Apical height: 2.5–10.0 mm	Apical height: 10.0 mm or larger
	Largest basal diameter: 5 mm	Largest basal diameter: 5–16 mm	Largest basal diameter: 16 mm or larger
Objective of study	To describe time to tumor growth and determine baseline characteristics associated with growth of small tumors	¹²⁵ I brachytherapy versus enucleation for treatment of medium tumors	Pre-enucleation radiation versus enucleation alone for treatment of large tumors
Findings of study	21% grew by 2 years 31% grew by 5 years Characteristics associated with growth: initial tumor thickness and diameter, presence of orange pigment, absence of drusen, absence of retinal pigment epithelial changes	No clinically or statistically significant difference in survival rates between the two treatments for up to 12 years after treatment	No significant difference in survival rates between the two treatments Age and largest basal diameter of the tumor are the only factors that affect prognosis

Genetic analysis

In recent years, interest in analysis of chromosomal changes and gene expression patterns in choroidal melanoma has greatly increased. Several chromosomal abnormalities, including gain or loss of chromosomal material in chromosomes 3, 6, and 8, have been detected in primary uveal melanoma tissue and have been associated with metastasis. Monosomy 3 in uveal melanoma is a statistically significant predictor of both relapse-free and overall survival.³¹

Gene expression microarray analysis is used to distinguish 2 groups: class 1 (low-grade tumors) and class 2 (high-grade tumors).³² These classifications strongly predicted metastatic death with a 95% Kaplan–Meier-based survival prediction at 92 months of 95% in class 1 and 31% in class 2. In one study,

the classifications outperformed other clinical and pathologic prognostic indicators. Specific gene mutations have been identified to correlate with survival: for instance, somatic BAP1 mutations are found in 84% of high-risk class 2 tumors.³² Furthermore, germline BAP1 mutations may occur in 3–5% of patients with choroidal nevi or melanomas and have been associated with a hereditary cancer syndrome consisting of malignancies such as mesothelioma and cancers of the kidney and stomach. Recently two other mutations (SF3B1 and EIF1AX) have reportedly been associated with a more favorable prognosis and are more commonly found in male patients.³³

The number of clinical centers performing karyotyping, single nucleotide polymorphism (SNP) analysis, fluorescent *in situ* hybridization (FISH) analysis, and/or comparative genomic hybridization (CGH) on fine-needle aspiration and enucleation specimens has dramatically increased in the last few years. Some groups have also begun to perform FISH or microsatellite array on fine-needle aspiration biopsy specimens. Biopsies have been attempted via pars plana and transscleral approaches. Because few effective treatments are available for metastatic uveal melanoma at this time, it is unclear what, if any, interventions or screening programs for metastases should be offered to patients whose lesions are shown to be high risk for metastasis on biopsy. Nonetheless, as new treatments (such as selumetinib³⁴) or prophylactic drugs for metastatic melanoma are developed and available for clinical trials, it will be important to identify which patients are appropriate for entry into such studies.

Treatment and prognosis of small melanomas

In the COMS, the definition of a small melanoma was a lesion that was 1–2.5 mm in thickness and 5–16 mm in largest basal diameter. This observational study demonstrated that, of choroidal melanomas initially managed by observation, 21% demonstrated growth to medium or large tumors by 2 years and 31% by 5 years. However, there were no defined criteria or threshold for treatment and this group may have included patients whose lesions demonstrated no growth or high-risk features. Factors significantly associated with growth by statistical analysis in the study were greater initial tumor thickness and diameter, presence of orange pigment, absence of drusen, and absence of areas of retinal pigment epithelial changes adjacent to the tumor ([Table 6](#)).

As the COMS brachytherapy trials were published, most ophthalmologists in the United States have continued to use the COMS tumor size guidelines in order to designate a tumor as medium and institute brachytherapy. Nonetheless, some investigators have raised the question of whether small melanomas should also be treated with brachytherapy and/or biopsied for gene profiles. Although the COMS indicated that the long-term mortality rate for these patients is low (8-year all-cause mortality of 14.9%),³⁵ it may be significant enough to justify the consideration of brachytherapy in these patients. There has been only one study examining the outcomes of patients with small melanomas initially observed, then treated with a standardized brachytherapy protocol after growth or new orange pigment was observed. The melanoma-specific 5-year mortality rate for the tumors in the COMS small tumor study was 1%³⁵; however, the calculation of this rate included a substantial number of patients whose suspected tumors did not grow and were never treated. A randomized, prospective trial of visual and survival outcomes in patients managed by observation versus prompt treatment is needed to answer this critical question.

Treatment and prognosis of medium melanomas

The COMS completed a prospective, randomized clinical trial enrolling 1317 patients with medium-sized melanomas in which patients were randomly assigned to enucleation or brachytherapy with ¹²⁵I plaques at a tumor dose of 10,000 cGy.³⁶ The study concluded mortality rates following brachytherapy (81% 5-year

survival) did not differ from mortality rates following enucleation (82% 5-year survival) for up to 12 years after treatment. Given the findings of this study, patients with medium-sized melanomas are offered both enucleation and brachytherapy as potential treatment options. Brachytherapy with ^{125}I plaques is usually administered at doses of 7500–10,000 cGy to the tumor apex. The fractionation schemes vary markedly without an apparent effect on local control, metastasis, or complications. Complications include radiation retinopathy and optic neuropathy. As a result of these complications, 43% of patients have 20/200 vision or worse by 3 years of follow-up.

Treatment and prognosis of large melanomas

In the past, patients with large tumors were generally treated with enucleation, with or without preoperative radiation. The COMS prospective, randomized clinical trial for patients with large tumors found that there was no survival difference between patients treated with enucleation alone (5-year survival 57%) and patients treated with pre-enucleation radiation (5-year survival 62%).³⁷ The patients assigned to the pre-enucleation radiation group in this study were treated with five fractions of 200 cGy external-beam radiation and enucleation within 72 h. Patients with large melanomas are now generally treated with enucleation alone.

Ocular surface squamous neoplasia (OSSN)

Ocular surface squamous neoplasia (OSSN) is the term that refers to both intraepithelial neoplasia and squamous cell carcinoma of the conjunctiva/cornea. The incidence of this disease has geographic variability, with some of the highest rates in Africa. Ultraviolet radiation is an important risk factor, but viral, particularly human papilloma virus, and genetic etiologies are also believed to be implicated. Squamous cell carcinoma is more aggressive in patients with human immunodeficiency virus.

OSSN has variability in its appearance, but typically presents as a slowly progressive redness or irritation of the eye often with leukoplakia. Lesions can be isolated, but as they progress, they can invade into the adjacent skin, orbit, sclera, and interior of the eye. Well-circumscribed lesions can be removed with excisional biopsy and an adequate tissue margin with adjuvant cryotherapy and/or topical chemotherapy. In more extensive and advanced cases, radiation or even exenteration (removal of orbital contents) may be indicated. The risk of metastases from squamous cell carcinoma ranges from <1% to 8% and is more common in mucoepidermoid/spindle cell subtypes, tumors with a high mitotic index, or those that recur or invade the eyelid and orbit. Metastases are typically first found in the adjacent lymph nodes.

Metastatic disease

The most common malignant neoplasm in the eye or orbit, in children or adults, is metastatic carcinoma to the choroid. While there are only 350 cases of retinoblastoma and 1500 cases of choroidal melanoma yearly in the United States, it is estimated that 30,000–100,000 patients with cancer develop metastases to the eye each year.

Most cancers metastasize to the uveal tract (iris, ciliary body, and choroid), with choroidal metastases occurring most frequently. Metastases to the lids, conjunctiva, optic nerve, orbit, extraocular muscles, and orbital bones are also reported. Metastases to the retina are rare.

Choroidal metastases are usually amelanotic, multiple, bilateral, minimally elevated, and painful when situated around the optic nerve or invading the sclera. In contrast, ocular melanomas are typically pigmented, solitary, unilateral, significantly elevated, and painless. Metastatic tumors, such as ocular melanomas, always have an associated serous detachment but the amount of detachment is proportionally

greater with metastases. Ultrasonographically, most metastases have high reflectivity on ultrasound. Most ocular melanomas are detected on routine examinations, whereas ocular metastases are typically identified because of symptoms of decreased visual field and diminished visual acuity owing to serous retinal detachments.

Metastasis to the eye most commonly occurs in adults aged 55–65, the same age distribution as that for ocular melanomas. Metastases originate most commonly from a primary lung cancer and second most commonly from a primary breast cancer. As many as 34% of patients who present with metastases to the choroid have no previously known history of a primary cancer.³⁸ Many other cancers metastasize to the eye, including G.I., prostate (though more commonly to orbital bones), thyroid, ovarian, and cutaneous melanoma. Virtually all cancers have been found to be capable of metastasizing to the eye.

The most striking feature of metastatic ocular lesions is their association with concurrent CNS metastases. While the true concordance of these two lesions is unknown, it has been our experience that more than 75% of cases of ocular metastasis have concurrent CNS disease, although frequently the CNS disease is initially undetectable with imaging. It has therefore been speculated that some ocular metastases do not arrive through blood-borne routes but that CNS metastases may actually seed the choroid via the subarachnoid space as they do in childhood leukemia.

Treatment for ocular metastasis is considered when symptoms of diminished vision, pain, or diplopia are present. Treating the ocular lesion rarely has an impact on survival, except in carcinoid metastases, but may significantly alter the quality of life. Many ocular metastases respond to chemotherapy, targeted molecules, and biologics the way other systemic metastases respond. Chemotherapy and/or hormonal manipulation with the additional of intravitreal injections of anti-VEGF (vascular endothelial growth factor) may cause rapid regression of the tumor and of subretinal fluid. External-beam radiation and photodynamic therapy are used to palliate symptoms from ocular metastases. Except for carcinoid and breast cancer, however, median survival in patients with metastatic choroidal lesions is just over 6 months.

Cancer-associated retinopathy (CAR)

Cancer-associated retinopathy (CAR) is a paraneoplastic disorder characterized by visual loss in patients with cancer. Patients report photopsias or entopic phenomenon as well as light sensitivity and night blindness. Examination reveals decreased visual acuity, decreased color vision, and scotomas. A CAR antibody, a 23 kDa protein commonly found on blood testing, is known to be specific for a photoreceptor and bipolar cell-specific calcium binding protein. The underlying tumor is thought to express recoverin and stimulate this antibody response. The circulating antibodies then react with the retina resulting in photoreceptor degeneration. Although antibodies to recoverin account for the majority of cases, additional antibodies to 46, 45, 60, and 65 kDa proteins have been described. Lung cancer, endometrial sarcoma, lymphoma, and prostate cancer have been associated with the syndrome. Treatment is difficult. Steroids, plasmapheresis, intravenous immunoglobulin (IVIG), and treatment of the underlying tumor have been attempted. Although individual successes have been reported, most patients have little improvement and there is no clear consensus as to the best treatment.³⁹

Ocular lymphoid tumors

Non-Hodgkin lymphomas can occasionally infiltrate the intraocular tissues and become clinically apparent even before identification of the systemic disease. Immunocompromised patients, especially those with viral illness such as those with HIV/AIDS (human immunodeficiency virus infection and

acquired immune deficiency syndrome), show an increased incidence of this disease.

Primary malignant lymphomas of the eye have historically been called *reticulum cell sarcoma* or *microgliomatosis* and usually present with cells in the vitreous with associated retinal and optic nerve involvement. Diagnosis is made by vitrectomy or lumbar puncture. Treatment is accomplished with systemic steroids and external-beam radiation therapy of 2400 cGy to the affected eye and/or chemotherapy. Intravitreal injections of rituximab or methotrexate have been used, particularly in cases of visual decline from intraocular disease. These patients frequently have CNS disease but rarely have systemic disease. There is controversy about whether to treat the brain in those cases in which diagnostic lumbar puncture and MRI demonstrate no disease. Median survival is 3.5 years and is usually determined by the extent of brain involvement. Treatment of ocular lesions does not seem to affect the appearance or extraocular sites in the future.

Uveal lymphoid infiltration is a rare disorder characterized by localized or diffuse infiltration of the uveal tract by lymphoid cells. Patients typically present with painless, progressive visual loss. Nodular amelanotic thickening of the choroid or exudative retinal detachment with secondary glaucoma can be present. Biopsy confirmation should be targeted to the most accessible tissue. Management emphasizes globe conservation aimed at visual presentation and generally involves oral steroids and/or external-beam radiation. Prognosis for survival is excellent and generally based on the degree of systemic involvement. Associated CNS involvement is rare.

Adult ophthalmic oncology: orbital diseases

Introduction to orbital tumors

Fortunately, malignant tumors of the orbit are unusual. Neoplasms account for approximately 20–25% of orbital disease and are most common in patients in their sixties or older. Malignant primary cancers of the orbit that do require biopsy and surgical management include lacrimal gland tumors and orbital lymphoma.

All cases of suspected orbital tumor should undergo imaging, including ophthalmic ultrasound, CT scans with or without contrast, and/or MRI with or without contrast in order to define more clearly the location and characteristics of the tumor.

Benign and malignant disease

Well-delineated orbital masses

The most common benign orbital tumor of adults is the cavernous hemangioma. Patients have slowly progressive painless proptosis with a mass indenting the globe, showing striae in the retina and a flattened globe on imaging studies. Treatment is surgical, and complete removal is possible. Other well-circumscribed lesions include neurofibromas, schwannomas, hemangiopericytomas, meningioma, and gliomas.

A mucocele or mucopyocele is a cystic, encapsulated mass originating in a paranasal sinus (usually the frontal sinus) that follows repeated bouts of sinusitis often leading to recurrent orbital cellulitis. It is the most common cause of proptosis in children. The bony wall is not intact on imaging studies. Treatment involves antibiotics. Surgical drainage is necessary if antibiotics fail to achieve resolution of the pyomucocele or if optic nerve compression is present.

Diffuse orbital masses

Diffuse orbital masses usually require a biopsy and include orbital lymphoma, orbital cellulitis, fibrous histiocytoma (benign and malignant), neurofibromas, and sarcomas. Lymphoproliferative neoplasms account for >20% of all orbital mass lesions. The incidence of non-Hodgkins lymphoma of all anatomic sites has been increasing at a rate of 3–4% per year and orbital lymphomas have been increasing at an even greater rate, although the factors responsible for this rise are poorly understood. Historically, lymphoid tumors were classified as either active lymphoid hyperplasia or malignant lymphoma. More recently, it has been recognized that lymphoproliferative lesions represent a continuum and that ultimate behavior is difficult to predict. Currently, 70–90% of orbital lymphoproliferative lesions are designated as malignant lymphomas on the basis of molecular genetic studies and monoclonal cell surface markers.

The typical lymphoproliferative lesion presents as a gradually progressive painless mass. It can be located anteriorly in the orbit or beneath the conjunctiva. Orbital imaging reveals the characteristic molding of the tumor around normal structures, and bony erosion is rare except in high-grade lesions. Up to 50% of all lesions arise in the lacrimal fossa, and up to 17% of lesions occur bilaterally. For all lesions, early biopsy is recommended to establish a diagnosis and characterize the lesions to reflect distinct morphologic, immunologic, cytogenetic, and molecular properties under the Revised European American Lymphoma (REAL) classification.⁴⁰ This classification has been shown to predict differences in the clinical behavior of these lesions. The classification allocates adnexal lymphomas to one of five categories: marginal zone lymphoma (MALT), diffuse lymphoplasmacytoid/lymphoplasmacytic lymphoma, follicle center lymphoma, diffuse large B-cell lymphoma, and other rare lymphomas.

Management of adnexal lymphoma involves a metastatic work-up by an oncologist. Ocular disease is generally treated with 2000–3000 cGy of external-beam radiation therapy, which results in local control in virtually all cases and may prevent systemic spread. However, at least 50% of patients eventually have systemic lymphoma detected and treatment of systemic dissemination is based on the pathologic grade of the lesion and its characteristic degree of aggressiveness. Some indolent lymphomas are refractory to chemotherapy and are associated with long-term survival, whereas more aggressive lymphomas may be cured with aggressive chemotherapy and/or radiation.

Some studies suggest that patients with bilateral orbital involvement have a poorer prognosis. Conjunctival lesions have the lowest likelihood (20%) of developing systemic disease. Eyelid lymphomas have the highest likelihood (67%), with orbital lesions in between (35%).

Lacrimal gland tumors

Lacrimal gland tumors can be easily identified with ophthalmic ultrasonography, but a more clear definition of tumor location, especially bony involvement, is best demonstrated with CT scans. When lacrimal gland masses are bilateral on orbital imaging, they generally represent lesions such as sarcoid, orbital pseudotumor, or lymphoma. Of those lacrimal gland masses not presenting with inflammatory signs, the majority represent lymphoproliferative disorders, as fully 50% of orbital lymphomas develop in the lacrimal fossa. Only a minority of lacrimal fossa lesions are primary epithelial neoplasms of the lacrimal gland. Biopsy is necessary in suspected cases to establish a pathologic diagnosis.

Approximately 50% of primary epithelial neoplasms of the lacrimal gland are benign mixed tumors (pleomorphic adenomas) and about 50% are carcinomas. Approximately half of the carcinomas are adenoid cystic tumors ([Figure 7](#)), and the remainder include malignant mixed tumors, primary adenocarcinomas, mucoepidermoid carcinomas, and squamous carcinomas. Treatment for primary malignant lacrimal gland tumors includes excisional surgery and radiation therapy. Except for

pleomorphic adenomas that undergo successful surgical removal without a preliminary biopsy (with resultant tumor capsule rupture, increasing risk of recurrence), the clinical course for most of these tumors is that of multiple painful recurrences with ultimate mortality from intracranial extension or systemic metastases, often occurring a decade or more after initial presentation.

Figure 7 Adenoid cystic carcinoma of the lacrimal gland in a patient who underwent 2 biopsies of the mass, both of which were equivocal. The patient developed metastases to the parotid gland and later died.

Neoplasms of the endocrine glands: pituitary neoplasms

Chirag D. Gandhi, MD, FACS, FAANS ■ Margaret Pain, MD ■ Kalmon D. Post, MD, FACS, FAANS

Overview

Pituitary neoplasms represent a phenotypically and pathologically diverse family of tumors. Treatment and classification are both patient and tumor specific as symptoms may derive from abnormal hormone production, compression of adjacent nervous system structures, and, in rare cases, metastases. Transsphenoidal surgery represents a common and well-tolerated treatment for most pituitary adenomas; however, advances in radiation and chemotherapy have increased treatment options, enhancing treatment efficacy, and eligibility.

Pituitary adenomas are epithelial tumors arising from the adenohypophysis that can manifest with neurological symptoms from local mass effect such as headaches, visual disturbances, increased intracranial pressure, and cranial nerve palsies or as a variety of clinical entities depending on the hormones they secrete. In rare cases (<1%), patients can also present with diabetes insipidus. Pituitary adenomas constitute 10–15% of intracranial tumors, although the incidence is as high as 24% in autopsy series. They are most common in the third and fourth decades of life and overall affect both sexes equally. However, there are differences in frequency of certain subtypes between the sexes. Cushing's disease, for example, is more common in women; Prolactin (PRL)-secreting adenomas are more common in young women; and null-cell adenomas, oncocytomas, and gonadotropin-secreting adenomas are more common in men.

Distinction between pituitary neoplasm subtypes has been refined progressively as we have come to understand more about the pathology and biochemistry of the pituitary gland. Early on, tumors were classified based on the light microscopy characteristics of the predominant cell cytoplasm and were therefore divided into categories as acidophilic, basophilic, or chromophobic tumors. Acidophils were thought to produce excess amounts of growth hormone (GH) and were linked to acromegaly and gigantism; basophils were thought to secrete adrenocorticotrophic hormone (ACTH) and to cause Cushing's disease; and chromophobes were regarded as hormonally inactive. This system has become too simplistic for modern treatment algorithms as hormone secretion is only loosely associated with hematoxylin and eosin staining. It has been well established that both acidophilic and basophilic adenomas may secrete other hormones and that chromophobes can be hormonally active capable of secreting GH, PRL, ACTH, thyroid-secreting hormone (TSH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), or α -subunit.¹

From a medical perspective, tumors are frequently categorized based on the predominant hormone that they secrete.^{2,3} Tumors are further categorized as hormonally active or inactive and are considered active only if the amount of hormone they secrete exceeds normal levels in the blood and is clinically evident. Inactive adenomas contain secretory and cellular components necessary for hormone production, but they are not associated with clinical or biochemical evidence of hormone excess. There are several theories about the etiology of inactive adenomas. One theory is that the gland cells become neoplastic but inherently have low hormone production. Another proposed theory is that the cells produce abnormal

hormone that is not recognized by antibodies in the standard radioimmunoassays, and finally that the cells have lost the ability to produce hormone through some acquired genetic defect.⁴ This functional classification is now being further modified to incorporate recent advances in molecular and immunohistochemical advances in pituitary research.

Anatomically and radiologically, tumors can also be classified based on their relationship to and involvement within the cavernous sinus. Magnetic resonance imaging (MRI) is the modality of choice and should be requested with a special consideration given toward imaging the pituitary. This can usually be achieved by obtaining thin slices through the pituitary in the coronal and sagittal planes ([Figure 1](#)). With high sensitivity for intracranial pathology, coronal T_2 -weighted images give greater clarity to possible optic chiasm displacement as well as hemorrhagic and cystic changes within the tumor. Gadolinium contrast enhancement is essential for increasing the diagnostic yield for microadenomas (<10 mm) and is also useful in delineating normal from abnormal tissue in macroadenomas (T_1 -weighted images pre- and postgadolinium).⁵ In general, pituitary adenomas appear as a hypointense lesion on a T_1 precontrast image and will enhance less than normal pituitary tissue on T1 postcontrast series. Radiographic appearance has been used to further categorize parasellar invasive tumors according to the schema derived by Jules Hardy and/or Engelbert Knosp ([Figure 2](#)). The Knosp classification scheme has emerged as a relevant strategy for preoperative prediction of cavernous sinus invasion. Briefly, the MRI appearance of the tumor and its influence on the medial wall of the sinus relative to the position of the intracavernous internal carotid artery are used to estimate the likelihood of invasion. Increasing mass effect of the tumor on the medial wall correlates with increased likelihood of invasiveness. When compared with noninvasive tumors, invasive tumors are more likely to demonstrate aggressive behavior.⁷

Figure 1 A 38-year-old woman with an ACTH-secreting adenoma. (a) Coronal T1-weighted magnetic resonance with contrast demonstrates a hypointense macroadenoma within the sella that extends into the left cavernous sinus and encases part of the carotid artery. (b) Sagittal T1-weighted magnetic resonance with contrast demonstrates a hyperintense macroadenoma within the sella.

Molecular biological investigation into pituitary tumorigenesis has demonstrated that adenomas are a result of monoclonal proliferation^{8–10} and that neoplastic progression is related to both oncogenes and dysfunctional tumor suppression. Although several mutations have been implicated in pituitary tumorigenesis, only one mutation has been identified with significant prevalence in affected patients. Approximately 10–40% of GH-secreting adenomas result from a point mutation affecting the α -chain of the GTP-binding protein, leading to constitutive cAMP activation. It is postulated that the elevated cAMP formation leads to GH hypersecretion and adenoma proliferation.¹¹ Although it has been theorized that adenomas with this gsp oncogene mutation are smaller and more sensitive to medical therapy, recent studies have failed to demonstrate any phenotypic differences between patient with the mutation and those without it.¹² Many other additional factors have been identified to influence tumor progression. Oncogenes linked to adenoma progression include cAMP-responsive nuclear transcription factor, CREB, which is thought to be promoted by the overexpression of Gs α ¹²; ras oncogene mutations that have been detected in aggressive prolactinomas¹³; and the pituitary tumor transforming gene (PTTG) thought to be a marker for invasiveness in secretory adenomas.^{14, 15} Tumor suppressor genes such as Rb, menin, TP53, p27, p16,^{16, 17} hormone-promoting factors such as hypothalamic neurohormones, and locally produced growth factors and cytokines are also being studied for their contribution to adenoma growth.¹⁸ With research into galectin-3 (Gal-3), a therapeutic drug target found only in PRL- and ACTH-secreting tumors, as well as nuclear receptor, peroxisome proliferator-activated receptor gamma (PPAR- γ), isolated from a number of studied adenomas, there is promise for novel drug development.^{19–21}

Evaluation of a patient with suspected or known pituitary adenoma requires both complete radiographic and endocrinological and potentially genetic assessment before initiation of therapy.²² Endocrine assessment should include a complete metabolic panel, pregnancy test, serum GH, insulin-like growth

factor (IGF-1), TSH, free T4, T3, PRL, ACTH, cortisol, LH, FSH, and testosterone. Following these tests, the determination of further medical or surgical treatments can be made.

Surgery is the preferred and definitive treatment of all pituitary adenomas with the exception of prolactinomas and asymptomatic, hormonally inactive tumors (incidentalomas). On the basis of the innovative work of Cushing, Guiot, and Hardy, the transsphenoidal approach is the preferred surgical technique for most adenomas and is associated with minimal morbidity and rapid recovery.^{23, 24} The goals of surgery include the reduction of tumor-related mass effect on adjacent structures, the cessation of endocrine hyperactivity, and the preservation or restoration of normal pituitary function. Adjuvant treatment can then be initiated based on the histopathology and immunochemistry, postoperative hormone secretory status, and the degree of extrasellar extension. In contrast, prolactinomas frequently respond well to medical therapy and incidental tumors require only observation until they are associated with symptoms.

Finally, a small percentage of pituitary neoplasms demonstrate aggressive behavior or carcinomatous change. Hormonally active tumors usually require hormone-specific therapy but this may not be sufficient for disease control. Temozolomide, an oral alkylating agent, has emerged as an effective adjunctive therapy for these patients.²⁵ Its efficacy is explained by the phenotype of low O⁶-methylguanine-DNA methyltransferase (MGMT) expression frequently found in aggressive pituitary neoplasms.²⁶

Prolactin-secreting pituitary adenomas

Prolactinomas are the most commonly diagnosed pituitary adenoma, representing approximately 30% of cases.²⁷ Although rarely life threatening, when symptomatic, they can present with clinical findings relating to hyperprolactinemia (abnormal reproductive or sexual function) or mass effect on adjacent structures owing to size. Because of their reliable responsiveness to medical management, chemotherapeutics are often the first-line treatment for these tumors ([Figure 3](#)). However, surgical treatment has been shown to be equally effective and may be indicated at a primary intervention for certain cases.

Figure 3 A 52-year-old male with diminished libido and a macroprolactinoma. (a) Sagittal T1-weighted magnetic resonance with contrast demonstrates a large sellar/suprasellar adenoma with compression of the optic chiasm. (b) Sagittal T1-weighted with contrast demonstrates a significant reduction in tumor volume after being treated medically with bromocriptine.

Clinical presentation

Although autopsy studies have demonstrated that prolactinomas have similar prevalence between the genders, women are four times more likely than men to become symptomatic. In women of reproductive age, hyperprolactinemia may cause oligomenorrhea, secondary amenorrhea, galactorrhea, and sterility. Less common symptoms in this population are decreased libido, dry vaginal mucosa caused by estrogen deficiency, weight gain, and psychological symptoms such as depression and anxiety. Prolactinomas account for approximately 5% of women with primary amenorrhea and 25% of women with secondary amenorrhea (excluding pregnancy).²⁸ When the presentations of amenorrhea are accompanied by concomitant galactorrhea, the incidence of prolactinoma increases to 70–80%.²⁹

In men and postmenopausal women, where symptomatic hyperprolactinemia is much more subtle, the tumors may grow to much larger sizes and are detected only when they begin to produce symptoms related to mass effect. Macroadenoma-related mass effect may result in headaches, visual disturbances (typically bitemporal hemianopsia as a result of chiasmatic compression), hypopituitarism, ophthalmoplegia, and, rarely, noncommunicating hydrocephalus from obstruction of the foramen of Monro. Men may also experience a diminished libido, impotence, gynecomastia, and infertility from decreased androgen production. The mechanism of hypogonadism caused by hyperprolactinemia is still controversial. One possibility is that PRL alters the hypothalamic release of gonadotropin-releasing hormone (GnRH) through dopamine inhibition, which in turn causes disruptions in the normal pulsatile secretion of LH.³⁰ Prolonged periods of hyperprolactinemia have also been linked to bone demineralization by way of hypogonadism as bone density is normal in eumenorrheic hyperprolactinemic women.³¹

Diagnosis

Beside prolactinomas, hyperprolactinemia can be associated with a variety of causes such as pregnancy, hypothyroidism, PRL-stimulating drugs (e.g., phenothiazines, butyrophenones, and metoclopramide), and renal failure that need to be considered in the differential diagnosis. In addition, physiological hyperprolactinemia can occur from psychological and physical stresses, such as exercise, surgery, and

hypoglycemia, but the PRL level rarely exceeded 40 ng/mL in these cases.³² A definitive diagnosis of prolactinoma is difficult and in most cases requires radiographic evidence in addition to elevated PRL levels. In men, a basal PRL value greater than 100 ng/mL is almost always indicative of a prolactinoma. In women, PRL levels of 100–200 ng/mL should raise suspicion for prolactinoma, while a level of over 200 ng/mL is highly suggestive of prolactinoma.^{33, 34} The greatest diagnostic uncertainty lies in patients with PRL levels between 50 and 100 ng/mL. Within this range, hyperprolactinemia may also be related to “stalk effect,” where mass of a tumor interferes with the flow of prolactin-inhibitory factor (PRIF) from the hypothalamus. Although various endocrine stimulation tests to differentiate these two possibilities have been suggested, they have not been proven reliable.³⁵

Serum PRL levels are an index of secretory activity and have been found to be associated with the size of the prolactinoma (excluding cystic or necrotic components). Eighty percent of tumors producing less than 200 ng/mL are microadenomas, while at levels above 200 ng/mL only 20% are microadenomas. This relationship becomes unreliable for very large tumors (>4 cm). While the total PRL level may usually correlate with size and may even be greater than 1000 ng/mL, the laboratory value may be falsely low (25–150 ng/mL) and not reflect the actual serum concentration because of a phenomenon known as the “Hook effect.”^{36, 37} Briefly, the Hook effect results from saturation of the antibody binding sites during the radioimmunoassay and therefore distorting the binding curve. This can be resolved by performing serial dilutions and should be considered for all giant pituitary adenomas.

Treatment

The treatment options available to a patient with a prolactinoma include observation, medical therapy, surgery, and radiotherapy. Treatment decisions should take into consideration the tumor size, PRL level, clinical manifestations, tolerance of medical therapy, and the desire for fertility. The vast majority of microprolactinomas (<10 mm) do not increase in size.³⁴ Together with autopsy studies suggesting higher prevalence of undiagnosed tumors within the population, many clinicians and patient opt for observation and against treatment for microadenomas in the absence of clinical hyperprolactinemia, normal pituitary function, and no desire for pregnancy.

Dopamine agonists have been shown to be highly effective in suppressing tumor growth and PRL production because dopamine, when secreted by the hypothalamus, is an endogenous inhibitor of PRL production. Bromocriptine was the first dopamine agonist to be used for treatment of prolactinomas, but newer agents such as cabergoline, quinagolide, lisuride, and terguride have also gained widespread acceptance. On a molecular level, dopamine agonists selectively activate type D2 dopamine receptors, thereby blocking transcription of the PRL gene.³⁸ The shrinkage of PRL cells results in amyloid deposition and fibrosis of the tumor.³⁹ Dopamine agonists have been shown to have a high response rate with normalization of PRL levels in 70–80% of patients, tumor shrinkage in 80–90%, and restoration of ovulation in 80–90%.⁴⁰ On the basis of these results, some argue that medical treatment should be used in all patients except the 10% who experience significant side effects.⁴¹ In addition, there is evidence to suggest that a significant percentage of patients who respond to cabergoline with normalization of PRL levels and tumor shrinkage will remain in remission following discontinuation of the drug after 2 years.^{42, 43} However, even in patients who have optimal response to cabergoline (normalization of PRL, tumor volume reduction, no invasion of critical structures, or optic chiasm compression), the majority do experience recurrence and so close follow-up after treatment discontinuation is critical.⁴³

Dopamine agonists do have some significant disadvantages that may temper their use. For many patients, the effects are reversible and therefore lifelong compliance is needed to control the disease. In addition,

significant side effects such as nausea, vomiting, postural hypotension, headaches, XX depression, and anxiety have been reported with medication use. In cases of pituitary apoplexy and in tumors with large cystic components, dopamine agonists are not effective in shrinkage as tumor size is not correlated with tumor cellularity. More harmful side effects of dopamine agonists have also been reported. At much higher doses of cabergoline than the maximum dose used for prolactinomas, cardiac toxicity has occurred. Although subclinical valvular fibrosis and trace mitral regurgitation with cabergoline therapy of prolactinomas has been reported, no patients experienced clinically significant change in cardiac function as a result.^{44, 45, 136} Finally, dopamine agonists are not always effective for the treatment of prolactinomas. Bromocriptine resistance may be an indicator of increased tumor aggressiveness, and there may be an association between gland medication resistance.⁴⁶

Currently, there is controversy in the role of surgery for treatment of prolactinomas. With requirement for strict long-term compliance and frequent medical follow-up, some argue that surgery should be the initial treatment with medical therapy as an adjunct only in cases without remission.⁴⁷ The rate of long-term remission after surgery varies significantly with preoperative PRL levels and tumor size. Remission rates are best, 50–80%, for microadenomas with preoperative PRL levels of less than 200 ng/mL.^{40, 47–49} Rates drop significantly for macroadenomas and in patients with PRL levels of 200–500 ng/mL. Surgery has not been shown to be useful in giant adenomas and tumors with PRL levels greater than 500 ng/mL, as a complete resection is rarely possible. Even in these patients, however, dopamine agonists appear to be beneficial. Meta-analysis has found that three-fourths of patients experienced significant reduction in tumor volume and normalization of PRL level in 60–70%.⁵⁰ There is evidence to suggest that surgery is more effective when dopamine agonists are used as neo-adjuvant therapy.⁵¹ In addition, some have demonstrated that surgery to be beneficial in cases of dopamine resistance as partial tumor resection was associated with better hormonal control and lower doses of dopamine agonists.^{52, 53} Overall, there is an inverse correlation between PRL levels and remission rates.

Conventional radiotherapy is generally not considered a primary mode of treatment.⁵⁴ The use of stereotactic radiosurgery as either a primary⁵⁵ or adjuvant⁵⁶ therapy is becoming increasingly common. Radiosurgery has been shown to be successful in decreasing PRL levels (and in one study, 30% of patients achieved an endocrinological cure).⁵⁷ As radiotherapy is rarely used alone, these data may be skewed by confounding factors.

Medical therapy by means of dopamine agonists remains the first-line treatment for most prolactinomas⁵⁸ This treatment should be considered for all patients, including those desiring pregnancy and those with primary amenorrhea.

For tumors larger than 2 cm or with PRL levels between 200 and 500 ng/mL, neo-adjuvant treatment with dopamine agonists appears to reduce tumor volume, followed by surgery. Any residual tumor can then be treated medically. For very large, invasive, or tumors associated with PRL levels of greater than 500 ng/mL, medical therapy should be the primary treatment modality.⁵⁰

Special consideration should be given to patients with prolactinomas during pregnancy. There is a small but serious risk of rapid expansion of the tumor off medication. Complications related to this growth occur primarily from macroadenomas with suprasellar extension; they are much less frequent for microadenomas.⁵⁹ If these patients become symptomatic, a dopamine agonist can be administered. Both bromocriptine and cabergolide are US FDA pregnancy category B, indicating that animal studies have not shown risk to the fetus but that randomized, controlled trials in humans are inadequate to assess the risk comprehensively.^{60, 61} During pregnancy, surgery should be undertaken only if the tumor does not respond

to medical treatment or if there are progressive neurological symptoms. To reduce the risk of pregnancy-related complications, patients with macroadenomas who desire pregnancy should undergo transsphenoidal resection before conception or remain on bromocriptine throughout the pregnancy.

Growth hormone-secreting pituitary adenomas

GH secretion is under hypothalamic control through somatostatin and growth hormone-releasing hormone (GHRH). Upon release, GH causes the production of IGF-1 from the liver, which affects bone and tissue growth and provides negative-feedback inhibition to GH and GHRH secretion. Acromegaly, the clinical condition associated with GH-producing adenomas, results in autonomous GH secretion and loss of this negative-feedback inhibition. However, the clinical manifestations of GH-secreting tumors have been found to correlate better with IGF-1 levels than with GH levels.

Clinical presentation

GH-secreting pituitary adenomas account for about 30% of all endocrine-active pituitary tumors. Most patients present in their third to fifth decade with macroadenomas and a long history of subclinical symptoms that usually ranges between 4 and 10 years.⁶² GH excess classically presents as acromegaly or gigantism, both marked by an insidious coarsening of features with frontal bossing and prognathism, macroglossia, and exaggerated acral growth. Patients are also found to develop organomegaly, hypertension, cardiomyopathy, congestive heart failure, restrictive lung disease, sleep apnea, and arthropathies. In addition, a very high percentage of these patients develop impaired glucose metabolism and diabetes mellitus. Common presenting symptoms include fatigue, headaches, arthralgias, oily skin, and hyperhidrosis. For patients with variant tumors that also cosecrete PRL, amenorrhea, galactorrhea, and loss of libido may also be present. With an insidious onset and high rate of medical comorbidities at time of presentation, untreated patients have a high rate of early mortality- as high as 50% at 50 years old and 2–3 times that of the general population.⁶³

Diagnosis

Acromegaly is frequently suspected based on change of appearance and sub-clinical history. Hormone hypersecretion can be assessed through analysis of basal fasting GH levels or age- and gender-adjusted IGF-1. Elevated basal fasting GH levels greater than 2.5 ng/mL suggest acromegaly. However, because GH has both a short half-life and is secreted in a pulsatile manner, assessment of IGF-1 often generates a more accurate assessment of GH excess.⁶⁴ Dynamic testing is typically reserved for monitoring therapeutic efficacy. The oral glucose tolerance test (OGTT) tracks GH response to a large oral glucose load (75–100g). Normal patients respond to the glucose load with GH suppression and levels fall below 1 ng/mL. Loss of glucose-induced suppression is diagnostic for a GH—secreting tumor. A study of 92 patients with acromegaly suggests that nadir levels of GH did not vary significantly based on either age or gender.⁶⁵

Although rare, ectopic GHRH has been reported to account for approximately 1% of acromegaly cases. When responsible for GH excess, the ectopic GHRH production can usually be attributed to tumors in the chest or abdomen. To avoid unnecessary surgery, image confirmation of a pituitary tumor should be obtained after making a clinical and biochemical diagnosis.

Treatment

The clinical definition for cure of acromegaly has been refined several times since the introduction of the GH assay in the 1960s. Currently, the biochemical goals of therapy are to reduce basal GH levels to less than 2.5 ng/mL, normalize IGF-1 levels, and achieve a nadir GH level of less than 1 ng/mL during an OGTT.⁶⁶ A complete cure should lead to recovery of normal pituitary function and, in most cases, a slow reversal of both cosmetic and physiological abnormalities.

Transsphenoidal surgery remains the first-line therapy for GH-secreting tumors.⁶³ The advantages of surgery include a prompt decrease in GH levels and a tissue diagnosis. At our institution, a 14-year review of 115 patients demonstrated that surgery alone produced biochemical remission in 61% of cases.⁶⁷ The rate was 88% for microadenomas and 53% for macroadenomas. There was a negative correlation of surgical outcome with tumor size and preoperative GH levels. Immediate postoperative GH levels were found to correlate with long-term outcome. In cases where the postoperative GH level was less than 3 ng/mL, the chance of a favorable long-term outcome was 89%. Postoperative radiotherapy was given to 32 patients and led to remission in 31% of these patients. An additional three patients achieved remission with a combination of surgery, radiotherapy, and medical treatment. The overall complication rate was 6.9% with no CSF leaks, meningitis, permanent diabetes insipidus, or new hypopituitarism. The recurrence rate was 5.4%. Other published studies reflect similar results.^{68, 69}

Both radiotherapy and radiosurgery have been used for treatment of acromegaly. The use of conventional external beam radiation has been found to reduce GH levels to less than 5 ng/mL in 50–70% of cases, but the effects can take as long as a decade to occur.⁷⁰ Hypopituitarism has been found in 50% of patients 10 years after irradiation, with an increasing incidence annually thereafter.⁷¹ Radiosurgery has demonstrated normalization of GH levels within 3–5 years.⁷² The likelihood of hypopituitarism is similar. In addition, radiation to sensitive adjacent structures such as the optic chiasm remains a concern and a 4-mm safety boundary is recommended for radiotherapy for all pituitary adenomas. In general, radiosurgery continues to be an adjunctive therapy after failed transsphenoidal surgery.^{68, 73, 74} These results are somewhat difficult to interpret as the definition of “normal” was inconsistent.⁵⁷ Endocrine cure rates in a variety of small studies were found to range from 0% to 96% and improvement in 0–67%. Out of the 20 studies reviewed, 6 did not cite their criteria for cure, and 11 of 14 used different criteria to define cure. Unfortunately, the studies are further confounded by the inconsistent use of somatostatin analogs in patients undergoing radiosurgery. Current studies on the efficacy of radiosurgery also have limited long-term follow-up. Additional randomized studies are needed. A more recent retrospective study assessed endocrine cure rates by normal OGTT for patients with adjuvant radiosurgery and found that 65% of patients achieved remission at 61.5 months with a trend toward increased remission at later time points.⁷⁵ In spite of normalization of the oral glucose tolerance, a subset of patients experience persistent elevation of IGF-1 after radiotherapy, demonstrating persistent pituitary axis dysfunction and subtle clinical symptoms of acromegaly.⁷⁶

Medical management as the primary or adjuvant treatment of acromegaly remains a controversial topic. In patients with no visual loss, some endocrinologists have advocated treatment with somatostatin analogs as the first-line therapy.⁷⁷ However, in the context of the significant long-term morbidity associated with acromegaly, most practitioners recommend surgery as the first-line treatment with adjuvant medical or radiotherapy, if needed. Three classes of drugs are used to treat acromegaly: dopamine agonists, somatostatin analogs, and GH-receptor blockers. Dopamine agonists such as bromocriptine and cabergoline have been shown to provide symptomatic relief in some acromegalic patients.⁷⁸ Although they have limited efficacy, these medications remain popular treatments for acromegaly because of their low cost and oral administration. In comparison, somatostatin analogs have been shown to be more

effective. Octreotide was found to normalize IGF-1 and reduce GH levels to less than 5 ng/mL in approximately 50% of patients.⁷⁹ The long-acting analogs such as lanreotide and octreotide LAR are slightly more effective and reduce GH to less than 2.5 ng/mL for 70% of patients and normalize IGF-1 in 88% of patients.^{80–82} Another class of medication for treatment of acromegaly are GH-receptor antagonists. At this time, pegvisomant is the only medication in this class with FDA approval. This class of medications is unique in that the site of action is not within the pituitary gland but rather on the receptors for GH. By preventing dimerization of the GH receptor, pegvisomant inhibits production of IGF-1, the hormone responsible for most of the clinical sequelae of acromegaly. Because it does not affect tumor size or GH production, this medication is typically reserved for cases of acromegaly that are refractory to other treatments. The medication has notable side effects including hepatic transaminitis and an association with rare tumor growth.⁸³ Because of this, it is recommended that patients prescribed pegvisomant be monitored with regular MRI exams and liver function tests.

Medical treatment demonstrates good results with regard to management of the clinical effects of GH excess. It has been found to provide symptomatic relief of headaches and hyperhidrosis as well as to improve arthropathy and cardiac function. If the medication is able to normalize IGF-1 levels and GH levels in the OGTT, patients experience significant improvement in left ventricular ejection fraction. This is especially notable as patients with uncontrolled acromegaly tend to also have deterioration of LVEF.^{84, 85} Unlike prolactinomas, medication does not cure acromegaly. Although current medical therapies are well tolerated and demonstrate good efficacy, lifelong treatment is required in order to avoid recurrence. This presents a serious downside to medical therapy as its success is both expensive and dependent on long-term compliance. Because of this, many practitioners and patients use chemotherapy as an adjuvant to either surgery or radiotherapy. There has not been statistically significant benefit demonstrated for the use of neo-adjuvant somatostatin analog treatment.⁸⁶

A minority (20–30%) of GH-secreting adenomas also secrete PRL. If symptomatic, patients may experience amenorrhea, galactorrhea, impotence, or loss of libido. Dopamine agonists are particularly effective in the treatment of mixed GH- and PRL-secreting tumors, but transsphenoidal surgery still remains the first-line treatment.⁸⁷

Adrenocorticotrophic hormone-secreting adenomas

Cushing's disease represents the most frequent cause of clinical hypercortisolism, or “Cushing's syndrome.” ACTH-producing tumors stimulate adrenal hyperplasia and ultimately result in hypercortisolism. Many consider Cushing's disease the most challenging pituitary endocrinopathy both to diagnose and to treat. Tumors are often small and evade detection by radiological imaging. Macroadenomas are often aggressive and have a high rate of recurrence. Demographically, Cushing's disease is nine times more common in women with a peak incidence in the third and fourth decades of life.

Clinical presentation

Only about 10–20% of ACTH-secreting adenomas are large enough to produce mass effect with resultant visual field deficits, cranial neuropathies, or hypopituitarism. The majority of tumors are less than 5 mm and present with clinical hypercortisolism. Common presenting features of Cushing's disease include central obesity, moon facies, buffalo hump, hirsutism, purple abdominal striae, and acne. Other clinical findings include hypertension, osteopenia, proximal myopathy, diabetes mellitus, and, very frequently, psychiatric disorders. Affected patients experience significant morbidity from the condition with a 5-year

mortality rate of 50% in those left untreated.⁸⁸ The increased morbidity and mortality are unique to secretory Cushing's disease patients, thought to be sequelae of increased cortisol exposure. Among the predictors of increased mortality in Cushing's patients, duration of clinical hypercortisolism, preoperative ACTH concentration, and depression have been shown to be significant.⁸⁹

Diagnosis

Accurate diagnosis of Cushing's disease depends on identifying evidence of hypercortisolism and localizing the pathology to the pituitary gland. Accuracy in diagnosis approaches 100% with a complete workup;⁹⁰ however, each individual test has a failure rate of 10–30% ([Table 1](#)).⁹¹

Table 1 Biochemical evaluation for Cushing syndrome

A. Screening for Cushing syndrome

1. Measurement of 24 h UFC in two or three collections. Test is unequivocal for hypercortisolism if the cortisol level is fourfold that of normal in two of three screens. If equivocal, proceed to the low-dose DST. Salivary cortisol levels are also highly sensitive and specific
2. Low-dose DST. 1 mg dexamethasone is administered at 11 p.m. and serum cortisol is drawn the following day at 8 a.m. A 2-day test is also commonly performed
 - If $< 5 \mu\text{g/dL}$: Cushing syndrome is excluded
 - If $5\text{--}10 \mu\text{g/dL}$: Indeterminate and retesting is necessary
 - If $> 10 \mu\text{g/dL}$: Cushing syndrome is probably present

B. Tests to distinguish primary Cushing disease from ectopic or adrenal tumors

1.
 - Serum ACTH is low in adrenal tumors. Plasma ACTH (values $> 10 \text{ pg/mL}$ are suggestive of ACTH-dependent disease; values $< 5 \text{ pg/mL}$ are suggestive of ACTH-independent disease)
 - Abdominal CT can help identify a unilateral adrenal mass or bilateral adrenal enlargement in ACTH-dependent cases
2.
 - High-dose DST. 8 mg of dexamethasone is administered at 11 p.m. and serum cortisol is drawn the following day at 8 a.m. A 2-day test is also commonly performed
 - In 95% of cases of Cushing disease, plasma cortisol is suppressed by 50%
 - No suppression is seen with ectopic or adrenal sources
3.
 - CRH stimulation test. Can be used after an equivocal high-dose DST
 - Cushing disease responds to CRH with further increases in plasma cortisol levels
 - Ectopic and adrenal tumors do not respond to CRH
4.
 - IPSS is reserved for persistent equivocal testing or in re-operations in which IPSS was not initially performed
 - After CRH administration, an inferior petrosal sinus/plasma ACTH gradient $> 3 : 1$ is suggestive of Cushing disease and aids with lateralization

Abbreviations: DST, dexamethasone suppression test; UFC, urinary free cortisol; CRH, corticotrophin releasing hormone; IPSS, inferior petrosal sinus sampling.

Hypercortisolism can be demonstrated through elevation in 24-h urinary free cortisol and 17-OH corticosteroids. Assays for midnight salivary cortisol have also been shown to be both sensitive and

specific for hypercortisolism.⁹² The etiology of hypercortisolism should be assessed first with a low-dose dexamethasone suppression test. This test assesses functioning of the hypothalamic–pituitary–adrenal negative-feedback loop for cortisol secretion. Patients with Cushing's disease will have hypercortisolism that persists in spite of a low-dose bolus of dexamethasone. However, 95% of Cushing's disease patients demonstrate a 50% decrease in plasma cortisol when a high dose of dexamethasone is used. Plasma ACTH levels should be assessed to differentiate a diagnosis of Cushing's disease from adrenal causes of hypercortisolism.⁹³ Diagnostic sensitivity for Cushing's disease can be further increased if a corticotrophin-releasing hormone (CRH) stimulation test is added to the workup.⁹⁴ Finally, inferior petrosal sinus sampling (IPSS) can be performed to improve tumor localization and diagnostic specificity if the previous workup is not definitive. While MRI is a sensitive study for tumor localization for tumors larger than 3 mm in diameter, conventional sequences fail to detect a high percentage of tumors.⁹⁵ However, with optimization of T1 postcontrast sequences or utilizing spoiled gradient recalled acquisition (SPGR), significantly more tumors can be visualized.^{95, 96} IPSS and cavernous sinus sampling can be helpful in these situations as they can confirm a pituitary pathology but laterality is incorrect in 25–30% of exams.⁹⁷

Treatment

Transsphenoidal surgery is the first-line treatment for Cushing's disease. The overall remission rate following surgery ranges from 76% to 91%.⁹⁸ Microadenomas tended to have slightly better outcomes with remission rates between 84% and 94%.⁹⁸ The major determining factor for success was the ability to localize the tumor on MRI.⁹⁹ In contrast, remission rates for macroadenomas appear to depend chiefly on the degree of invasiveness. Surgery alone achieves remission for 64% of patients, and when combined with adjuvant radiotherapy or radiosurgery, this number improves to 83% and 70%, respectively.^{98, 100}

While the postoperative course is unique for every patient, many patients with a successful tumor resection experience a rapid decline in their serum cortisol and ACTH levels. In some patients, this leads to life-threatening hypocortisolism (Addisonian crisis). Most patients require replacement therapy for up to 1 year as their hypothalamic–pituitary–adrenal axis recovers from the chronic ACTH overstimulation. Good prognostic factors for full postoperative remission include lower than normal serum levels of cortisol and ACTH. However, even with immediate improvement in serum cortisol, 15–25% of patients experience a recurrence.^{21, 101} In our experience, even normal cortisol and restoration of a normal response to dexamethasone suppression do not guarantee lasting remission. Because of this, long-term follow-up is essential in these patients.

Radiotherapy and radiosurgery are frequently used as adjuvant treatment when surgical results are inadequate. Conventional radiotherapy cure rates are as high as 90% at 5 years post-treatment.¹⁰² However, a large proportion of these patients began to experience hypopituitarism in later years and 5% developed Nelson's syndrome.¹⁰² Conventional radiation is not used as a primary modality because the effects of treatment take several years to develop while the symptoms and morbidities of Cushing's disease persist. In contrast, radiosurgery for Cushing's disease produces results much sooner. Remission is achieved in 35–90% of patients with much lower rates of hypopituitarism.^{103, 104} Full interpretation of these data is complicated by the fact that there was discrepancy in what constituted a “cure” and long-term follow-up was limited.

While medical therapy is not recommended as a primary treatment of Cushing's disease, it may be suitable for patients who do not experience improvement after surgery or who are otherwise not good candidates for surgery. Pasireotide was approved by the US FDA for these indications in 2012. A somatostatin

analog with high specificity for the somatostatin receptor 5, it has been shown to be clinically effective in reduction of cortisol levels and should be considered the preferred medication to treat Cushing's disease.¹⁰⁵ In addition, chemotherapy can temporize patients with severe hypercortisolism as they await surgery. In these cases, ketoconazole is often the drug of choice as it works to block adrenal steroid synthesis. Up to 90% of patients experience normalization of serum cortisol and ACTH while taking ketoconazole. However, the effects of this medication end immediately after cessation and patients on this medication must be closely monitored for hepatotoxicity.¹⁰⁶ Other medical treatments for Cushing's disease include aminoglutethimide, metyrapone, mitotane, and cyproheptadine. Dopamine agonists such as cabergoline have also been shown to be successful in the treatment of ACTH-secreting tumors. After 3 months of cabergoline treatment, 60% of patients demonstrated cortisol inhibition and 40% had normalization of cortisol secretion.¹⁰⁷ This finding could be explained by the observation that the majority of ACTH-secreting adenomas demonstrate positive dopamine receptor (D2) immunostaining.¹⁰⁷

There are more radical surgical options for patients who do not respond to the above measures. Total adrenalectomy offers absolute control of cortisol secretion but requires lifelong dependence on exogenous glucocorticoid and mineralocorticoid replacement. Nelson's syndrome, a rapid enlargement of the pituitary adenoma from loss of cortisol negative-feedback inhibition, results in 10–30% of patients.¹⁰⁸ Nelson's syndrome typically presents with hyperpigmentation caused by stimulation of melanocytes by elevated ACTH. Most patients with Nelson's syndrome harbor large, invasive pituitary adenomas. Studies examining the effectiveness of neurosurgery for treatment of Nelson's syndrome have demonstrated variable rates of success.^{109–111} There appears to be some prophylactic value in hypophyseal radiosurgery before adrenalectomy.¹¹²

In the event that ACTH and cortisol levels remain elevated after surgery, additional exploration of the pituitary is usually effective.¹¹³ To increase the likelihood of success during the second surgery, IPSS should be performed before the operation. A complete hypophysectomy can be considered if previous treatments were unsuccessful but it is rarely indicated.

Silent ACTH-secreting adenomas

There is a subset of pituitary adenomas where immunohistochemical staining suggests ACTH production but the patient does not have clinical evidence of hypercortisolism. The exact incidence of this phenomenon is unclear but has been reported to be between 6% and 43%.¹¹⁴ There is evidence that these tumors behave more aggressively than other ACTH-producing tumors and have a 37% rate of recurrence.^{115, 116} However, when compared to ACTH-negative nonfunctioning pituitary adenomas, these tumors demonstrated similar regrowth rates.¹¹⁷ A subset of patients with these tumors also goes on to develop HPA axis dysfunction postoperatively and require postoperative steroid replacement.¹¹⁴

Gonadotropin-secreting and nonsecretory pituitary adenomas

Approximately one-third of pituitary tumors are considered nonsecretory adenomas. The peak incidence is in the fifth decade and patients typically present with symptomatic hypopituitarism, visual field defects, and visual concerns. Despite their similar clinical presentation, these tumors comprise a heterogeneous group of pathologies. Ultrastructural examination frequently demonstrates secretory granules and staining to suggest production of FH, LSH, and the α -subunit. A smaller subset produces other anterior pituitary hormones without clinical manifestation.¹¹⁸ With such a heterogeneous group of tumors, there is no clear or consistent treatment algorithm or prognosis.

Clinical presentation

Because they are not associated with hypersecretion syndromes, patients with these tumors usually present with symptoms of mass effect. This can range from hypopituitarism to vision changes or headaches. The majority of cases are associated with a macroadenoma.

Treatment

Surgery remains the primary treatment of patients with inactive adenomas. The goals are to relieve the mass effect, restore pituitary function, and obtain a tissue diagnosis. As with other pituitary adenomas, a transsphenoidal approach is often preferred unless there is significant extrasellar extension. With no clear criteria for what is considered a cure, surgical efficacy is not as well described as with other tumors. Many patients do experience improvement in preoperative symptoms, and 70–80% experience significant improvement in visual function.¹¹⁹ Nearly 100% experience improvement in headaches¹²⁰ and 15–57% with improvement in pituitary function.¹¹⁹ However, this improvement is largely due to decompression of mass effect and should not be taken to be indicative of complete remission. The extent of resection should be assessed routinely with an MRI 3–4 months postoperatively. Imaging acquired earlier than this is often confounded by edema and otherwise normal postoperative changes. Residual tumor is identified in 66–86% of patients but the rate of recurrence is highly variable.^{121, 122}

Radiotherapy or radiosurgery is increasingly utilized either for primary or adjuvant treatment of nonsecretory adenomas. A recent multicenter study analyzing the safety and efficacy of radiosurgery for residual lesions found that overall tumor control was achieved in greater than 90% of patients at follow-up with low incidence of side effects.¹²³ The same group later went on to study radiosurgery as a primary treatment modality in patients not well suited for surgery. They found tumor control in 85% of patients at 10 years with a 24% rate of new or worsened hypopituitarism.¹²⁴ Because of the risks of radiation to the pituitary, many clinicians advocate reserving radiotherapy only for tumors that demonstrate growth in serial postoperative imaging.^{125, 126} Studies of the natural history of these tumors have demonstrated a difference in growth patterns and proliferation index (MIB-1) between patients younger patients and those 61 years of age or older.¹²⁷ Time to tumor doubling was significantly longer for older patients, suggesting that adjuvant treatment may not always be necessary in this age group.

In addition, medical therapy has only limited efficacy for this class of tumors. In a study of nine patients with nonsecretory adenomas treated for 1 year with cabergoline, tumor dopamine receptor expression was demonstrated in 67%, but only 56% demonstrated response to cabergoline.¹²⁸ This response was clinically significant in only two patients. Other medical treatments such as bromocriptine, other dopamine agonists, octreotide, and GnRH agonists or antagonists have been used but their results have been inconsistent.

TSH-secreting pituitary adenomas

TSH-secreting adenomas are the least common variant of pituitary tumors, representing only 1–2% of cases.¹²⁹

Clinical presentation

Patients present with signs and symptoms suggestive of hyperthyroidism, such as heat intolerance, diarrhea, visual changes, weight loss, tremulousness, fatigue, and exophthalmos. This frequently leads to a

work up and presumptive diagnosis of Graves' disease. As a result, patients with TSH-secreting pituitary adenomas are often diagnosed later in their course of illness, when their tumors are large and locally invasive. Thus, they may also suffer from symptoms related to tumor mass effect, such as headaches, vision changes, and hypopituitarism.¹³⁰

Diagnosis

The majority of TSH-secreting adenomas is associated with elevated levels of TSH, in spite of elevated T3 and free T4. There is increased diagnostic sensitivity with an increased α -subunit/TSH ratio. Finally, ultrasensitive immunometric TSH assays allow for distinction between patients with primary hyperthyroidism from those with central hypothyroidism or resistance to thyroid hormone.

Treatment

Hyperthyroidism presents significant anesthesia and surgical risk owing to its effects on heart rate and cardiac function. Therefore, treatment of hyperthyroidism before surgery is essential. This is frequently accomplished through beta blockade. If surgery is nonemergent, an antithyroid drug (propylthiouracil or methimazole) may also be added. Transsphenoidal surgery is the primary treatment for this type of tumor but is associated with low rates of remission (35–62%). When adjuvant medical therapy or radiotherapy is added, the rate of remission increases to 55–81%.^{131–134} Remission is frequently characterized by resolution of clinical symptoms of hyperthyroidism. The criteria for remission are not well established. External radiation is used if clinical remission is not attained with surgery alone but is not used as first-line treatment.

Octreotide has demonstrated clinical efficacy in 92% of cases and is associated with a normalization of TSH and tumor shrinkage for the vast majority.¹³⁵ While useful as an adjuvant therapy, significant long-term costs and continued compliance make octreotide unpopular for the primary treatment modality. Recent reports suggest that lanreotide, a long-acting octreotide analog, may have similar efficacy while avoiding some of the downsides of octreotide.

Conclusion

Pituitary adenomas are a heterogeneous group of tumors requiring treatments specific to their underlying pathology. Transsphenoidal surgery remains the most common intervention while medical and radiation therapies play important roles in long-term control. As our understanding of molecular biology, drug development, and radiosurgery evolves, there will no doubt be further improvements to clinical outcomes and patient satisfaction.

Summary

Pituitary neoplasms arise from the adenohypophysis and can be classified based on their cell type as well as their radiographic appearance. Transsphenoidal surgery is the treatment of choice for all adenomas except prolactinomas, for which medical therapy is the primary therapy. Hormone-specific chemotherapy and radiotherapy have demonstrated clinical benefit for many tumor subtypes. Prognosis depends heavily on hormonal control as the systemic effects from hormone overproduction are often more severe than mass effect from the neoplasm. Research developments into the genetics of these tumors as well as their tumor biology have led to a number of promising

Chapter 80

Neoplasms of the thyroid

Steven I. Sherman, MD ■ Maria E. Cabanillas, MD ■ Stephen Y. Lai, MD, PhD

Overview

Thyroid carcinomas, particularly, papillary cancers, exhibit increasing incidence but, generally, low risk for mortality. An optimal approach to an undiagnosed thyroid mass relies upon ultrasound characterization and guided fine needle aspiration of lesions at risk for clinically significant malignancy. Given the absence of prospective trials, controversy continues over the most appropriate initial treatment strategy for differentiated carcinoma, including extent of thyroidectomy and neck dissection and use of adjuvant radioiodine. Medullary carcinoma is treated initially with thyroidectomy, central and possible lateral neck dissections, and early evaluation to distinguish sporadic from hereditary disease. Recent developments in systemic, targeted therapies have led to multiple anti-angiogenic drugs available to treat progressive metastatic differentiated or medullary carcinoma with significant improvement in progression-free survival, though improvements in overall survival are lacking. In distinct contrast, anaplastic carcinoma remains one of the most fulminantly aggressive malignancies, with limited and generally palliative benefit only from selected use of multimodality therapy with surgery, radiation, and chemotherapy.

Historical perspective

Thyroid carcinoma, historically an uncommon disease, has transformed into one of the most commonly diagnosed malignancies, with escalating worldwide incidence. Although most patients require localized therapy only, treatment of advanced disease has changed with advent of targeted therapies. Even initial treatment has undergone revision, with recognition that more conservative approaches are sufficient.

Incidence and epidemiology—local and worldwide

About 62,450 persons were diagnosed in 2015 with carcinoma of the thyroid gland in the United States, with disease-related mortality of nearly 2000.¹ Globally, the incidence is six times higher, whereas disease-related mortality is >20 times higher.² Female incidence is about twice that of males, peaking in South Korea, where thyroid cancer is the leading malignancy diagnosed in women. The escalating incidence is seen primarily in small tumors confined to the gland and has been associated with increased thyroid imaging, higher socioeconomic status, and “overdiagnosis.”³

Differentiated thyroid carcinomas (DTC), derived from the hormone-producing follicular epithelial cells, account for 96% of thyroid cancers, including papillary thyroid cancer (PTC), follicular thyroid cancer (FTC), and oxyphilic carcinomas (88%, 6%, and 2%, respectively).⁴ Another 2% are medullary thyroid cancer (MTC) carcinomas, derived from neuroendocrine “C” cells, and the remaining 1% are poorly differentiated thyroid cancer (PDTC) carcinoma or highly aggressive, undifferentiated, anaplastic thyroid cancer (ATC) carcinomas.

Risk factors—genetic, behavioral, environmental

Although most lack an obvious cause for DTC, the best established risk factor is radiation exposure, especially during childhood and adolescence. Between 0.1 and 10 Gy of exposure, the excess relative risk is 7.7 per Gy, with risk leveling above 10 Gy and after age 20 at time of exposure.⁵ Obesity has also been associated with higher risk of DTC (relative risk about 1.3).⁶ Iodine deficiency has been associated with a higher frequency of FTC, and possibly contributes to risk for ATC.⁷ DTC is a component of certain genetic syndromes, including familial adenomatous polyposis, Cowden syndrome, and Carney complex.⁸ ⁹ Familial nonmedullary carcinoma, occurring in at least two first-degree relatives, has been reported in 5% of all PTC patients, although genetic loci and mechanisms are unclear.¹⁰ Hereditary MTC syndromes, including subtypes of multiple endocrine neoplasia (MEN) type 2A and MEN2B, account for 25% of all cases of MTC; environmental factors are not known to influence development of MTC.¹¹

Prevention

Other than use of potassium iodide prophylaxis in the setting of a nuclear accident or mechanical shielding of the thyroid from external radiation,¹² there is no known strategy to prevent development of DTC. Thyroidectomy following prospective screening of children at high risk for hereditary MTC may prevent development of aggressive malignancy.¹³

Pathology

Conventional PTCs are characterized by papillae with a fibrovascular core surrounded by tumor cells with large, oval, often overlapping nuclei containing hypodense powdery chromatin, cytoplasmic pseudoinclusions, and grooves ([Figure 1](#)). The follicular variant accounts for about 10% of PTCs, with cells displaying nuclear features of PTC but organized into follicles rather than papillae. In contrast, the uncommon tall cell variant of PTC is a more aggressive tumor, characterized by eosinophilic tumor cells that are twice as tall as they are wide. The primary tumors are larger, invasive, and frequently metastatic.

Figure 1 Pathologic features of thyroid carcinoma. (a) Papillary carcinoma, with characteristic fibrovascular papillary formation, crowded nuclei, and nuclear clearing. (b) Follicular variant of papillary carcinoma, with typical cells of papillary carcinoma in follicular formations. (c) Tall cell variant of papillary carcinoma, with cells at least twice as tall as they are wide and eosinophilic cytoplasm. (d) Follicular carcinoma, demonstrating invasion across a thick capsule into neighboring thyroid. (e) Medullary thyroid carcinoma, with nests of spindle-shaped cells. Such nests are often interspersed with clusters of round-to-oval cells. (f) Anaplastic carcinoma, showing large, discohesive, pleomorphic tumor cells.

FTCs are distinguished from follicular adenomas by demonstrating invasiveness in one or more foci along the capsule or across vascular endothelial walls. The extent of invasion separates FTC into minimally

invasive and widely invasive lesions, the former demonstrating only scattered foci of capsular or vascular invasion. Cytologic features do not reliably distinguish benign from malignant follicular lesions. Oxyphilic (or Hürthle cell) neoplasms are formed by cells containing numerous mitochondria, imparting a granular, eosinophilic cytoplasmic appearance.¹⁴ Most have a follicular architecture and are diagnosed as carcinomas by the presence of invasion.

PDTC is often considered intermediate between DTC and ATC and may represent a partial dedifferentiated state. Cells tend to be nested with solid or insular architectural patterns, without the nuclear features of PTC. Diagnostic criteria also require one of (1) convoluted nuclei, (2) tumor necrosis, or (3) at least three mitoses per high power field.¹⁵ ATC is usually macroscopically infiltrative; microscopically, the tumor is heterogeneous, with pleomorphic nuclei, sheets of spindle, epithelioid, or giant cells, areas of necrosis, and extensive inflammatory infiltrate. While PTC, FTC, and even PDTC generally stain positive for thyroglobulin (Tg) and other follicular cell-specific antigens, ATC may stain only for cytokeratin and PAX8.¹⁶

MTCs commonly contain nests and sheets of rounded or spindle-shaped neuroendocrine cells, surrounded by a fibrovascular stroma. Nuclei tend to have speckled chromatin, and the cytoplasm is usually granular and eosinophilic. Amyloid deposition within the stroma is pathognomonic. Calcitonin and neuroendocrine immunohistochemical markers are usually detected. MTC in hereditary syndromes arises from a background of C cell hyperplasia.

Pathogenesis and natural history

Molecular alterations

Oncogenes associated with PTC include mutually exclusive activating mutations in *BRAF* (62%), *RAS* (13%), and *RET/PTC* chromosomal rearrangements (7%), all upstream of the mitogen-activated protein (MAP) kinase.¹⁷ *BRAF* mutations are most common in conventional PTC and tall cell variants, whereas *RAS* mutations are seen in the follicular variant of PTC and FTC. Comprehensive analysis of genomic, transcriptional, epigenetic, and microRNA changes identifies clear signaling differences between *BRAF* and *RAS*-type tumors.¹⁷ In FTC, chromosomal rearrangements fusing a thyroid-specific transcription factor to peroxisome proliferator-activated receptor gamma-1 to form the PAX8-PPAR γ oncogene may also be seen.¹⁸ In PDTC and ATC (which may arise from pre-existing DTC), coexisting mutations are more common, including *RAS*, *BRAF*, *TP53*, *CTNNB1*, *PIK3CA*, and *PTEN* mutations and loss of heterozygosity. Other factors contributing to progression of DTC include overexpression of other intracellular kinases, deoxyribonucleic acid hypermethylation and histone deacetylation leading to silencing of tumor-suppressor genes, and cell-cycle dysregulation.^{17, 19}

Mutations in exons 8, 10, 11, and 13–16 of the tyrosine kinase receptor *RET* occur in nearly all families with hereditary MTC.^{10, 11} Somatic mutations are also found in 40–50% of sporadic MTC tumors, particularly the highly activating codon 918 mutation associated with poorer patient prognosis.²⁰ Strong genotype–phenotype correlations allow stratification of mutations to predict disease aggressiveness.²¹ *RAS* mutations are reported in 20–70% of sporadic MTC lacking *RET* changes.

Screening

RET mutations in hereditary MTC are inherited in an autosomal dominant manner with generally high

penetrance. In addition to known kindreds, about 6% of patients with clinically sporadic MTC carry a germ line mutation in *RET*, leading to identification of new families.²² Genetic counseling and testing for *RET* proto-oncogene mutations should be offered to all patients newly diagnosed with clinically apparent sporadic MTC, as well as for screening children and adults in known families with inherited forms of MTC.^{21, 23} In the patient with clinically sporadic MTC, the likelihood of a false negative *RET* germ line test for familial disease is <1%; however, if the family history is suggestive for an autosomal inherited disorder, complete sequencing of *RET* can be considered, and the family should be screened clinically and biochemically for possible MTC. For patients with familial adenomatous polyposis or Cowden syndrome, at higher risk for DTC, annual examination and possible ultrasound of the thyroid have been suggested.²⁴

Diagnosis

While about 5% of individuals have a palpable thyroid nodule, and ultrasonography reveals nodules in up to half of individuals without palpable lesions, only 5% of nodules are malignant.^{25, 26} Most are asymptomatic, and few clinical features are specific for malignancy. Sonographic criteria that increase malignancy likelihood include microcalcifications, irregular margins, and shape taller than wide.²⁷ Incidentally detected thyroid nodules are also seen in 1–2% of fluorodeoxyglucose-positron emission tomography (FDG-PET) scans, for which the risk of malignancy is 40%.²⁸ Thyroid ultrasound with cytologic examination of a fine needle aspirate (FNA) of solitary nodules at least 1 cm in size is the most appropriate diagnostic procedure; in the setting of multiple nodules, those with suspicious sonographic appearances (and if none are present, the largest) should be preferentially aspirated.²⁹ PTC, MTC, and ATC can be readily diagnosed on the basis of cytologic criteria.³⁰ The false-positive and false-negative rates for nodules characterized as “malignant” and “benign,” respectively, are <5%. However, as FTC is distinguished from benign follicular adenoma by invasion through the tumor capsule or vascular wall, these nodules are usually reported cytologically (along with follicular variants of PTC) as indeterminate follicular lesions or neoplasms, with an overall 20% risk of malignancy.^{30, 31} Molecular testing with a gene expression classifier can reduce the risk of malignancy in indeterminate nodules to as low as 5%; detection of *BRAF* mutations, although uncommon in indeterminate nodules, carries a very high positive predictive value for malignancy.^{32–35} Although not routinely recommended for initial nodule evaluation, a random serum calcitonin level >100 pg/mL has high predictive value for MTC. Once malignancy is suspected, ultrasonography of the nodal chains in the neck is recommended before surgery; computed tomography (CT) or magnetic resonance imaging (MRI) may also provide occasional benefit in surgical planning for invasive or bulky disease.

Patients with aggressive disease, especially PDTC and ATC, commonly present with extensive local invasion and distant metastases.³⁶ The lungs and pleura are the most common sites of distant metastases, being seen in up to 90% of patients with distant disease, followed by bones, brain, skin, liver, and kidneys. CT of the neck and mediastinum can accurately determine the extent of the thyroid tumor and identify tumor invasion of the great vessels and upper aerodigestive tract structures. Metastatic work-up to detect distant disease is necessary but should not delay therapy.³⁷

In half of MTC patients, metastatic cervical adenopathy is noted at initial presentation, and symptoms of upper aerodigestive tract compression or invasion are reported in up to 15% of patients with sporadic disease. Distant metastases are most commonly found in the liver. The ability of the tumor to over-secrete measurable quantities of Ct, occasionally along with other peptides and biogenic amines such as adrenocorticotrophic hormone or calcitonin gene-related peptide, leads to unexplained diarrhea or

symptoms of Cushing syndrome in many patients.

TNM staging, classification

The seventh edition of the American Joint Committee on Cancer (AJCC)/UICC (Union for International Cancer Control) staging system is recommended for standard clinicopathologic staging and assessment of risk for mortality for all thyroid cancers ([Table 1](#)).^{21, 37, 38, 40} However, there are significant concerns that it may overestimate risk for small tumors and underestimate risk for young patients with DTC.^{41, 42} The important prognostic value of histologic subtypes of DTC is also excluded. Risk for DTC recurrence may be better predicted by other proposed schemes following completion of initial therapy.^{40, 43, 44}

Table 1 Tumor, node, metastases (TNM): The American Joint Committee on Cancer (AJCC) Staging Scheme for Thyroid Carcinomas (Seventh Edition).³⁸

<i>T: Tumor status</i>		
T0	No evidence of primary tumor	
T1a	Tumor ≤1 cm, without extrathyroidal extension	
T1b	Tumor >1 cm but ≤2 cm in greatest dimension, without extrathyroidal extension	
T2	Tumor >2 cm but ≤4 cm in greatest dimension, without extrathyroidal extension	
T3	Tumor >4 cm in greatest dimension limited to the thyroid -or- Any size tumor with minimal extrathyroid extension (e.g., extension into sternothyroid muscle or perithyroidal soft tissues)	
T4a	Tumor of any size extending beyond the thyroid capsule to invade subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve	
T4b	Tumor of any size invading prevertebral fascia or encasing carotid artery or mediastinal vessels	
Tx	Tumor status unknown	
<i>N: Regional node status</i>		
N0	No metastatic nodes	
N1a	Metastases to level VI (pretracheal, paratracheal, and prelaryngeal/Delphian lymph nodes)	
N1b	Metastases to unilateral, bilateral, or contralateral cervical (level I, II, III, IV, or V) or retropharyngeal or superior mediastinal lymph nodes (level VII)	
Nx	Nodes status unknown	
<i>M: Distant metastases</i>		
M0	No distant metastases	
M1	Distant metastases	
Mx	Metastases status unknown	
	<45 years	≥45 years
<i>Stage assignments: differentiated thyroid carcinoma</i>		

Stage I	Any T, any N, M0	T1, N0 M0
Stage II	Any T, any N, M1	T2, N0, M0
Stage III		T3, N0, M0
		T1–3, N1a, M0
Stage IV		A: T4a, any N, M0
		Any T, N1b, M0
		B: T4b, any N, M0
		C: Any T, any N, M1
Stage assignments: medullary thyroid carcinoma		
Stage I	T1, N0, M0	
Stage II	T2–3, N0, M0	
Stage III	T1–3, N1a, M0	
Stage IVA	T4a, N0, M0	
Stage IVB	T4a, N1a, M0	
	Any T, N1b, M0	
Stage IVC	Any T, any N, M1	
Anaplastic thyroid carcinoma		
All are classified as stage IV

Prognostic factors

In the Surveillance, Epidemiology, and End Results (SEER) report of 15,700 patients, the overall 10-year age- and gender-corrected survival rates were 98% for PTC, 92% for FTC, 80% for MTC, and 13% for ATC.⁴⁵ Older age at diagnosis and greater extent of disease including increasing tumor size, extrathyroidal invasion and distant metastases, are associated with a worse prognosis, independent of the type of cancer. In PTC, *BRAF* mutations may be prognostic for locoregional recurrence and perhaps

Multidisciplinary care

Surgery—standard operations, complications, outcomes

Total thyroidectomy has been the initial surgical procedure advocated for most patients with DTC, given that (1) foci of PTC are commonly bilateral^{49, 50}; (2) contralateral recurrence occurs in 5–10% of patients who undergo unilateral surgery; and (3) efficacy of therapy with radioiodine is maximized by total resection. Earlier cohort studies support the contention that recurrence rates are 2–3 times higher following lobectomy compared with total thyroidectomy for primary PTC >1 cm, with possible improvements in survival in multivariate analyses.^{51–53} More recently, larger studies have challenged these conclusions, suggesting no improvement in survival following total thyroidectomy.^{54, 55} Active surveillance has even been advocated for selected patients with small PTC confined to the gland, given infrequent progression on serial imaging.⁵⁶ In the absence of randomized prospective trials, total thyroidectomy is recommended for DTC patients with primary tumors >4 cm or clinical evidence preoperatively of extrathyroidal invasion or nodal or distant metastases. Either total thyroidectomy or ipsilateral lobectomy may be appropriate for smaller primary tumors without metastatic or invasive disease and lobectomy or active surveillance optimal for subcentimeter primary tumors.

Although microscopic regional nodes with PTC occur in up to 80% of patients, only about 35% have clinical cervical or mediastinal node metastasis, typically in lateral cervical compartments.⁵⁷ With clinically involved lateral neck disease, a comprehensive neck dissection (levels II–V) should be performed.^{58, 59} While resection of clinically involved central compartment (level VI and superior mediastinal nodes) nodes has been associated with improved survival and is commonly recommended, the potential benefit of prophylactic central neck dissection may outweigh the potential surgical morbidity only when performed by experienced thyroid surgeons.⁶⁰ In the presence of invasion of aerodigestive tract structures, similar survival rates are achieved from either complete surgical resection or shave excision leaving only microscopic residual disease.⁶¹ However, half of patients die within 4 years following shave excision for frank cartilage destruction or intraluminal involvement. Surgery in patients with extensively invasive thyroid carcinoma should aim, therefore, to remove all gross tumors, maximizing functionality, unless the disease is unresectable or patient refuses the proposed surgery.⁶²

For newly diagnosed MTC, serum calcium and plasma-free metanephrines should be measured to exclude coexistent hyperparathyroidism and pheochromocytoma, unless MEN2 has been ruled out by germ line *RET* testing. Total thyroidectomy is indicated in all patients with MTC, especially given the high frequency of bilateral disease in both sporadic and familial disease, and has been associated with improved survival.^{21, 63} Even in the absence of clinically detectable nodal metastases, central neck compartment dissection should be performed in all patients, and ipsilateral lateral neck and/or mediastinal dissections should be strongly considered when the primary tumor is >1 cm or when central compartment disease is present. Disfiguring radical neck dissections do not improve prognosis and are not indicated. In the presence of grossly invasive disease, more extended procedures with resection of involved neck structures may be appropriate, but function-preserving approaches are preferred.

Given the identification of patients with malignant disease as early as age 6 years, prophylactic thyroidectomy by age 5 is recommended for carriers of a familial *RET* mutation; given potential for earlier metastatic disease, surgery should be performed by age 1 year in children with MEN2B. Of 50

RET mutation carriers, 88% had normal levels of plasma calcitonin when evaluated 5–10 years after prophylactic thyroidectomy.¹³ Surveillance with calcitonin measurements, thyroid ultrasound and delayed surgery may be appropriate for children with the least virulent *RET* mutations in codons 768, 790, 791, 804, and 891, particularly if the family history is of less aggressive disease.²³

Minimally invasive surgical approaches, including approach to the thyroid from remote incisions in the axilla, may improve cosmesis and decrease postoperative discomfort.^{64, 65} These approaches afford surgeons superior visualization of critical structures through the use of endoscopic instruments. Robotic technology provides novel surgical approaches to the thyroid gland, including true three-dimensional visualization, highly articulated endo-wrist capability, and motion scaling. Natural orifice techniques are being developed, including transoral endoscopic thyroidectomy adopted for robotic instrumentation.^{66, 67} Implementing these approaches requires documenting improved operative outcomes relative to traditional open surgeries.^{68, 69}

Except for patients whose tumors are small and confined entirely to the thyroid, total thyroidectomy with complete tumor resection does not prolong survival in ATC.^{70, 71} Grossly incomplete resection is often of little palliative benefit given the rapid rate of tumor growth and high rate of distant metastases.

Radiation oncology—standard approaches, modalities, complications, and outcomes

Radioiodine

Adjuvant radioiodine therapy following primary surgery for DTC aims to destroy any residual microscopic foci of disease within a thyroid bed remnant or in regional nodal metastases, and should increase the predictive value of subsequent serum Tg measurements for detection of recurrent or metastatic disease by eliminating residual normal thyroid cells (referred to as “ablation”). Conflicting data have been reported from multiple retrospective studies of the efficacy of radioiodine.⁷² In a recent multicenter thyroid cancer registry, improved survival was associated with postoperative radioiodine use in stages II–IV disease patients after adjustment for extent of thyroidectomy, and in stage III–IV patients when also adjusted for thyroid hormone suppression therapy.⁵² For patients with residual disease or metastases, radioiodine therapy is recommended. In contrast, ablation may be withheld for patients with small solitary primary tumors without evidence of extrathyroidal invasion or metastasis. As MTC and ATC lack the capacity to concentrate iodine, radioiodine has no role in their management.

The efficacy of radioiodine depends on patient preparation, tumor-specific characteristics, sites of disease, and administered radioiodine activity. Iodide uptake by thyroid tissue is stimulated by thyrotropin (thyroid stimulating hormone, TSH) and is suppressed by increased endogenous iodide stores. Sufficiently elevated TSH levels can result from either endogenous production following thyroid hormone withdrawal or exogenously administered recombinant human TSH.⁷³ Diagnostic whole body radioiodine scans for localization of uptake before ablation or therapy are frequently performed 24–72 h after administration of 2–5 mCi of either ¹²³I or ¹³¹I.^{74, 75} Most patients demonstrate significant uptake of radioiodine within the thyroid bed following thyroidectomy, presumably from normal residual thyroid. However, scanning before ablation may be considered optional for patients who are apparently free from gross metastases.^{40, 76}

¹³¹I, 30–100 mCi, is routinely administered if thyroid bed uptake is visualized on diagnostic scanning, or empirically if no pretherapy scanning has been performed in a patient selected for adjuvant treatment. Higher amounts, 150–200 mCi, are given if scanning demonstrates uptake in locoregional or distant

metastatic disease. ^{131}I treatment of regional nodal metastases yields a complete response in 80% of patients but can be suboptimal in those with residual bulky disease.⁷⁷ Patients treated for iodine-concentrating pulmonary metastases, which occur in 5% of DTC patients, have a 5-year survival rate of 60–80%, as compared with 30% for those whose tumors do not concentrate iodine.^{78, 79} Long-term survival is highest in those patients with micronodular pulmonary metastases identified only by ^{131}I scanning.⁷⁸ ^{131}I treatment, 200 mCi, of skeletal metastases may yield complete resolution of disease in fewer than 10% of treated patients and partial remission in only 35%.⁸⁰ Following surgical debulking, radioiodine therapy can also be administered to patients with iodine-concentrating intracerebral metastases.⁸¹

Transient complications of radioiodine include sialoadenitis, oligospermia, leukopenia, and ovarian failure.^{82, 83} Chronically, radioiodine is associated with dose-related development of secondary neoplasms, including colorectal carcinoma, salivary tumors, and acute leukemias (excess absolute risks: 14.4 solid cancers and 0.8 leukemias per GBq of ^{131}I at 10,000 person-years of follow-up).⁸⁴ Patients who receive repeated doses of radioiodine treatment for diffuse pulmonary metastases, rarely, can develop pulmonary fibrosis.

External beam radiation therapy (EBRT)

EBRT (external beam radiation therapy) may be effective adjuvant therapy to prevent locoregional recurrence in older patients with grossly invasive PTC.^{85, 86} In a review of 282 patients treated with EBRT, a subgroup of 155 PTC patients with presumed microscopic residual disease experienced significant reduction in 10-year rates of locoregional control (93% vs 78%) and disease-specific survival (100% vs 95%).⁸⁷ Adjuvant EBRT is likely of little benefit to those younger than age 45 years, and esophageal and tracheal side effects may be poorly tolerated by the more elderly patient. Intensity-modulated radiotherapy (IMRT) may be associated with reduced short-term toxicity.⁸⁸ EBRT, 40–50 Gy to the thyroid bed, is recommended in the setting of gross extrathyroidal invasion with presumed microscopic residual disease, as well as following incomplete resection near aerodigestive structures.

For MTC, EBRT should be considered after maximal surgical therapy for those at high risk for regional recurrence, owing to gross extraglandular invasion or extensive bulky nodal metastases. In one study, the 10 years locoregional relapse-free rate was 86% after adjuvant EBRT, as compared with 52% for those patients who did not receive such therapy.⁸⁹ With conformal or IMRT, 60 Gy administered in 30 fractions, local control is readily achieved with acceptable toxicity even in the setting of distant metastases.⁹⁰

For ATC, primary treatment with EBRT, administered in conventional doses, does not prolong survival, despite initial response in up to 40% of patients.^{91, 92} Hyperfractionated radiotherapy, combined with radiosensitizing chemotherapy, may increase the local response rate to about 80%, with subsequent median survival of 1 year with eventual mortality from distant metastases.

Thyroid hormone treatment

DTC patients require life-long thyroid hormone administration to treat postsurgical hypothyroidism and minimize TSH stimulation to tumor growth. With TSH-suppressive thyroid hormone therapy, both overall survival and disease-free survival may be improved two- to threefold, particularly in stage III and IV patients.⁵² Lesser degrees of suppression may also improve overall survival in stage I and II patients.^{52, 93} However, potential morbidity from overly aggressive thyroid hormone therapy includes acceleration of osteoporosis,⁹⁴ provocation of atrial fibrillation,⁹⁵ and possibly, cardiac hypertrophy and dysfunction and

impaired quality of life.⁹⁶ During initial follow-up, patients at lower risk for thyroid cancer recurrence and mortality should have their TSH levels maintained between 0.1 and 0.5 mU/L, whereas patients at higher risk should have TSH levels suppressed to <0.1 mU/L.⁴⁰ Patients who remain disease free for 5–10 years may potentially have their degree of TSH suppression reduced by lowering their doses of thyroid hormone. However, those with metastatic disease should have TSH levels maintained below 0.1 mU/L as tolerated.⁹⁷ Following surgery for MTC, thyroid hormone therapy is indicated, but TSH suppression is not appropriate as C cells lack TSH receptors.

Monitoring for recurrence

Serum biomarker monitoring

Measurement of serum Tg, a characteristic product of follicular cells, aids detection of residual, recurrent, or metastatic DTC, given the correlation between tumor size and Tg level. After thyroidectomy and remnant ablation, serum Tg concentration should approach undetectability but may take several years to decline to nadir following primary therapy.⁹⁸ Detection of residual cancer is enhanced by elevation of serum TSH, which stimulates Tg production; sensitivity of Tg following TSH stimulation is 85–95% but as low as 50% during TSH suppression or with dedifferentiated tumors.⁹⁹ Tg assays with functional sensitivities as low as 0.1 ng/mL may obviate need for TSH stimulation.¹⁰⁰ Tg levels that double in <1 year are associated with worse recurrence rates and mortality.^{101, 102}

Ct and CEA levels are similarly valuable biomarkers for MTC. Most patients with detectable serum calcitonin values postoperatively have residual disease. Values <150 pg/mL can be followed conservatively, but values >150 pg/mL should be re-evaluated for either residual resectable disease in the neck or the presence of distant metastases. Five-year survival rates of 100%, 92%, and 25% are reported in patients with postoperative calcitonin levels that double in >24, 6–24, and <6 months, respectively.^{103, 104}

Diagnostic imaging

Follow-up imaging for most DTC and MTC patients is based on cervical ultrasound, which accurately identifies locoregional metastases and recurrence measuring several millimeters in diameter. Ultrasound facilitates confirmatory FNA of suspicious lesions, sensitivity of which can be enhanced by measurement of either Tg or calcitonin in the needle washout.^{105–108} Further imaging should be performed to identify foci of disease that could be surgically resected or treated by other means. For DTC patients, radioiodine scans may detect residual or metastatic disease that could respond to further therapy. Contrast-enhanced CT of the neck and chest is appropriate when Tg levels are elevated during follow-up, and FDG-PET imaging can be useful when Tg levels are >10 ng/mL and radioiodine imaging is negative and in mitochondria-rich oxyphilic tumors.^{109, 110} For MTC, contrast-enhanced CT of neck, chest, and liver (with three-phase enhancement) and MRI of the axial skeleton are appropriate when calcitonin levels exceed 150 pg/mL.^{21, 111}

Management of recurrent or metastatic disease

Surgery

Comprehensive neck dissection (levels II–V) should be performed for DTC patients with metastatic nodes >1 cm in diameter, though undetectable thyroglobulin levels result in fewer than half of patients.^{112,}

¹¹³ Recurrence of disease may require re-exploration of the thyroid bed or dissection of the central and/or lateral nodes, although there may be higher risk for complications given fibrosis from prior surgery.¹¹⁴ With aerodigestive tract invasion, complete surgical excision of gross disease can improve survival, but may require more extensive procedures such as tracheal resection and anastomosis or pharyngectomy. Tracheal stents, tracheotomy, and laser ablation or partial excision can be of palliative value. Among patients with brain metastases, resection or radiosurgery may improve survival.^{81, 115} In MTC, reoperative lymphadenectomy or excision of palpable disease rarely normalizes serum calcitonin levels, and thus, only patients with gross disease in the neck should undergo reoperative neck surgery.

Radioiodine

Repeat treatment with ¹³¹I can be beneficial for patients with metastatic DTC identified by radioiodine imaging, though cumulative ¹³¹I activities >600 mCi are rarely effective.⁷⁸ Radioiodine-refractory disease is characterized by tumors detectable on CT or MRI but lacking uptake on radioiodine imaging, or disease that progresses radiographically despite uptake of prior radioiodine therapy.

External-beam radiation

Patients with unresectable invasive disease in the neck may benefit from EBRT, with 5-year local control and disease-specific survival rates of about 65%.⁸⁷ EBRT can also palliate patients with painful skeletal metastases. Radiation doses of 50 Gy in 25 fractions may be given for solitary lesions, but reduced doses should be administered for vertebral foci.

Chemotherapy

Multitargeted kinase inhibitors are indicated treatment for DTC and MTC patients with multiple measurable, progressive metastases in one or more organs.¹¹⁶ Targets contributing to efficacy of these agents include pro-angiogenic receptors, such as the vascular endothelial growth factor receptor (VEGFR) and fibroblast growth factor receptor (FGFR). In addition to being pro-angiogenic, these receptor kinases also have been identified on tumor cells themselves, likely contributing to tumor proliferation. Activated signaling in *BRAF*-mutated PTC and *RET*-mutated MTC suggests additional targets for more selective kinase inhibitors.

Lenvatinib and sorafenib both prolong progression-free survival (PFS) in DTC patients with progressive radioiodine-refractory disease.^{117, 118} In the SELECT phase III trial of lenvatinib, median PFS was markedly prolonged compared with placebo, 18.3 months versus 3.6 months [hazard ratio (HR) 0.21, 99% confidence interval (CI) 0.14–0.31; $p < 0.0001$].¹¹⁷ Response rate with lenvatinib was 65%, including four patients with prolonged complete responses. Common lenvatinib-related adverse events included hypertension, diarrhea, fatigue, decreased appetite, nausea, vomiting, decreased weight, and stomatitis. In the DECISION phase III trial of sorafenib, median PFS was prolonged compared with placebo, 10.8 versus 5.8 months (HR 0.59, 95% CI 0.45–0.76; $p < 0.0001$).¹¹⁸ Response rate with sorafenib was 12%, all partial responses. Common sorafenib-related adverse events included palmar-plantar erythrodysesthesia, diarrhea, alopecia, rash, fatigue, weight loss, and hypertension. Other kinase inhibitors with evidence of efficacy in advanced DTC include the multitargeted agents vandetanib¹¹⁹ and pazopanib,¹²⁰ and the BRAF inhibitors vemurafenib¹²¹ and dabrafenib.¹²²

In patients with progressive MTC, cabozantinib and vandetanib both prolong PFS.^{123, 124} In the EXAM phase III trial of cabozantinib in patients with progressive MTC, median PFS was prolonged compared with placebo, 11.2 months versus 4.0 months (HR, 0.28, 95% CI 0.19–0.40; $p < 0.001$). Response rate

was 28%, all partial responses. In subgroup analysis, patients whose tumors contained either *RET* or *RAS* mutations were more likely to benefit, whereas no improvement in PFS was seen in those lacking either of these mutations.¹²⁵ Common cabozantinib-related adverse events included diarrhea, palmar-plantar erythrodysesthesia, decreased weight, nausea, and fatigue. In the ZETA phase III trial of vandetanib in patients with MTC, median PFS was prolonged compared with placebo, 30.5 months versus 19.3 months (HR 0.46, 95% CI, 0.31–0.69, $p < 0.001$). Subgroup analysis suggested PFS improvements in patients with progressive disease as well as those with *RET* M918T mutations. Common vandetanib-related adverse events included diarrhea, rash, nausea, hypertension, and headache; prolongation of cardiac QT intervals warrants careful observation of electrolytes and electrocardiography (ECG) monitoring during therapy.

Cytotoxic chemotherapy is of limited value in both DTC and MTC.¹²⁶ Combination doxorubicin and cisplatin was compared with doxorubicin alone in a randomized trial for metastatic DTC; objective responses were seen in only 16% with combination therapy including two durable complete responses, whereas 31% had partial responses with doxorubicin monotherapy.¹²⁷ In MTC, responses in up to 30% of patients may be seen with dacarbazine combined with other agents including vincristine, 5-fluorouracil, cyclophosphamide, or doxorubicin.¹²⁸

In ATC, paclitaxel may yield short-term stabilization and palliative benefit in a minority of patients.¹²⁹ Although formal trials documenting benefit are lacking, consensus guidelines recommend combination regimens including taxanes, anthracyclines, and platinum-containing compounds.³⁷ A randomized phase III trial of fosbretabulin, paclitaxel and carboplatin versus paclitaxel and carboplatin demonstrated no improvement in survival although enrollment was incomplete.¹³⁰ Despite preclinical suggestions of efficacy, neither sorafenib nor pazopanib demonstrated single agent activity.^{131, 132}

Chapter 81

Neoplasms of the adrenal cortex

Tito Fojo, MD, PhD

Overview

Adrenocortical cancer (ACC) is a rare malignancy, with varied presentations and a poor prognosis. Imaging studies have emerged as central to a work up, and in most cases a biopsy is not needed and should not be performed. Pathologic examination is very valuable with the Weiss criteria used to discriminate a small adenomas from carcinomas. Management is multidisciplinary and includes surgical resection or ablation, oral mitotane, intravenous chemotherapy, and palliative radiation. Surgery remains the only proven curative option, must be considered at presentation, and relapse with laparoscopic resection avoided. Mitotane is approved for the treatment of inoperable functional and nonfunctional ACC and its clinical value is primarily as an anti-hormonal agent. In a patient whose tumor is producing an excess of hormones mitotane is indispensable, however, its use in the adjuvant setting is uncertain. Replacement steroids are needed. Systemic chemotherapy using mitotane in combination with etoposide, doxorubicin, and cisplatin (EDP-M) or with streptozotocin (S-M) are the preferred options. These should not be discarded in favor of a “novel targeted therapy”, none of which have shown any proven efficacy. Increasing evidence suggests that palliative radiation therapy is beneficial for patients with metastatic disease. Radiofrequency ablation (RFA) or cryoablation have emerged as surgical adjuncts or stand-alone modalities for recurrences. As with most rare diseases, enrollment in clinical trials is strongly encouraged.

Introduction

Adrenocortical cancer (ACC) is a rare malignancy, with an estimated incidence of 1.5–2 per million per year. Patients can present without symptoms, with local symptoms from a large, locally invasive primary tumor, or with the systemic manifestations of endocrine hypersecretion. A multidisciplinary approach to treatment is essential as the disease presents many management challenges.

General

The 5-year survival is ≈ 10 –25% with average survival from diagnosis of ≈ 14.5 months. Biochemical evidence of hormone excess can be found in $\approx 50\%$ with ≈ 10 –20% presenting with Cushing's syndrome. Other symptoms include hirsutism in females and gynecomastia in males. Several reviews provide in-depth summaries.^{1–5}

Evaluation and work-up

Initial evaluation should include a history, physical examination, with blood and urine studies to determine if tumor is functional. Computed tomography (CT) or magnetic resonance imaging (MRI) is

often diagnostic. Both can help differentiate benign adenomas from malignant lesions.^{6–9} MRI is superior in identifying liver metastases and extent of vascular invasion, especially the inferior vena cava. ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG-PET) can help assess extent of disease and may be valuable before a major surgery. However, FDG-PET is not of value for monitoring progress and should not be used as the primary modality.^{10–13}

The role of a biopsy

Most patients presenting with an adrenal mass suspicious for malignancy should have surgery and not a diagnostic biopsy given risk of seeding tumor, and difficulty differentiating benign from malignant in a small biopsy.^{14–16} Surgery can be performed without a biopsy in a patient (1) with evidence of hormone excess, where diagnosis of ACC is not in doubt or (2) without evidence of hormone production but with an isolated adrenal mass found during evaluation or incidentally on an imaging scan. Only with widespread metastases that make surgical resection unlikely to provide benefit or if disease elsewhere suggests a primary location other than adrenal, should a biopsy be performed.

Pathology

To distinguish a small ACC without local spread or distant metastases from a benign adenoma, the “Weiss criteria,” first proposed in 1984, are used.^{17–22} Weiss, noted nine criteria most useful in distinguishing malignant from benign: (1) nuclear grade III/IV, (2) mitotic rate >5 per 50 high-power fields, (3) atypical mitoses, (4) tumors with ≤25% clear cells, (5) diffuse architecture, (6) microscopic necrosis, (7) venous invasion, (8) sinusoidal invasion, and (9) capsular invasion. The presence of ≥3 criteria is the threshold for malignancy.

The Weiss criteria were developed to discriminate a small adenomas from carcinomas, but their prognostic value in larger tumors is not established. In 42 patients with a diagnosis of ACC, only mitotic rate had a *strong* statistical association with outcome.¹⁸ Tumor weight >250 g, size >10 cm, atypical mitoses, and capsular invasion showed a marginal association with poor survival ($P < 0.06$). However, other criteria were not associated with survival. A recent study confirmed the importance of mitotic rate.²²

Management of ACC

Options include surgical resection or ablation, oral mitotane, intravenous chemotherapy, and palliative radiation. Although controlled trials are generally lacking, this does not mean evidence is lacking nor does it mean anything is an option.

Surgical resection

Surgery remains the only proven curative option and must be considered at presentation and relapse. At presentation consider only complete resection of local disease given survival <1 year in patients with incomplete resection.^{2, 23, 24} The key at presentation is an open procedure by an experienced oncologic surgeon. While some argue laparoscopic surgery can be used in selected patients, the occurrence of peritoneal dissemination—a lethal complication—should discourage any approach other than open resection. Laparoscopic surgery for adrenal incidentalomas that do not seed the abdomen is appropriate.

However, intraoperative tumor spill rates as high as 50%—even by experienced surgeons—have been reported.^{25, 26} A study summarizing outcomes in 152 ACC patients²⁷ concluded that for ACCs ≤ 10 cm in diameter, laparoscopic was not inferior to open adrenalectomy. However, after extensive preselection only 23% underwent laparoscopy with one-third converted to open. These results in specialized referral centers have very limited to no applicability in the general community. In addition, laparoscopic resections have a higher incidence of positive margins and more rapid recurrence. A systematic review of laparoscopic surgery concluded, “There is no prospective randomized series to guide or endorse the use of laparoscopic resection for adrenocortical carcinoma.”²⁸

At the time of relapse, aggressive surgery may emerge as the preferred option especially in patients with less aggressive clinical presentations and a slower pace of tumor growth.^{29, 30} It must be recognized that studies addressing this approach have an inherent bias: those undergoing surgery likely have more limited disease, a better performance status, and possibly tumors with “more indolent biology.”

Mitotane

Initially identified as an adrenolytic agent, mitotane is approved for the treatment of inoperable functional and nonfunctional ACC. However, its tumoricidal activity is limited and its clinical value is primarily an antihormonal agent, with data suggesting that mitotane modifies peripheral metabolism of steroids. *In a patient whose tumor is producing an excess of hormones*, mitotane is indispensable, must be started as soon as possible, and continues indefinitely, even if disease progression occurs.

Mitotane's use in the adjuvant setting is uncertain. Several small and one large study encumbered by the biases all retrospective studies must bear suggest adjuvant mitotane continued indefinitely, can delay and possibly prevent a recurrence of disease.^{31, 32} Identifying those who will benefit is important as only a fraction of patients tolerate mitotane well. Mitotane therapy should be viewed as a marathon not a sprint and its administration adjusted accordingly. Starting at 1–2 g/day it should be gradually advanced until a maximum dose of 4–6 g/day is reached 2–3 months later. Serum levels guide adjustments beyond that and eventually as little as 0.5–1 g/day is needed. Replacement steroids can start with mitotane or when clinical or laboratory parameters indicate incipient adrenal insufficiency. Give hydrocortisone and fludrocortisone and instruct the patient to wear a bracelet labeled adrenal insufficiency. When discontinued, mitotane elimination takes months and supplementation is required 6–12 additional months.

Systemic chemotherapy

Two therapeutic regimens have emerged as the preferred options for ACC both using mitotane in combination with etoposide, doxorubicin, and cisplatin (EDP-M) or with streptozotocin (S-M). These should not be discarded in favor of a “novel targeted therapy,” none of which have any proven efficacy. Both regimens were evaluated in the FIRM-ACT trial,³³ which found significantly better response rate (23.2% vs 9.2%, $P < 0.001$) and progression-free survival (PFS) (5.0 vs 2.1 months, HR 0.55 and $P < 0.001$) with EDP-M than with S-M as first-line therapy, with similar rates of toxic events. There was no significant difference in overall survival, possibly owing to crossover. Importantly, as the 185 patients who received EDP-M as second line had a similar median PFS, there exists a window to enroll in an experimental regimen. The FIRM-ACT results also suggest that the therapies are not cross-resistant and thus may be administered in succession.

Finally, $\geq 50\%$ of patients with ACC have undergone a nephrectomy often prompting the use of carboplatin instead of cisplatin. However, given that in other cancers the activity profiles have been dissimilar, the drug of choice should remain cisplatin.

Radiation therapy

Increasing evidence suggests palliative radiation therapy is beneficial for patients with metastatic disease. Its use for other than palliation is not supported by data nor its use following primary surgery. Initial studies found no benefit from adjuvant radiation, and although later studies using better techniques claim benefit with little toxicity, this should not be routinely adapted.^{34, 35} Benefit is uncertain but harm is guaranteed—including acute complications of radiation and the likelihood, a subsequent surgery that may be the only curative option will be made more difficult. Only in a patient with known positive margins after surgery performed by a highly qualified surgical oncologist would one consider post-surgical radiation and then only if reoperation is deemed not possible owing to associated comorbidities.

Interventional radiology as a treatment modality

Given the value of surgery in the management of ACC, radiofrequency ablation (RFA) or cryoablation has emerged as surgical adjuncts or stand-alone modalities for recurrences.³⁶ In the decision paradigm, ablation should be viewed as surgical interventions, albeit less invasive. The value of embolization to reduce tumor size and reduce vascular supply making a subsequent surgical intervention is established, albeit not with randomized data.

Management of hormonal excess and deficiency

In the preoperative setting assesses a patient's hormonal status, as any functioning tumor can suppress corticotropin with involution of the contralateral adrenal. In this way, determine the need for steroid replacement in the postoperative period.

The severe consequences of uncontrolled hormone production and the need for aggressive and sustained attention must be recognized.³⁷ Using chemotherapy to solve the problem of hormonal excess is a flawed strategy. In addition to mitotane, the cornerstone for managing hormonal excess, ketoconazole, metyrapone, and etomidate should be added singly or in combination. The management must be proactive and forward thinking.

Conclusion

Surgery remains the cornerstone for managing ACC, with RFA and cryoablation of value. Chemotherapy has a role in many patients but new paradigms are needed and referral to clinical trials is essential. Radiation therapy should be reserved for palliative indications. Attention must be given to hormonal excess as in patients with this complication, it is the major factor affecting the quality of their life. A multidisciplinary effort is mandatory.

Chapter 82

Tumors of the diffuse neuroendocrine and gastroenteropancreatic system

Evan Vosburgh, MD

Overview

The diffuse neuroendocrine system (DES) is represented by a small number of cells spread throughout the body, and the tumors that derive from these cells present a wide spectrum of epidemiologic, pathologic, biologic, genetic, and clinical features. Clinical and scientific investigation of the inherited multiple endocrine neoplasia (e.g., MEN-1, MEN-2) syndromes, and the various unique clinical syndromes secondary to secretion of specific peptides (e.g., insulinomas, glucagonomas, VIPomas) are challenging. Clinical presentation can be dramatic, nonspecific, or incidentally noted in absence of symptoms. Tumors might be small, difficult to detect tumors (<1 cm in size) or bulky hepatic metastases in a well patient. Cancer registry data show five-year survivals for tumors of the neuroendocrine system that have not improved in the past several decades, and that remain about 30–60%. The same registry data documents a rising and unexplained incidence of these tumors, particularly the neuroendocrine tumors of the gastroenteropancreatic system (GEP-NETs), that when coupled with the long average survival results in prevalence figures similar to cancers such as testicular, ovarian, and multiple myeloma.

Recent advances in understanding of the genetics, biology, clinical features, and response to therapy are better defining subtypes of neuroendocrine tumors once clustered and studied as “carcinoids.” Revised histologic grouping and staging are informing ongoing clinical trials and are providing more informed clinical care of these diverse tumors. Recent approvals of several targeted therapies with progression-free survival benefit suggest that the status quo is changing for tumors of the DES.

The diffuse neuroendocrine system (DES) is represented by a small number of cells spread throughout the body, and the collection of tumors that derive from these cells present a bewildering spectrum of epidemiologic, pathologic, biologic, genetic, and clinical features. Clinical and scientific investigation of these rare tumors, which include inherited multiple endocrine neoplasia (e.g., MEN-1, MEN-2), unique clinical syndromes secondary to secretion of specific peptides (e.g., insulinomas, glucagonomas, VIPomas), and many patients with long survival, are challenging. Clinical presentation can be dramatic, nonspecific, or incidentally noted in absence of symptoms. Tumors might be small, difficult to detect tumors (<1 cm in size) or bulky hepatic metastases in a well patient. Cancer registry data show five-year survivals for tumors of the neuroendocrine system have not improved in the past several decades, and that remain about 30–60%, leading many to argue stridently for the avoidance of the term “benign” for neuroendocrine tumors as a group. The same registry data documents a rising and unexplained incidence of these tumors, particularly the neuroendocrine tumors of the gastroenteropancreatic system (GEP-NETs), that when coupled with the long average survival results in prevalence figures similar to cancers such as testicular, ovarian, and multiple myeloma.

Recent advances in understanding of the genetics, biology, clinical features, and response to therapy are better defining subtypes of neuroendocrine tumors once clustered and studied as “carcinoids.” Revised

histologic grouping and staging are informing ongoing clinical trials and are providing more informed clinical care of these diverse tumors. Recent approvals of several targeted therapies with progression-free survival benefit suggest that the status quo is changing for tumors of the DES.

This chapter will focus on the gastroenteropancreatic neuroendocrine tumors (GEP-NETs), representing the majority of all NETs:

- GI-NET (gastrointestinal neuroendocrine tumors)—often referred to by the term “carcinoid.”
- PNET (pancreatic neuroendocrine tumors)—both nonsecretory and those defined by secretion of specific peptides (i.e., insulinomas).
- MEN-1 & MEN-2 (multiple endocrine neoplasia syndromes) and MTC (medullary thyroid carcinoma). Cancer syndromes with defined gene mutations.
- Pheochromocytoma and parathyroid tumors—both as sporadic cases and in association with MEN syndromes.

Epidemiology

One of the challenges facing the classification systems over the past century for *carcinoid* and related neuroendocrine tumors is that the histology is not particularly informative and tends to be similar for benign and malignant biologic phenotypes. One distinction that has been maintained with some consistency over time has been the separation of classic *carcinoid* tumors of the GI tract from the pancreatic islet cell tumors or PNETs.

In comprehensive epidemiologic reviews of *carcinoid* tumors, Modlin et al.¹ and Yao et al.² report SEER (Surveillance, Epidemiology, and End Results) cancer registry data of incidence and prevalence spanning over a half century. The multidecade analysis of over 13,000 and 35,000 cases respectively show an increase in overall incidence for the past 30 years. Over 65% of NET are in the two broad groups of tumors, *carcinoid* (renamed GI-NET), and islet cell tumors (renamed PNET), together referred to as GEP-NET ([Figure 1](#)). Within the GI-NET, the small bowel remains the most common site with a stable incidence over time, as opposed to the gastric and rectal carcinoids that have increased in recent decades. The PNET are divided roughly into nonfunctional PNET and functional PNET. Functional PNET in order of decreasing incidence are gastrinoma, insulinoma, VIPoma, glucagonoma, and the very rare neurotensinoma, somatostatinoma, and other ectopic hormone-secreting tumors. The changes in gastric and rectal incidence are thought to represent an increased detection rate with the increasing use of upper and lower endoscopies. Over the same period, the incidence of carcinoids of the appendix decreased, perhaps reflecting the decrease in open abdominal procedures and bystander appendectomies.¹ The gastric, rectal and appendiceal NET are often diagnosed incidentally and as superficial lesions whose management is not discussed in this chapter.

Figure 1 Estimated relative incidence of neuroendocrine tumors (NET) by anatomical site. Compiled for illustrative purpose from numerous publications, and estimated by combining classification systems that have varied over time and by source. Data from¹

The over 50 years of data documents little change in overall survival, survival by site and extent of disease, including documentation of metastatic disease at diagnosis in a relatively constant 10-12%. It should be noted that the low incidence of GEP-NET tumors is somewhat deceptive, as Yao et al.² demonstrated that the overall survival that exceeds many other tumors types translates to *prevalence* figures of GEP-NET that exceed other gastrointestinal tumors including esophageal, gastric, pancreatic, and hepatobiliary.

The diffuse endocrine system

The diffuse endocrine system (DES) had its descriptive origins in early histology and cell biology that defined a population of normal chromium-avid epithelial cells widely scattered through the intestinal tract (enterochromaffin cells) and organs including brain, parathyroid, pituitary, thyroid, lungs, adrenal glands (chromaffin or clear cells).³ In the gastrointestinal (GI) tract, cells of the DES are found from the stomach to rectum and represent less than 1% of the surrounding cell population. The cells of the gut DES share phenotypic and biochemical features with neural cells. Along with the large core dense vesicles (LCDV) of endocrine cells, the DES cells also contain synaptic-like microvesicles (SLMV) characteristic of the synaptic regions of neural cells. The complex and diverse biochemistry and control of secretion of over 100 amines, peptides, and eicosinoids from the LCDV and SLMV of the DES cells is discussed in detail by Weidenmann et al.⁴ Cells of the DES may or may not share a single embryologic origin. However, it is known that gut enteroendocrine cells arise from gut endoderm,⁵ and the four epithelial cell types of the gut, including neuroendocrine cells, are derived from a common pluripotential stem cell found in the intestinal crypts,⁶ a stem cell characterized by expression of leucine-rich repeat-containing G-protein

coupled receptor 5 (LGR5).⁷ The pancreatic neuroendocrine cells are derived from pluripotent cell of the islets of Langerhans. The genetic, epigenetic, and biological characterization of the cells of origin and determinates of the numerous phenotypes of NET tumors are only just beginning to be defined.

Neuroendocrine markers

Neuroendocrine markers are utilized in the histologic and immunohistochemical categorization of NETs, and to some degree as clinical markers for diagnosis and assessment of response and relapse. Markers include:

Serotonin and Metabolites—The rate-limiting step in NETs that synthesize and secrete serotonin is the conversion of tryptophan into 5-hydroxytryptophan (5-HTP). 5-HTP is rapidly converted to 5-hydroxytryptamine that is either stored in the neurosecretory granules or may be secreted directly into the vascular compartment where it is converted into the urinary metabolite 5-hydroxyindoleacetic acid (5-HIAA).⁸ The quantification of 5-HIAA in a 24-h urine collection is the best characterized and most frequently used clinical assay for diagnosis and follow-up for those NETs that synthesize and secrete serotonin.⁹

Chromogranin A (CgA) is a member of the chromogranin family of glycoproteins that are stored along with numerous peptide hormones in the large dense core vesicles (LDCV) of endocrine and neuroendocrine cells.¹⁰ It therefore can serve as an immunohistochemical marker for tissue staining and a plasma marker. CgA has been generally accepted as the most useful diagnostic marker for GEP-NET patients with sensitivity above 90%.¹¹ The CgA level correlates with metastatic versus nonmetastatic disease at presentation and can be used to follow patients for relapse following surgery.¹²

Synaptophysin (p38) is a major neuronal protein concentrated in the membrane of small synaptic vesicles of nerve cells.¹³ Weidenmann et al.¹⁴ demonstrated the presence of synaptophysin in a wide range of normal neuroendocrine cells and neuroendocrine tumors.

Neuron-Specific Enolase (NSE) was demonstrated by Bishop and colleagues¹⁵ to be found in all identifiable endocrine and nerve cells of the GI tract and pancreas. NSE has replaced earlier histologic argentaffin stains as a general cytosolic marker of normal neuroendocrine cells and tumors.

Somatostatin and somatostatin receptors

The biology of somatostatin and the somatostatin receptors (SSTRs) and their expression on GEP-NET have yielded information that remains central to the diagnosis and therapy of this group of tumors. Somatostatin analogues are early examples of *targeted* cancer therapy and have broad symptomatic benefit and limited antiproliferative activity that have contributed greatly to the medical and surgical management of NET. The development of radioconjugated somatostatin analogues as imaging agents provide valuable clinical data, and the further extension of these agents as peptide receptor radiotherapy (PRRT) resulted in measurable responses in refractory patients.

Somatostatin is a peptide that inhibits a wide variety of physiologic activities, the most relevant for the treatment of NET being the inhibition of hormone secretion. Somatostatin is found in the central nervous system, hypothalamic pituitary system, GI tract, exocrine and endocrine pancreas, and immune effector cells. It exists as somatostatin-28 and somatostatin-14.¹⁶

Somatostatin and analogues bind at the plasma membrane with varying affinities to a family of G-protein-coupled receptors (GPCR) subtypes, referred to as SSTR isoforms 1–5, resulting in a decrease in cellular

proliferation and induction of apoptosis.^{17, 18}

The GEP-NET, particularly tumors of the small bowel and pancreatic islets, express multiple SSTR subtypes, the most common and highest density being SSTR2 in over 80% of cases, followed by SSTR5.^{19–21} The expression of SSTR2 has been central to the development of somatostatin analogues as therapy to control secretory symptoms, for diagnostic and follow-up nuclear imaging, and for the emerging therapeutic option of PRRT.

Histology and staging of neuroendocrine tumors

Modlin²² detailed the rich history of NET dating from Siegfried Oberndorfer's 1907 description of a group of monotonous-appearing GI tumors labeled “karzinoide” (carcinoid = carcinoma-like), as distinct from the more aggressive adenocarcinomas. The term *carcinoid* has, for almost 100 years, been generally applied to all tumors of the DES that share a similar histological appearance described as monotonous small cells with regular, well-rounded nuclei with insular, trabecular, glandular, undifferentiated, and mixed growth patterns.²³ With an increased understanding of the DES, more specifically the GEP cells, and the parallels between normal cell types and specific tumor types, the description and classification of “carcinoids” has evolved, and a series of revised classifications systems have been made to further classify tumors into more biologically and clinically relevant groups.

Histology and staging

Recognizing the importance of site of origin, differentiation, the revised WHO classification published in 2000 by Solcia et al.²⁴ adapted the term (*neuro*) *endocrine* to avoid the inconsistent historical definitions of *carcinoid*. The 2000 WHO classification introduced the term GEP-NET, and defined three broad groups based on differentiation, leaving site of origin as the lead descriptor to accommodate the breadth of NET subtypes. More recent refinements by UICC/AJCC/WHO²⁵ and modifications by the European Neuroendocrine Society (ENETS)²⁶ and North American Neuroendocrine Tumor Society (NANETS)²⁷ recognize the common and shared importance of histologic *differentiation*, and placed further emphasis on *grade* as determined by mitotic rate and/or Ki67 percentage ([Table 1](#)). TMN staging was incorporated for the first time in 2010,²⁸ and prospective and retrospective validation of its prognostic use are ongoing.

Table 1 Classification of GEP-NET

WHO 2010 Nomenclature	AJCC/ENETs Nomenclature
Neuroendocrine neoplasm, grade 1	Neuroendocrine tumor, grade 1
Neuroendocrine neoplasm, grade 2	Neuroendocrine tumor, grade 2
Neuroendocrine carcinoma, grade 3	Neuroendocrine carcinoma, grade 3
<ul style="list-style-type: none">• Small cell carcinoma• Large cell neuroendocrine carcinoma	<ul style="list-style-type: none">• Small cell carcinoma• Large cell neuroendocrine carcinoma

Both systems emphasize the importance of grade, as determined by mitoses/hpf or Ki-67 percentage. Data from^{25–27}

Clinical features of tumors of the DES

Generally speaking, tumors of the DES are difficult to recognize at initial presentation. Pulmonary

nodules, pancreatic masses, hepatic metastases, and gastric and rectal lesions at endoscopy often are thought to be more common malignancies prior to pathology reports being issued. The early symptoms are often nonspecific (i.e., abdominal pain and diarrhea), and even when more dramatic or classic secretory symptoms occur, the primary tumors are often small and difficult to localize. Patients often have long-standing symptoms and are diagnosed following the development of symptoms related to more advanced local or distant metastatic disease. However, once the diagnosis is considered, advancements in nonspecific (i.e., CgA) and specific tumor markers (i.e., 5-HIAA, gastrin) along with the imaging capabilities with radio-labeled somatostatin analogues, complemented by ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET) scanning, permit a strong presumptive or confirmed diagnosis to guide medical and surgical management. The variability in the location, secretory status, and biological behavior of these rare tumors has made clinical investigation difficult. Despite the lack of comparative trials, consensus based on clinical evidence is available for guiding management of NET.²⁹

Imaging

Somatostatin receptor scintigraphy (SRS) is central to the diagnosis and localization of most cases of GEP-NET. The OctreoScan™, ([¹¹¹Indium-DTPA-pentetreotide]), has for decades been the scan of choice, now just recently being replaced in some institutions by the increased specificity and sensitivity of ⁶⁸Ga-PET/CT.³⁰ The low proliferative capacity of neuroendocrine tumors is thought to account for the low sensitivity of standard ¹⁸FDG-PET.³¹ CT and MRI generally provide further anatomical definition of SRS-documented disease and are more useful than SRS in following tumor growth or response.³² Most reports support SRS as the initial imaging modality for locating both primary and metastatic lesions (including bone) in patients with confirmed and suspected GEP-NET, except those with insulinoma.^{33, 34} A European multicenter trial in 350 patients with a histologically or biochemically proven neuroendocrine gastroenteropancreatic (GEP-NET) tumors compared conventional imaging methods (positive in 88% of cases) to SRS (positive in 80% of cases). The SRS detection rates varied with tumor type: glucagonomas (100%), VIPomas (88%), GI-NET (87%), and nonfunctioning PNET (82%). The low detection rate (46%) noted for insulinomas is related to the lower density of SSTR2 on insulinoma cells. Fasting insulin levels coupled with endoscopic ultrasound (EUS) is the most sensitive method of preoperative localization for insulinomas.³⁵

Gastrointestinal neuroendocrine tumors (GI-NETs)

Well-differentiated neuroendocrine tumors of the small bowel (GI-NETs) are the most common neuroendocrine tumors. In the small bowel, where tumors in general are rare, they account for 13–34% of all tumors and 17–46% of all malignant tumors.³⁶

GI-NETs have been reported from the first to the tenth decade. Modlin et al.¹ reported the average age at diagnosis has increased from 59.9 to 61.4 years over several decades. Except for the small percentage of patients who present with undifferentiated neuroendocrine carcinomas,³⁷ GI-NETs are generally slow growing, often remain undiagnosed for many years, and sometimes are recognized only by symptoms related to metastatic spread to lymph nodes, liver, and, less often, bone.

Small bowel GI-NET can present with small bowel obstruction, abdominal pain, diarrhea, or GI bleeding. Because tumors located in the distal small bowel in most cases have a low intramural profile ([Figure 2](#)), it is not surprising that many of these tumors can grow to larger than 2 cm and remain

undiagnosed. The ability of small tumors to cause significant local symptoms is in part related to the development of events such as ischemia, strangulation, and intussusception from the marked fibrotic reaction they produce. The likelihood of metastases relates to tumor size. The incidence of metastases associated with ileal GI-NET is less than 15% with a tumor smaller than 1 cm, but increases to 95% with tumors larger than 2 cm. When not diagnosed incidentally during a surgical or endoscopic procedure, the confirmation of GI-NET tumors might be made only after lengthy evaluation of abdominal complaints or iron-deficiency anemia, or astute recognition of the *carcinoid syndrome*.

Figure 2 Multiple carcinoids of the small bowel. Three small (<1 cm) intestinal carcinoids found in a young male on inspection of the terminal ileum at colonoscopy. Source: Courtesy of Ed Uthman, MD.

Carcinoid syndrome

Carcinoid syndrome occurs at diagnosis in less than 10% of patients with small bowel GI-NET tumors, but small bowel GI-NET account for upwards of 90% of patients with the carcinoid syndrome.³⁸ Over 90% of cases of carcinoid syndrome only occur after metastatic spread to the liver, with principal features of diarrhea (83%), flushing (49%), wheezing (6%), abdominal pain, and very rarely, pellagra.³⁷ Serotonin and its metabolites are thought to account for the majority of carcinoid syndrome symptoms, but other mediators, such as prostaglandins, substance P, kallikrein, dopamine, and neuropeptide K, may also be involved.⁹ No single measurement detects all cases of carcinoid syndrome, although the urine 5-HIAA appears to be the best screening procedure, detecting about 84% of patients with NET-related carcinoid syndrome.⁴⁰ False positives can occur with ingestion of serotonin rich foods, such as nuts, avocados, kiwi, pineapple, and bananas.⁴¹ CgA has been found to be elevated in 100% of carcinoid syndrome patients, but is lacking in specificity of tumor location because it is elevated in PNET and other

Carcinoid heart disease

Carcinoid heart disease develops in half to two-thirds of patients with the *carcinoid syndrome*^{43, 44} and is characterized by predominantly right-sided valvular lesions described as plaques with proliferation of myofibroblasts and dense extracellular collagen and myxoid deposits.⁴⁵ The cardiac disease is a structural disease with thickening and retraction of the valves causing regurgitation (followed later by fusion of fibrous changes to cause stenosis) resulting most often in right-sided congestive heart failure.⁴⁶ Moller et al.⁴⁷ reported on over 100 patients followed with serial echocardiograms or referred for surgery based on initial echocardiograms and found median survival of 1.6 years for those with documented carcinoid heart disease versus 4.6 years for those without carcinoid heart disease. Peak 5-HIAA levels and prior chemotherapy were independent predictors of progression of carcinoid heart disease. Indirect evidence of the role of serotonin and metabolites includes the histologic similarities to the valvular lesions seen with the diet drugs fenfluramine-phentermine.⁴⁸ Studies to date suggest that control of serotonin (5-HIAA) levels *after* carcinoid heart disease that has been established does not prevent progression of valvular disease.^{47, 49} It is generally accepted, but not proven, that early and improved control of serotonin secretion at diagnosis with somatostatin analogues has reduced the incidence of symptomatic carcinoid heart disease.

Pancreatic net (PNET) (islet-cell tumors)

The second most common GEP-NET occurs in the pancreas. As a group, they have histologic features that are similar to other GEP-NET.⁵⁰ The PNET represent about 15% of all GEP-NET, but represent only a small fraction, 1–2%, of all pancreatic tumors. Nonfunctioning PNET and gastrinoma are the most common PNETs, followed by insulinoma and a list of increasingly rare tumors defined by the clinical syndromes associated with their specific secretory products ([Table 2](#)).

Table 2 The Clinical Syndromes

Clinical Syndrome	Tumor Type	Site	Hormone(s)
Flushing/diarrhea/wheezing	Carcinoid	Mid foregut	Serotonin, substance P
		Pancreas/foregut Adrenal medulla	NKA, TCT, PP, CGRP, VIP
Ulcer disease	Gastrinoma	Pancreas (85%), duodenum (15%)	Gastrin
Hypoglycemia	Insulinoma	Pancreas/uterus	Insulin/TNF
	sarcomas		
	Hepatoma	Retroperitoneal liver	IGF/BP
Dermatitis/dementia	Glucagonoma	Pancreas	Glucagon
Diabetes/DVT			
Diabetes/steatorrhea	Somatostatinoma	Pancreas	Somatostatin
Cholelithiasis/neurofibromatosis	Somatostatinoma	Duodenum	Somatostatin
Silent/liver mets	PPoma	Pancreas	PP
Acromegaly	GEP	Pancreas	GH (GHRH)
Cushing	GEP	Pancreas	ACTH/CRF
Hypercalcemia	VIPoma	Pancreas	VIP
	GEP	Pancreas	PTHrP
Pigmentation	GEP	Pancreas	MSH

Abbreviations: ACTH, adrenocorticotrophic hormone (corticotrophin); BP, binding protein; CGRP, calcitonin gene, related peptide; CRF, corticotropin releasing factor; DVT, deep venous thrombosis; GEP, gastroenteropancreatic; GH, growth hormone, somatotropin; GHRH, growth hormone-releasing hormone; IGF, insulin-like growth factor; MSH, melanocyte stimulating hormone; NKA, neurokinin A; PP, pancreatic polypeptide; PTHrP, parathyroid hormone related peptide; TCT, thyrocalcitonin; TNF, tumor necrosis factor; VIP, vasoactive intestinal peptide; WDHHA, watery diarrhea, hypokalemia, hypochlorhydria, and acidosis.

Nonfunctioning PNET

Nonfunctioning PNET have no specific clinical syndrome, despite staining for one or more peptides and amines or even having quantifiable serum levels of certain neuroendocrine markers. Nonfunctional PNETs account for about 15–30% of the PNET, often diagnosed in the fourth or fifth decade of life, presenting with bulky disease causing abdominal pain in 36%, jaundice in 28%, and or as an incidental finding at surgery in 16%.⁵¹ There is a high reported incidence of local or distant metastases at diagnosis that ranges from 60% to 90%. Serum CgA is elevated in close to 100% of nonfunctioning PNETs.⁴² SRS, CT and MRI are used to stage and follow for recurrence and development of metastatic disease.

As for most GEP-NET, the treatment of choice and the only therapy that can achieve a cure is surgery. Given the late presentation and high percentage of patients with metastatic disease at presentation, surgical cure is not often possible for a nonfunctional PNET. However, procedures such as surgical debunking and relief of biliary obstruction can provide significant palliation. The impact of earlier detection due to increased use of imaging has yet to be documented.

Gastrinoma

The gastrinoma syndrome, also named the Zollinger–Ellison Syndrome (ZES), originated with a report of two patients with severe peptic ulcer disease and non β islet-cell tumors of the pancreas,⁵² with later identification of gastrin as the secreted hormone.⁵³ Gastrinoma patients have a severe ulcer diathesis and persistently elevated basal gastric acid hypersecretion. The acid hypersecretion is also responsible for the frequent symptom of diarrhea, the only symptom in upwards of 20% of patients.⁵⁴ Gastrinomas account for about 25% of all PNET, are found primarily in the duodenum (70%) and pancreas (25%), and demonstrate malignant behavior in approximately 50% of cases.^{55, 56} About 20% of gastrinoma patients are eventually found to have germline mutations in *MEN-1*,⁵⁴ and their presentation and course differ from sporadic cases (see MEN-1 Syndrome).

The diagnosis requires the demonstration of an elevated fasting serum gastrin and elevated basal acid output, both also seen in *Helicobacter pylori* infection, antisecretory therapy (i.e., omeprazole), chronic gastritis, pernicious anemia, atrophic gastritis, and postvagotomy states.⁵⁷ The most sensitive and accurate test remains the secretin stimulation test.⁵⁸

Treatment of the gastrinoma syndrome with medical therapy (i.e., omeprazole) is successful in about 95% of patients,⁵⁹ such that the long-term survival of patients with very slow growing gastrinomas is now determined largely by the eventual malignant behavior of the tumor rather than ulcer diathesis and diarrhea.⁶⁰ Surgery has evolved from gastric resections to control ulcer disease to complex surgery using pre- and intraoperative imaging to localize and resect often small local and regional metastatic disease. The overall survival rate for gastrinomas at 5 years, excluding patients with MEN-1, is between 60% and 80%, and at 10 years is between 45% and 75%.^{56, 61, 62}

Insulinoma

Insulinomas were first described by Whipple in a 1938 report of 30 patients with pancreatic adenomas and hypoglycemia.⁶³ Insulinomas are the second most common functioning PNET, with an incidence of 0.8–0.9 cases per million. Overall, the incidence of metastatic disease, about 5–15%, is low compared with other PNET. The tumors are often well encapsulated as a single solitary nodule, or multiple nodules evenly distributed throughout the pancreas.⁶⁴ The finding of multiple insulinomas should prompt testing for MEN-1.⁶⁵ In a prospective database of patients operated for insulinomas, 88% of MEN-1 patients had multifocal lesions versus only 4% of nonMEN-1 patients.⁶⁶

Almost all cases of insulinoma present with symptoms of hypoglycemia, with neuroglycopenic symptoms (visual complaints, altered consciousness, weakness) more common than adrenergic symptoms alone (sweating, tremulousness).⁶⁴ Diagnosis of suspected cases is made by a supervised fast, where over 90% of patients will develop a serum glucose of <50 mg/dL during a 48-h fast, and the corresponding serum insulin level at the time of hypoglycemia will equal or exceed 5 U/mL.⁶⁷

With surgery, 80–90% of all insulinoma patients will be cured.⁶⁴ EUS, which has a reported sensitivity of 80%, can localize tumors < 1 cm,⁶⁸ and intraoperative ultrasound (IOUS) can be used to avoid blind pancreatic resections when EUS cannot localize a lesion. A diet of small, frequent meals coupled with medical therapy with diazoxide to directly block release of insulin from the β -cell along with octreotide can control symptoms in as many as 60% of patients preoperatively or with unresectable lesions.⁶⁹

VIPoma

The VIPoma (vasoactive intestinal polypeptide) was first described by Verner and Morrison⁷⁰ followed

by a review of 55 patients with the WDHA syndrome (watery diarrhea, hypokalemia, and achlorhydria).⁷¹ The VIPomas are quite rare, accounting for only about 5% of PNET, and unlike other PNETs, have distinct adult and pediatric subsets of patients. In adults, 90% of the tumors are found in the pancreas, most often as solitary nodules and upwards of 60% of cases present with or develop metastatic disease. In children, most VIP-secreting tumors are extrapancreatic and are neurogenic in origin, with the most common histology being ganglioneuroblastomas and ganglioneuromas.⁷² The diagnosis requires the documentation of elevated plasma VIP concentrations and documentation of large volume secretory diarrhea.⁷³

Octreotide controls symptoms in over 80% of patients, corresponding with a drop in the VIP plasma level.⁶⁹ Long et al.⁷² reported that in 52 patients with pancreatic VIPomas, the average lesion was 9 cm in diameter, and thus readily visible by CT or ultrasound. Some VIPomas require angiography with or without selective venous sampling for VIP levels.⁷³ Complete resections have resulted in long-term control of symptoms in 30–50% of adult patients.⁷⁴

Glucagonoma

Glucagonoma was first reported in 1966 by McGavran et al.,⁷⁵ who called attention to a syndrome that included acquired diabetes and glucagon-producing tumors. This rare tumor, estimated to account for 1% of GEP-NET, was later recognized to include a characteristic skin rash labeled *necrolytic migratory erythema* (NME).^{76, 77} The tumor occurs almost exclusively in adults over 40 years of age and has been associated with MEN-1 in a few cases.⁷⁸

The largest single-institution experience by the Mayo Clinic reported on 21 patients seen between 1975 and 1991.⁷⁹ The main presenting features of the glucagonoma syndrome included weight loss (71%), NME rash (67%), mild diabetes mellitus (38%), diarrhea (29%), and painful glossitis and angular stomatitis (29%).

Glucagonomas are almost all found as single lesions in the pancreas (tail > body), averaging 5–10 cm in size, and metastatic disease is already present in over 60% of patients, most often to the liver.⁸⁰ If the diagnosis is made while the tumor is still localized, surgical resection can be curative.⁸¹ Due to the slow growth of tumors and available therapies, the 10 years survival is 51.6% for patients with metastases and 64.3% for patients without metastases at diagnosis.⁸² Both the NME rash and diarrhea, but generally not the glucose intolerance/diabetes, respond to octreotide in over 50% of the patients, with complete disappearance of symptoms in about 30% of patients.⁶⁹

Somatostatinoma

Somatostatinomas are rare PNET, with about 50 cases reported to date. The first cases were reported in 1977 by Ganda et al.⁸³ and Larsson et al.⁸⁴ Krejs et al.⁸⁵ reported a series of 8 cases in 1979, and Vinik et al.⁸⁶ reported the largest review on 48 cases in 1986. Somatostatinomas are rarely seen in association with MEN-1.⁷⁸

Despite a defined clinical syndrome of diabetes, diarrhea, steatorrhea, gallbladder disease, hypochlorhydria, and weight loss,⁸⁷ most cases are diagnosed at laparotomy or laparoscopy, or identified on imaging studies for abdominal complaints or jaundice. A markedly elevated plasma level of somatostatin is thought to be responsible for the majority of symptoms. The tumors tend to present as large masses, reflecting the high levels of somatostatin thought necessary to create symptoms. At diagnosis,

85% of the pancreatic and 50% of the intestinal primaries had evidence of metastatic spread.⁸⁸ Though the data are minimal; the outlook for those with somatostatinomas is poor, given the high incidence of malignant spread. Close to half of reported patients died within a year and others survived up to as long as 5 years.⁸⁷

Therapy for GEP-NET

In general, GEP-NET are slow growing and symptoms are most often attributable to secretory products or pain from bulky disease. For those patients whose tumors are not resectable at diagnosis or who later develop metastatic disease, the focus is on control of symptoms. The use of the long-acting somatostatin analogues to decrease secretion of vasoactive and other hormones, combined with bulk-reducing procedures primarily directed at hepatic lesions, the quality of life of GEP-NET patients can be maintained for extended periods of time. Recent data demonstrates for selected patients, somatostatin analogues, sunitinib, and everolimus can prolong progression-free survival in patients with metastatic disease.

Surgery primary

Prophylactic treatment with a somatostatin analogue should be considered before all surgical procedures in GEP-NET patients to avoid precipitation of the *carcinoid syndrome* or other secretory crises.⁸⁹ Gastric and duodenal GEP-NET can, in selected cases with tumors <1 cm, be excised endoscopically.⁹⁰ GI-NETs of the small bowel that appear localized should be resected en bloc with lymphadenectomy and removal of the mesentery.⁹¹ GI-NETs of the appendix are generally treated by appendectomy if <2 cm, and resection if >2 cm.⁹²

Liver-directed therapies

Given the high frequency of metastatic spread to the liver, a number of liver-directed therapies have been used in the management of GEP-NETs. It is estimated that >90% of patients with hepatic metastases have lesions that are too large, too numerous, or too diffuse to permit resection. Hepatic Resections: Que et al.⁹³ recently performed a meta-analysis summarizing reports of involving hemihepatectomy, trisegmentectomy, or wedge resection for GEP-NET. The operative mortality after partial hepatectomy for GEP-NETs in this series was 2.3%. More than 80% had improvement in symptoms related to hormone excess (i.e., carcinoid syndrome), and the duration of response ranged from 4 to 120 months.

Radiofrequency ablation

Radiofrequency ablation (RFA) has been used in these patients to reduce bulk of disease and control symptoms. The largest series to date of RFA in metastatic neuroendocrine tumors involving patients treated over a 10-year period at a single institution demonstrated perioperative morbidity of <5%, a 90% partial and 72% complete relief of symptoms, and median duration of symptom control of approximately one year.⁹⁴

Hepatic artery vaso-occlusive therapy

Overall, vascular-occlusion therapies have led to biochemical responses as high as 50%, and tumor reduction as high as 40%, all generally of short duration.⁹⁵ Hepatic arterial occlusion combined with sequential chemotherapy has resulted in biochemical responses as high as 80%, with a median duration of

response of 18 months or more.^{96–98}

Hepatic transplantation

A recent review of the first 103 liver transplants in Europe for NET tumors showed 5-year overall and disease-free survival of 46% and 24% respectively.⁹⁹ However, the restrictive transplant criteria, significant morbidity and mortality of the procedure, and the general lack of transplantable organs make transplant a limited therapeutic option.

Somatostatin analogues

Somatostatin analogues have had a major impact on the flushing, diarrhea, and wheezing in patients with metastatic carcinoid and the carcinoid syndrome and can control many of the other secretory symptoms associated with various NET. Yao's analysis of SEER data has shown an increase in survival in GEP-NET following the introduction of octreotide in the United States in 1998,² perhaps reflecting an antiproliferative effect combined with reduced risks of surgery, allowing patients to benefit from more aggressive approach to metastatic disease. Janson et al.¹⁰⁰ and Kvols et al.¹⁰¹ have shown that a positive SRS (OctreoScan™) predicts for patient symptomatic response to somatostatin analogues. Octreotide, a long-acting formulation (somatostatin-LAR)¹⁰² and recently approved lanreotide are available in the United States.¹⁰³ SOM 230 (pasreotide), a somatostatin analogue with broad binding affinity to SSTR1-5, is currently in phase III development for GEP-NET, and recently approved in the United States for Cushing's disease.¹⁰³

Use of somatostatin analogues over many decades, both short and long acting formulations,^{104, 105} are associated with biochemical responses in 70–80% of patients, symptomatic control of diarrhea and flushing in over 80% of patients, and a decrease in 5-HIAA levels (if elevated at baseline) in over 70% of patients.^{106, 107} Recent studies of somatostatin analogues in *asymptomatic* GEP-NET patients with significant tumor burden have shown clinical benefit beyond symptom control. The PROMID trial was a phase III, randomized, placebo-controlled, double-blind study of small bowel GI-NET patients with minimally or asymptomatic metastatic disease that compared long-acting octreotide to placebo. The median time to progression for octreotide was 14.3 months and placebo was 6.0 months, with stable disease at 6 months for octreotide of 67% and placebo of 37%. Median overall survival was not assessed owing to a crossover design.¹⁰⁸ The CLARINET trial was a phase III, randomized, placebo-controlled, double-blind study of both well-differentiated GI-NET and PNET patients with asymptomatic but progressive metastatic disease. The trial compared long-acting lanreotide to placebo. The primary end point of progression-free survival was significantly greater for lanreotide (not reached) versus 18 months for placebo, with no significant difference in overall survival.¹⁰⁹

Biologic agents

Oberg pioneered the use of leukocyte interferon in GEP-NET¹¹⁰ and reviewed the early trials in 2000¹¹² demonstrating a biochemical response in 63–77% of patients, with stable disease reported in over 50%, and a rare complete or partial tumor response. One of the few multicenter, randomized, comparative trials done in the field of GEP-NET to date, however, showed that the objective responses were no higher with the combination as compared with either agent alone.¹¹¹ Though a higher symptomatic and biochemical response rate was seen in the combination therapy group, it was at the expense of increased toxicity.

Peptide receptor radiotherapy (PRRT)

Targeting the SSTR provided by somatostatin analogues has led to the development of PRRT reagents for GEP-NET whereby the localization with the Octreoscan documents the opportunity for selective delivery of a radiopharmaceutical at the site of SSTR2, 5 expressing tumors.¹¹² Trials of several different radionuclide-somatostatin analogue combinations have been studied in phase I, II clinical trials, but no phase III trials have been completed. Response rates (CR + PR) ranging from about 10–30%, with 40–60% of patients developing stable disease have been reported.^{113, 114} Currently no PRRT are approved for therapeutic indications, and they remain available only through clinical trials or for compassionate use in selected centers in Europe.

Cytotoxic chemotherapy for GEP-NET

Several authors have reviewed the history of treatment of GEP-NET, with single-agent and multiagent chemotherapy.^{9, 115} In the absence of randomized trials that contain a no-treatment arm, there is no persuasive evidence that single-agent or combination chemotherapy provides any significant impact on disease progression or on survival in patients with metastatic NET. The approved agents, DTIC and Streptozocin, have significant toxicities and questionable benefit. Recent studies of temozolomide, in combination with thalidomide,¹¹⁶ or in a retrospective study with capecitabine¹¹⁷ are encouraging. Chemotherapy is generally reserved to provide palliation of hormone excess and symptoms related to tumor bulk.

Targeted therapies

Early phase trials have been completed for several targeted therapies. Minimal or no response was seen in phase II studies of the tyrosine kinases inhibitors imatinib¹¹⁸ and gefitinib.¹¹⁹ More encouraging are the responses seen in phase II trials of the VEGF inhibitor bevacizumab.¹²⁰ A series of clinical trials has led to FDA approval in 2011 for both everolimus and sunitinib for PNET. GI-NET patients were included in the trials and responded, but below the level required for approval.

Everolimus, an oral inhibitor of m-TOR, studied in the RADIANT-3 phase III, randomized, placebo-controlled study of well differentiated PNET patients with advanced and progressive disease demonstrated a median PFS of 11.0 months for everolimus versus 4.6 months for placebo.¹²¹ The earlier RADIANT-2 phase III, randomized, placebo-controlled study of well differentiated GI-NET patients with advanced and progressive disease and carcinoid syndrome, demonstrated a non-significant difference in median PFS of 16.4 months for everolimus versus 11.3 months for placebo.¹²²

Sunitinib, and oral multi-tyrosine kinase inhibitor, was shown in a phase III, randomized, placebo-controlled study of well differentiated PNET that were locally advanced or metastatic and with recent progression, to have a PFS of 11.4 months versus 5.5 months for placebo. Though assessments were confounded by early closure by a data safety committee, and possible bias from investigator response assessment, the FDA approved sunitinib for this indication after an independent data review.¹²³

MEN syndromes

The MEN-1 and MEN-2 syndromes, first referred to as Werner syndrome, were based on the author's observation of groups of individuals with multiple adenomas that appeared to be inherited in an autosomal dominant pattern.¹²⁴ The MEN-1 and MEN-2 syndromes differ in genetics, clinical presentation, the type and frequency of involvement of certain endocrine tissues, preventive and therapeutic surgery, and follow-up of affected individuals and family members. The neuroendocrine

tumors that occur within the MEN syndromes have both similarities and differences to the same tumors when they occur sporadically.

MEN-1 syndrome

A somewhat unpredictable cluster of neuroendocrine and nonendocrine tumors from a total of about 20 different histologic types characterizes MEN-1 syndrome cases and families (Table 3). Though there is no “typical” grouping of neuroendocrine tumors, data from many families show that the most common tumors are parathyroid (including hyperplasia) (90%), enteropancreatic (70%), and anterior pituitary (25%).¹²⁶ A practical clinical guideline for diagnosis of an MEN-1 individual is to have two of the three principal tumors diagnosed, and a MEN-1 family would involve at least one case as defined above and at least one first-degree relative with at least one of the principal tumor types.

Table 3 MEN-1 Tumor Type Distribution and Estimated Penetrance (%) by Age 40 Years

Endocrine Tumors (Common)	Endocrine Tumors (Less Common)	Nonendocrine Features
Parathyroid adenoma (90%)	Thymic carcinoid (2%)	Collagenomas (70%)
Gastrinoma (40%) PP (nonfunctioning) oma (20%)	Bronchial carcinoid (2%) PNET (VIPoma, glucagonoma, etc) (2%)	Facial angiofibromas (85%)
Prolactinoma (20%)	ACTH, GH (2%)	Lipomas (30%)
Insulinoma (10%)	Pheochromocytoma (<1%)	
ECL tumor (10%)	TSH (rare)	

^a Nonfunctioning adrenal tumors are found in as high as 25% of MEN-1 patients on full evaluation.

Source: Data taken in part from Giusti et al.¹²⁵

About 80% of familial MEN-1 individuals and about 50% of sporadic MEN-1 individuals have a heterozygous germline mutation in the *MEN-1* gene.^{127, 128} A recent update described 1336 mutations spread across the coding region of the *MEN-1* gene.¹²⁹ MENIN, the product of the *MEN-1* gene, acts as a tumor suppressor with the various mutations resulting in loss-of-function. Despite the varied genotypes, no correlation of genotype to clinical phenotype has been determined that could allow a more focused algorithm to justify preventive surgery and a more focused screening of affected family members with specific mutations.¹²⁹

MEN-1 and parathyroid lesions

Most patients first present with symptoms of hyperparathyroidism (HPT), asymptomatic hypercalcemia, or if in a known MEN-1 family undergoing screening, with biochemical or imaging evidence of parathyroid tumor(s). The average age of onset is 25–30 years old, and by age 50, nearly 100% of the MEN-1 patients will have evidence of HPT. In contrast, only 2–4% of cases of sporadic HPT investigated will be found to have mutations in the *MEN-1* gene,¹³⁰ and the average age of onset is 55–60 years old.

MEN-1 and gastrinoma

Gastrinomas are the next most common “tumor” to follow HPT in MEN-1 patients.

Approximately 20% of gastrinomas are associated with the MEN-1 syndrome,⁵⁴ present at an earlier age, often are multiple small or undetectable primaries, and are less frequently (7–12%) malignant than sporadic gastrinomas. When there is no evidence of metastatic disease and venous sampling demonstrates an anatomically localized source of gastrin, enucleation (pancreatic head), or resection (body or tail) may offer excellent palliation, but rarely a cure.⁹ It is generally recommended to avoid surgery and manage medically with periodic evaluations for radiological progression of tumors.

MEN-1 medical and surgical management

The clinical features of patients with MEN-1 depend entirely upon the natural history of the individual tumors and endocrine hyperfunction. Treatment of the MEN-1 syndrome is dependent on the phenotypic expression in the individual patient. Most patients with MEN-1 pancreatic disease requiring surgical intervention present with a syndrome caused by hypersecretion of a specific hormone such as gastrin, insulin, VIP, or glucagon. Overall, patients with familial MEN-1 neoplasms have longer survival than patients with sporadic endocrine pancreatic tumors.⁹ Regardless of initial findings; MEN-1 patients must be followed for life for involvement of the pituitary gland, parathyroid glands, endocrine pancreas or duodenum, adrenal glands, thymus, and lungs (bronchial carcinoids). Family members who are screened with *MEN-1* gene sequencing and are found to be positive should undergo similar lifelong surveillance.¹³¹

MEN-2 syndromes

The MEN-2 syndromes represent several distinct clusters of neuroendocrine tumors with an association between specific gene mutations of the *RET* proto-oncogene and phenotype. MEN-2A patients are characterized by MTC (95%), pheochromocytoma (50%), and hyperplasia/adenoma of the parathyroid glands (15–30%) of cases.¹³² MEN-2B patients have MTC (100%), pheochromocytoma (50%), and varied reported incidences of mucosal neuromas and marfanoid body habitus ([Table 4](#)).^{132, 134} There have been almost 1000 MEN-2 families reported worldwide, with the subtype MEN-2B representing about 80% of families.¹³⁵ Over 70 distinct *RET* mutations have been identified, and with increasing data on large kindreds, the genotype–phenotype relationships with each mutation have become *less* distinct than originally reported.¹³⁶

[Table 4](#) Classification of MEN-2 Syndromes

	MEN-2 Cases	MTC	Pheo	Parathyroid Hyperplasia/Adenoma
MEN-2A	60–90%	95%	50%	20–30%
MEN-2B	5%	100%	50%	Uncommon
FMTC	5-35%	100%	0%	0%

Abbreviations: FMTC, familial medullary thyroid carcinoma; MTC, medullary thyroid carcinoma; Pheo, pheochromocytoma.

Source: Data from Moline et al.¹³³

Medullary thyroid carcinoma

MTC represents about 5–10% of new cases of thyroid cancers, or about 1000 cases per year in the United States. Of these, about 75% have no family history of MTC (sporadic MTC) and are generally diagnosed

around the age of 50–60 years.¹³⁷ Both MEN-2A and 2B patients are at high risk of MTC ([Table 4](#)). MEN-2A patients often present with MTC before pheochromocytoma or parathyroid disease. In known MEN-2A families, biochemical evidence of MTC usually occurs between the ages of 5 and 25 years.¹³⁸ The MEN-2B patients have an earlier age of onset of cancers and a more aggressive phenotype of MTC leading to a worse prognosis compared with MEN-2A patients.^{139, 140} Fortunately, some of these children are recognized prior to the diagnosis of MTC based on genetic screening or clinical recognition of marfanoid body habitus and mucosal neuromas.¹⁴¹ MTC is suspected in the presence of elevated serum calcitonin levels, a sensitive and specific marker. Patients not identified by genetic testing or biochemical screening, about 30% of MTC patients, will present with a (painful) neck mass, and/or diarrhea associated with high calcitonin levels. Unfortunately most of these patients already have local or distant spread of their tumors.¹³⁷

Familial medullary thyroid carcinoma

The designation of familial medullary thyroid carcinoma (FMTC), as opposed to MEN-2A, MEN-2B, and sporadic MTC, is defined as families with four or more cases of MTC in the absence of a diagnosis of pheochromocytoma or parathyroid hyperplasia/adenoma. Of these cases, almost 90% will be found to have an identifiable *RET* mutation.¹⁴² It is recommended that all FMTC cases undergo regular screening tests for pheochromocytoma and parathyroid disease given that some families are later classified as MEN-2A or 2B.¹⁴³ The therapy for FMTC is the same as for MTC in association with MEN-2A, MEN-2B, though the clinical course and prognosis is more favorable for FMTC.¹⁴²

Treatment of medullary thyroid carcinoma

Prophylactic thyroidectomy (and autotransplant of parathyroid tissue) is accepted therapy for MEN-2B patients with documented *RET* germline mutations. The timing of the surgery, still controversial, can in fact be guided by the specific *RET* codon affected.¹²⁶ Treatment of established MTC involves total thyroidectomy and lymph node dissection in almost all cases, followed by lifelong thyroid replacement. Of these patients, approximately 50% will develop recurrent disease,¹⁴⁴ necessitating yearly screening with a calcitonin stimulation test. Clinical studies of chemotherapy and radiotherapy have not demonstrated any durable responses.¹⁴⁵ However, clinical investigation of various targeted multikinase inhibitors have shown promising results, and led to the recent FDA approval of two new agents for MTC.

Vandetanib is an oral inhibitor of VEGF2-3, RET, EGFR that in a phase III randomized, placebo-controlled trial against placebo achieved the primary endpoint of an increase in progression-free survival of 30.5 months versus 19.3 months for placebo.¹⁴⁶ Partial response of 45% was seen, with even higher biochemical responses in calcitonin and CEA. No overall survival benefit has been demonstrated as yet, and significant toxicity including QTc prolongation requiring a *black box warning* was required at FDA approval in 2011.¹⁴⁷

Cabozantinib is an oral inhibitor VEGF2-3, RET, MET that in a phase III randomized, placebo-controlled trial of patients (with documented recent progression) against placebo achieved the primary endpoint of an increase in progression-free survival of 11.2 months versus 4.0 months for placebo. Partial response was 28%, with no overall survival benefit yet demonstrated. Toxicities were similar to vandetanib, excluding effects on QTc.¹⁴⁸

Clinical trials of vandetanib, cabozantinib, and several other multikinase inhibitors alone and in combination are ongoing.¹⁴⁹

Pheochromocytoma

Pheochromocytomas arise in the chromaffin cells of the adrenal medulla. Paragangliomas of the sympathetic nervous system, often called extra-adrenal pheochromocytomas, are most often located in the retroperitoneum. Paragangliomas of the parasympathetic nervous system are often located in the region of the aortic arch, neck, and base of skull (i.e., carotid body paragangliomas).¹⁵⁰ Mayo Clinic data estimates that approximately 800 cases of pheochromocytoma are diagnosed in the United States each year.¹⁵¹ They are found in approximately 0.05–0.1% of hypertensive patients.¹⁵²

Clinical features and diagnosis

Discussions of the diagnosis and management of pheochromocytoma often consider the “rough rule of tens”: 10% of neoplasms occur in children, 10% of sporadic cases are bilateral, 10% are extra-adrenal, and 10% are malignant. Previously, this rule included that 10% of pheochromocytomas were familial, but recent updates document that over 40% of pheochromocytoma patients without personal or family history of associated endocrine neoplasia have a germ-line mutation in one of the following genes: *VHL*, *RET*, *NF-1*, *MEN-1*, succinate dehydrogenase subunits D,B,C (*SDHD*, *SDHB*, *SDHC*, *SDHAF2*), *SMAD4*, *ENG*, *ALK1*, *TMEM127*, *MAX*, *HIF2A*.^{153, 154} It is now recommended that genetic counseling and possible genetic testing, be considered for all patients diagnosed with pheochromocytoma, particularly those diagnosed under age 50 years with a family history or multifocal disease.¹⁵⁵

Patients may present anywhere in the spectrum from normotensive and asymptomatic to a severe, life-threatening hypertensive crisis. The fundamental basis for the diagnosis of pheochromocytoma is a high index of clinical suspicion with confirmation by biochemical determinations for catecholamines or catecholamine metabolites by assays for plasma metanephrines or the more widely available measurements of 24-hour urinary excretion for catecholamines, metanephrines, or vanillylmandelic acid (VMA).¹⁵⁶ CT scanning, as well as MRI, can visualize over 90% of adrenal pheochromocytomas in patients with biochemical evidence of a pheochromocytoma.¹⁵⁷

Surgical management of benign or recurrent resectable disease

Nearly all benign pheochromocytomas can be cured by surgical resection. Because of its slow growth rate and accompanying significant morbidity, complete resection of local recurrence or limited metastases of malignant pheochromocytoma should be attempted. The value of debulking surgery for patients whose tumor cannot be completely resected is not established, but reports of successful control of symptoms following surgery have been reported.¹⁵⁸ An international consensus on preoperative management summarizes the critical need to control blood pressure, manage cardiac rate and rhythm, normalize fluid status and prevent a “catecholamine storm” at the time of invasive procedures and surgery.¹⁵⁹

Medical treatment of recurrent or metastatic disease

It is estimated that only about 5–25% of all pheochromocytomas are malignant.¹⁵¹ The CVD (cyclophosphamide, vincristine, and dacarbazine) regimen that is effective in children with advanced neuroblastoma is considered the preferred treatment of symptomatic, disseminated pheochromocytoma.¹⁶⁰

MEN-2 and pheochromocytoma

Pheochromocytomas in MEN-2 patients are diagnosed between the ages of 20–30 years, earlier than the

sporadic pheochromocytomas diagnosed between 35–45 years old,¹⁶¹ in part owing to MEN-2 patients being actively screened. About 25% of MEN-2A patients present with pheochromocytoma as their first tumor.^{162, 163} Up to 75% of patients are diagnosed concurrently with MTC.¹⁶¹ MEN-2 patients with pheochromocytomas develop bilateral tumors and appear to have a lower incidence of malignant transformation than patients with sporadic tumors.¹⁶⁴ Given the low incidence of malignancy in MEN-2 patients, unilateral or bilateral subtotal resection with preservation of adrenocortical function can be considered in this population to avoid lifelong replacement therapy. The MEN-2A patients are often asymptomatic, but can develop hypertensive crises during surgery undertaken for HPT or MTC. Therefore, all patients with MEN-2 should be carefully screened for the presence of pheochromocytoma before any surgery or invasive procedure and, if present, treated with α -adrenergic blockade to control blood pressure.¹⁵⁹

Within MEN-2 families, the specific *RET* mutation at codon 634 is highly associated with the presence or eventual development of pheochromocytoma and should be considered in following these patients. Overall, the general recommendation is to screen all MEN-2 patients for pheochromocytoma on a yearly basis.¹⁵⁵

Chapter 83

Neoplasms of the head and neck

Renata Ferrarotto, MD ■ Merrill S. Kies, MD ■ Adam S. Garden, MD ■ Michael E. Kupferman, MD

Overview

Head and neck cancers (HNCs) comprise a diverse group of malignancies affecting the upper aerodigestive tract. The most common tumor type is squamous cell carcinoma. While the main risk factors for HNC remain tobacco and alcohol abuse, oncogenic viruses such as human papilloma virus and Epstein–Barr virus play a major carcinogenic role in tumors of the oropharynx and nasopharynx, respectively. The management of head and neck malignancies is site and histology specific, and requires a multidisciplinary team approach. In this chapter, we review the current knowledge of HNC, with focus on squamous and salivary cancers, and discuss ongoing and future research aiming to improve the management and outcomes of patients with these malignancies.

Introduction

Approximately 62,000 new cases of head and neck cancer (HNC) will be diagnosed in the United States and over 13,000 Americans will die from these malignancies in 2016, accounting for 4% of all new cancer cases and 2% of cancer deaths annually.^{1, 2} Tobacco and alcohol are the primary etiologic agents for squamous cell carcinomas (SCCs).³ However, a rising proportion of these cancers (particularly those found in the oropharynx) are attributable to oncogenic human papilloma virus (HPV)⁴ and the preventive efficacy of population-wide HPV vaccination on incidence rates has yet to be determined. HNCs have a much greater impact in certain parts of the world, especially where cigarette smoking and/or chewing of carcinogenic stimulants is more prevalent.^{1, 5, 6} The more widespread adoption of multidisciplinary care likely underlies improvements in survival rates for some sites (nasopharynx and oropharynx);⁷ however, long-term survival rates are stagnant for other sites.⁸

Despite marked advances in reconstructive surgery, rehabilitation, and intensity-modulated radiotherapy (IMRT), head and neck squamous cell carcinoma (HNSCC) patients continue to have significant functional deficits which affect quality of life. Combined-modality approaches involving chemotherapy and radiation are now standards of care for “nonsurgical” locally advanced disease with objectives of disease eradication and organ preservation. Understanding the biology of HNC and developing molecularly targeted therapeutic agents and chemoprevention strategies have advanced substantially. These new therapeutic and preventive approaches appear to hold great promise for improving the control of HNC and its sequelae. This chapter reviews the current status of and future investigative directions for the epidemiology, biology, diagnosis, and therapy of HNC.

Descriptive epidemiology

Incidence

In the United States, estimates for 2015 are for approximately 45,780 new cases of oral cavity and oropharynx cancer, 13,560 new cases of laryngeal cancer, 3200 nasopharyngeal carcinoma (NPC), 3100 malignant salivary gland tumors, and 2000 nasal cavity and paranasal sinus neoplasias.² The United States has benefited from tobacco control efforts with declining smoking prevalence beginning in the 1960s and subsequent declines in incidence rates for most HNC beginning in the 1980s.⁹ Approximately one in two oral cavity cancers occur in women, while only one in four pharyngeal and laryngeal cancers occur in women. Death rates from oral cavity and pharyngeal cancers have declined among whites and blacks over the years from 1993 to 2007, the largest changes in black men and women with 12 years of education. Although blacks and whites have similar rates of oral cavity/pharyngeal cancer, black men have double the rate of laryngeal cancer of white men; and black women have a 40% higher rate of laryngeal cancer than that of white women. Hispanics have the lowest incidence of oral cavity/pharyngeal cancer, and Asians have the lowest rates of laryngeal cancer.¹⁰ The median age at diagnosis for HNSCC is approximately 60 years, but the incidence of these cancers in young adults (age <45 years) appears to be increasing, related to increasing numbers of oropharyngeal cancers associated with oncogenic HPV.⁴ HPV-positive oropharyngeal cancers are more common in white men, presumably related to the prevalence of oral sexual practices.⁹

Worldwide, HNC incidence was approximately 550,000 cases in 2011. Melanesia has the highest incidence of oral cavity cancer (36 : 100,000), followed by South-Central Asia, and Central and Eastern Europe.¹⁰ While mortality rates attributed to oral cavity cancer have been decreasing in most countries in Europe and Asia, rates continue to increase in Eastern European countries, particularly in females, reflecting the tobacco epidemic in that region. Although 80% of HNC cases in South-Central Asia are oral cavity and pharyngeal (excluding nasopharyngeal), in other regions of the world, laryngeal and nasopharyngeal cancers are more common. Laryngeal cancer accounts for approximately one-third of HNC in the developed world, and approximately 40% of cases in Southern and Eastern Europe. In South-Eastern Asia, nasopharynx carcinoma is the sixth most common malignancy overall in males, accounting for ~70% of all HNC in countries like Malaysia, Indonesia and Singapore.¹⁰

Prevalence

Highlighting the impact of cancer survivorship, approximately 350,000 individuals were living in the United States with a history of HNC in November, 2007. As expected, the sex distribution of these prevalent cases reflects the sex of the incident cases. However, African Americans accounted for only 11.5% and 7.3% of the prevalent population of individuals with a history of laryngeal and oral cavity/pharyngeal cancer, respectively. These small percentages likely reflect the poorer overall survival (OS) of African Americans diagnosed with HNSCC. Over the past decade, African Americans have demonstrated survival rates approximately 20% and 15% worse than whites for oral cavity/pharyngeal and for laryngeal cancer, respectively.¹¹

Mortality

In 2015 in the United States, 8650 deaths will be attributed to oral cavity and oropharyngeal cancer, and 3640 to laryngeal cancer.² Broader use of and improvements in multidisciplinary care, and the declining incidence attributable to tobacco control, likely underlie the significantly improved survival rates for nasopharyngeal, oropharyngeal, and hypopharyngeal cancer patients, and trends toward improved oral cavity cancer survival rates; however, laryngeal cancer survival rates appear to be worsening.^{7,8} As with other cancer sites, mortality/incidence ratios for HNC are much higher in developing countries as

compared with the United States.^{1, 10}

Risk factors

Tobacco

In the late 1950s, a landmark case-control study by Dr. Ernst Wynder established the link between tobacco use and oral cavity cancer. A year later, a cohort study of over 180,000 men demonstrated an increased risk of death from HNSCC in cigarette smokers as compared with men who never smoked.¹² In 1964, the Advisory Committee to the Surgeon General on Smoking and Health published its report linking smoking to cancer.¹³ The strength and consistency of the association between smoking and HNSCC have been demonstrated in numerous case-control and cohort studies with significant relative risks or odds ratios in the 5- to 25-fold range.^{14, 15} Furthermore, a dose-response effect is consistently shown between the duration and dose of smoking with increasing risk of HNSCC and between the time since quitting and the decreasing risk of HNSCC. Other mucosal malignancies of the head and neck such as NPC and sinonasal malignancies have a weaker association with tobacco smoking.¹⁶

Although the risk of bronchogenic carcinoma appears to be less significant for cigar and pipe smokers than for cigarette smokers, these forms of tobacco use are also clearly associated with an increased risk of HNSCC.¹⁷ The pooling of saliva containing carcinogens in gravity-dependent regions may account for the site distribution of HNSCC based on consumption patterns; in the United States, floor of mouth (FOM), laryngeal, and hypopharyngeal cancers are almost exclusively found in smokers. Smokeless tobacco and related product users and pipe smokers often have a habitual position for the quid or pipe stem, and these products are also associated with cancer of the oral cavity. In South-Central Asia where the use of such products is common, the gingivobuccal region is the most common site for HNSCC.^{6, 18}

Although smoking rates are declining in the developed world, they are rising in developing countries. In 1965, 42.4% of the U.S. adult population was actively smoking, while in 2013 only 17.8% were current smokers.¹⁹ Although the reduction in cigarette smoking has been much greater in men over the past three decades, the rate of current cigarette use remains higher in men (20.5%) than in women (15.3%), and 26.1% of Native Americans continue to smoke.²⁰ Worldwide, striking variations in HNC sites and incidence are seen among different regions, cultures, and demographic groups and are due, in large part, to differing patterns of tobacco and other substance abuse. For instance, in South-Central Asia, “pano” (betel leaf, lime, catechu, and areca nut) is commonly chewed and is a strong risk factor independent of tobacco use for carcinoma of the oral cavity, one of the most common cancers in men and women in this region.^{10, 21}

Alcohol

Alcohol, too, is an important promoter of carcinogenesis in at least 30% of HNSCCs.^{10, 22} Furthermore, alcohol appears to have an effect on HNSCC risk independent of tobacco smoking, but these effects are consistently significant only at the highest level of alcohol consumption.²³ Although studies attempting to correlate the type of alcoholic beverage with specific cancer risks have been conflicting, most investigators believe that ethanol itself is the main causative factor. Nevertheless, it appears that the major clinical significance of alcohol consumption is that it potentiates the carcinogenic effect of tobacco. The synergistic relationship between smoking and alcohol results in a 30-fold increased risk of HNC.^{22, 24}

Infectious agents

Although various infectious agents have been suggested to play a role in head and neck carcinogenesis, current scientific evidence implicates only Epstein–Barr virus (EBV) and HPV as etiologic agents. Although herpes simplex viruses have been suggested as a risk factor for oral cavity cancer,²⁵ and *Helicobacter pylori* for laryngeal cancer,²⁶ confirmation is lacking.

Human papilloma virus

In contrast to non-oro-pharyngeal cancers, the incidence of oropharyngeal squamous cell carcinoma (OPSCC) has increased in recent decades, specifically among younger age groups,^{27–31} given the rising incidence of oropharyngeal cancers associated with HPV infection.^{32, 33} HPV is associated with approximately 70% of OPSCC in the United States.³⁴ HPV may also play a role in the etiology of SCCs arising in the sinonasal tract.³⁵

HPVs are deoxyribonucleic acid (DNA) viruses with a unique affinity for human epithelia, and HPV-associated cancers arise from the tonsillar crypts without an overlying epithelial dysplasia. HPV has been well established as an etiologic agent in cervical and anal cancer,³⁶ and over the past decade, several investigators have indicated that infection with HPV is a significant risk factor for oropharyngeal carcinoma.^{37–44} Over 120 different HPV types have been isolated, with low-risk types (e.g., HPV 6, 11) inducing benign hyperproliferation of the epithelium, leading to lesions such as papillomas and warts, and high-risk types (e.g., HPV 16, 18, 31, 33, 35) associated with carcinogenesis.⁴⁵ The prototypical oncogenic types 16 and 18 account for over 90% of HPV-related OPSCC, and are capable of malignant transformation of primary human keratinocytes from genital or upper respiratory tract epithelia.⁴⁶ This transforming potential is attributed to the two HPV oncoproteins, E6 and E7, that inactivate two human tumor-suppressor proteins, p53 and pRb, respectively.^{47, 48} These viral oncoproteins are not only necessary for transformation but also stimulate cellular proliferation, delay cellular differentiation, increase the frequency of spontaneous and mutagen-induced mutations, and promote focal and broad chromosomal instability in transfected cell lines.⁴⁹ Furthermore, in order to maintain a malignant phenotype, a transcriptionally active viral genome appears to be necessary.^{50–53}

The risk factors associated with HPV-associated OPSCC are distinct from HPV-negative tumors, and include oral sexual behaviors and marijuana use. Furthermore, a dose–response relationship has been identified between the risk of developing HPV-positive OPSCC with number of oral sex partners and joint years of marijuana use.⁵⁴ Although oropharyngeal cancer patients presenting without the classic tobacco exposures more commonly have HPV-16-associated tumors,³⁷ it is also possible that there may be synergistic interactions between the traditional oropharyngeal risk factors of tobacco and alcohol with HPV.⁴¹ The potential effect of HPV-16 immunizations in the prevention of cervical carcinomas may help prevent oropharyngeal cancers as well.⁴

EBV

The epidemiologic link between EBV and NPC is quite strong,^{42, 43} and is further supported by the identification of EBV DNA in premalignant nasopharyngeal lesions. Although World Health Organization (WHO) types II and III are overwhelmingly positive for EBV, the virus is also associated with well-differentiated (WHO type I) NPC.⁴⁶ Both serologic and mucosal swab evidence of EBV infection has been used to enhance screening for NPC in endemic areas.⁴² Evidence of EBV DNA in cervical lymph node metastases of unknown primary origin has been used to identify nasopharyngeal primaries. More recently, the detection of EBV DNA in peripheral blood (both cellular and cell-free component) has demonstrated prognostic significance for predicting survival and distant metastases and may become a

biomarker to follow up on these patients.⁵¹

Genetic susceptibility

Since only a fraction of smokers develop cancer, variations in genetic susceptibility may be equally important in disease etiology. A genetic component to this disease is also supported by large family studies demonstrating a three- to eightfold increased risk of HNSCC in first-degree relatives of patients with HNSCC.^{53, 55} According to this hypothesis, inherited differences in the efficiencies of carcinogen metabolizing systems, DNA repair systems, and/or cell-cycle control/apoptosis systems influence risk of tobacco-induced cancers.^{56, 57} Identifying such at-risk individuals in the general population by use of biomarker assays would have a profound impact on primary prevention, early detection, and secondary prevention strategies. Three recent high-impact publications of genome-wide association studies have identified the same lung cancer susceptibility locus in separate populations.^{54, 58, 59} These studies will likely be followed in the near future by similar explorations of genome-wide HNSCC association studies and suggest that tailored prevention of tobacco-associated cancers may be a realistic goal.

Environmental tobacco smoke

In a study of 173 cases of HNSCC and 176 cancer-free controls, environmental tobacco smoke was associated with a more than twofold increased risk of HNSCC, and a dose–response relationship was also observed.⁶⁰ In a separate study of 44 nonsmokers with HNSCC and 132 cancer-free nonsmoker controls, environmental tobacco smoke was associated with a significantly increased risk of HNSCC, and this was particularly true for females and for those reporting exposure at work.⁶¹

Laryngopharyngeal reflux

Observational and anecdotal studies have long suggested that gastroesophageal reflux (GERD) may be associated with laryngeal cancer.^{62, 63} Furthermore, multiple studies have documented a high prevalence of gastric reflux into the laryngopharynx in patients with laryngeal cancer via 24-h pH probe monitoring.⁶⁴ A case-control study of 10,140 hospitalized patients and 12,061 outpatients with laryngeal and pharyngeal cancer and 40,561 hospitalized and 48,244 outpatient controls has been performed using U.S. Department of Veterans Affairs databases.⁶⁵ The diagnosis of GERD was associated with a significantly elevated risk of laryngeal cancer (OR, odds ratio = 2.4 and OR = 2.3 for hospitalized and outpatient groups, respectively) and of pharyngeal cancer (OR = 2.4 and OR = 1.9 for hospitalized and outpatient groups, respectively). However, a large Swedish cohort study of 66,965 patients with discharge diagnoses of heartburn, hiatal hernia, or esophagitis with a follow-up of 376,622 person-years concluded that there was no evidence of a causal association between GERD and either laryngeal or pharyngeal cancer.⁶⁶

Marijuana

Marijuana smoke has a four times higher tar burden and a 50% higher concentration of benzopyrene and aromatic hydrocarbons than does tobacco smoke. Although anecdotal evidence has long suggested that marijuana is a risk factor for HNSCC, few reports have found direct evidence of marijuana as an etiologic factor for HNSCC because most users of marijuana are also exposed to tobacco and alcohol.^{67, 68} A recent case-control study including 240 HNSCC patients and 322 cancer-free controls demonstrated a positive association of fivefold between marijuana use and HPV-related HNSCC, with a dose–response relationship.⁶⁹ However, a large retrospective cohort of 64,855 health maintenance organization (HMO) members found no association of marijuana use with tobacco-related cancers.⁷⁰ Problems of

underreporting of marijuana use and limited sample size of heavy users limit conclusions regarding marijuana use and HNSCC risk.⁷¹

Diet

Epidemiologic evidence from case-control studies suggests that diets high in animal fats and low in fruits and vegetables may be risk factors for HNSCC.^{72, 73} Case-control studies have correlated salted fish consumption with NPC risk, which may be due to the high content of nitrosamine compounds in preserved foods.^{74, 75} Some evidence suggests vitamin A and beta-carotene may be responsible for the protective effect of diets high in fruits and vegetables, and carotenoid deficiency has been considered to be a risk factor for HNSCC and lung cancers.⁷⁶ It is not known, however, which of the more than 500 carotenoids are protective, what chemical interactions may occur, or what protective role other micronutrients in carotenoid-rich foods may play. Others have found that total intake of vitamins C and E are also protective.⁷³ Moreover, diets are complex and difficult to assess and validate; in particular, there are often inaccuracies in translating foods into constituent nutrients. It may be impossible to determine which of the vast array of compounds is most beneficial, and controlling for other dietary variables and confounding risk factors has remained a difficult methodological problem.

Occupation/air pollution

Although occupational exposures probably play a minor role overall in the development of HNSCC, they are major risk factors for malignancies of the sinonasal region.^{77–79} The most important exposures occur in the metalworking, refining, woodworking, and leather/textile industries.^{77, 78} Indoor air pollution is a significant problem in much of the developing world where indoor stoves using biomass or fossil fuels are the primary method of cooking and heating. Although controversial, an expert committee of the National Academy of Sciences has concluded that there is sufficient evidence to consider asbestos as a significant independent risk factor for laryngeal cancer.⁸⁰

Radiation

No significant association has been demonstrated between ionizing radiation and the development of HNSCC. However, SCCs of the lip, like skin cancers, are associated with ultraviolet radiation exposure. Furthermore, exposure to gamma radiation is associated with thyroid cancers, sarcomas of the head and neck, salivary gland malignancies, and paranasal sinus cancers. Although therapeutic irradiation of HNC does not appear to induce second primary SCCs of the aerodigestive tract, it is associated with an increased risk of sarcomas of the head and neck.⁸¹ This is a particular concern for children requiring radiotherapy. Furthermore, environmental, medical diagnostic, and therapeutic radiation exposure to the head and neck are all significantly associated with salivary gland malignancies, with a dose–response relationship.^{82, 83} Mucoepidermoid carcinomas (MECs) appear to be the most common radiation-induced salivary malignancy.^{82, 83} Occupational studies have suggested that indoor exposure to radon gas or volatile chemicals may also increase the risk for HNSCC.⁷⁹

Ultimately, the public health goal is better prevention and early detection of these malignancies by reducing the use of tobacco and alcohol, preventive vaccination against high-risk oncogenic HPV, discovering and avoiding other causative agents, and identifying the genetically susceptible. Unfortunately, HNSCC screening has not been effective, likely due to the rarity of the disease and expertise required for examination.⁸⁴ However, in parts of the world where HNSCC accounts for a major portion of the cancer burden, prevention and screening programs have had some measure of efficacy

where implemented.⁶

Pathologic assessment and biology

Aside from stating that a particular tumor is SCC, additional information reported by the pathologist usually includes tumor grade or differentiation. Unfortunately, differentiation factors have not been consistently accurate in reflecting the biologic aggressiveness of HNSCC.⁸⁵ Prognosis is influenced by many factors other than grade.^{86, 87} These include tumor size, nodal status, site, surface expression of epidermal growth factor receptor (EGFR), host immune response, age, and performance status. P16 expression/HPV status is the strongest independent prognostic factor for survival among patients with OPSCC.⁸⁸

Features reflecting aggressive disease include lymphatic invasion, perineural invasion, lymph node metastases, and penetration of the tumor through the capsule of involved lymph nodes (extracapsular spread [ECS]). A complete discussion of the molecular pathology underpinning HNSCC is beyond the scope of this chapter, and the reader is referred to some of the many reviews in this area.^{89, 90} Intense investigation is ongoing regarding the complex interplay of cellular and genetic alterations that contribute to carcinogenesis and the metastatic phenotype in HNSCC. The fundamental roles of p53, dysregulated receptor tyrosine kinase signaling, apoptotic resistance, angiogenesis, and chemotherapeutic resistance are under active study.

Anatomy

The term “cancer of the head and neck” refers to a diverse collection of neoplasms arising from the anatomic sites that make up the upper aerodigestive tract (UADT). This chapter, however, deals predominantly with SCC, as it accounts for approximately 90% of malignancies in this region. The UADT consists of a complex mucosa-covered conduit for food and air that extends from the vermilion surface of the lips to the cervical esophagus. In common usage, this terminology has been applied primarily to those cancers arising from the mucosal surfaces of the lips, oral cavity, pharynx, larynx, and cervical esophagus. Included in this designation, however, are other important sites, such as the nose and paranasal sinuses, salivary glands (major and minor), thyroid and parathyroid, and skin (both melanoma and nonmelanoma skin cancers). Some cancers arising in this region are typically excluded from the generic designation of HNC. Examples are tumors of the central nervous system, ocular neoplasms, and primary tumors of lymphatic origin.

Because of the diversity of sites and tissues of origin, the biology of tumor growth, patterns of metastases, and natural boundaries for tumor extension, signs and symptoms of disease are quite varied. The anatomy of the region has also dictated that optimal evaluation, diagnosis, and treatment require specific multidisciplinary expertise, including neurosurgery, otolaryngology, head and neck surgery, oral and maxillofacial surgery, cosmetic and reconstructive disciplines, and specialists in radiology, pathology, radiation therapy, and medical oncology. Although the anatomic structures are only millimeters apart, the low metastatic potential and high curability of vocal cord cancers stand in contrast to the early dissemination and poor prognosis of stage-matched pyriform sinus cancers.⁹¹ Clinical differences between cancers in different sites are explained by anatomic factors and major biologic differences. Regrettably, the relatively small number of HNC patients often requires grouping patients for trials. Associated morbidities of disease and treatment involve the special senses to varying degrees, notably speech, mastication and swallowing, smell, and respiratory function, all critically important for social

interaction, a good quality of life, and ultimately, survival.

Oral cavity

The oral cavity is defined as starting at the vermillion border of the lips and extending posteriorly to include the lips, buccal mucosa, anterior tongue, floor of the mouth (FOM), hard palate, upper and lower gingiva, and retromolar trigone. The tongue occupies a major portion of the oral cavity and is contiguous with the FOM. The gingival mucosa overlying the mandibular and maxillary alveolar ridges adheres to the underlying periosteum. The hard palate forms the roof of the oral cavity and consists of mucosa overlying the palatine portion of the maxilla extending from the superior alveolar ridge to the junction with the soft palate, which is the anterior border of the oropharynx. Although the delineation between the oral cavity and oropharynx might seem artificial, the distinction is important because of varying natural history and sensitivity to nonsurgical therapy and numerous functional considerations after surgical resection, which is the mainstay of treatment for this subgroup of diseases.

Pharynx

The pharynx is a musculomembranous tube suspended from the skull base to the level of the sixth cervical vertebra, supported by overlapping constrictor muscles and other muscles arising from the styloid process and skull base. This conduit communicates with the oral cavity anteriorly, the nasopharynx superiorly, and the hypopharynx and larynx inferiorly. It is divided into four sites of clinical importance: the tonsillar area, which makes up the major portion of the lateral pharyngeal wall and blends with the tongue base, soft palate and retromolar trigone, the tongue base, and the posterior pharyngeal wall. Innervation of the pharynx is via the pharyngeal plexus, with contributions from the glossopharyngeal (sensory) and vagus nerves (motor and sensory).

The hypopharynx is divided into three distinct regions: the pyriform sinuses; the posterior surface of the larynx (postcricoid area); and the inferior, posterior, and lateral pharyngeal walls. The pyriform sinuses are paired mucosal pouches wrapped around the larynx, which funnel food around the larynx and into the esophagus. They are bounded superiorly by the pharyngoepiglottic folds and inferiorly by the cricoid cartilage. The sinuses come together at the esophageal introitus and cervical esophagus at the level of C6.

Larynx

The larynx consists of a mucosa-covered cartilaginous framework (thyroid and cricoid cartilages) suspended from the hyoid bone above by the thyrohyoid membrane and attached below to the trachea. The opening to the larynx is continuous with the pharyngeal airway. Unlike the rest of the pharynx, the mucosa of the larynx consists largely of columnar, ciliated, respiratory-type epithelium. Stratified squamous epithelium is found on the upper posterior epiglottis, aryepiglottic folds, and true vocal folds. Notably, lymphatics in the upper larynx are sparse in the true vocal folds, or glottis.

The larynx is divided into three anatomic regions: the supraglottic, glottic, and subglottic larynx. The supraglottic larynx includes the epiglottis, aryepiglottic folds, laryngeal surface of the arytenoids, false vocal cords, and ventricles. The glottic larynx consists of both true vocal cords and the mucosa of the anterior and posterior commissures. It extends from the lateral-most apex of the laryngeal ventricle to 1 cm below the free edge of the vocal folds toward the cricoid. It has few, if any, lymphatics. The subglottic larynx consists of the region bounded by the glottis above and the inferior border of the cricoid cartilage. Lymphatic supply to the subglottic larynx is extensive and bilateral. The infraglottic lymphatics drain to the cervical nodes through the cricothyroid membrane, while supraglottic lymphatics drain through the

thyrohyoid membrane.

Nose and paranasal sinuses

The term “nose and paranasal sinuses” refers to the region of the UADT that starts at the vestibule of the nose anteriorly, is covered by squamous epithelium, and extends posteriorly to the choana, where the nasopharynx begins. By definition, paranasal sinus malignancy does not include the nasopharynx unless by extension. It does include the paranasal sinuses, specifically, the maxillary, ethmoid, frontal, and sphenoid sinuses. Although the most common malignancy of the nose and paranasal sinuses is SCC, the nose and paranasal sinuses pose a particular set of problems that deserve separate consideration. Moreover, nonsquamous cancers may also occur with distinctive patterns of tumor progression and requirements for effective therapy.

Neck

Anatomic considerations in the treatment of cancers of the head and neck must include a thorough understanding of the neural, vascular, and, especially, the lymphatic structures of the neck. Detailed anatomic studies have described the organization of the lymphatic drainage of the UADT. Specific regions of the head and neck and the tumors that arise therein have lymphatic drainage that is consistent and predictable. There are 12 major groups of lymph nodes (six each bilaterally) in the head and neck ([Figure 1](#)),⁹² although only levels I to V play a major role in HNSCC. Primary and secondary echelons of lymph node drainage have been defined for each major region of the head and neck mucosa. A standard rule of thumb is that the lymphatic drainage for any particular region is predicted by the arterial supply of that region. The lip, cheek, and anterior gingiva drain into the submandibular and submental lymph node groups. In addition, the cheek and upper lip also drain into the inferior parotid and facial nodes, while the posterior gingiva and palate drain into the internal jugular chain and lateral retropharyngeal groups. Lymphatic drainage for the mobile tongue is into the internal jugular, subdigastric, omohyoid, submandibular, and submental nodal groups. Midline lesions often drain bilaterally. Although metastases to the lower neck nodes are infrequent from the oral cavity, generally the more anterior the tumor location in the tongue, the more likely it is that metastases also will spread to lower jugular nodes. FOM drainage is similar to that of the tongue. The upper portion of the pharynx drains directly into the upper cervical lymph nodes along the internal jugular chain. The oropharynx and tonsil drain through the parapharyngeal space into the midjugular region, particularly into the jugulodigastric nodes. Retro and lateral pharyngeal nodes can also be involved. The regions of the hypopharynx and larynx drain primarily along the routes of their vascular supply to either the deep cervical nodes along the midjugular (upper pharynx, larynx) or the deep nodes along the lower jugular and paratracheal region (lower pharynx, larynx).

Figure 1 Nodal levels in the head and neck.

For the purposes of local treatment, the various lymph node groups of the neck have been divided into levels. Level I includes the submental group of nodes (IA), located within the triangle bounded by the anterior belly of the digastric muscles and the hyoid bone, and the submandibular group (IB), bounded by both bellies of the digastric muscle and the body of the mandible. Level II nodes consist of the upper jugular lymph nodes located in proximity to the upper third of the internal jugular vein and extending from the skull base to the level of the bifurcation of the carotid artery. The anterior and posterior boundaries are the lateral border of the sternohyoid muscle and the posterior border of the sternocleidomastoid muscle, respectively. Level II is further divided into those lymph nodes located anteroinferior to the vertical plane of the spinal accessory nerve (IIA) and those posterosuperior to the nerve (IIB). Level III nodes include those nodes located adjacent to the middle third of the internal jugular vein from the carotid bifurcation to the plane marked by the omohyoid muscle's crossing over the jugular vein (the level of the cricoid cartilage). Anterior and posterior boundaries are the same as level II. Level IV nodes include the lower jugular group extending from the omohyoid muscle above to the clavicle below. Level V nodes are those located in the posterior triangle in the region of the spinal accessory nerve and the transverse cervical artery. This level is bounded by the anterior border of the trapezius muscle, the posterior border of the sternocleidomastoid muscle, and the clavicle below. This level is further divided into Va and Vb

nodes, with Va nodes being those nodes located above the plane along the inferior edge of the cricoid and including the chain of nodes superior to the spinal accessory nerve posterior to the sternocleidomastoid muscle. Vb nodes are the nodes below the cricoid plane, inferior to the spinal accessory nerve and include the nodes along the transverse cervical artery and all of the supraclavicular fossa.

Diagnosis and staging

Since site and stage of disease at the time of diagnosis are the most important prognostic factors in the treatment of HNSCC, the identification and treatment of early-stage cancers generally correlates with excellent survival. Most dysplastic lesions or *in situ* carcinomas of the oral mucosa occur as red (erythroplasia) or white (leukoplakia) patches that may be readily apparent on visual examination. In areas less easily visualized directly, such as the larynx and hypopharynx, early lesions cause such symptoms as chronic hoarseness and sore throat and, with progression, referred otalgia or dysphagia. Such symptoms demand visualization of the larynx and hypopharynx usually by fiberoptic approaches.

Dysphagia, odynophagia, otalgia, hoarseness, mucosal irregularities and ulceration, oral or oropharyngeal pain, weight loss, and the presence of an unexplained neck mass are the most common presenting symptoms of invasive HNSCC. The predominant symptoms vary with the site: chronic dysphagia or odynophagia demands thorough visualization of the oropharynx, hypopharynx, and esophagus; chronic hoarseness demands visualization of the larynx; chronic unilateral serous otitis media in an adult may be a result of cancer of the nasopharynx blocking the eustachian tube; and unilateral nasal polyps, nasal obstruction, or epistaxis is a common presenting sign of nasal cavity or paranasal sinus neoplasms. A firm or hard unilateral cervical mass represents malignancy until proved otherwise. In persons older than 20 years, such a mass represents neoplasm more than 80% of the time, and 60% of these neoplasms are due to metastatic spread from an UADT primary.

In patients presenting with a suspicious neck mass, a complete head and neck examination usually reveals the primary malignant tumor ([Figure 2](#)). If it does not, a thorough search for occult primary cancers both above and below the clavicles is warranted. Technologic advances in fiberoptics and in flexible and rigid endoscopes now provide excellent upper airway visualization and biopsy capabilities that can be performed routinely in the clinic setting.⁹³ Endoscopic evaluation should include the nasopharynx, oropharynx, hypopharynx, larynx, and upper esophagus. Endoscopic evaluation should be accompanied by chest radiography and axial imaging of the head and neck. If these fail to reveal a primary, then consideration should be given for esophagoscopy as well, since it is more sensitive for mucosal lesions of the esophagus than is computed tomography (CT). Most commonly, occult primaries responsible for neck metastases occur in the nasopharynx, tongue base, tonsil, or hypopharynx. In the absence of an identifiable mass, directed biopsies of these sites are indicated during endoscopic evaluation, and, if present, bilateral tonsillectomies should be performed if a primary is not identified. Metastasis to a solitary left supraclavicular lymph node (Virchow's node) is occasionally seen with infraclavicular cancer, especially colon cancer. Generally, isolated metastatic supraclavicular masses (level IV) derive from breast, lung, or infradiaphragmatic neoplasms. Thyroid malignancies may also metastasize to this area.

Figure 2 Untreated N3 disease in a patient with HNSCC.

Imaging with CT and magnetic resonance imaging (MRI) is frequently used to supplement the clinical evaluation and staging of the primary tumor and regional lymph nodes. Ultrasonography, when combined with fine-needle aspiration (FNA) technique, is an effective means for staging the neck, thyroid, and salivary glands. Open biopsies should be performed only after attempts by FNA of suspicious nodes are nondiagnostic. If an excisional biopsy is required because FNA is inconclusive or not feasible, then the surgeon and patient should discuss the advisability of neck dissection if the mass should prove to be metastatic SCC. The potential ramifications of false-negative results on FNA are inherently obvious. Accuracy of the cytological interpretation of the aspirate is directly dependent on the skill and experience of the ultrasonographer and pathologist.

Positron emission tomography (PET) imaging has a demonstrated role in management of HNC. Highly elevated primary tumor fluorodeoxyglucose standardized uptake values (FDG SUVs) may predict for more aggressive disease and inferior treatment outcomes.^{94–96} FDG-PET can provide over 90% sensitivity and specificity for upfront staging of both primary and cervical neck nodal disease,⁹⁷ can localize occult local primary disease,^{98, 99} or distant metastases¹⁰⁰ not elicited by anatomic imaging or physical examination. Combined FDG-PET/CT imaging may further improve neck staging accuracy results.^{101, 102} Incremental superiority of FDG-PET for regional staging of the neck relative to CT or MRI alone was confirmed by a meta-analysis of retrospective and prospective studies encompassing over 1200 FDG-PET imaging cases with confirmatory neck dissection pathology.¹⁰³ Analysis of this dataset revealed FDG-PET to be sensitive (79%) and specific (86%) for this indication. Recent prospective series in early-intermediate T-stage oral cavity and oropharyngeal cancer patients suggest that FDG-PET can potentially guide more appropriate management of clinically N0 patients when directly correlated with CT and sentinel node biopsy¹⁰⁴ or with CT/MRI findings.¹⁰⁵

Considerable interest has recently focused on FDG-PET monitoring of disease response to radiotherapy or chemoradiotherapy. A number of groups have found that FDG-PET posttreatment restaging provides

high negative predictive power;^{106–108} accordingly, there is now growing acceptance of withholding consolidative neck dissection following radiotherapy in the absence of residual FDG-avid adenopathy,¹⁰⁹ although others argue that expert clinical interpretation of serial CT imaging could achieve similar results.^{61, 110} FDG-PET/CT may eventually prove useful for improving delineation of disease targets for advanced radiotherapy planning.¹¹¹ However, challenges for this remain, particularly for identification of validated thresholding techniques to precisely distinguish FDG-avid disease from bystander tissues.^{112, 113} At MD Anderson Cancer Center, we routinely use FDG-PET/CT to supplement anatomic imaging and clinical examination for radiotherapy planning; however, we do not use negative FDG-PET results to defer treatment of suspicious findings identified by examination or conventional restaging techniques after chemotherapy.

Staging criteria for cancers arising in the UADT, paranasal sinuses, and salivary glands have been developed by the American Joint Committee on Cancer (AJCC) ([Table 1](#)). The criteria undergo regular reevaluation and modification. The most current version referred to in this chapter is the 7th edition.¹¹⁴ The stage groupings are based on T (primary tumor), N (regional node), and M (distant metastasis) designations. Because of variations in the growth, behavior, and prognosis of HNCs according to site of origin and extent, differences exist in the staging criteria for each anatomic site. However, except for tumors arising in the nasopharynx and those of the thyroid, there is uniformity in the nodal staging criteria and stage grouping ([Table 2](#)).

Table 1 AJCC clinical tumor stage and groupings for head and neck cancer

Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T1	N1	M0
	T2	N1	M0
	T3	N1	M0
Stage IVA	T4a	N0, N1, or N2	M0
	Any T	N2	M0
Stage IVB	Any T	N3	M0
	T4b	Any N	M0
Stage IVC	Any T	Any N	M1

Table 2 AJCC clinical tumor staging characteristics for regional lymph nodes and distant metastases

Regional lymph nodes	
Nx	Regional lymph nodes cannot be assessed
N0	No evidence of regional lymph node metastases
N1	Metastasis in single, ipsilateral regional lymph node <3 cm in greatest dimension
N2a	Metastasis in single, ipsilateral regional lymph node between 3 and 6 cm in greatest dimension
N2b	Metastasis in multiple ipsilateral regional lymph nodes, none >6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral regional lymph nodes, none >6 cm in greatest dimension
N3	Metastasis to regional lymph node >6 cm in greatest dimension
Distant metastases	
Mx	Presence of distant metastasis cannot be assessed
M0	No evidence of distant metastasis
M1	Distant metastases are present in one or more locations

Careful documentation of tumor extent and accurate staging classification are crucial for discussions of the results of different treatment approaches. Restaging after treatment or for recurrent cancers must be clearly designated and separate from the primary staging of previously untreated cancers. Postsurgical, or pathologic, staging is important in the primary treatment of HNC because of the increasing use of postoperative radiation therapy (PORT) and/or adjuvant chemotherapy for patients with locally aggressive tumors, ECS into the soft tissues of the neck, close or positive margins, and perineural invasion.

It should be noted, however, that as good as the widely accepted AJCC staging system is for HNC, it still falls short in that it too often fails to distinguish between deeply infiltrative tumors and those that are superficial or exophytic. Experience shows that this distinction is an important one and can have a significant impact on survival. Moreover, the recent emergence of HPV-positive cancers presents an essentially distinctive group of patients for whom some of the older baseline staging data may not be fully applicable.¹¹⁵ Future revisions to the AJCC for HPV status, particularly for oropharyngeal cancers, are anticipated.

General principles of treatment

After a histological diagnosis has been established and tumor extent determined, the selection of appropriate treatment of a specific cancer depends on a complex array of variables, including tumor site and stage, HPV status, prognosis, relative morbidity of various treatment options, patient performance and nutritional status, concurrent health problems, social and logistic factors, therapeutic options for potential recurrences or second primaries, and patient preference. These variables are each considered with respect to the established effectiveness of various treatment regimens available.

The overall management goals in treating patients with HNC are to achieve the highest cure rates at the lowest cost in terms of functional and cosmetic morbidity. The achievement of these goals requires the close cooperation of an interdisciplinary team of practitioners representing surgery, radiation and medical oncology, prosthodontics, dentistry, speech language pathology, social services, dietetics, physical and

rehabilitative medicine, pathology, nursing, and often psychiatry.

Effective rehabilitation is an important part of the overall treatment of HNC. Modern advances in surgical reconstruction, microvascular free-tissue transfer, and prosthodontics have significantly improved posttreatment function.¹¹⁶ Rehabilitation concerns must be addressed at initial treatment planning and carefully integrated with the various treatment modalities used. Pretreatment dental evaluations, and speech and swallowing assessments should be routinely performed. Needed dental care and/or extractions should be performed prior to radiation to reduce the risks of dental-associated mucositis and osteoradionecrosis. The overall impact of treatment and rehabilitation on patient quality of life is an important issue that may require specialized social or psychiatric support systems for the patient and family. Furthermore, attention must be paid to nutritional support, and early intervention with the placement of enteral access for gastrostomy feeding should be entertained in selected patients. Contemporary combined approaches of chemotherapy and radiotherapy are often associated with severe mucocutaneous treatment effects that must be addressed. Finally, the prolonged nature of treatment for advanced disease, which may extend over many months, requires consideration of the social and financial impact of treatment decisions on the patient, the family, and the patient's career.

Biopsies of primary tumors need not be excisional unless the biopsy procedure is sufficient for local control. Oncologic principles of surgical resection must not be compromised by ill-conceived reconstructive efforts or attempts at modifying the necessary resection in order to minimize functional or cosmetic morbidity. Gross residual cancer or positive surgical margins after tumor resection portend high risk for treatment failure. Appropriate management must also include the use of precise modern techniques of conservative surgical resection (e.g., partial laryngectomy and functional neck dissection) that, in selected patients, have cure rates similar to those of more radical techniques.

Oral premalignancy

Appropriate management of leukoplakia and erythroplakia lesions includes a high index of suspicion, particularly in high-risk individuals. Although both lesions are considered premalignant, erythroplasia lesions are of greater clinical concern, since approximately half of these lesions contain carcinoma *in situ* (CIS) or invasive cancer. Erythroplakia mandates biopsy to rule out invasive cancer. The management of erythroplakia and leukoplakia depends on the location, extent, and histology. The diffuse field effect and multifocal nature of the epithelial carcinogenic process support the need for effective prevention. Various molecular markers, including aneuploidy, loss of heterozygosity (LOH) and podoplanin expression portend a high risk of transformation in dysplastic oral intraepithelial neoplasia (IEN).^{117–119} White lesions can be confused with mucositis; lichen planus; local tissue irritation from mechanical, thermal, or chemical trauma; histoplasmosis; candidiasis; and other infectious processes.

Topical supravital staining with toluidine blue of suspicious lesions can be helpful in identifying areas for biopsy and in screening high-risk populations. Toluidine blue staining was found to be associated with LOH in dysplastic, minimally dysplastic, or nondysplastic oral IEN, which suggests the potential of toluidine blue for identifying oral IEN with a high risk of cancer and perhaps for helping guide surgical margin widths.^{120, 121} Lesions that persist despite the removal of local irritating factors, or those that are associated with ulceration, vertical growth, induration, a recent change in size, or pain, should be sampled by biopsy and/or excised. Despite aggressive local therapy, complete surgical resection (as defined by the absence of dysplasia at the margins) does not prevent oral carcinoma development in cases of aneuploid dysplastic leukoplakia.¹¹⁸ In this context, a targeted therapy prevention approach has been tested in a phase II randomized trial (EPOC). This study compared erlotinib, an EGFR inhibitor, versus

placebo in patients with high-risk oral premalignant lesions harboring LOH. Despite the negative results for the overall population, there was a trend toward improved oral cancer-free survival in patients who did not have a prior oral cancer.¹²² Future research in this area should evaluate the roles of optimal surgical margin width and complete resection as confirmed by molecular analyses in reducing the cancer risk associated with molecularly defined high-risk oral IEN.

Overview of natural history and treatment by site

Oral cavity

Both tumor and treatment may significantly compromise speech and deglutition, particularly for those patients in whom cancer involves the tongue, FOM, or mandible. Despite the fact that this region is readily amenable to visual examination and bimanual palpation, more than 50% of patients are diagnosed in advanced stages. The current T staging of oral cavity primaries is presented in [Table 3](#).

Table 3 Primary tumor staging characteristics for oral cavity and oropharynx carcinoma

Tx	Primary tumor cannot be assessed (as occurs after excisional biopsy)
T0	No evidence of primary (as in unknown primary tumors)
Tis	Carcinoma <i>in situ</i>
T1	Tumor is 2 cm or less in greatest dimension
T2	Tumor is between 2 and 4 cm in greatest dimension
T3	Tumor is >4 cm in greatest dimension
T4	A: Moderately advanced local disease: Tumor invades adjacent structures (through cortical bone, maxillary sinus, skin, tongue musculature, deep tissue, nerves)
	B: Very advanced local disease: Oral cavity: tumor invades masticator space, pterygoid plates, skull base, encases carotid artery Oropharynx: tumor invades prevertebral fascia, encases carotid artery, or involves mediastinal structures

Lips

SCCs of the mucosal surface of the lips are the most common oral cavity cancers. An important distinction must be made with cancers of the skin surrounding the lips, which are considered cutaneous malignancies. Over 90% occur on the lower lip, usually on the exposed vermilion border, midway between the midline and the oral commissure.¹²³ Well-differentiated and verrucous cancers rarely metastasize. Poorly differentiated and spindle cell varieties tend to grow aggressively and metastasize commonly. Perineural infiltration of large nerves is indicative of aggressive disease and often requires combined therapies.

Considerations in the treatment of lip cancers include (1) oncological control of the disease, (2) a functional oral sphincter with oral competence, and (3) acceptable cosmetic outcome. These goals may be achieved with either primary radiation or surgery when the tumors are less than 2 cm in size or very superficial. Larger or deeply invasive lesions, however, are best treated with surgical resection and reconstruction, which allow for greater accuracy in evaluating the extent of tumor and nerve or lymphatic

involvement. Frequently, adjacent precancerous changes are present, which can also be treated with surgery (lip shaving and advancement) to prevent recurrences or the development of second primary tumors.^{124, 125} For larger lesions, primary reconstruction with local, regional, and sometimes free-tissue flaps avoids defects that result from tissue loss with radiotherapy, provides for future reconstructive and treatment options, and decreases the risk of osteoradionecrosis of the mandible. Lesions demonstrating extensive infiltration, bone involvement, or lymphatic metastases should be managed with combined surgery and PORT.

Radiation therapy techniques for management of lip cancers include external irradiation, interstitial implants, and combinations of both. Local tumor control rates with irradiation exceed 80%,^{126, 127} with determinant survival at 5 years (including surgical salvage) in excess of 95%. Similar tumor control and survival rates are reported with primary surgical excision.¹²⁸ Regional metastasis decreases the survival rates to approximately 55%.^{129, 130} The 5-year survival rates for patients with carcinomas of the upper lip are lower than for those with similar lower lip lesions and range from 40% to 60%.¹³¹ Involvement of both lips and the lateral commissure is uncommon. The prognosis for commissure lesions is not as good as for cancers of other areas of the lip.

Tongue

Tongue cancers account for approximately 25% of oral cavity SCCs and most commonly arise in the anterior two-thirds of the tongue on the lateral or ventral surface. Infiltration of the underlying tongue musculature occurs early. The biologic aggressiveness of T1 and T2 (<4 cm) tongue cancers is noteworthy and is reflected in higher rates of occult regional metastases than those of similarly staged lesions arising from other oral sites. Occult nodal metastases are present in 30–40% of early lesions.¹³² Bilateral nodal involvement can occur with cancers of the tip or the midline of the tongue. Locoregional recurrence in patients with tongue cancer accounts for 60–70% of cancer deaths. Distant metastases account for 10–15% of deaths, and second primaries in the UADT account for approximately 20–40%.^{132, 133} The management of carcinomas of the tongue has been significantly influenced by an increased appreciation of the aggressiveness of seemingly small but deeply infiltrative lesions, the high rate of occult lymph node metastases, and improvements in soft tissue and bony reconstruction. Although surgical excision alone has been the mainstay of treatment, combined surgery and adjuvant radiation therapy to include the primary site and regional nodes is commonly used for advanced cancers (stages III and IV) and is being used increasingly for small stage II cancers that exhibit pathologic indicators of lymph node metastasis or perineural invasion ([Figure 3](#)). Postoperative chemoradiotherapy is indicated for adverse pathologic findings of perineural invasion, nodal ECS, or close surgical margins.¹³⁴

Figure 3 (a) T1 N0 SCCA of the oral cavity. (b) CT scan revealing no lymphatic metastasis. (c) Hemiglossectomy resection. (d) Staging supraomohyoid neck dissection.

For stage I cancers, surgical excision is effective and expeditious, with excellent preservation of function. For stage II lesions that are infiltrative, hemiglossectomy or partial glossectomy achieves excellent tumor control rates and should be combined with dissection of neck nodes at risk (supraomohyoid dissection) to provide accurate information about staging and determine the need for PORT. Free-tissue transfer reconstruction can significantly offset the morbidity of hemiglossectomy.

Extension of cancer to the FOM or the mandible may necessitate partial mandibulectomy or segmental mandibular resection. Modern reconstructive techniques with vascularized composite bone and soft tissue free flaps, titanium metal prostheses, and dental implants have improved the functional and cosmetic results of major mandibular resections. An elective neck dissection is recommended for lesions with >4 mm of invasion owing to the risk of occult nodal disease.

For more advanced primary lesions (stages III and IV), surgery and postoperative external beam radiation are generally used. No prospective controlled trials have proved the superiority of combined therapy over surgery alone for disease without nodal metastases, but retrospective studies indicate improved

locoregional control rates.^{135–138} These improvements have generally been offset, in part, by an increased frequency of distant metastases and second primaries. Surgical management generally consists of partial glossectomy and neck dissection, with the mandible being spared unless directly involved. In instances with limited periosteal invasion, partial mandibular resections that spare mandibular continuity and maintain function can be performed. When tumors extend to the midline or involve the tongue base, subtotal or total glossectomy may be necessary. Continued advances in reconstructive techniques have improved the functional results of these aggressive resections. Provision for temporary tracheostomy and prolonged enteral nutrition should be made. Total glossectomy or sacrifice of both hypoglossal nerves frequently necessitates permanent feeding gastrostomy. Current experience indicates that total glossectomy can, in highly select patients, be accomplished without the need for laryngectomy, although prolonged or even permanent parenteral feeding will likely be required.¹³⁹ PORT is generally administered within 4–6 weeks of surgery. High-risk surgical margins or ECS can be treated to a high-dose or with concomitant chemoradiotherapy. For advanced oral cavity cancers, both ipsilateral and contralateral necks are irradiated, with the dosage determined by the extent of disease. Close surgical margins are often treated to high doses (66–70 Gy) because of the difficulty in eradicating even small amounts of tumor in the tongue after glossectomy. Even with combined therapy, estimated 2-year disease-free survival (DFS) and OS rates for advanced disease are about 50%. The 5-year survival rates range from 50% to 70% for stages I and II to 15–30% for stages III and IV.^{140–144}

Floor of mouth (FOM)

FOM cancers occur with a frequency similar to that of tongue cancer. Early spread to adjacent areas (gingiva and periosteum of the mandible) is common. The periosteum of the mandible is a natural barrier to invasion. Fixation of the tongue is a sign of deep invasion. The tumor may extend to or through the mylohyoid muscle, which serves as a natural barrier to direct spread below the hyoid bone. Lymph node metastases at presentation are seen in approximately 40% of patients. The occult metastatic rate increases with the T stage of the primary: T2 tumors have a 40% and T3 tumors a 70% occult metastasis rate.^{145, 146}

First-echelon nodes of lymphatic drainage include the submandibular and jugulodigastric lymph nodes (levels I and II). Evaluation for early mandibular involvement is facilitated by palpation. since fixation to the mandible indicates periosteal involvement and direct bone invasion is present in 50–60% of such tumors. This distinction is often aided with bone windows on CT.

Small cancers (T1, T2) are generally treated effectively by wide resection. Lateral FOM tumors can often be resected transorally and the resection defect closed with the advancement of adjacent mucosa, skin grafts, or secondary intention. Sialodochoplasty of the severed submandibular duct can be performed for superficial lesions. An elective selected neck dissection is performed for T1 tumors with more than 4 mm of invasion and for all T2–4 cancers. Bilateral neck dissections should be performed for anterior FOM lesions, as both necks are at risk for occult metastasis due to the nature of lymphatic drainage in this region. If nodal metastases are present, therapeutic neck dissection is indicated. Surgery remains the mainstay of treatment of early FOM malignancies, achieving excellent functional and curative results.

More advanced FOM cancers (T3, T4) are generally treated with resection combined with similar approaches to that described for oral tongue cancers in the prior section ([Figure 4](#)). Again, mandibular continuity-sparing procedures with cortical resections can often be employed. In these instances, we have found fasciocutaneous flaps to offer excellent FOM and tongue reconstructive potential. Large mucosal and soft tissue surgical defects are typically reconstructed with free-tissue transfers, and contemporary management of mandibular defects entails bony reconstruction with either a fibula or scapula free flap.

Figure 4 (a) T3 N0 floor of mouth SCCA. (b) Deep infiltration of the intrinsic tongue musculature on axial imaging.

Treatment results are influenced by the size of the primary tumor, presence of lymph node metastases, degree of mandibular involvement, and adequacy of resection. The 5-year survival rates for stage I and II FOM carcinomas range around 80%.¹⁴⁶ Cancers that cross the midline or involve the tongue or the mandible are associated with 5-year survival rates of 50–60%.¹⁴⁷ Survival rates for more advanced lesions (stages III and IV) are less than 50%. The major advantage of combined treatment (radiation and surgery) in these patients is improved control of neck disease. Recurrence in the untreated, clinically negative neck is the most frequent site of failure in patients treated only with surgery.¹⁴⁸ For patients with multiple nodal metastases, induction chemotherapy (IC) is under study¹⁴⁹ as there is high risk for later development of distant metastases. Continuing surveillance for metachronous second primary cancers in the head and neck, esophagus, or lungs is advised.^{150, 151}

Gingival and buccal mucosa

Gingival cancers occur most commonly (80%) in the lower gingiva, posterior to the bicusps. For both sites, trismus is an ominous sign indicating extension to the masseter or pterygoid muscles. Occult nodal metastases have been documented in as high as 30% of buccal cancers and elective neck dissection recommended in all but the earliest of cancers.¹⁵² Exophytic tumors tend to be papillary or verrucous in appearance and can be confused with benign hyperkeratosis.

Small, superficial gingival cancers can be effectively treated with surgical resection transorally with excellent preservation of function. Even larger lesions requiring partial maxillectomy or alveolectomy can be resected without external incision. For larger lesions (T3 and T4), segmental mandibulectomy and/or maxillectomy is required, and adjuvant radiation is frequently recommended (Figure 5). Elective neck dissection should be performed for advanced lesions of the mandibular gingival, as these lesions tend to have occult metastases. Limited data are available on the behavior of maxillary ridge and hard palate cancers, but these lesions can metastasize to the lateral neck nodes, and thus elective management of the neck is strongly encouraged, whether with neck dissection or neck irradiation.¹⁵³ Clinically positive neck nodes warrant neck dissection at the time of the resection of the primary tumor.

OS rates for gingival and buccal cancers depend on tumor size, bone involvement, and node metastases. Surgical results are clearly superior to those of radiation when bone involvement is present.^{152, 154}

Retromolar trigone

Cancers arising in the retromolar trigone are rarely confined to that gingiva, but often involve adjacent buccal mucosa, anterior tonsillar pillar, the FOM, and/or posterior gingiva. The risk of clinically positive and occult lymph node metastases is higher than with other gingival cancers. Frequent involvement of periosteum mandates partial (rim or marginal) mandibulectomy as part of the surgical management, even for small lesions. Primary radiation therapy is reserved for superficial lesions that cover a large surface area, such as extension to the soft palate or buccal mucosa, and remain mobile. Moderately advanced or deeply invasive lesions are best treated with surgical resection (mandibulectomy and neck dissection), followed by postoperative adjuvant therapy, as indicated.

Oropharynx

The clinical staging of oropharyngeal cancers is similar to the staging of oral cavity cancers ([Table 3](#)). Tumors arise most commonly from the palatine arch, which includes the tonsillar fossa and base of the tongue. The recent identification of HPV as the major etiological factor in the development of OPSCC has led to a recognition of a distinct disease phenotype. Many of these patients are younger and without any history of smoking, and molecular analysis of these tumors reveals the presence of HPV DNA. Clinically, HPV-associated tumors are small, but the nodal burden is more robust.³⁷ Aside from a cervical mass of unknown etiology, the most common presenting symptom is chronic odynophagia (often unilateral) and referred otalgia. Change in voice, dysphagia, and trismus are late signs. Regional lymphatic metastases occur frequently and are related to the depth of tumor invasion and tumor size. Upper cervical nodes are generally first involved, but lower nodes can become clinically involved with skipping of the upper first-echelon nodes. Bilateral lymphatic metastases can occur, particularly with cancers of the soft palate, tongue base, and midline pharyngeal wall. The retropharyngeal lymph nodes are also common sites of metastasis and warrant evaluation when planning treatment.

Management of oropharyngeal cancers is very challenging, given the essential role this anatomic site plays in breathing, speech, and swallowing. Therefore, the goal of treatment is to not only achieve oncologic cure but also to preserve the multimodal function of the oropharynx. Traditional surgical approaches to the oropharynx are associated with significant morbidity, which prompted a shift toward nonsurgical modalities in the 1990s, specifically utilizing radiation or chemoradiation, which have been the mainstay therapeutic approaches for the past 15–20 years.^{155, 156} However, recent technological innovations have led to a resurrection of surgical options through a transoral robotic approach (TORS), which allows for adjuvant therapy to be modified on the basis of pathological findings of disease. This novel paradigm can reduce radiation doses and may theoretically decrease long-term side effects. These advantages become imperative considering the emerging population of young patients with HPV-related cancer.

Tumor-related contraindications for TORS include unresectable cervical lymphadenopathy, mandibular invasion, pharyngeal wall or tongue base involvement requiring resection of greater than 50% of these sites, radiologic evidence of carotid involvement, and fixation to the prevertebral fascia. The other limitation of TORS is access, and therefore a thorough preoperative assessment of the patient and tumor

characteristics is essential. This should include an evaluation of the dentition, presence of trismus or tort, tongue size, degree of neck extension, sequelae of previous treatment, and the tumor extent. The oncologic outcomes for robotic surgery have been favorable thus far, with OS and DFS rates ranging 82–100% and 86–96%, respectively. Although the role of TORS is still being determined, early oncologic results from several case series are comparable to the outcomes observed with radiation or concurrent chemoradiation.¹⁵⁷

Tonsil

The traditional treatment of stage I and II tonsillar neoplasms is radiation therapy as a single modality. Transoral wide local excision of small, superficial lesions may be locally effective, but does not address the high potential of occult lymph node metastasis. While surgery and primary radiation offer comparable locoregional control for small tumors, patients with HPV-negative tumors may more often require PORT.¹⁵⁸ For patients with early-stage HPV-positive tumors, TORS with neck dissection offers excellent local-regional control, without the need for adjuvant radiotherapy.¹⁵⁷ Surgical management of advanced cancers results in poor patient function and, therefore, combined chemotherapy and radiotherapy approaches are utilized ([Figure 6](#)). For patients with nodal disease (N1-2), the addition of PORT to TORS is associated with excellent oncological and functional outcomes, and spares the need for concurrent chemoradiotherapy. There is a growing rationale for avoiding XRT, particularly among patients with p16-positive (HPV-related) small tumors (T1–2) and small volume neck disease (N1), and this approach is currently under investigation in a multi-institutional clinical trial (ECOG 3311).

Figure 6 (a) T2 N2b SCCA of the oropharynx, clinically small lesion. (b) Deep infiltration into the parapharyngeal space is evident on CT scanning. (c) On PET-CT imaging, two distinct lesions are evident, the primary tumor and a posterior lymphatic metastasis.

Alternatively, radiation for early tonsillar cancers offers the advantage of treating upper echelon lymph nodes along with the primary tumor. Treatment is usually unilateral unless extension to the tongue base or midline soft palate is present.¹⁵⁹ Ipsilateral treatment portals allow sparing of the contralateral mucosa and salivary glands. Modern treatment techniques, such as IMRT, permit conformal dose delivery which can reduce the potential morbidity of radiation treatment, particularly by reducing radiation-related xerostomia. Initial institutional reports have indicated encouraging treatment outcomes with the use of IMRT in oropharyngeal cancer patients,^{160–164} this is discussed in greater detail in the section titled “Radiotherapy.”

Survival rates for patients with advanced (stage III/IV) tumors vary according to HPV/p16 expression status and smoking history. Patients with HPV-positive tumors and less than 10 pack-year smoking history

(low-risk) treated with the combination of chemotherapy and radiotherapy have a 3-year survival rate of 93%; while a smoking history of more than 10 pack-years and HPV-/p16-negative tumor undergoing chemoradiation have a 3-year survival rate of 46.2%.⁸⁸ In general, surgery is rarely recommended for advanced tonsillar tumors unless the mandible is grossly invaded. When surgery is planned, postoperative concurrent therapy should be anticipated in the properly selected patient.

Tongue base

Cancers of the base of the tongue pose a more difficult therapeutic problem than do tonsillar carcinomas, particularly for HPV-negative malignancies. Most patients with HPV-negative tumors present with advanced primary site disease due to the silent nature of these tumors, resulting in frequent regional metastases, greater treatment morbidity, and poor patient survival. Due to the aggressive nature of HPV-negative tumors, most are treated with definitive radiation with or without chemotherapy, although a role for TORS is currently under clinical investigation. Owing to the rich network of lymphatics present in the base of the tongue, 75% of patients will present with stage III or IV disease ([Figure 7](#)). Understaging of the primary tumor is common because these cancers tend to be diffusely infiltrative beyond their clinical appearance.¹⁶⁵

Figure 7 (a) Massive T4 N2c SCCA of the oropharynx (left base of tongue). (b) Multilevel bilateral nodal metastases present.

The results of radiation therapy alone as definitive treatment of small primary tumors (T1, T2) are better for exophytic than for deeply invasive tumors.¹⁶⁶ Radiation alone is generally reserved for those patients without clinical nodal metastases, but can be combined with planned neck dissection for patients with clinically positive nodes that persist after the completion of radiation-based approaches.

Surgical management of early primary tongue-base tumors (T1–2) achieves results similar to those from radiation alone. Advances in robotic surgery have prompted the application of this technology in the management of tongue-base cancers, and is now a well-established approach in the HPV-positive population.¹⁶⁷ Elective neck dissection can serve as a staging procedure, thereby providing a rationale for adjuvant radiation therapy. To date, no prospective randomized trial data that compare surgery alone with combined surgery with either preoperative or postoperative radiation are available.

Radiation therapy is a standard approach for definitive treatment for the oropharynx which combines the goal of an oncological cure with organ preservation. The current XRT regimens are the results of several large randomized trials that have demonstrated favorable OS and DFS,¹⁶⁸ although permanent dysphagia and gastrostomy tube usage rates remain substantial.¹⁵⁶ Total radiation dosages and overall treatment times are regarded as important variables for oncologic response and for tissue toxicity. Several studies have shown that altered fractionation improved the locoregional rate, and a meta-analysis of 15 trials demonstrated a survival advantage with altered fractionation regimens.¹⁶⁹ Since cancers of the oropharynx are adjacent to several critical structures, the ideal dose distributions would tightly conform to the target area and spare the nonaffected surrounding tissue, which has led to the use of IMRT as a standard of care for HNSCC.¹⁷⁰

The classic pattern of relapse after RT in OPSCC has been locoregional recurrence, attributed to the development of radioresistant tumor cells that persist after treatment. To overcome this resistance, chemotherapy has been added to sensitize the tumor cells to the damaging effects of ionizing radiation. For patients with locally advanced oropharyngeal cancer, a pivotal randomized phase III trial by the French GORTEC group revealed an improvement in both progression-free survival (PFS) and 5-year OS for patients receiving combined modality therapy (42% and 51%) versus radiation therapy alone (22.4% and 15.8%) and improvement in locoregional control rates in the chemoradiation arm (66%) versus radiation therapy alone (42%). Despite these benefits, similar rates of distant metastases were observed in both arms (11%) and more significant side effects, including hematologic toxicities and grades 3 and 4 mucositis were observed in the chemotherapy arm.^{171, 172} These toxicities led to a higher rate of temporary gastrostomy tube usage in the combination arm compared to the radiation therapy alone arm. Taken together, these results suggest that the addition of chemotherapy concurrently to radiation therapy improves locoregional control, which translates into both a PFS and OS benefit for these patients, at the expense of more acute toxicities.

The risk of recurrence for locally advanced OPSCC following surgical resection has traditionally been high. For patients with high-risk features, including perineural invasion, multiple positive nodes, and advanced T stage, PORT has been shown to decrease locoregional recurrences. Furthermore, it has been shown that the addition of chemotherapy given concurrently with radiation can improve locoregional control rates in patients with high-risk features, particularly when surgical margins are positive or ECS is present.^{134, 173} Thus, patients who undergo surgical resection for OPSCC should be considered for adjuvant chemoradiotherapy when adverse pathological features are present. Whether this treatment paradigm is necessary for HPV-positive patients is currently under investigation.

Soft palate and pharyngeal wall

Cancers of the soft palate and pharyngeal wall are less common than other oropharyngeal neoplasms. Many soft palate and posterior wall cancers tend to be superficial. Advanced lesions with deep invasion have ready access to the prevertebral fascia, infratemporal fossa, and skull base and can be associated with extensive submucosal spread with clinical skip areas.

Radiation-based approaches as curative treatment are preferred in most cases, even for T3 primary tumors. Resection of most soft palate lesions is associated with severe functional disability. The rates of occult regional metastases are difficult to determine because elective irradiation of bilateral nodal groups is included as part of primary treatment and must include the retropharyngeal lymphatics. Clinically positive lymph nodes at presentation occur in 30% of patients.¹⁷⁴ Small primary tumors with positive nodes can be effectively treated with definitive radiation to the primary tumor and neck. Neck dissections should be performed if disease in the neck persists at 6 to 8 weeks following the completion of XRT.

Pharyngeal wall cancers or palate cancers with extension to the tonsil and those cases with advanced regional metastases are usually treated with combined chemoradiotherapy approaches unless gross mandibular involvement is noted. Overall 5-year survival rates for soft palate and faucial pillar cancers are 60–70% and range from 80% to 90% for T1 and T2 lesions to 30–60% for stages III and IV lesions.¹⁷⁵

Hypopharynx

The hypopharynx represents one of the most lethal sites for HNSCC. Lymph node metastases are clinically evident at time of diagnosis in 70–80% of patients.¹⁷⁶ Primary tumor extension beyond the hypopharynx is common.¹⁷⁷ Hypopharyngeal cancers are characterized by a propensity to spread submucosally to involve the oropharynx or esophagus. Ulcerated deep infiltration and skip areas are anticipated. This leads to difficulties in adequately assessing the margins of the tumor and contributes to poor local tumor control, even with the addition of adjuvant radiation. More than 75% of hypopharyngeal cancers arise in the pyriform sinus, while 20% occur in the posterior pharyngeal wall ([Figure 8](#)). Postcricoid cancers are rare (<5%). Because of the locale of hypopharyngeal cancers, their growth patterns and proximity to the larynx, surgical management often entails total laryngopharyngectomy. Extension to the esophagus will necessitate a cervical esophagectomy.

Figure 8 T1 SCCA of the hypopharynx, involving the posterior pharyngeal wall and extending into the esophageal inlet.

The staging of hypopharyngeal cancer is based on the subsite involved, the size of the tumor, the presence of vocal cord fixation, and the extent of lymph node metastases.¹¹⁴ Staging is critical for treatment planning and must include endoscopic evaluation.¹⁷⁸

Because of the necessity to remove the larynx as part of the surgical treatment of most hypopharyngeal cancers, radiation therapy for early T1 and T2 and in combination with chemotherapy for T3 disease has been investigated.¹⁷⁹ Retrospective analyses have consistently demonstrated that survival rates are lower and locoregional failure rates higher with radiation alone as compared with surgery or surgery and radiotherapy.^{180, 181}

Nevertheless, the functional implications of primary surgery for even the earliest of hypopharyngeal cancers have brought about the primary role of radiation-based approaches. For small (T1) cancers of the hypopharynx, and particularly for superficial posterior pharyngeal wall lesions, radiation therapy alone has been used effectively, with surgery reserved for salvage.¹⁸² Radiation therapy offers the advantage of treating bilateral occult lymph node disease, including that of retropharyngeal nodes, which are frequently involved when cancer arises from the posterior pharyngeal wall. Most patients, however, present with advanced primary tumors (T3–4) and positive lymph nodes. In such patients, local control rates with radiation alone decrease to 50% and salvage surgery is rarely successful. Thus, surgical management remains the mainstay of treatment of most advanced hypopharyngeal cancers. This is especially true when function is poor at diagnosis.

Tumors arising in the lower hypopharynx or postcricoid mucosa often spread to involve the esophagus. Distal submucosal spread into the esophagus can be extensive and requires partial or total esophagectomy. Reconstruction with transposition of the stomach (gastric pull-up), jejunal free graft, or tubed fasciocutaneous free flap is currently recommended.^{183–185} With improved locoregional control following the advent of total laryngopharyngectomy and PORT, disease recurrence more commonly occurs in distant sites (i.e., the lung). Treatment approaches with combined preoperative or postoperative radiation have dramatically improved the control of locoregional disease, but survival rates have not improved as substantially over those with surgery alone because of the increased rates of distant metastases. Postoperative radiation is currently preferred to preoperative radiation because of its lower local recurrence rates, fewer complications, and less difficulty in accurately assessing tumor margins.^{180, 186} The presence of lymph node metastases, extracapsular lymph node involvement, and direct extension of the primary tumor into the soft tissues of the neck are adverse prognostic factors and are indications for postoperative chemoradiotherapy.^{187, 188}

Overall 5-year survival rates range from 10% to 30% for posterior pharyngeal wall cancers and from 20% to 40% for pyriform sinus cancers. The rates of distant metastases range from 20% to 50%^{123, 127} and increase with the extent of lymph node disease.^{176, 189–191}

Larynx

Because of the prominent role the larynx plays in communication, swallowing, respiration, and protection of the lower airway, the treatment of cancer of the larynx presents formidable dilemmas regarding functional consequences in addition to the intrinsic threat to life posed by these cancers. More so than with any other site of HNC, quality-of-life issues have been incorporated into treatment decisions and have echoed throughout the management strategy of the other head and neck sites.

The larynx is divided into three subsites: supraglottic, glottic, and subglottic. Each site is associated with differences in patterns of local spread, risks of lymphatic metastasis, and control rates. Anatomic studies of the vascular and lymphatic compartments of the larynx have defined natural anatomic barriers to cancer spread within the larynx and have contributed to the development of select surgical procedures for partial laryngeal resections of certain cancers.^{192, 193}

The true vocal cords present an effective boundary between supraglottic and subglottic lymphatic spread within the larynx. This anatomic barrier can be compromised by tumors involving the anterior or posterior commissures and with deeply invasive tumors that extend vertically across the true and false vocal cords (transglottic cancers). Normally, the inner perichondrium of the thyroid cartilage also presents an effective barrier to cancer spread. However, cancer involvement of the anterior commissure or transglottic extension is associated with invasion of the thyroid cartilage in 40–60% of cases.¹⁹⁴

Early diagnosis is critical for achieving high survival rates and larynx preservation. Most cancers that are diagnosed at an early stage arise in the glottic larynx. This is because minimal changes of the vibrating vocal cord from tumor growth result in dysphonia or hoarseness. Supraglottic cancers are usually more advanced than glottic cancers at the time of diagnosis because they do not generally produce early symptoms of hoarseness. Rather, the earliest symptoms of a supraglottic cancer are usually sore throat, dysphagia, referred otalgia, or the development of a neck mass representing regional metastasis. Airway compromise may be an early symptom with subglottic cancer.

Modern clinical evaluation of laryngeal cancers includes fiberoptic laryngoscopy, direct laryngoscopy, CT, or MRI of the larynx and neck, as well as videostroboscopic analysis ([Figure 9](#)). Radiological imaging is of value in assessing direct extension to the preepiglottic and paraglottic spaces, detecting cartilage invasion, and evaluating the soft tissues and lymph nodes of the neck. However, the precise evaluation of tumor extent still requires direct laryngoscopy under anesthesia. With large, obstructive tumors, tracheostomy may be required. In some patients, debulking the tumor mass at the time of direct laryngoscopy can obviate the need for tracheostomy and thereby reduce the potential risk of tumor seeding of the tracheostomy site. Even with precise clinical evaluation, inaccurate estimation of tumor extent (usually underestimation) occurs in 30–40% of cases.^{195, 196}

Figure 9 (a) Normal larynx. (b) T3 left glottic SCCA, with obliteration of the normal vocal cord anatomy. Extension onto the supraglottis and onto the arytenoid is evident.

Supraglottic primary tumors account for approximately 35% of all laryngeal cancers.⁸ The staging of supraglottic cancers is based on the subsite or region of the supraglottis involved. Subsites include the false vocal cords, arytenoids, lingual and laryngeal surfaces of the epiglottis, and aryepiglottic folds. The epiglottis itself is also subdivided into the region extending above the plane of the hyoid and that below the hyoid. Suprahyoid tumors tend to have a better prognosis than infrahyoid, with the exception of those invading the aryepiglottic fold to involve the pyriform sinus. This, again, is due to the richer network of lymphatics in the infrahyoid portion of the epiglottis. Early cancers (T1 and T2) can involve one or more subsites but have normal vocal cord motion. Those cancers that cause fixation of the arytenoid or involve the postcricoid region, medial wall of the pyriform sinus, or preepiglottic space are staged T3. Those that extend beyond the larynx or invade thyroid cartilage are staged T4.

Functional and anatomic features also determine the staging of glottic carcinomas. Cancers limited to the true vocal cords are T1, those with extension to an adjacent site or with impaired cord mobility are T2, arytenoid fixation and vocal cord immobility upstages a lesion to a T3. Those tumors with cartilage involvement or extension outside the larynx are T4.

True subglottic cancers that are limited to the subglottic region (T1) or to the subglottis and true vocal cords (T2) are early cancers. Fixation of the vocal cord (T3) and cartilage invasion or extension outside the larynx (T4) is associated with a worse prognosis. The nodal classification for staging is the same as for other HNSCC sites.

Although controversy exists regarding the optimal treatment for larynx cancer, at the University of Texas MD Anderson Cancer Center, curative radiotherapy is generally the treatment of choice for early-stage laryngeal lesions. For moderately advanced lesions, one must consider the trade-offs between definitive radiotherapy with salvage surgery held in reserve versus definitive surgery or combined chemotherapy and radiation therapy approaches. A number of factors, aside from stage, warrant consideration in determining the optimal treatment strategy, including patient's age, medical comorbidities, laryngeal function, and rehabilitative potential. Advanced T4 lesions are treated with surgery and PORT.

Radiation therapy remains the management of choice for early glottic cancers. Nevertheless, in some instances, patients may choose conservation laryngeal surgery, including endoscopic laser excision of localized lesions, or partial laryngeal surgery. Both require frozen-section analysis of margins if the patient and tumor factors support such an approach. In addition, conservation laryngeal surgical salvage is effective in those 10–20% of cases in which external beam therapy has been unsuccessful for stages I and II cancers.

The treatment of more advanced laryngeal cancers (T3 and T4) has historically included surgery with or without radiation therapy. Prospective randomized studies have shown convincingly that chemotherapy and radiation therapy (including surgical salvage) are equally effective in the long-term survival of patients with T3 laryngeal cancers as compared with surgery with or without radiation therapy. It is important to note that approximately 60% of patients may preserve their larynx, and thus quality of life has significantly improved.^{197–199} Speech communication profiles are clearly better in the group of patients randomized to the larynx preservation arm, but there was no determination of swallowing function.²⁰⁰ However, local control was poorer for patients with T4 lesions. Current standard of care argues that laryngeal preservation approaches or protocols be considered in treating such patients, with the corollary that patients with poor function at diagnosis will likely have poor laryngeal function after conservation treatment. Thus, a primary surgical approach should be strongly considered for patients with significant aspiration based on pretreatment swallowing studies. In addition, due to the toxicity of combined chemoradiotherapy regimens, those with pulmonary and cardiac comorbidities that may limit treatment intensity may be best managed with surgery and radiotherapy.

Many surgical procedures for laryngeal carcinoma involve the creation of a tracheal stoma. This area is at significant risk of tumor recurrence, which is most likely associated with paratracheal nodal metastases. For this reason, bilateral paratracheal dissections should be performed in T4 glottic cancers and radiation therapy provided postoperatively if metastases to this echelon of nodes are found pathologically. Once a stomal recurrence has developed, the prognosis is grave regardless of salvage treatment, with a reported 5-year survival of 17%.²⁰¹ If risk factors for stomal recurrence are present, then the tracheal stoma should be irradiated as part of the initial management.

Supraglottic cancers

Important factors in selecting therapy for supraglottic cancers are tumor location, cord fixation, and pre-epiglottic extension. Tumors limited to the suprahoid epiglottis are amenable to radiation with fields that encompass neck regions at risk of lymphatic metastases. In addition, some proponents of limited surgical interventions recommend endoscopic laser excision separate from management of the neck. Tumors involving the aryepiglottic folds, pyriform sinuses, or infrahyoid epiglottis tend to be more aggressive,

are deeply infiltrative, and frequently involve the pre-epiglottic space. Radiation alone is less effective than surgery, resulting in more frequent local recurrences that require surgical salvage. The addition of systemic concurrent chemotherapy will positively impact the outcomes of patients with these tumors. Persistent postradiation edema of the supraglottic larynx is not uncommon and contributes to difficulty in detecting recurrence, which occurs in 40–50% of cases.^{202, 203} Most patients who have recurrence will ultimately require a salvage total laryngectomy.

In any patient undergoing partial laryngectomy, preoperative consent should be obtained for total laryngectomy in case the surgical findings dictate that more extensive surgery is needed. Approximately 20% of patients require prolonged tracheostomy, and this is usually related to edema secondary to PORT. The rates of persistent swallowing difficulties are low, however, and the need for completion laryngectomy for persistent aspiration ranges only from 0% to 5%.^{204, 205}

The frequency of neck node metastases is at least 20% with T2 or greater tumors. Treatment of the clinically negative neck may be accomplished with surgery or radiation.²⁰⁶ Cure rates range from 73% to 75% for radiotherapy and increase to 80–85% with the addition of surgical salvage.^{207–209} Most recurrences are local, and preservation of voice is successful in 65–70% of patients when salvage surgery is included.²⁰⁷

The treatment of more advanced supraglottic cancers (T3, T4) remains controversial, with laryngeal preservation remaining a focus of treatment ([Figure 10](#)). Combined chemoradiotherapy is often curative, but toxicities remain significant. As described, patients with T4 lesions are best managed with laryngectomy and radiotherapy, as cartilage and bone invasion are difficult to control with radiation. However, some experienced centers have treated patients having minimal laryngeal framework invasion with combined chemoradiotherapy with high success. One area of controversy surrounds the management of patients with bulky T3 lesions and poor pretreatment function. These patients may require long-term or permanent enteral nutrition and tracheostomy for significant aspiration, and may ultimately require a laryngectomy for pulmonary toilet. One novel approach that has been advocated is to utilize IC to assess both tumor and functional responses. Those with improvement of their function after one cycle of chemotherapy may tolerate concurrent chemoradiotherapy and avoid laryngectomy. Alternatively, those with minimal or no response would be best managed with surgery and PORT.

Figure 10 (a) T3 N0 SCCA of the supraglottis. Destruction of the epiglottis is evident. (b) Invasion of the pre-epiglottic space is seen on CT scan, prior to concurrent chemoradiotherapy. (c) Posttreatment imaging, demonstrating a complete response at the primary site.

Although the stigma of laryngectomy remains, contemporary postoperative laryngeal rehabilitation offers quite acceptable functional outcomes. The advent of tracheo-esophageal punctures (TEP), in conjunction with intense rehabilitation, has markedly improved the functional outcomes of laryngectomized patients. A laryngeal speech can be realized within 2 weeks of surgery. In the salvage surgical setting, TEP placement should be deferred for at least 3 months while the surgical site matures. Early TEP placement resulted in fistula formation and poor wound healing.

Planned neck dissection at the conclusion of treatment for N2 disease or greater is often performed. In the clinically negative neck, elective neck dissection revealed metastases in 15–30% of patients, and thus bilateral elective neck irradiation is warranted. Failure to control disease in the neck is a major cause of mortality in supraglottic cancers. In most reports, radiation alone for the control of supraglottic cancers with N2 or N3 nodes is inferior to combined therapy. Overall 5-year survival rates for supraglottic cancers range from 40% to 50%. Local failures occur in approximately 10% of patients and regional failures in 15–20%. Rates of distant metastases range from 11% to 18%, with rates approaching 30% in patients with stage IV disease. Second primaries (20–25% of failures) are a major cause of death and intercurrent illness accounts for up to 20% of deaths.^{209–211}

Glottic and subglottic cancers

The treatment of glottic cancer is greatly influenced by the secondary goal of voice preservation. For small cancers (T1, T2) with mobile vocal cords, radiation therapy alone achieves excellent local control rates of 80–95% and OS rates similar to those for surgical resection.^{212, 213} Voice quality, although often impaired by radiation, is generally better than that following surgical resection.²¹⁴ Local recurrences after definitive radiation can often be salvaged by subsequent surgery. Tumor involvement of the anterior commissure or arytenoids has been associated with higher local recurrence rates for radiation alone, but this may have been related to understaging. The “irradiate-and-watch” treatment strategy is predicated on close follow-up in order to detect recurrences when they are still salvageable by surgery. Delay in the diagnosis of recurrent glottic cancers after radiation is more frequent than with supraglottic cancers and may require total laryngectomy for cure. Partial laser resection is another primary or salvage treatment option of glottic carcinomas.

Lesions with impaired mobility owing to muscle invasion behave more like T3 cancers and have a poorer prognosis with radiotherapy alone.^{215–218} Transglottic cancers and those with subglottic extension have higher rates of regional metastases and more often require total laryngectomy for cure ([Figure 11](#)). In selected patients with these more advanced lesions, extended supraglottic laryngectomy or supracricoid partial laryngectomy may effectively salvage the patient and avoid a permanent stoma.²¹⁹ Voice quality is typically poor with these procedures, and permanent tracheostomy may be needed. In addition, these procedures are technically challenging and require a high level of training and experience.

Figure 11 Small volume laryngeal SCCA with both glottic (a) and subglottic (b) involvement. The lesion is staged T4 due to the extensive cartilaginous invasion, with extension into the soft tissue of the neck.

The design of radiation treatment must be tailored to the individual patient, but some general comments can be made. Early-stage (T1–2, N0) glottic lesions are treated with conventional fields localized to the larynx only; for T2 tumors with significant subglottic spread, the upper trachea is also included. T1 tumors are typically treated once-daily to doses of approximately 6300–6600 cGy, while T2 tumors are treated more aggressively with twice-daily or concurrent-boost fractionation.²²⁰ T2 tumors with bulky subglottic extension or with anterior involvement with potential extralaryngeal spread outside the thyroid cartilage are at higher risk for treatment failure, and can be considered for concurrent chemoradiotherapy. There has been recent interest in using IMRT to minimize dose to the adjacent carotid vessels; and for very early lesions, there have also been reports of single vocal cord irradiation²²¹ to further reduce the volume of irradiated tissue. Management of advanced T3 glottic cancers has historically consisted of total laryngectomy with or without PORT. Although older series show suboptimal control rates (20–35%) and survival rates (10–50%) for unselected sets of T3 and T4 tumors treated with radiation alone, it is now recognized that with proper selection, radiotherapy control rates for T3 lesions can approach 70–80%,^{222, 223} which is enhanced by the addition of platinum-based chemotherapy. In patients without regional metastases, local tumor control rates with surgery alone are excellent. Significant increases in local control with the addition of radiation therapy have not been clearly demonstrated. However, in patients with regional metastases, overall prognosis is poor and recurrence in the neck is a major problem when surgery alone is used. Improved regional tumor control rates are achieved with the addition of adjuvant radiation therapy.²²⁴ Because rates of occult regional metastases approach 30% in patients with advanced glottic (T3, T4) cancers, elective modified or selective node dissections for staging purposes are recommended when surgery is performed for primary disease. Demonstration of histologically positive nodal metastases has been used as an indication for PORT. Surgery alone is curative in 50–80% of patients without nodal metastases,^{216, 225–228} but this decreases to less than 40% if metastases are present.^{216, 229, 230}

As T3–4 tumors have a greater propensity for nodal metastases, larger radiation fields that encompass levels 2–4 are recommended. In the postoperative setting, radiation targets include the tumor bed and draining lymphatics including the upper paratracheal nodes. The stoma is included in the treatment fields,

particularly when there is subglottic or nodal disease (especially with ECS) or when a tracheostomy was done emergently prior to oncologic therapy.

Subsets of laryngeal cancers that warrant special consideration are those that involve both the glottic and supraglottic regions (transglottic). These cancers are usually advanced and are associated with a high incidence (30–50%) of regional metastases.^{231, 232} These tumors can be difficult to control with radiation alone, and may warrant the addition of chemotherapy in the treatment plan.

Distant spread is approximately four times more common with supraglottic than with glottic cancers.²³³ Rates of distant metastases associated with glottic cancer have increased, however, with the use of combined therapy and have been reported in approximately 20% of patients with advanced disease. Rates appear to be directly related to the extent of nodal disease, with reported rates as high as 40–50% in patients with N2 or N3 disease.²³⁴

Subglottic carcinomas are a rare variant of squamous carcinomas of the larynx possessing a high risk for paratracheal metastases, local recurrence, and death from disease. Surgery is the preferred therapy except in early superficial diseases of this site.^{235, 236} Tumors originating from or involving the subglottic larynx can spread to the upper paratracheal nodes as well as to the nodes in the cervical chain; therefore, radiation fields for this disease must include the upper mediastinum.²³⁷

Carcinoma in situ (CIS)

A special issue relates to the treatment of CIS of the vocal cords. This disease often can be managed with vocal cord stripping, but if enough serial sections are examined, foci of invasive carcinoma are often found. For diffuse CIS of the glottis, radiation therapy has been advocated, due to significant risk of malignant transformation and the inability to clear this disease surgically. Very superficial cancers limited to the free edge of the vocal cord or CIS can be effectively treated by limited excision by conventional means or with laser excision, with excellent voice preservation.²³⁸ More extensive disease requires cordectomy, vertical hemilaryngectomy, or supracricoid laryngectomy.

Nonsurgical treatment

There has been an increasing focus on the use of chemotherapy in the management of laryngeal cancers of all stages. Randomized trials have demonstrated that the concurrent administration of chemotherapy and radiotherapy improves local-regional disease control and OS in patients with locally advanced HNSCC. IC has long been recognized as highly active, with clinical partial and complete responses observed in 80–90% of patients.^{239–241} It was postulated that a substantial response to initial treatment with chemotherapy would lead to an improvement of therapeutic efficacy for surgery or radiotherapy. This led to the Department of Veterans Affairs Laryngeal Cancer Study,¹⁵⁵ in which 332 patients with stage III or IV SCC of the larynx were randomized to receive either IC consisting of cisplatin and fluorouracil followed by radiotherapy or surgery and PORT. Patients who experienced no tumor response to chemotherapy or those who had locally persistent or recurrent cancer underwent salvage laryngectomy. Two-year survival for both treatment groups was 68%, and 41% of patients randomly assigned to the experimental arm were alive with a functional larynx at 2 years. Thus, the efficacy of chemotherapy followed by radiotherapy (with surgical salvage) was similar to that of surgery followed by radiotherapy and established organ preservation as a realistic goal of nonsurgical treatment administered with curative intent. Lefebvre et al.¹⁷⁹ later reported the potential for effective sequential IC followed by radiotherapy in a European trial involving patients with cancers of the hypopharynx.

In the Veterans Affairs study, there were observed trends in patterns of tumor relapse, with 20% of

patients in the chemotherapy arm having locoregional recurrence versus 7% in the surgery arm. Distant disease recurrence was more likely in the surgical arm, affecting 17% of patients versus 11% in the chemotherapy/radiotherapy group. Salvage laryngectomy was required more often in patients with glottic cancer than in those with supraglottic primary sites (43% vs 31%), in patients with fixed vocal cords than in those with mobile vocal cords (41% vs 29%), and in patients with gross invasion of thyroid cartilage compared with patients without (41% vs 35%). Salvage laryngectomy was required in 56% of patients with T4 cancers compared with 29% of patients with smaller primary tumors ($p = 0.001$).

The Veterans Affairs Larynx study prompted further investigations of sequential chemotherapy and radiotherapy in the treatment of intermediate-stage larynx cancer. These trials indicate that for patients with intermediate-stage SCC of the larynx, a combined treatment program with the objectives of tumor eradication and laryngeal preservation is appropriate. It is also important to recognize that patients with locally advanced destructive primary laryngeal cancers were not included in the multi-institutional trial. These patients may require total laryngectomy for optimal tumor control and to preserve swallowing function.

Nasopharynx

Presentation and staging

In the United States, NPC accounts for 2% of all HNSCC. Its unusual epidemiologic and natural history features include a remarkable tendency toward early regional and distant dissemination. NPC also is extremely sensitive to radiotherapy and cytotoxic chemotherapy.

The nasopharynx is a chamber bounded anteriorly by the choana of the nasal cavity, superiorly by the clivus, and inferiorly by the soft palate. Its posterior wall is the mucosa that overlies the superior constrictor muscles of the pharynx and the C1 and C2 vertebral bodies. The lateral walls contain the eustachian tube orifices. The region is richly endowed with lymphatics that drain to the retropharyngeal and deep cervical nodes.

Malignant neoplasms of the nasopharynx are primarily epithelial, with the presence of keratin associated with a poorer prognosis. The WHO recognizes three histopathologic types of NPC: type 1, differentiated SCC (of varying degrees); type 2, nonkeratinizing carcinoma; and type 3, undifferentiated lymphoepithelial carcinoma. Mixed patterns are common.

About one-third of patients present with a neck mass without other complaints, and about 70–75% of patients have enlarged neck nodes at presentation. Other common symptoms are epistaxis, nasal stuffiness, headache, and hearing loss (generally unilateral). The tumor can spread laterally and superiorly to cause bony destruction of the base of the skull. Frequently, there are cranial nerve findings, with the sixth nerve being most commonly involved. There are two principal cranial nerve syndromes associated with NPC: (1) the retroparotidian syndrome, involving cranial nerves IX, X, XI, and XII and (2) the petrosphenoidal syndrome, involving cranial nerves III, IV, V, and VI (and occasionally cranial nerve II via extension through the foramen lacerum into the middle cranial fossa). Evaluation of the nasopharynx should consist of direct visualization with a fiberoptic scope. An MRI scan is important in evaluating base-of-skull involvement and the possible presence of occult-involved lymph nodes.

The most recent revision of the AJCC/Union Internationale Contre le Cancer (UICC) staging system recognizes the uniqueness of NPC among other head and neck tumors.¹¹⁴

Treatment

Standard treatment of NPC is radiation therapy or concurrent chemoradiotherapy for early and locally advanced disease, respectively. Surgical resection even for early-stage disease is technically difficult because of the anatomic location of the primary tumor and frequent bilateral cervical and retropharyngeal node involvement. The role of the surgeon is limited to obtaining tissue for diagnosis, resecting residual adenopathy after definitive radiotherapy, and surgery for rare non-WHO histologies such as adenoid cystic carcinoma.²⁴² Prior to initiating therapy, dental consultation is advised since it is necessary to irradiate the parotid glands bilaterally, and the resulting xerostomia predisposes to serious oral problems.

The nasopharynx is a disease site for which IMRT has been utilized in an attempt to improve the therapeutic index of external beam radiotherapy. Increasing the conformality of radiation delivery is desired, given the many critical neural, vascular, and soft tissues surrounding this anatomic site.

A clear correlation exists between the degree of cervical adenopathy and the subsequent development of distant metastases, with patients with bilateral adenopathy having an 80% 5-year actuarial risk of distant metastases. Common sites of distant metastases are the lung, bone, and liver. In selected cases, a failure at the primary site alone can be salvaged using a combination of external beam radiotherapy and an intracavitary implant.^{243, 244} Five-year local control rates were the best for patients with persistent disease (87.2%) versus those with a first recurrence (62.7%) or a second recurrence (23.4%, $p = 0.0004$). Overall 5-year survival rates for these three patient groups were 79.1%, 53.6%, and 42.9%, respectively.

The efficacy and toxicity of systemic therapy is presently evaluated in trials that include NPC as a distinct entity, and efforts are made to define patient cohorts according to the WHO classification. Including NPC with squamous cancers in studies of other head and neck sites will confound study outcomes in part because of the exquisite sensitivity of NPC to chemotherapy and radiation, but also because of the distinctive patient demographics and patterns of tumor recurrence in NPC.

Reports of phase II trials demonstrate single-agent activity for cisplatin, carboplatin, fluorouracil, bleomycin, methotrexate, anthracycline, vinca alkaloids, and taxanes.^{245, 246} Response rates range from 20% to 60%. More recent reports of cisplatin-based drug combinations describe tumor responses in 50–80% of patients, clinically complete in 20–25% of these.^{247–250} Moreover, Fandi et al.²⁵¹ have reported durable disease remissions in a cohort of patients followed up over a period of years. Chan et al.²⁵² have reported that the combination of carboplatin and cetuximab, a chimeric monoclonal antibody directed against EGFR, has activity (overall disease-control rate 60%) even in heavily previously treated NPC patients.

For patients with stage III or IV at diagnosis, chemoradiotherapy has become the standard of care. In the United States, an Intergroup Cooperative Study (IG0099) tested radiotherapy-alone arm versus an experimental arm consisting of concurrent cisplatin given on days 1, 22, and 43 during radiotherapy followed by three courses of adjuvant cisplatin and 5-FU chemotherapy.²⁵³ A total of 147 evaluable patients with stages III and IV tumors were enrolled. Notably, approximately one-third of patients were classified WHO 1, unlike most reports from the Pacific Rim in which >95% of patients are WHO 2/3. At 3 years, there was improved PFS (69% vs 24%, $p = 0.001$), improved OS (76% vs 46%, $p = 0.005$), and reduced distant metastases (13% vs 35%, $p = 0.002$) for the experimental arm. The results of this trial established the standard of care in the United States. These data were corroborated by another randomized phase III trial, which compared concurrent cisplatin (40 mg/m² weekly) and radiotherapy with radiotherapy alone in 350 patients with local and regionally advanced (N2 and N3, or N1 with nodal disease ≥ 4 cm) NPC.²⁵⁴ This study found that treatment with combined chemotherapy plus radiotherapy prolonged PFS. The treatment effect had a notable covariate interaction with tumor stage, and subgroup

analysis showed a significant difference in patients with T3 disease in favor of the concurrent-therapy arm ($p = 0.0075$). The time to first distant failure also was statistically prolonged in patients with T3 tumors in the concurrent-treatment arm ($p = 0.016$). An updated report²⁵⁵ concludes that OS benefit after chemoradiotherapy was most clearly obtained in patients with T3/4 staging ($p = 0.013$). Lin et al.²⁵⁶ conducted a prospective phase III trial with randomization to radiation therapy alone or XRT with two cycles of concurrent cisplatin and fluorouracil administered during weeks 1 and 5 of XRT. OS again favored the combined treatment arm (Table 4).

Table 4 Selected concurrent chemoradiotherapy trials in locally advanced NPC

Study	n	Treatment arms	Outcomes
Al-Sarraf et al. ²⁵³	78	cddp 100 mg/m ² weeks 1,4,7-RT + adj cddp/fu	5-Year PFS 58% and OS 67% CM vs 29% 29% and 37% RT
	69	RT	($p < 0.001$)

Alternatively, strategies with IC have much appeal because of the high risk of systemic tumor dissemination in patients with NPC. However, a survival advantage for this approach has not been conclusively demonstrated. Chua et al.²⁵⁸ have analyzed pooled data from two large phase III trials investigating the role of IC in NPC. In these trials, a total of 784 patients were randomized to receive 2–3 cycles of cisplatin-based combination drug therapy followed by XRT or radiotherapy alone. The 5-year relapse-free survival was 50.9% and 42.7%, respectively ($p = 0.014$), and disease-specific survival was 63.5% and 58.1% ($p = 0.029$). OS was not found to be significantly different between the arms ($p = 0.092$). Hui et al.²⁵⁷ have recently reported favorable PFS and OS results in a phase II study of induction cisplatin and docetaxel followed by chemoradiotherapy. Phase III trials investigating the value of IC are under way. NRG-HN001 is an ongoing phase II/III study investigating the value of measuring plasma EBV DNA as a marker of efficacy of concurrent chemoradiotherapy. With undetectable DNA, patients are randomized to observation or adjuvant chemotherapy. Patients with detectable DNA after chemoradiotherapy receive additional treatment, testing an alternative regimen consisting of paclitaxel and gemcitabine versus cisplatin and fluorouracil.

Nose and paranasal sinuses

The nose and the paranasal sinuses pose a unique set of problems that deserve separate consideration from SCC of the UADT. The three most common malignant histologies of the paranasal sinuses are SCC,

adenocarcinoma, and adenoid cystic carcinoma, but a number of other histologies are prevalent in this region, including sinonasal undifferentiated carcinoma (SNUC), neuroendocrine carcinoma, and esthesioneuroblastoma (often referred to as olfactory neuroblastoma).

Cancer of the nose and paranasal sinuses is relatively rare. It accounts for approximately 3% of cancers of the UADT and tends to occur in the fifth decade of life.²⁵⁹ These tumors tend to be asymptomatic and usually contained within either a sinus or the nasal cavity. Early symptoms usually include nasal airway obstruction, rhinorrhea, sinusitis, epistaxis, and, occasionally, dental problems such as dental pain, numbness, and loose teeth. Late symptoms include cranial nerve deficits, proptosis, facial pain and swelling, ulceration through the palate, and trismus, all of which are ominous signs ([Figure 12](#)).

Figure 12 (a) T4 SCCA of the maxillary sinus, with extension into the oral cavity. (b) Bone windows on CT scan reveals complete replacement of the maxillary sinus with tumor and destruction of the pterygoid plates. (c) Soft tissue windows reveal extraosseous extension into the midface.

The diagnosis of nose and paranasal sinus cancers is made by having a high index of suspicion in a patient who presents with nasal airway obstruction and a nasal mass. A thorough endoscopic or fiberoptic examination of the entire nasal cavity is critical to rule out benign disease such as nasal polyposis or sinusitis. Biopsy is indicated when a mass is found. Great care should be taken as these lesions can hemorrhage, especially neuroendocrine carcinoma and esthesioneuroblastoma. When taking a patient to the operating room for an endoscopic examination and biopsy, a frozen section should be obtained. It is critical to consider minimizing exposure of uninvolved structures; therefore, biopsy only should be performed without Caldwell Luc procedures, septoplasty, or entry into uninvolved sinuses. Imaging plays an important part in not only the diagnosis and staging of these lesions but also the surgical planning. The combination of CT and MRI provides useful information, especially with regard to skull-base involvement.

Because these malignancies rarely present as early stage, the accepted staging systems are not commonly used in clinical practice. Special note is made of “Ohngren's line,” or the malignant plane. The plane is defined by an imaginary line drawn from the medial canthus to the ipsilateral angle of mandible and passes through the infraorbital foramen. Tumors above this line (suprastructure) are unfavorable, while those below (infrastructure) are considered favorable.

Treatment

Treatment of neoplasms of the sinonasal cavity is primarily determined by the histology. Traditionally, surgery with PORT has been advocated for many of these tumors. Although very effective for smaller

tumors of selected histologies, this approach provides poor control for advanced disease involving the orbit, skull base and soft tissues of the face. An IC-based approach, with patients triaged to either concurrent chemoradiotherapy or surgery with PORT based on the response to chemotherapy is currently under investigation among patients with advanced tumors (clinical trial registration number NCT00707473).²⁶⁰

A complete discussion of the surgical management of paranasal sinus malignancies is beyond the scope of this chapter, but highlights of surgical considerations are briefly presented. Surgical approaches include (1) open transfacial, (2) midface degloving/sublabial, and (3) endoscopic. Surgical resections include (1) medial maxillectomy, (2) infrastructure maxillectomy, (3) total maxillectomy with or without orbital exenteration, and (4) craniofacial resection. The approach and resection utilized should be personalized, based on tumor location, extent, histology, cosmesis, and patient preference.

The endoscopic approach is being increasingly used in the management of paranasal sinus cancers. It provides excellent visualization with angled telescopes, the ability to remove bone with high-speed drills and soft tissue with microdebriders and can also be complemented by intraoperative surgical navigation. However, this approach requires a high degree of comfort with the technology and experience with endoscopic techniques, as well as the ability to convert to an open approach when necessary. Some of the limitations include inability to repair large defects, access to the orbit, and the need for an experienced surgical assistant for a two-handed technique.

Radiotherapy plays a major role in the management of sinonasal malignancies. It is used both preoperatively and postoperatively and, in select cases, as definitive therapy for small T1 and T2 lesions, especially those limited to the nasal vestibule and anterior nasal cavity.²⁶¹ In this situation, high locoregional control rates and good cosmetic outcome should be expected. With the increased use of radiotherapy in combination with surgery, ever-improving rates of locoregional control have been achieved. Surgery with PORT remains the standard of care for advanced sinonasal cavity tumors. As mentioned, concurrent chemoradiotherapy can be utilized in selected patients. Patients with inoperable tumors or those who are not considered good surgical candidates may be best treated with radiation therapy alone for local control and palliation.

Treatment-related sequelae from radiation to the paranasal sinuses and skull base are common. Acute complications include skin desquamation, nasal dryness, mucositis, xerophthalmia, and fistula formation. Chronic side effects include nasal dryness, xerophthalmia, visual impairment, atrophic rhinitis, osteoradionecrosis, and pituitary dysfunction. Dry eye can range from mild dryness to corneal ulceration, and even blindness. Enucleation may be necessary for debilitating ophthalmoplegia. Although the retina, like most neural structures, is radioresistant, visual impairment can occur as a result of damage to the lens and/or microvasculature that support both the retina and optic nerve. Frontal lobe necrosis is a devastating complication that may require neurosurgical intervention.

Although chemotherapy as a component of concurrent treatment with radiation is covered more extensively in a separate section, some aspects of chemotherapy are mentioned briefly here. The use of IC in selected patients with involvement of the eye has shown promising results in preserving the orbit.²⁶² Choi and colleagues reported results of concurrent chemoradiotherapy and investigators at the University of Chicago have used IC with cisplatin and infusional 5-FU to achieve improved rates of locoregional control and preserve the eye.^{262, 263} Studies at various centers are currently ongoing to validate the use of this approach for advanced sinonasal malignancies. Some investigators have utilized intra-arterial chemotherapy followed by surgery and/or radiation therapy for advanced sinonasal malignancies.^{264–266} Although these studies have shown some benefit with regard to locoregional control, the morbidity

associated with intra-arterial therapy does not appear to justify this approach. For patients with unresectable skull-base neoplasms, concurrent chemoradiotherapy is a reasonable approach that may offer locoregional control in up to 50% of patients.²⁶² SNUC, neuroendocrine carcinoma, and esthesioneuroblastoma represent a spectrum of tumors with neuroendocrine differentiation that can be difficult to distinguish histologically. Immunohistochemistry is often necessary to accurately diagnose these lesions, which may also be confused with sinonasal melanoma, rhabdomyosarcoma, PNET, or lymphoma. An experienced head and neck pathologist should be consulted prior to determining a treatment plan.

SNUC is a rare but lethal cancer typically presenting as advanced disease in elderly patients. Traditional treatment has been surgery followed by PORT, but this has provided poor long-term control. These tumors may be chemosensitive and a response to IC may identify patients for concurrent chemoradiotherapy as definitive treatment.^{267–269} Surgical salvage has a uniformly dismal prognosis, but in light of the poor locoregional control achieved with traditional surgery and PORT, most agree that study of concurrent chemoradiotherapy is warranted.

Esthesioneuroblastoma is a rare neoplasm emanating from the olfactory neurofilaments at the cribriform plate. Invasion of the anterior cranial fossa occurs early in the disease process, and eventually involves the brain parenchyma ([Figure 13](#)). Patients often present with nasal obstruction and epistaxis. Treatment centers around surgical resection and PORT, which offers effective locoregional control and favorable survival outcomes.²⁷⁰ Chemotherapy is reserved for patients with extensive intracranial or orbital disease that would otherwise require an extensive resection. It may also be used in the neoadjuvant setting as a cytoreductive approach to allow complete surgical resection.²⁷¹

Figure 13 (a) Esthesioneuroblastoma involving the central skull base, with intracranial extension. (b) Involvement of the left frontal lobe on MRI. (c) Invasion of the left orbital apex.

Salivary glands

Anatomy

Salivary gland tissue is ubiquitous in the submucosa of the upper gastrointestinal tract and with three major salivary glands: parotid, submaxillary (or submandibular), and sublingual glands. The most common sites of tumors of minor salivary glands are the palate, the base of the tongue, and the buccal mucosa.²⁷²

The majority of salivary gland tumors arise in the parotid glands, and although nearly 80% of these are benign, these glands are the origin of the majority of malignant tumors. Tumors arising in the submandibular, sublingual, or minor salivary glands are more likely to be malignant.

The largest salivary glands are the parotids, which are located on the cheeks anterior to the external auditory canal and pinna. The gland wraps around the mandible, and as the facial nerve passes through the parotid, it divides it into superficial, or lateral, and deep lobes. About 80% of the gland lies lateral to the facial nerve, and 20% lies deep to this nerve, behind and medial to the mandible. The internal carotid artery, the internal jugular vein, the cervical sympathetic chain, and cranial nerves IX, X, and XI are in close proximity to the deep lobe of the parotid. The lymphatic drainage of parotid tumors is into intraparotid lymph nodes, external jugular chain, and the upper jugular lymph nodes (levels II and III). Additional lymphatic drainage is into adjacent levels, including the posterior triangle or level V. The presence of nerves within the parotid gland, especially the facial nerve and the auriculotemporal branch of the trigeminal, can be involved by tumors, especially adenoid cystic carcinoma and SCC. Any parotid mass warrants evaluation, and surgical excision is often the only solution since progression of even benign neoplasms may not only cause facial asymmetry but also place the facial nerve at risk. Further, benign lesions may transform into high-grade malignancies over time, as in the case of carcinoma ex-pleomorphic.

The second largest glands are the submandibular glands, located in the triangle formed by the two bellies of the digastric muscle and the mandible. Malignant tumors in this location can spread to the lymph nodes in levels II, III, and IV, as well as grow along the nerves, preferentially the branches of the lingual nerve, and occasionally the mandibular branch of the facial nerve.

The sublingual glands are the smallest of the major salivary glands and are formed of a conglomeration of glands located underneath the mucosa of the FOM and surrounding the excretory duct of the submandibular gland, Wharton's duct.

Diagnosis

The clinical presentation of malignant salivary gland tumors is variable, depending on the site and histology. The presence of a facial nerve paralysis is uncommon but generally indicates a malignant lesion. Tumors of the deep lobe of the parotid are notorious for producing dysphagia and submucosal deformity of the soft palate. When major invasion of the parapharyngeal space occurs, involvement of cranial nerves IX, X, XI, and even XII can occur. The usual presentation of submandibular gland tumors is a painless swelling below the mandible, and such tumors need to be distinguished from the much more frequent bacterial sialoadenitis of this gland.

On physical examination, a palpable mass without superficial ulceration of either skin or mucosa is the most frequent finding. An important cytological diagnostic procedure to be considered is FNA, which can exclude or confirm neoplasia. This procedure, especially in the parotid and submandibular gland, has gained increasing acceptance and should be considered whenever the information that can be obtained will have an impact on treatment or prognosis. The accurate typing of tumor is often less important and may be deferred to the definitive histological examination. This has to be applied judiciously in spite of the high accuracy reported by experts (i.e., sensitivity, 94%; specificity, 97%; accuracy, 95%).²⁷³

Histopathology

Benign lesions are the most frequent tumor of the parotid gland. The histological classification of malignant salivary tumors has been reviewed and expanded over the years and the present WHO

classification is the most often quoted ([Table 5](#)).²⁷⁴ MEC is the most frequent cancer of the parotid gland and is classified into high-grade, intermediate, and low-grade tumors ([Figure 14](#)).^{275, 276} Low-grade MEC is characterized by a slow growth rate, a low recurrence rate after complete surgical excision (about 15%), and rare incidence of metastasis. High-grade tumors are more aggressive, and the local recurrence rate after surgery alone approaches 60%.²⁷⁷ Local recurrences and distant metastases may occur many years after treatment. About 50% of patients with high-grade MEC present with regional metastases, and 30% develop metastases at distant sites.^{275, 278} Acinic cell carcinomas are usually well differentiated and account for approximately 13% of the cancers arising from the parotid glands. Lymph node metastases occur in about 15% of cases. Local recurrence and distant metastases may occur many years after treatment.²⁷⁹ Adenoid cystic carcinoma accounts for approximately 10% of parotid gland malignancies but it accounts for 60% of malignant neoplasms of the submandibular or minor salivary glands.^{272, 280} Three subtypes that correlate to biological behavior—cribriform, tubular, and solid (most aggressive)—have been identified. A remarkable feature of this neoplasm is its propensity to invade major nerves and spread along the endoneural and perineural sheaths. This has significant prognostic importance and must be taken into account when deciding treatment and, specifically, when considering PORT. Although these tumors often follow an indolent course, as many as 40% of patients ultimately develop regional and distant metastases.²⁸⁰

Table 5 Most common malignant tumors of salivary glands

Mucoepidermoid carcinoma (low, intermediate, or high grade)
Acinic cell carcinoma
Adenoid cystic carcinoma
Adenocarcinoma
Malignant mixed tumor (carcinoma-expleomorphic adenoma)
Squamous cell carcinoma

Figure 14 Mucoepidermoid carcinoma of the left parotid gland.

Adenocarcinomas are more common in the minor salivary glands. The majority of them are high-grade tumors. About 36% of patients either present with or subsequently develop regional lymph node metastases; therefore, the regional lymph nodes need to be addressed in treatment strategies for high-grade adenocarcinomas.²⁸¹ Lung and bone are frequent sites of distant metastases.

Carcinoma ex-pleomorphic arises from preexisting benign pleomorphic adenoma. The risk of malignant transformation increases with time and age of the patient. Of adenomas of less than 5 years' duration, 1.6% can dedifferentiate; when present for more than 15 years, the dedifferentiation rate increases to 9.4%.²⁸² True malignant mixed tumors are rare, constituting only 2–5% of all malignant salivary gland tumors. These are typically aggressive tumors. A histology that deserves mention is salivary ductal carcinoma, which appears microscopically similar to breast carcinoma. Primary SCC of the salivary gland is rare, accounting for less than 3% of parotid neoplasms. This lesion must be distinguished from metastatic SCC to the parotid lymph nodes from cutaneous malignancies or from other sites. Primary SCCs of the parotid gland may develop regional lymph node metastases in 50% of patients, a clinical feature that must be considered when patients are treated by surgery and PORT.

Treatment

The accepted staging system for salivary gland tumors can be found in the monographs of the AJCC and UICC.¹¹⁴ The treatment of benign and malignant salivary gland tumors is surgery. Early-stage (T1 or T2) and especially low-grade tumors should be treated with comprehensive excision with free surgical margins. Such tumors arising in the parotid gland are generally treated by parotidectomy with preservation of the facial nerve. Early-stage high-grade tumors of any histology are treated with surgical resection of the primary site, with an attempt to achieve free surgical margins. This often is not possible,

and microscopic spread, especially of adenoid cystic carcinoma, may occur along tissue planes, submucosal spaces, and perineural pathways. The dissection of regional lymph nodes should be done judiciously; elective nodal dissection is seldom indicated except in high-grade malignancies, especially salivary duct carcinoma, MEC, and SCC.²⁸³ Salivary gland malignancies were thought to be resistant to conventional photon radiation, but over the years it has become established that postoperative irradiation is highly effective for eradicating subclinical disease.^{280, 284, 285}

PORT is also indicated for major and minor salivary gland cancers when (1) the tumor is high grade or is metastatic SCC, regardless of surgical margins; (2) the surgical margins are close or microscopically positive, regardless of grade; (3) a resection has been performed for a recurrent cancer, regardless of the histology or margin status; (4) the tumor has invaded beyond the capsule of the gland into skin, bone, nerve, or glandular tissue; (5) regional lymph nodes contain metastatic cancer; or (6) if there is gross residual or unresectable disease. In addition, preoperative radiotherapy prior to planned surgery may facilitate parotidectomy in advanced cases and allow preservation of the facial nerve.^{284, 286} If the facial nerve is involved at presentation, surgery and PORT are favored.

For T3 and T4 parotid cancer, unless the facial nerve is circumferentially encompassed by tumor or grossly enlarged by cancer, nerve-sparing surgery may be used followed by radiotherapy. Radiation therapy doses to the primary site and involved structures are in the range of 55–65 Gy. Generally, for low-grade MEC and acinic cell carcinomas, it is not necessary to treat the clinically uninvolved neck. For all other high-grade histologies, the neck nodal drainage is generally treated to doses in the range of 50 Gy. In the case of adenoid cystic carcinomas, the radiation fields should include the anatomic course of named nerve trunks to the base of the skull.²⁸⁰ Management of the facial nerve is one of the more controversial and complex issues surrounding the treatment of salivary gland cancers. Resection of the nerve results in profound cosmetic and functional deficits. Even resection of a single branch, particularly the frontal branch, can lead to significant morbidity. Thus, patients must be extensively counseled preoperatively regarding the intraoperative management of the nerve. Compromised function preoperatively portends poor functional outcome, even with nerve grafting. When the normally functioning facial nerve is found intraoperatively to be involved by cancer and cannot be preserved, resection and primary nerve grafting should be performed. PORT can be administered to nerve grafts, although the long-term functional outcomes remain suboptimal.

The results of treatment depend on histological type and tumor site. In a series from the University of Texas MD Anderson Cancer Center, 5-year survival rates were 100% for patients with acinic cell carcinoma, 95% for patients with adenoid cystic carcinoma, 90% for patients with low-grade MEC, 80% for patients with high-grade MEC, 70% for patients with adenocarcinoma, and 59% for patients with malignant mixed tumors.^{281, 284} At the Princess Margaret Hospital, primary parotid disease was controlled by surgery alone in 24% of cases and by surgery and radiotherapy in 74% of cases.²⁸⁷

Minor salivary gland tumors, especially tumors in the paranasal sinuses, often present with advanced-stage disease. In the MD Anderson series, the 2-year local control rate was 47% in patients treated with surgery alone and 76% in patients treated with surgery and PORT.^{284, 288, 289}

For patients with large inoperable salivary gland tumors or for patients who are at high risk of local recurrence after an incomplete resection, fast-neutron radiotherapy is an alternative to standard XRT. Fast neutrons have different radiobiological properties when compared with standard radiation, and *in vivo* data from Battermann et al.²⁹⁰ on the response of pulmonary metastases to fractionated radiotherapy show a relative biologic effectiveness (RBE) factor in the range of 8.0 for salivary gland tumors, compared with RBEs in the range of 3.0 to 3.5 for late effects in most normal tissues. To put this in perspective, if

one were to give a dose of 20 neutron-Gy to a parotid tumor, the biologic effect in terms of the mucosa and temporomandibular joint would be equivalent to 60–70 photon-Gy, but the biologic effect on the tumor would be equivalent to 160 photon-Gy—a theoretical therapeutic gain of a factor of 2.3 to 2.6.

The Radiation Therapy Oncology Group (RTOG) in the United States and the Medical Research Council (MRC) in the United Kingdom performed a phase III randomized clinical trial to compare fast-neutron radiotherapy versus conventional photon irradiation for inoperable salivary gland tumors. The fast-neutron group achieved significantly improved tumor clearance at both the primary site and in the regional lymph nodes. At the 2-year endpoint, the local/regional control rates were 67% for the neutron group compared with 17% for the photon group ($p < 0.005$), and survivals were 62% for the neutron group compared with 25% for the photon group ($p = 0.1$). Because of the significantly greater locoregional control rate achieved in the fast-neutron group, the study was closed early for ethical reasons. Ten-year data continued to show improved locoregional control on the neutron arm (56% vs 17%, $p = 0.009$) but no difference in OS because of deaths from distant metastases.²⁹¹

As neutron therapy is only available in very few centers, and results of neutrons are mixed and dependent on the site of disease, other alternatives for inoperable salivary gland cancers have been studied, albeit the reports are very small retrospective series. Samant et al.²⁹² describe encouraging results in patients with unresectable adenoid cystic carcinoma treated with concurrent chemoradiation. A team from Massachusetts General Hospital²⁹³ has described encouraging outcomes of patients with adenoid cystic carcinoma involving the skull base treated with proton therapy. Intrigued with the role of high-energy particle therapy, German investigators have performed a small phase II trial (COSMIC) combining IMRT with a carbon ion boost. Results are very preliminary, but the response rate in 16 patients with unresected malignant salivary gland tumors was 69%.²⁹⁴

Systemic therapy

Systemic therapy for salivary cancer remains an investigational endeavor, with no standard regimen universally accepted. Chemotherapy may be used in the primary management of patients with locally advanced and unresectable disease concurrently with radiation therapy. More often, chemotherapy becomes a treatment option for patients with distant disease recurrence. Previous studies have demonstrated single-agent activity for methotrexate, doxorubicin, cisplatin, 5-FU, vinca alkaloids, and taxanes. Response rates are in the range of 15–20%. Combination therapy provides some increase in response but with no clear survival advantages. A regimen with cyclophosphamide, doxorubicin, and cisplatin (CAP) has produced responses in 40–50% of patients treated, with duration 4–6 months.²⁹⁵ Cisplatin and vinorelbine render responses in 44–54% of patients.^{296, 297} Responses are more often observed in patients with adenocarcinomas, and less likely in adenoid cystic carcinoma. Anti-VEGF inhibitors such as sunitinib and axitinib have demonstrated minimum activity with mostly disease stabilization in metastatic adenoid cystic carcinomas.^{298, 299}

A decision to proceed with systemic therapy should be considered with attention given to tumor histology, stage, time to disease progression after primary therapy, patient performance status, and the pace of disease progression. Efforts are also under way to identify molecular markers, which may enhance our ability to individualize therapy. Most head and neck oncologists tend to separate patients with adenoid cystic carcinoma from others in developing a treatment strategy. As metastatic adenoid cystic carcinoma will often be indolent in its growth pattern, a short period of observation is typically indicated. At times, there may be only slow growth over a period of years. However, if serial evaluations show more aggressive cancer, then it would be appropriate to consider an investigational trial or chemotherapy.^{295,}

^{300–303} In patients with high-grade MEC or salivary duct adenocarcinoma, traditional cisplatin-based chemotherapy combinations may be more routinely active. Taxanes are active as single agents and are being tested in combination chemotherapy regimens.³⁰⁴

Approximately 70% of salivary gland malignancies overexpress EGFR. Our group conducted a clinical trial with gefitinib, a small-molecule EGFR tyrosine kinase inhibitor, in patients with advanced salivary tumors; however, no tumor responses were seen.³⁰⁵ A high level of c-KIT expression has been identified in adenoid cystic carcinoma, but preliminary trials with imatinib mesylate, a tyrosine kinase inhibitor against KIT, have not demonstrated clinical benefit.³⁰⁶ Salivary duct carcinomas overexpress HER2 in up to 50% of cases, and approximately 20% are HER2 amplified.³⁰⁷ Androgen receptor overexpression is seen in 80% of salivary duct carcinomas. Responses to trastuzumab, a monoclonal antibody that targets HER2, and to androgen blockage have been reported.^{308–311} A clinical trial investigating the role of hormone manipulation in androgen-receptor-positive salivary duct carcinoma is planned (clinical trial identification NCT 01969578). Given the relative rarity of salivary cancers in general, formal trials require collaboration among multiple, large tertiary centers or implementation through the cooperative oncology group mechanism.

Radiation therapy

Radiotherapy plays an integral role in the treatment of most HNCs. Used as the sole modality for the treatment of selected early-stage disease, radiation gives comparable results to a surgical resection, often with less morbidity. Radiation therapy is the treatment of choice for early-stage NPC. It is also a very effective therapy for early-stage oropharynx cancers, though the advent of minimally invasive intraoral approaches has raised the question of whether surgery or radiation is preferred for these cancers. Radiation (combined external beam and brachytherapy) is also an alternative to surgery for early cancers of the oral cavity, particularly the mobile tongue, and while not commonly used in the United States, it is common practice in some international centers. For tumors arising in the larynx, radiation may be preferred to surgery because it can offer retention of function and good vocal quality.

For advanced-sized lesions, radiation is used as a component of multimodality therapy. For patients planned for surgery, radiation is often used as an adjuvant in order to improve locoregional control. The sequencing for radiation when combined with surgery has been a topic of debate, as preoperative and postoperative radiation has advantages and disadvantages. The RTOG conducted a randomized trial comparing preoperative and postoperative radiation, and concluded that postoperative radiation resulted in improved local-regional control with a suggestion of an improvement in survival.³¹² The results of this study combined with general practice patterns have led to performing radiation postoperatively. A principle advantage of performing surgery first is that pathology can be assessed. Currently, a trichotomous risk assessment system is used, assigning patients into “low”, “intermediate” and “high”-risk categories. For low-risk patients, recurrence is uncommon; therefore, the benefits of adjuvant treatment may not be warranted. High-risk patients, typically those with inadequate surgical margins or extracapsular nodal disease, have a very high rate of recurrence such that prior and current studies are assessing methods to enhance adjuvant radiation by altered radiation fractionation or chemosensitization.³¹³

When used as an adjuvant, it is important that there be good communication between the surgeon and the radiation oncologist in order to avoid inadvertent delays that can compromise outcome. Several groups have highlighted the importance of minimizing the treatment “package” time, the time from surgery to the

completion of PORT, to maximize local and regional control.^{314, 315}

For advanced tumors arising in certain sites, such as the pharynx and larynx, nonoperative therapy, consisting of combined radiation and chemotherapy, may be preferred. Combination chemotherapy and radiation is the preferred treatment for advanced NPC and locally advanced oropharyngeal cancer. In particular, HPV-associated cancers of the oropharynx have been demonstrated to be very responsive to chemotherapy and radiation, with high survival rates seen in patients treated with concurrent chemoradiation.⁸⁸ The optimal therapy (see above) for advanced laryngeal and hypopharyngeal cancer remains a topic of controversy. The concept of laryngeal preservation remains an exciting idea; however, several decades of study have led investigators to be more cautious with the realization that larynx preservation may come with a trade-off of increased dysphagia and risk of aspiration. Further, some have questioned whether the zeal for laryngeal preservation has led to a decrease in the survival rate of patients with locally advanced laryngeal cancer.⁸

Ionizing radiation (high-energy photons, electrons, neutrons, protons, and other charged particles) interacts with matter in subtle ways and should not be thought of as simply a form of cautery.³¹⁶ Tumors and normal tissues can vary dramatically in their ability to repair the cellular damage caused by ionizing radiation. This makes it possible to use treatments such as chemotherapy and hyperthermia to reduce the repair capability of tumors and to design fractionation schemes that effectively widen the therapeutic window between tumor control and normal tissue damage. HNSCCs are generally characterized as being “moderately radiosensitive,” meaning that fairly large amounts of radiation must be delivered in order to achieve a high probability of tumor control. Fortunately, the required doses are within the tolerance range of most tissues in the head and neck.

The effectiveness of a given dose of radiation depends on how it is given.³¹⁷ In the United States, the traditional “curative” treatment regimen consists of giving 180–200 cGy once a day for 5 days a week to a total dose of 6500–7400 cGy; in the United Kingdom and Canada, higher daily doses of 220–250 cGy are given once a day for 5 days a week to a total dose of 5000–5500 cGy. These two schemas have evolved empirically; and a review of the literature indicates that they provide comparable tumor control, with the main debate relating to differences in complications. Various altered fractionation regimens have been compared with the standard regimens in clinical trials and some of these appear to be evolving into new “standards”.

Radiation kills the stem cells in the basal layer of the skin and mucosa; and several weeks later, the cells in the more superficial protective layers are not adequately replaced when they are lost through normal physiologic processes. This denudes the epithelium, giving rise to a mucosal reaction that can greatly inhibit a patient's ability to swallow solids and liquids. This does not occur immediately but is progressive after several weeks of radiotherapy. The use of concurrent chemotherapy and/or altered fractionation treatment regimens can make this reaction occur sooner and be more severe. Patients must be monitored closely to ensure that they maintain adequate nutrition during therapy, and often a feeding tube is required. Placement of such a tube is preferable to giving the patient a break in therapy, which can lower the tumor control probability due to repopulation.^{318–320} A similar reaction can occur in the skin in the treatment portals, giving rise to a severe sunburn-like reaction. Radiation to the head and neck area can cause significant changes in salivary gland function and taste perception.^{321–323} Radioprotectors and salivary stimulants have been extensively studied and have limited success in minimizing xerostomia. The more significant advances in xerostomia reduction have been in using the newer conformal techniques to lower the dose to the salivary glands.³²⁴ The severity and duration of these changes are dose dependent. There is transient loss of saliva and taste after doses of 1000–1500 cGy; however, these lower doses

often do not cause permanent late effects. Doses of 7000 cGy almost always cause permanent changes. Studies by the Universities of Michigan and Utrecht³²⁵ have demonstrated the absence of a threshold dose for gland damage, and the TD (50), or dose leading to 50% complication probability in the parotid gland, is 40 Gy.

Both the decrease in the amount of saliva and the changes in its chemical composition allow changes in the distribution of microorganisms inhabiting the mouth, which in turn can markedly increase the risk of dental caries. Aggressive dental prophylaxis prior to beginning radiotherapy is mandatory in the dentulous patient because the incidence of osteoradionecrosis can be considerably reduced if the necessary repairs and/or extractions are done prior to treatment rather than in heavily irradiated tissues.³²⁶ If extractions are necessary, a delay of 2–3 weeks between the extractions and the initiation of radiotherapy is necessary in order to allow for adequate healing. If extractions or other invasive procedures are required after high-dose XRT, hyperbaric oxygen treatments are helpful in reducing the risk of osteoradionecrosis, particularly if the mandible is involved.^{327, 328}

Technologic advances

Modern radiotherapy centers use sophisticated linear accelerators producing photon beams of different energies and megavoltage electron beams that can easily treat posterior neck lymph nodes without risk of spinal cord damage. Computer-controlled multileaf collimators facilitate custom blocking techniques to spare uninvolved normal tissues. CT and MRI are used to locate tumors, with many radiation oncology centers having dedicated scanners used exclusively for simulation and treatment planning. CT, MRI, and PET scans are fused to give the clinician a broader perspective in locating regions at risk of tumor.

Intensity-modulated radiotherapy (IMRT)

The principal goal of radiation is to deliver the appropriate dose to areas harboring cancer, while avoiding radiation to adjacent normal tissues. This concept is referred to as conformal therapy. IMRT was developed during the last decade of the twentieth century and is currently an accepted standard for achieving conformal therapy in HNC. In this approach, many different treatment fields are used, with each field being divided into multiple segments, and each segment delivering a prescribed amount of radiation.³²⁹ Recently, these techniques have further evolved in that the treatment can be delivered dynamically, with either treatment accelerators built with computed tomographic units, or with arc-rotational techniques (volumetric-modulated arc therapy). These techniques allow for a continued rotation of the therapy machine as well as a fluid change in the field collimation, ideally achieving even more conformality.

These IMRT systems are further enhanced by software innovations that allow for inverse treatment planning. This form of planning enables the clinician to specify normal tissue dose constraints in combination with specific dose goals to be delivered to the treatment target. In HNCs, there often are critical normal structures in close proximity to the tumor, and achieving a sharp dose gradient around the target while limiting the normal tissue dose offers the potential for significant therapeutic gain. The ability to reduce the dose to the parotid glands and to reduce the subsequent xerostomia experienced by the patient is an important advantage of this technique, and has been demonstrated in several trials including the randomized phase III PARSPORT trial.³²⁴ Likewise, additional anatomic regions important for functional swallowing, such as larynx and pharyngeal constrictor muscles, are being identified for future IMRT dose-sparing strategies to improve functional recovery following treatment.³³⁰

The advantages of improved tumor imaging are obvious as there should be fewer “marginal misses” than

in the past. Another advantage relates to being able to give higher radiation doses to the tumor in a safe manner. In the case of HNSCC, dose–response curves generally exhibit a steep region, wherein modest increases in radiation dose will give rise to significant improvement in outcome.^{331–333} Taking oropharyngeal cancer as an example, Setton et al.³³⁴ from the Memorial Sloan-Kettering Cancer Center reported results for 442 patients with oropharyngeal primaries (73% of whom had stage IV disease) treated with IMRT and a median follow-up for survivors of 37 months. Three-year estimates of local progression-free, regional progression-free, distant metastases-free, and OS were 95%, 94%, 87%, and 85%, respectively. Reported grade 2 or greater late xerostomia severity was 29%. Garden et al.¹⁶³ reported our results from the MD Anderson Cancer Center for 776 patients with oropharyngeal cancer treated with IMRT from 2000 to 2007. Median follow-up was 54 months. The 5-year actuarial locoregional control, recurrence-free, and OS rates were 84%, 90%, and 82%, respectively. Additional series echo these encouraging locoregional disease-control rates for oropharyngeal disease.^{160, 162, 164} Similar excellent results are seen for NPC, a disease that often approximates critical neural structures adding to the complexity of treatment. The RTOG phase II study 0225 tested the feasibility of transporting IMRT for NPC to a multi-institutional setting. The estimated 2-year PFS was nearly 93%.³³⁵ More recently, large series, particularly from China where NPC is endemic, report similar high rates of disease control.³³⁶

Given the complexity of IMRT treatment planning and delivery, rigorous quality assurance and technical support, as well as adequate clinician experience are critical to its ultimate effectiveness.³³⁷

Combined surgery and radiotherapy

Radiotherapy is often given as an adjuvant to surgery for moderately advanced but resectable tumors. For most head and neck sites, giving adjuvant radiotherapy improves local control for T3 or T4 primaries or in situations where there is pathologic involvement of cervical lymph nodes.

Radiotherapy can be given either preoperatively or postoperatively. The aims of preoperative radiotherapy are to sterilize microscopic disease outside the resection field and to shrink the tumor bulk. Theoretically, preoperative radiotherapy should also reduce the risk of disseminating viable tumor cells at the time of surgery. Dosages of 5000 cGy over 5 to 5.5 weeks are generally given, with no significant wound healing problems occurring at this dosage. Preoperative radiotherapy is rarely indicated today.

In the postoperative setting, the surgical procedure has disrupted the regional blood supply. Conventional wisdom suggests that higher doses of radiation are needed because of the increased likelihood of hypoxic tumor cells, which would be more radioresistant than their well-oxygenated counterparts. Generally, 5500–6000 cGy in 180–200 cGy fractions are given for microscopic residual disease. If the surgical margins are grossly positive or if there is a high likelihood of macroscopic residual disease, higher doses are used. Peters et al.³³⁸ have shown that at least 6300 cGy should be given if extracapsular nodal extension is found in the operative specimen. PORT has the advantage of being given only to those patients thought to be at significant risk of locoregional recurrence based on a review of the pathologic data. It has the additional advantage of not delaying the surgical procedure, which is the most important treatment modality for patients with advanced, operable tumors.

Although it is generally felt that there is little use for a debulking surgical procedure, there may be situations where a gross total resection followed by high-dose radiotherapy is preferable to treatment with radiotherapy alone. An analysis by the Head and Neck Intergroup (IG0034) showed that excluded patients with positive surgical margins had improved locoregional tumor control compared with matched cohorts from the RTOG databases of patients treated with radiotherapy alone.³³⁹ At 4 years, respective

Locoregional control rates were 44% versus 24% ($p = 0.007$). Since this was not a randomized study, the authors do not argue for changing traditional resectability criteria, but, rather, testing this concept in the context of a controlled clinical trial.

Locoregional disease relapse following surgery is particularly common in patients with positive surgical margins, extracapsular nodal disease, or multiple positive nodes. Based on retrospective analyses,^{340, 341} adjuvant radiation reduces the relative risk of relapse by approximately 50%; however, locoregional recurrence rates remain as high as 35–60% in this population.³⁴² Two landmark multi-institutional phase III trials demonstrated improved outcomes with concurrent chemoradiation in patients with high risk of recurrence following surgery. In the first trial,¹⁷³ the EORTC randomized 334 subjects to 66 Gy with or without cisplatin $100 \text{ mg/m}^2 \times 3$ cycles. Estimated 3-year local control (85% vs 70%), DFS (60% vs 40%), and OS (65% vs 50%) were improved by the addition of cisplatin. Acute toxicity was exacerbated by chemotherapy, but severity of late effects purportedly remained equivalent. The RTOG conducted a complementary trial,¹³⁴ randomizing 459 patients to nearly identical treatment arms as the EORTC trial: 60–66 Gy with or without cisplatin $100 \text{ mg/m}^2 \times 3$ cycles. Chemotherapy improved estimated 2-year local control (82% vs 72%, $p = 0.01$) and DFS (70% vs 60%, $p = 0.05$). As with the EORTC trial, this was at the cost of higher acute grade 3 or greater toxicity. The trials had different inclusion criteria, study populations, and follow-up intervals. However, joint reanalysis of both trials strongly suggested significant clinical benefit to combined adjuvant therapy for patients with either positive surgical margins or extracapsular nodal disease.¹⁷³

Systemic therapy

Chemotherapy and radiation for locally advanced disease

Induction chemotherapy

Treatment with chemotherapy used in sequence before surgery or radiotherapy—known as induction or neoadjuvant chemotherapy—has potential advantages. It is feasible. Drug activity may be optimal because there has been no disruption of normal vascularity. Effective systemic therapy in this setting is likely to induce a favorable tumor response and there is a reduction in the risk of distant disease recurrence.^{155, 199, 343, 344} The potential for IC to affect local disease control following surgery or radiotherapy continues to be under study. Early trials demonstrated that PF is a highly active regimen;³⁴⁵ a substantial response to chemotherapy predicts tumor sensitivity to radiotherapy; and that there appeared not to be a major adverse effect on surgical or radiotherapy morbidity.³⁴⁴

Discussed in part above, the VA Laryngeal Cancer Study Group¹⁵⁵ demonstrated the feasibility of induction PF followed by radiotherapy for patients with stage III/IV SCC of the larynx. Patients were randomly assigned to receive standard laryngectomy and PORT or 2–3 cycles of PF followed by radiotherapy. Surgery was reserved for salvage of patients with persistent or progressive disease. After 3 years' follow-up, 66% of surviving patients in the induction therapy group had a preserved and functional larynx. Moreover, there were no OS differences between the treatment arms. A subsequent study conducted by the EORTC in patients with squamous cancer of the hypopharynx compared induction PF followed by radiotherapy in responding patients to laryngopharyngectomy and radiation.¹⁷⁹ No survival differences were observed and 28% of the chemotherapy group survived with a functional larynx. The larynx preservation rate at 3 years was 42%. These studies demonstrated the potential for sequential chemotherapy and radiotherapy to be effective treatment strategies and that anatomic organ preservation is

a reasonable therapeutic objective for many patients.

In follow-up to the VA study,¹⁹⁹ the Head and Neck Intergroup conducted a prospective three-arm study with sequential PF and radiotherapy as the control arm compared to concurrent cisplatin and radiotherapy, and radiotherapy administered as a single modality. Surgical salvage was implemented for patients with persistent or progressive tumor. For entry, patients had stage III/VI disease, but T1 and advanced T4 lesions were not eligible. The concurrent arm produced superior local disease control resulting in larynx preservation at 10 years in 82% versus 68% in patients receiving sequential chemotherapy and radiation and 64% in patients treated with radiation alone. However, gains in disease control seemed to have been negated by an increase in the number of non-cancer-related deaths in the concurrent arm; thus, there were no significant survival differences observed between the concurrent and sequential treatment arms.³⁴⁶ A sequence of studies has focused on the addition of taxanes to the PF regimen to advance the antitumor activity. The EORTC studied 358 patients in a prospective trial (TAX323)³⁴⁷ comparing induction PF versus docetaxel, cisplatin and fluorouracil (TPF). After IC for four cycles, all patients received radiotherapy as a single modality. With a median follow-up of 32 months, TPF produced superior tumor responses, a PFS advantage with HR 0.72, and increased survival, HR 0.73. In the TAX 324 phase III trial³⁴⁸ 501 patients were randomized to receive IC with docetaxel (75 mg/m²), cisplatin (100 mg/m²), and fluorouracil (1000 mg/m²/day continuous infusion × 4 days) or the standard PF regimen. After three cycles, chemoradiotherapy with weekly carboplatin was administered. A fraction of patients underwent surgery for advanced nodal disease. A significant difference in DFS and OS was obtained, with 62% of patients receiving TPF alive at 36 months compared to 48% of the control group.

To build on the more modern IC platform of incorporating a taxane, GORTEC conducted the TREMPLIN phase II randomized trial comparing concurrent cisplatin versus concurrent cetuximab following a partial response to induction TPF.³⁴⁹ OS was equivalent in both arms, and the authors concluded they could not determine the optimal regimen to test against a control of IC followed by radiation alone.

While the addition of docetaxel to the PF backbone chemotherapy regimen improved outcomes in TAX323 and 324, it remained undetermined if the three-drug IC regimen was superior to concurrent chemoradiation. At least four clinical trials attempted to answer this question. The PARADIGM study randomized 145 unresectable stage III or IV HNSCC patients to receive TPF followed by concurrent chemoradiation with carboplatin (for patients who responded to IC) or docetaxel (for nonresponders to IC), versus concurrent radiation therapy with cisplatin (100 mg/m² every 3 weeks × 2 doses). The 3 year OS was not statistically different between the two groups (73% in the IC arm vs 78% in the concurrent chemoradiation arm). Higher hematological toxicity and one treatment-related death was seen in the IC arm. Given slow accrual, the study did not meet its patient target number, limiting its power and interpretation.³⁵⁰ The DeCIDE trial included 285 patients with N2 or N3 nodal status (therefore, with a higher risk of distant recurrence). Patients were randomized to receive two cycles of TPF followed by concurrent chemoradiation with DFHX (docetaxel, 5-fluorouracil, and hydroxyurea) versus the same concurrent definitive chemoradiation regimen. Once again, due to slow accrual, sample size was adjusted and the study was closed early. The 3-year OS rates were similar between the two groups, with 75% in the IC arm and 73% in the concurrent chemoradiation arm. Significantly lower distant metastasis was seen in the group that received IC (10% vs 19%, $p = 0.025$) and there was a trend to survival benefit for the patients with N2c and N3 disease who received IC ($p = 0.19$).³⁵¹ Both PARADIGM and DeCIDE were underpowered studies. Patient outcomes were better than historical control, most likely because the majority of the population had oropharynx carcinoma primaries, possibly HPV related. Hitt et al.³⁵² evaluated in a randomized phase III trial IC with either PF or TPF followed by concurrent chemoradiation

with high-dose cisplatin versus the same concurrent chemoradiation schema. There was no difference in median PFS, time to treatment failure, or OS between the two arms. Preliminary results of a phase II/III European trial presented at the 2014 ASCO meeting, evaluated induction TPF versus no IC followed by chemoradiation with either cetuximab or PF in 415 patients. The median survival was of 53.7 months in the induction arm versus 30.3 months in the upfront chemoradiation arm (HR 0.72, $p = 0.025$), with a reduced risk of distant metastases in patients who received IC. The difference in outcomes observed in this trial versus DeCIDE and PARADIGM is likely due to different patient populations and inclusion criteria.³⁵³

Based on the results of these trials, together with the MACH-NC meta-analysis,¹⁶⁸ concurrent chemoradiation with cisplatin remains as standard of care treatment for locally advanced HNSCC. Given the reduction in distant metastasis rates, further studies with IC in a risk-stratified population based on HPV status, smoking history, N stage, and molecular markers correlates might identify the population that will benefit the most from this treatment strategy. In our institution, IC is used for a larynx preservation approach and in selected oropharynx cases, in patients with bulk N2c/N3 disease, low neck adenopathy, and with good performance status.

Concurrent chemotherapy and radiation

A sequence of randomized trials^{171, 199, 354–361} and meta-analysis³⁶² demonstrate that the concurrent administration of chemotherapy and radiation leads to improved local control and OS in patients with locally advanced SCC, particularly of the oropharynx. However, most reported trials include patients with invasive SCC from a mix of primary sites. Scrutiny of these manuscripts is advised as the percentage of patients with oral cavity, pharyngeal, and laryngeal primary sites may vary in reports from different centers, and this may markedly affect study outcomes. It should be emphasized that concurrent chemoradiotherapy is associated with marked, acute mucocutaneous toxicity requiring expert supportive medical care. Speech and swallow rehabilitation consultation is routinely needed. Gastrostomy feeding tubes are placed in a high percentage of patients. The risk of long-term complications such as osteonecrosis and oropharyngeal fibrosis are under study.

Oral cavity primary tumors are most often approached surgically if there are no medical contraindications. Depending upon tumor histology, size, pathologic margins, and the extent of nodal involvement, PORT is administered. Patients with positive surgical margins or nodal ECS are more likely to benefit from adjuvant concurrent chemoradiation rather than radiotherapy administered as a single modality, as previously discussed.^{134, 173, 313}

With regard to toxicity, usually a brisk mucocutaneous reaction occurs with chemoradiation, necessitating the use of oral rinses for hygiene, analgesics, attention to fluid and calorie intake, and involvement of speech and swallowing rehabilitation specialists. Moreover, there is concern that long-term xerostomia, fibrosis, and related swallowing dysfunction may be more likely after concurrent chemoradiotherapy than radiation therapy alone. Long-term functional data for most patients have not been routinely reported. In the Intergroup larynx trial¹⁹⁹ and the postoperative chemoradiotherapy trials,^{134, 173, 313} there appeared not to be a high risk of chronic deleterious effects of combined therapy relative to control groups treated with radiotherapy alone. Setton et al.³⁶³ reported on nearly 1500 oropharyngeal cancer patients treated with concurrent chemotherapy and radiation. The 2-year gastrostomy tube dependence rate was 4.4%. A prospective study conducted at the MD Anderson Cancer Center evaluating the long-term outcomes of 47 patients who underwent IC followed by a risk-adjusted local treatment, including radiation therapy, concurrent chemoradiation, or surgery for oral cavity primary, demonstrated at 2 years a nonsignificant 13% average reduction in swallowing efficiency relative to baseline ($p = 0.191$), a rate of chronic

dysphagia of 7.1%, and gastrostomy dependency in 4.8% of the patients.³⁶⁴

In a landmark study, Bonner et al.³⁶⁵ conducted a prospectively randomized trial in which previously untreated patients with locally advanced SCC of the oropharynx, hypopharynx, or larynx received definitive radiotherapy with or without cetuximab. Cetuximab is a chimeric human and murine monoclonal antibody directed against the EGFR. In this phase III trial, 424 patients were entered and median duration of follow-up was 38 months. Notably, there was no increase in severe-grade radiation-related mucocutaneous toxicity. Moreover, median survival (28 months vs 54 months) and 3-year survival (44% vs 57%) favored the combined therapy arm with a significant advantage in locoregional tumor control. This study led to the approval of cetuximab to be administered concurrently with radiation therapy for locally advanced HNSCC.

A follow-up phase III study, RTOG 0522, evaluated the addition of cetuximab to the standard concurrent cisplatin and radiotherapy treatment in 891 patients with stage III or IV HNSCC. Patients were randomized to receive radiation and cisplatin with or without cetuximab. The addition of cetuximab to cisplatin-radiation led to significantly more interruptions in treatment, an increased rate of acute grades 3 and 4 toxicity, and was not associated with improved patient outcomes.³⁶⁶ Concert 1 and 2 trials have further explored bioradiotherapy with panitumumab (Table 6),^{367, 368} showing no OS or local disease control advantage after matching chemoradiotherapy with the addition or substitution of the antibody.

Table 6 EGFR-based bioradiotherapy with Panitumumab (P)

	N	2-Year LRC (%)
<i>Concert 1</i>		
CT – RT	63	68
CT – RT + P	87	61
<i>Concert 2</i>		
CT – RT	61	61
P – RT	90	51

LRC, locoregional control.

Thus, the current standard of care for patients with stage III and IV HNSCC, who are not candidates for surgery, is to be treated with definitive concurrent chemoradiotherapy. Cisplatin 100 mg/m² administered on weeks 1, 4, and 7 with once-daily radiotherapy, or cisplatin 40 mg/m² weekly, are widely accepted. Concurrent radiation therapy with cetuximab is an alternative for patients not eligible to receive cisplatin (e.g., renal insufficiency, hearing loss, advanced age, or poor performance status).

Given that patients with HPV-related OPSCC have a better prognosis and treatment outcomes, de-escalation therapy is being extensively studied in this patient population. The ongoing RTOG 1016 trial is randomizing patients with HPV-related OPSCC to receive definitive radiation therapy with cisplatin versus cetuximab. Accrual has been completed and results are awaited.

Recurrent and metastatic disease: cytotoxics

Activity of cytotoxic chemotherapy with single agents has been demonstrated in phase II trials, and expected response rates for multiple drugs are presented in Table 7. Benefit is more likely to be obtained in patients with ECOG performance status 0 or 1; in patients presenting with recurrence greater than 6 months from primary therapy; and in patients with sites of involvement not previously radiated.

Table 7 Single-agent activity in recurrent head and neck cancer

Agent	Approximate response (%)
Methotrexate	25
Bleomycin	15
Cisplatin	25
Carboplatin	20
5-Fluorouracil	15
Paclitaxel	30
Docetaxel	30
Ifosfamide	20
Cetuximab	13

Phase III studies have directly compared cisplatin and methotrexate (randomized, two-arm design). In one of these studies, Hong et al.³⁶⁹ gave cisplatin at 50 mg/m² on days 1 and 8 every month versus methotrexate at 40–60 mg/m²/week. Response rates were 28.6% and 23.5%, respectively. The taxanes constitute a distinctive class of established active agents in HNSCC.^{370–372} Use of docetaxel has produced response rates ranging from 21% to 42% in phase II studies in patients who had not previously received palliative chemotherapy.^{370, 372}

Combination chemotherapy may produce responses in 30–40% of patients, but without significant survival advantages over single-agent therapy, which is usually in the range of 6–9 months ([Table 8](#)). Gibson et al.³⁷⁸ conducted a prospective phase III trial comparing cisplatin and infusional fluorouracil with cisplatin and paclitaxel in 218 patients. There was no difference in response rate (27% and 26%, respectively) or median survival (8.7 months vs 8.1 months). Toxicity was similar.

Table 8 Selected randomized phase III trials of chemotherapy in recurrent or metastatic squamous cell carcinoma of the head and neck

Trial	No. of patients	Regimen	Response rate (%)	Survival (<i>p</i> value)
Jacobs et al. ³⁷³	79	cddp/fu	32	NS
	83	Cddp	17	
	83	Fu	13	
Forastiere et al. ³⁷⁴	87	cddp/fu	32	NS
	86	cbdca/fu	21	
	88	Mtx	10	
Clavel et al. ³⁷⁵	127	cddp/mtx/bleo/vcr	34	NS
	116	cddp/fu	31	
	122	Cddp	15	
Schrijvers et al. ³⁷⁶	122	cddp/fu/ifnα-2b	47	NS
	122	cddp/fu	38	
Forastiere et al. ³⁷⁷	101	cddp/pac (high dose)	35	NS
	98	cddp/pac (low dose)	36	
Gibson et al. ³⁷⁸	104	cddp/fu	22	NS
	100	cddp/pac	28	
Vermorken et al. ³⁴⁷	215	platin/fu	20	7.4 mos median
	219	platin/fu—cet	36	10.1 mos median <i>p</i> = 0.04

Abbreviations: bleo, bleomycin; cbdca, carboplatin; cddp, cisplatin; fu, fluorouracil; ifnα-2b, interferon alfa-2b; mtx, methotrexate; NS, not statistically significant; pac, paclitaxel; vcr, vincristine.

In a randomized phase III prospective trial, Vermorken et al.³⁷⁹ evaluated the addition of cetuximab to the platin-fluorouracil combination in 442 patients with recurrent or metastatic HNSCC. A response advantage and improved median survival from 7.4 to 10.1 months was observed. There was no unusual toxicity. This regimen has become the standard-of-care first-line therapy for suitable patients.

OS for patients with recurrent or metastatic HNSCC remains poor. Only approximately 30% of patients survive 1 year, highlighting the pressing need for new drug development and more efficacious systemic therapy strategies.

Novel therapeutics

Invasive SCCs emerge after the accumulation of multiple genomic events in a multistep process. There appear to be essential molecular alterations that are biologically significant, which confer a survival advantage for cancer cells and which constitute the process of carcinogenesis.³⁸⁰ As we understand better the underlying cancer biology, potential therapeutic targets have been identified and are leading to innovative treatment strategies.

Epidermal growth factor receptor

EGFR is a transmembrane glycoprotein, activation of which triggers a cascade of downstream intracellular signaling events important for regulation of epithelial cell growth.^{381–385} EGF and transforming growth factor- α (TGF- α) are ligands for the receptor. Overexpression of EGFR or TGF- α has been observed in approximately 90% of HNSCC.³⁸⁴

Gefitinib and erlotinib are small-molecule inhibitors of EGFR. Both agents have been tested as single agents in recurrent or metastatic HNSCC, showing minimum clinical activity.^{386, 387} Afatinib and dacomitinib, second-generation EGFR inhibitors, are under investigation in platinum refractory metastatic HNSCC. Preliminary results demonstrate some activity with responses rates around 10%.³⁸⁸

Cetuximab is a monoclonal antibody directed against the extracellular portion of EGFR. Binding of the monoclonal antibody competes with ligand activation and prevents receptor dimerization, with consequent abrogation of multiple downstream signals. Vermorken et al.³⁸⁹ have reported responses in 13% of platin-refractory patients treated with cetuximab single agent. As previously mentioned, Vermorken et al.³⁷⁹ have demonstrated in a phase III trial that the addition of cetuximab to cisplatin or carboplatin and fluorouracil favorably affects tumor response and improved overall median survival by 2.7 months (from 7.4 to 10.1 months in the cetuximab group). Bonner et al.³⁶⁵ have also reported, as discussed earlier, an increase in local tumor control and OS in the radiotherapy plus cetuximab combination arm versus radiotherapy alone.

An association between skin rash and tumor response has been repeatedly observed^{343, 390} and needs further exploration, possibly by escalating cetuximab dose until rash or dose-limiting toxicities develop. To date, cetuximab is the only Food and Drug Administration—approved targeted therapy for the treatment of HNSCC.

Angiogenesis

New blood vessel formation is a necessary process for tumor growth. Vascular endothelial growth factor (VEGF) is a multifunctional cytokine and a potent stimulator of the growth of endothelial cells. Increased VEGF protein expression is seen in many cancers, including HNSCC.^{391, 392}

Bevacizumab prevents VEGF binding to receptor tyrosine kinases (VEGFR1 and VEGFR2) with resultant inhibition of tumor cell growth. Argiris et al.³⁹³ evaluated in a single-arm phase II trial the activity of cetuximab and bevacizumab in 46 patients with recurrent or metastatic HNSCC that received up to one line of systemic therapy. The overall response rate was 16% and median PFS and OS were 2.8 and 7.5 months, respectively. A large phase III trial (E1305) with platin and docetaxel or platin and 5-fluorouracil plus or minus bevacizumab for patients with recurrent or metastatic HNSCC has been conducted and results are awaited (Clinical trial reference number NCT00588770). Newer generation small-molecule VEGFR inhibitors axitinib and pazopanib are currently being investigated clinically. Sorafenib and sunitinib are small-molecule pan-receptor tyrosine kinase inhibitors, with multiple targets including VEGFR. They have been tested in metastatic HNSCC with modest activity.^{394, 395}

Phosphatidylinositol-3 kinase (PI3K)

Advances in next-generation sequencing have revealed recurrent genetic alterations in HNSCC. The most frequent potentially targetable alterations consist of activation of the PI3K (phosphatidylinositol-3 kinase) pathway, either by PIK3CA mutations or amplification (~35%) or PTEN loss (~5%).^{396, 397} The PI3K/AKT/mTOR pathway is important in regulating the cell cycle and its deregulation is involved in

cancer cell proliferation. Various clinical trials with PI3K inhibitors as single agent or combined with other targeted therapy (e.g., EGFR inhibitors or MEK inhibitors) are being conducted in HNSCC.

Gene therapy

Approaches utilizing adenovirus-mediated wild-type *TP53* gene transfer have generated excitement following the demonstration of tumor responses in some patients.³⁹⁸ Khuri et al.³⁹⁹ conducted a multicenter phase II trial combining ONYX-015, which is a selective replicating adenovirus, with cisplatin and 5-FU in treating patients with advanced HNSCC. A response rate of 52% was observed in 30 patients with fully evaluable tumors. In a subset analysis of patients with tumors injectable and not accessible for injection, there was a substantial difference with tumor responses observed more often after chemotherapy and ONYX-015 administration ($p = 0.006$). Ongoing trials with TP53 replacement strategies continue for patients with recurrent HNSCC accessible to injection and as a chemoprevention strategy.

Immunotherapy

Recently, a new class of drugs that enhances antitumor immunity has emerged and is transforming the medical oncology field. One of the most promising pathways for manipulation involves programmed death ligand 1 (PD-L1). PD-L1 can be overexpressed in solid tumors, and upon binding to PD-1 expressing tumor-infiltrating T cells, it inhibits its activity and promotes immune tolerance, protecting the tumor cells from apoptosis. Blockage of PD-1-PD-L1 interaction enhances immune function and has shown meaningful clinical activity.^{400–402} Pembrolizumab and nivolumab, humanized monoclonal antibodies that target PD-1, have been approved for the treatment of metastatic refractory melanoma; and, more recently, nivolumab was approved as second-line therapy for lung SCC. The activity of these antibodies seems to correlate with PD-L1 expression in the tumor and/or stroma cells.

Preliminary results of the head and neck cohort of the KEYNOTE-012 phase I trial showed that 78% of the 104 patients with refractory metastatic/recurrent HNSCC screened expressed PD-L1 in at least 1% of the cells in the tumor microenvironment. Out of the 51 patients evaluable for response, 51% experienced decreased tumor burden, with an overall response rate by RECIST of 20%, irrespective of HPV status.⁴⁰³ Eight patients had disease stability over 6 months, and seven remained on treatment when the preliminary data of the study were presented. Treatment was well tolerated overall, with the main side effects being fatigue, pruritus, and rash.

Given these encouraging early results, numerous immunotherapy clinical trials with checkpoint inhibitors, costimulatory agonists, vaccines, and adoptive T-cell transfer are being conducted in HNSCC and hold great promise for the near future ([Figure 15](#)).

Current directions

Systemic therapy is an integral part of HNC treatment. Many patients with locally advanced disease are treated with chemotherapy and radiation. The increasing appreciation of HPV as an etiologic and favorable prognostic factor can be expected to affect patient management and de-escalation clinical studies are currently ongoing. Options for the treatment of recurrent disease now include reirradiation, cytotoxic chemotherapy, and molecularly targeted therapy. Insights into the genomics of HNC are leading to multiple targeted therapy trials in specific subgroups. The preliminary results of checkpoint inhibitors in metastatic HNSCC hold promise and might add to the systemic therapy armamentarium in the near future.

Chapter 84

Cancer of the lung

Charles Lu, MD, SM ■ Daniel Morgensztern, MD ■ Anne Chiang, MD, PhD ■ Amir Onn, MD ■ Boris Sepesi, MD ■ Ara A. Vaporciyan, MD ■ Joe Y. Chang, MD, PhD ■ Ritsuko K. Komaki, MD ■ Ignacio I. Wistuba, MD ■ Roy S. Herbst, MD, PhD

Overview

Worldwide, lung cancer is responsible for the largest number of cancer-related deaths, and reducing tobacco consumption is the most effective way to reduce lung cancer mortality. Standard therapy options continue to include surgery, radiotherapy, and/or chemotherapy. As lung cancer is a heterogeneous disease, it is hoped that translational proteomic and genomic research will advance our understanding of driver molecular pathways and allow development of more effective, less toxic, targeted therapies. Recent developments in immunotherapy have generated significant excitement and represent a novel therapeutic strategy, which has already impacted current standard of care.

Etiology and epidemiology

Worldwide, lung cancer is the most common (1.61 million of 12.7 million new cases) and the deadliest (1.38 million of 7.6 million cancer-related deaths) form of cancer.¹ The US 2015 cancer statistics indicate that lung cancer is the second most common cancer for both men and women (14% and 13% of all cases, respectively), but, as in previous years for both sexes, it is the number one cause of cancer death (86,380 men, 28% of all cancer-related deaths, and 71,660 women, 26% of all cancer-related deaths). In fact, more people in the United States die of lung cancer than of the next three causes of cancer-related deaths combined, which are prostate, breast, and colorectal cancer.² In 1920, fewer than 1000 cases of lung cancer were reported, and it was regarded as a rare malignancy. Since the 1950s, however, lung cancer has been recognized as a major public health problem. The incidence of new cases rose first in men and reached a peak in the mid 1980s; a steady decline has been noted since then. The incidence in women increased until the late 1990s and has recently stabilized. These changes occurred in parallel to the widespread adoption of cigarette smoking by both sexes. The decline in lung cancer incidence and mortality among men has been explained by reduction in smoking rates.³

Smoking and lung cancer

Tobacco is the world's single most avoidable cause of death. Lung cancer is the most common tobacco-related cause of cancer mortality: one case occurs for every 3 million cigarettes smoked. As described by Proctor,⁴ cancers caused by tobacco were among the earliest discovered environmental cancers. First reports on the association between tobacco use and cancer of the oral cavity and lip were published in Europe in the eighteenth and nineteenth centuries. More than 60 years ago, Muller in Germany was the first to recognize the positive association between cigarette smoking and lung cancer. Since then, multiple epidemiological studies have confirmed these observations and elaborated on the molecular mechanisms

of smoking carcinogenesis, providing sufficient evidence to establish a strong causal association between cigarette smoking and cancer of the aerodigestive tract, urinary bladder, kidney and uterine cervix, as well as myeloid leukemia. A meta-analysis of over 50 studies on never smokers showed a consistent and statistically significant association between exposure to environmental tobacco smoke and lung cancer risk.⁴

To date, smoking accounts for about 85–90% of lung cancer deaths in both sexes. The rate at which lung cancer develops is strongly correlated with the duration of tobacco exposure. After 45, 30, and 15 years of cigarette smoking, the annual incidence rates of lung cancer are 0.5%, 0.1%, and under 0.01%, respectively. Thus, a threefold increase in the duration of tobacco use can increase the annual incidence of lung cancer by 50-fold. As smoking ceases, the annual risk remains roughly constant thereafter. For instance, after 30 years of smoking, the risk is approximately 0.1%, and if a smoker stops after 30 years, this annual rate will persist indefinitely. Thus, 15 years later, the annual risk is 0.1% instead of 0.5%, which it would have been if smoking had continued. About 80% of the risk is, therefore, avoided by stopping smoking.⁵

Passive smoking

Smokers are not the only people at increased risk from exposure to tobacco smoke. “Passive smoking” from environmental tobacco smoke also increases the risk of lung cancer death. According to the Environmental Protection Agency, each year about 3000 nonsmoking adults die of lung cancer as a result of breathing the smoke of others' cigarettes. Analysis has shown that the sidestream smoke emitted from a smoldering cigarette between puffs contains virtually all carcinogenic compounds that have been identified in the mainstream smoke inhaled by smokers.

Familial predisposition

It is interesting that the vast majority of cigarette smokers, including heavy smokers, do not develop lung cancer. This suggests that cancer formation is dependent on an inherited predisposition or cofactors such as additional carcinogens. Studies that have compared risk factors of individuals with histologically confirmed lung cancer and of individuals with other smoking-related cancers found that having relatives with lung cancer did not increase the risk of developing lung cancer, but it did increase the risk of having cancer at some site.⁶ This suggests a heritable variation in response to carcinogens. Respiratory diseases also predispose to development of lung cancer. Studies of families predisposed to lung cancer showed that the development of lung cancer in young individuals (aged 50 years or younger) was compatible with Mendelian codominant inheritance or a rare autosomal gene.⁷

Other environmental causes

Lung cancer occurs in association with occupational and environmental exposures to carcinogenic agents other than tobacco smoke. Occupational agents classified as group 1 carcinogens by the International Agency for Research on Cancer include inorganic arsenic, asbestos, bis(chloromethyl)ether, chromium (hexavalent), nickel and nickel compounds, polycyclic aromatic compounds, radon, and vinyl chloride. Group 2A of probable carcinogens includes acrylonitrile, beryllium, cadmium, formaldehyde, acetaldehyde, synthetic fibers, silica, and welding fumes. Currently, occupational exposures have been estimated to account for 5–15% of all lung cancer cases worldwide ([Table 1](#)).

Table 1 Documented occupational lung carcinogens

Substance	Occupational exposures
Arsenic	Smelters, pesticide manufacturers
Asbestos	Miners, millers, insulators, railroad, and shipyard workers
Chloromethyl ethers	Ion-exchange resin manufacturers
Chromium	Chromate and pigment manufacturers
Hydrocarbons	Coal-gas workers, roofers
Mustard gas	Poison-gas manufacturers
Nickel	Refiners
Radiation	Miners of uranium and other ores

Molecular pathogenesis

The rapidly developing technology of molecular biology has allowed the identification of multiple genes responsible for lung carcinogenesis. Interestingly, these genes are altered forms of genes normally present in eukaryotic cells. The plethora of genetic abnormalities and redundancy of altered pathways induced by tobacco and other carcinogens determines lung cancer heterogeneity, which is remarkable in comparison to that of other solid tumors. In this regard, it has to be remembered that individual tumors are characterized by specific genetic alternation(s) and that there is a gradual accumulation of abnormalities in a given tumor, from normal epithelium to invasive carcinoma. [Table 2](#) lists genes that have been implicated in lung carcinogenesis. A detailed review of cancer biology may be found in other sections of this textbook.

Table 2 Summary of molecular abnormalities associated with the NSCLC adenocarcinoma and squamous-cell carcinoma histologies

Gene	Molecular change	Adenocarcinoma	Squamous-cell carcinoma
<i>EGFR</i>	Mutation	10–40%	Very rare
	Amplification/CNG ^a	15%	40%
	IHC ^b overexpression	15–39%	~58%
<i>KRAS</i>	Mutation	10–30%	Very rare
<i>BRAF</i>	Mutation	2%	3%
<i>EML4-ALK</i>	Translocation	13%	Very rare
<i>ROS1</i>	Translocation	1%	Very rare
<i>RET</i>	Translocation	1%	Very rare
<i>LKB1</i>	Mutation	8–30%	0–5%
<i>HER2</i>	Mutation	2–4%	Very rare
	Amplification	8%	2%
	IHC ^b overexpression	35%	1%
<i>DDR2</i>	Mutation	Very rare	4%
<i>TP53</i>	LOH ^c and mutations	50–70%	60–70%
<i>FGFR1</i>	Amplification	1–3%	8–22%
<i>PIK3CA</i>	Amplification/CNG ^a	2–6%	33–35%
	Mutation	2%	2%

^a CNG, copy number gain.

^b IHC, immunohistochemistry.

^c LOH, loss of heterozygosity.

Molecular abnormalities in premalignancy

Structural and genetic epithelial changes occur gradually, and invasive carcinoma develops 5–20 years after initial insult to the airways ([Figure 1](#)). Loss of specific chromosomal regions on a single allele [loss of heterozygosity (LOH)] has been detected frequently in lung cancers and bronchial epithelia exposed to tobacco carcinogens. The regions of the earliest and most frequent allelic loss are 3p21, 3p22–24, 3p25, and 9p21.⁹ It is noteworthy that many of these changes are seen in histologically normal bronchial epithelium from smokers, but not nonsmokers.^{10, 11} However, these changes appear to become more frequent and extensive in terms of chromosome loss with advancing abnormality of premalignancy. In some cases, these molecular changes appear to be clonally independent. Methylated sequences of tumor suppressor gene promoters can be detected in tumors, smoking-damaged normal lung (preneoplastic changes), sputum, and blood. These represent attractive surrogate biomarkers for early detection and monitoring of chemoprevention, smoking cessation, and response to therapy. Recent advances in the characterization of molecular abnormalities of lung cancer, including the reports of several novel

molecular pathways involved in the pathogenesis of invasive squamous cell carcinoma (SCC) and adenocarcinoma of the lung identified using high-throughput technologies such as next-generation sequencing of tumoral DNA and RNA,^{12, 13} have been extended to the analysis of molecular changes involved in the development of preneoplastic lesions of the lung airway.¹⁴ It has been shown that in lung adenocarcinoma harboring epidermal growth factor receptor (*EGFR*) mutations, those changes can be detected in bronchial normal epithelium adjacent to tumors.¹⁵ In SCC, gene amplification and protein overexpression of the cell lineage gene SOX-2 have been detected in a subset of bronchial dysplasia in patients with invasive squamous tumors.^{16, 17} High-throughput microarray profiling studies of the lung airway has shown that global alterations in the gene expression of normal epithelial cells can (1) predict cancer development in smokers,¹⁸ (2) identify the activation of pathways (e.g., PI3K) that can be potentially targeted using chemoprevention strategies,¹⁹ and (3) better define the localized molecular field of cancerization that can explain the development of different histologies of lung cancer.^{14, 20, 21}

Figure 1 Summary of histopathologic and molecular changes involved in the pathogenesis of squamous-cell carcinoma and adenocarcinomas of the lung.

Pathology of lung cancer

From histopathologic and biologic perspectives, lung cancer is a complex neoplasm. The 2004 WHO (World Health Organization) histologic classification of lung cancer has been recently revised with

support from the pathology panel of the International Association for the Study of Lung Cancer (IASLC).²² The new classification is based on the analysis of lung tumors by light microscopy with standard histology techniques and immunohistochemical analysis of proteins representing differentiation markers (Table 3).^{22, 23} The most common histologic types of lung cancer are non-small-cell lung carcinomas (NSCLC), which include SCC, adenocarcinoma [including minimally invasive adenocarcinoma (MIA) and large-cell carcinoma, and small-cell lung carcinomas (SCLC).²⁴ Lung neoplasms are generally classified by the best-differentiated region of the tumor and graded by its most poorly differentiated portion.

Table 3 Histological classification of lung cancer

I. Epithelial Tumors

a. Benign

i. Papillomas

- a. Squamous-cell papilloma**
- b. Glandular papilloma**
- c. Mixed squamous-cell and glandular papilloma**

ii. Adenomas

- a. Sclerosing pneumocytoma**
- b. Alveolar adenoma**
- c. Papillary adenoma**
- d. Mucinous cystadenoma**
- e. Pneumocytic adenomyoepithelioma**
- f. Mucous gland adenoma**

b. Preinvasive lesions

- 1. Atypical alveolar hyperplasia (AAH)**
- 2. Adenocarcinoma *in situ* (AIS)**
- 3. Squamous dysplasia and carcinoma *in situ***
- 4. Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia**

c. Malignant

i. Adenocarcinoma

- a. Minimally invasive adenocarcinoma (MIA)**
- b. Invasive adenocarcinoma**
- c. Variants of invasive adenocarcinoma: mucinous, colloid, fetal and enteric**

ii. Squamous-cell carcinoma

- a. Keratinizing**

- b. Nonkeratinizing
 - c. Basaloid carcinoma
- iii. Adenosquamous carcinoma
- iv. Sarcomatoid carcinoma
 - a. Pleomorphic
 - b. Spindle cell
 - c. Giant-cell carcinoma
 - d. Carcinosarcoma
 - e. Pulmonary blastoma
- v. Large-cell carcinoma
- vi. Neuroendocrine tumors
 - a. Typical carcinoid
 - b. Atypical carcinoid
 - c. Large-cell neuroendocrine carcinoma (LCNEC)
 - d. Small-cell carcinoma (SCLC)
- vii. Other and unclassified carcinomas
 - a. Lymphoepithelioma-like carcinoma
 - b. NUT-carcinoma
- viii. Salivary gland tumors
 - Mucoepidermoid carcinoma
 - Adenoid cystic carcinoma
 - Epithelial–myoepithelial carcinoma
 - Pleomorphic adenoma

II. Mesenchymal tumors

III. Lymphohistiocytic tumors

IV. Tumors of ectopic origin

V. Metastatic tumors

Precursor lesions

Lung cancers are believed to arise after the development of a series of progressive pathological changes (preneoplastic or precursor lesions) in the respiratory mucosa. The new WHO histological classification of preinvasive lesions of the lung lists three main morphologic forms: (1) squamous dysplasia and carcinoma *in situ* (CIS); (2) atypical adenomatous hyperplasia (AAH) and adenocarcinoma *in situ* (AIS); and (3) diffuse idiopathic pulmonary neuroendocrine cell hyperplasia (DIPNECH), which has been associated with the development of carcinoid tumors of the lung.^{22, 23} While the sequential preneoplastic

changes have been defined for centrally arising squamous carcinomas, they have been poorly documented for large-cell carcinomas, adenocarcinomas, and SCLCs.^{25, 26}

Invasive tumors

Minimally invasive adenocarcinoma (MIA)

This lesion is defined as a small (≤ 3 cm), solitary adenocarcinoma with a predominantly lepidic pattern and with ≤ 5 mm invasion area in greatest dimension.^{22, 27} MIA is usually composed of nonmucinous cells, but infrequently, it may be mucinous. The measurement of the invasive area should include the presence of histological subtypes other than a lepidic pattern (i.e., acinar, papillary, micropapillary, and/or solid), or the identification of malignant cells clearly infiltrating stroma.²² If a tumor invades lymphatics, blood vessels, or pleura or contains tumor necrosis, it should be diagnosed as invasive adenocarcinoma.

Adenocarcinoma

This tumor type accounts for nearly 40% of all lung cancers ([Figure 2a, b](#)). Most adenocarcinomas are histologically heterogeneous, and according to the new WHO classification, adenocarcinoma can be subclassified based on the predominant histological pattern present (i.e., acinar, papillary, solid with mucin production, micropapillary, and lepidic).²² When tumor cells grow in a purely lepidic manner without evidence of invasion, they are regarded as AIS.²² The solid adenocarcinoma pattern is, by definition, poorly differentiated, and these poorly differentiated tumors usually demonstrate mucus production as shown by mucicarmine or periodic acid-Schiff staining. Lung adenocarcinomas typically immunostain for thyroid transcription factor-1, Napsin A, and cytokeratin 7. There are four variants of adenocarcinoma tumors, including mucinous, colloid, fetal (low and high grade), and enteric. While adenocarcinomas of the lung spread primarily by lymphatic and hematogenous routes, aerogenous dissemination often occurs in mucinous tumors and is characterized by spread of tumor cells through the airways forming lesions separate from the main mass.²⁸

Figure 2 Histopathological characteristics of major forms of NSCLC: (a) invasive adenocarcinoma with acinar pattern, (b) adenocarcinoma with lepidic (noninvasive) pattern, (c) keratinizing squamous-cell carcinoma, and (d) large-cell carcinoma.

Squamous-cell carcinoma (SCC)

SCC accounts for approximately 30% of all lung cancers. Intercellular bridges, squamous pearl formation, and individual cell keratinization characterize squamous differentiation in this tumor type (Figure 2c). While all these features are very apparent in well-differentiated SCCs, they are difficult to find in poorly differentiated tumors. The histologic subtypes included in the new WHO classification include keratinizing, nonkeratinizing, and basaloid.²⁹ In tumors with keratinizing features, there is no need for immunohistochemistry analysis. The nonkeratinizing tumors necessitate immunohistochemistry examination to distinguish these tumors from large-cell carcinoma with a null immunophenotype in surgical resections or other types of poorly differentiated NSCLCs. For such tumors, diffuse positive staining with p40, p63, and/or CK5 or CK5/6 confirms their squamous phenotype and classification as a nonkeratinizing SCC. Both TTF-1 and mucin stains should be negative or only focally positive (<10% of cells with faint staining).

Approximately, 70% of SCCs of the lung present as central lung tumors.³⁰ The tumor may grow to a large size and central cavitation secondary to necrosis is a common gross finding.³¹

Adenosquamous carcinoma

Adenosquamous carcinoma of the lung is characterized by the presence of SCC and adenocarcinoma with each comprising at least 10% of the tumor.³² They account for 0.4–4% of lung cancers and are usually located in the periphery of the lung and may contain a central scar. The routes of dissemination and metastasis are similar to other NSCLCs.

Sarcomatoid carcinomas

Sarcomatoid carcinomas of the lung are a group of poorly differentiated NSCLCs that contain a component of sarcoma or sarcoma-like (spindle and/or giant cell) differentiation.³³ Currently, there are five variants identified: pleomorphic carcinoma, spindle-cell carcinoma, giant-cell carcinoma, carcinosarcoma, and pulmonary blastoma.^{33, 34} Sarcomatoid carcinomas are rare tumors (0.3–1.3% of lung tumors).^{33, 35}

Large-cell carcinoma

Large-cell carcinoma is defined as an undifferentiated NSCLC that lacks the cytologic, architectural, and immunohistochemical features of SCC, adenocarcinoma, or SCLC ([Figure 2d](#)). Thus, it is a diagnosis of exclusion. Large-cell carcinomas account for approximately 10% of all lung cancers, and they represent a spectrum of morphology, most consisting of large cells with abundant cytoplasm and large nuclei with prominent nucleoli ([Figure 2d](#)).³¹ The 2004 WHO classification listed four histological variants of large-cell carcinoma: large-cell neuroendocrine carcinoma (LCNEC), basaloid carcinoma, lymphoepithelioma-like carcinoma, clear-cell carcinoma, and large-cell carcinoma with rhabdoid phenotype. However, in the revised WHO classification, LCNEC is being reclassified into a new category (neuroendocrine carcinoma), and basaloid carcinoma is included as a variant of SCC. Pure large-cell carcinoma with clear cells or rhabdoid phenotype is extremely uncommon. If these components are detected in a large-cell carcinoma, their presence should be added in the description of the tumor.

Neuroendocrine tumors

Lung neuroendocrine tumors account for approximately 15% of lung cancers. They are composed of malignant cells showing neuroendocrine differentiation and representing a wide spectrum of tumors: typical and atypical carcinoids, considered low- and intermediate-grade malignancies, respectively, and LCNEC and SCLC, considered high-grade tumors ([Figure 3a–c](#)).

[Figure 3](#) Neuroendocrine tumors of the lung: (a) SCLC, (b) LNEC, and (c) typical carcinoid.

Carcinoid tumors

Carcinoid tumors are characterized by organoid growth pattern, uniform cytologic features, and immunohistochemical expression of neuroendocrine markers, such as chromogranin and synaptophysin ([Figure 3c](#)).³⁶ Carcinoid tumors have been divided into two categories, typical and atypical types, based

on their clinical behavior and pathologic features, with atypical crinoids having more malignant histologic and clinical features.³⁷ Typical and atypical crinoids are also referred to as low- and intermediate-grade neuroendocrine carcinomas, respectively. Histologically, typical carcinoids show fewer than 2 mitoses per 2 mm² field and lack necrosis, while atypical carcinoids show 2–10 mitoses per 2 mm² field and/or foci of necrosis.³⁶ Typical carcinoids are uniformly distributed throughout the lungs, whereas atypical carcinoids are more commonly peripheral tumors.³⁸ Compared to typical carcinoids, atypical carcinoids have a larger tumor size and a higher rate of metastases, and their survival is significantly reduced.³⁸ At presentation, approximately 10–15% of typical and 40–50% of atypical carcinoids demonstrate regional lymph node metastases.³⁶

Large-cell neuroendocrine carcinoma (LCNEC)

This tumor type is defined by the presence of large undifferentiated cells with prominent nucleoli, neuroendocrine pattern of growth, high mitotic rate, and neuroendocrine differentiation demonstrated by immunohistochemistry ([Figure 3b](#)).³⁹ They are usually peripheral, nodular masses, with necrosis. LCNEC is considered an aggressive malignancy with a prognosis similar to SCLC.³⁹ The term combined LCNEC is used for tumors associated with other better differentiated types of NSCLC, mostly adenocarcinomas.

Small-cell lung carcinoma (SCLC)

This tumor type accounts for approximately 15% of all lung cancers.²⁹ They characteristically consist of small epithelial tumor cells with finely granular chromatin and absent or inconspicuous nucleoli ([Figure 3a](#)). Necrosis is frequent and extensive and the mitotic count is high. Although there is not a precise upper limit for cell size to be defined as small cell, it has been suggested that the cells should measure approximately the diameter of two or three small mature lymphocytes.⁴⁰ While SCLC represents a light microscopic diagnosis, electron microscopy shows neuroendocrine granules in at least two-thirds of cases and immunohistochemistry for neuroendocrine markers (chromogranin and synaptophysin) is positive in most (~90%) cases.^{40, 41} Less than 10% of SCLCs demonstrate a mixture with NSCLC histologic types, usually adenocarcinoma, SCC, or large-cell carcinoma, and they are termed combined SCLCs.

NSCLC histological classification applied to small biopsies and cytology specimens

In these tumor samples, the NSCLC diagnosis has been lumped together without attention to more specific histologic typing. One of the major recent changes in lung cancer pathology has been the development of standardized criteria and terminology for pathologic diagnosis of lung cancer in small biopsies and cytology.⁴² In addition to the criteria and terminology, there is a paradigm shift for pathologists in tumor classification and management of specimens, which indicates the need to perform immunohistochemistry to further classify tumors formerly diagnosed as NSCLC not otherwise specified (NOS). Currently, if a NSCLC does not show clear glandular or squamous morphology in a small biopsy or cytology specimen, it is classified as NSCLC-NOS. Tumors with this morphology should be studied with limited special immunohistochemical markers to classify them further. It is recommended to use a single adenocarcinoma marker (i.e., TTF-1), a single squamous marker (i.e., p40 or p63), and/or mucin stains.⁴² Tumors that are positive for an adenocarcinoma marker or mucin are classified as NSCLC, favor adenocarcinoma. Tumors that are positive for an SCC marker with negative adenocarcinoma marker are classified as NSCLC, favor SCC. Cytology is also a powerful diagnostic tool that can accurately subtype NSCLC in most cases, and immunohistochemistry is readily available if cell blocks are prepared for the cytology samples.

Clinical manifestations

Clinical presentation

Some patients present with an asymptomatic lesion were discovered incidentally on chest radiograph. The majority of lung cancers, however, are discovered because of the development of a new or worsening clinical symptom or sign. Although no set of signs or symptoms is pathognomonic for lung cancer, they may be divided into four categories: (1) those due to local tumor growth and intrathoracic spread, (2) those due to distant metastases, (3) nonspecific systemic symptoms, and (4) paraneoplastic syndromes.

Manifestations of local tumor growth and intrathoracic spread

Signs and symptoms referable to the primary tumor vary depending on location and size of the tumor. Centrally located tumors produce cough, a localized wheeze, hemoptysis, and symptoms and signs of airway obstruction and postobstructive pneumonitis such as dyspnea, fever, and productive cough. Peripheral tumors are more likely to be asymptomatic when they are small and confined within the lung; occasionally, cough and pleuritic chest pain may be evident.

Intrathoracic spread of lung cancer, either by direct extension or by lymphatic metastasis, is associated with a variety of sign and symptom complexes. Mediastinal invasion may be manifested as vague, poorly localized chest pain in association with other findings of nerve entrapment, vascular obstruction, and/or compression or invasion of the esophagus. One of the most common neurologic disorders arising from mediastinal involvement is hoarseness owing to entrapment of the recurrent laryngeal nerve. Because of its longer intrathoracic course, the left recurrent laryngeal nerve is more likely to be the source of hoarseness than the right recurrent laryngeal nerve.⁴³ Compression of the esophagus by the tumor also may lead to dysphagia. The formation of a tracheoesophageal or bronchoesophageal fistula, which occurs with a frequency of 0.16%, can be manifested by vigorous cough, especially on swallowing, and recurrent aspiration pneumonia.⁴⁴ Involvement of the phrenic nerve is associated with hiccups early, and later leads to paralysis and elevation of the hemidiaphragm with resulting dyspnea.

The principal vascular syndrome associated with the extension of lung cancer into the mediastinum is superior vena cava (SVC) syndrome, most commonly caused by invasion of the vein and extrinsic compression by the tumor, but also by intraluminal thrombosis.⁴⁵ Lung cancer accounts for 65–90% of all cases of SVC syndrome, and in approximately 85% of these cases, the primary lung tumor is on the right, primarily in the right upper lobe or right mainstem bronchus. Establishment of a histologic diagnosis is important before initiating treatment, because the SVC syndrome is no longer considered a radiotherapeutic emergency.

With apical tumors, the classic Pancoast's syndrome (lower brachial plexopathy, Horner's syndrome, and shoulder pain) is due to local invasion of the lower brachial plexus (C8 and T1 nerve roots), satellite ganglion, and chest wall.⁴⁶ The tumor may cause symptoms through involvement of the first or second rib or vertebrae and other nerve roots. The radiographic signs are those of an asymmetric apical cap or an apical mass. Most superior sulcus tumors are SCCs, although they may be adenocarcinomas, or even in 1–2% of cases, SCLC, underscoring the importance of establishing a histologic diagnosis.

Approximately 15% of patients with lung cancer have pleural involvement at initial presentation, and 50% of patients with disseminated lung cancer develop pleural effusion during the course of their illness. A pleural effusion may cause dyspnea, cough, or chest pain.⁴⁷ A number of pathogenic mechanisms have been suggested, but the presence or absence of malignant cells in cytology specimens does not

significantly influence survival outcome, although the presence of malignant cells in pleural washings at the time of pulmonary resection for lung cancer has been shown to have a negative impact survival.⁴⁸

Pericardial involvement arises from direct extension of the tumor or as a result of retrograde spread through mediastinal and epicardial lymphatics. Lung cancer is the single most frequent source of pericardial metastases.⁴⁹Clinical findings include cardiac dysrhythmias, enlargement of the cardiac silhouette, and, infrequently, cardiac tamponade ([Table 4](#)).

Table 4 Clinical manifestations of lung cancer caused by local tumor growth and intrathoracic spread at presentation

Clinical manifestation	Frequency (%)	
	SCLC	NSCLC
Cough	50–76	40
Dyspnea	34–40	30–40
Chest pain	35–36	25–40
Hemoptysis	15–23	15–35
Pneumonitis	21–25	13–24
SVC syndrome	12	<10
Pleural effusion	10–15	15
Pancoast syndrome	Rare	3
Pericardial effusion	Uncommon	Rare

NSCLC, nonsmall-cell lung cancer; SCLC, small-cell lung cancer; SVC, superior vena cava.

Manifestations of distant metastases

Approximately 60% of SCLC and 30–40% of NSCLC patients present with stage IV metastatic disease. Although lung cancer can metastasize to virtually any organ site, the most common sites of hematogenous spread that are clinically apparent are the central nervous system (CNS), bones, liver, and adrenal glands. Many of these patients do not have symptoms that can be attributed to a specific distant site.

Systemic, nonspecific signs, and symptoms

As shown in [Table 5](#), systemic, nonspecific signs and symptoms are common in both SCLC and NSCLC. The 30% rate of anorexia is probably underreported. Weight loss, which is usually but not always accompanied by anorexia, occurs in approximately one-half of the patients and generalized weakness in one-third. Fever and anemia occur in fewer than 20% of the patients. Fever is generally not considered paraneoplastic in lung cancer patients; if present, it is usually associated with a documented infection (e.g., postobstructive pneumonia) or with liver metastases.

Table 5 Clinical manifestation caused by systemic effect at presentation

	Frequency (%)	
Clinical manifestation	SCLC	NSCLC
Anorexia	30	30
Weight loss (≥10 lb)	35–52	45–52
Fatigue	23–42	35
Fever	11–15	7–16
Anemia	11–15	16–20

NSCLC, nonsmall-cell lung cancer; SCLC, small-cell lung cancer.

Paraneoplastic syndromes

[Table 6](#) lists 21 paraneoplastic syndromes, which induce signs and symptoms away from the primary tumor or its metastasis. The major categories of paraneoplastic syndromes include endocrine, neurologic, cutaneous and musculoskeletal, and cardiovascular and hematological manifestations.⁵⁰

Table 6 Major paraneoplastic manifestations of lung cancer

Syndrome	Clinical frequency (%)	Comments
<i>Endocrine</i>		
Inappropriate ADH	5–10	Mainly SCLC
Atrial natriuretic factor	?	—
Ectopic ACTH	3–7	Most commonly with SCLC
Hypercalcemia of malignancy	10	Most commonly with squamous-cell types
Gynecomastia	6	More with large-cell type
Other hormones	—	No significant clinical manifestations
<i>Neurologic</i>		
Eaton–Lambert	6	Mainly SCLC
Subacute sensory neuropathy	Rare	Mainly SCLC
Subacute cerebellar degeneration	Rare	Mainly SCLC
Limbic encephalopathy	Rare	Mainly SCLC
Visual paraneoplastic syndrome	Rare	Mainly SCLC
Subacute necrotic myelopathy	Rare	Mainly SCLC
<i>Cutaneous/musculoskeletal</i>		
Hypertrophic pulmonary osteoarthropathy	<10	More with adenocarcinoma
Acanthosis nigricans	Rare	—
Tylosis	Rare	—
Tylosis	Rare	—
<i>Cardiovascular/hematologic</i>		
Nonbacterial thrombotic endocarditis	Uncommon	More with adenocarcinoma
Migratory thrombophlebitis	Uncommon	More with adenocarcinoma
Hypercoagulable status	10–15%	Renal
Glomerulonephritis	Rare	—
Nephrotic syndrome	Rare	—

ADH, antidiuretic hormone; SCLC, small-cell lung cancer; ACTH, adrenocorticotrophic hormone.

Endocrine syndromes

Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)

Excess secretion of arginine-vasopressin associated with hyponatremia is the hallmark of SIADH (syndrome of inappropriate secretion of antidiuretic hormone). The cardinal findings are hyponatremia with corresponding serum hypo-osmolality; continued renal excretion of sodium; absence of fluid volume depletion; inappropriately high urine osmolality; and normal kidney, adrenal, and thyroid function. SIADH may be caused by a variety of malignant tumors, and SCLC is the most common (up to 15%, though only

one-third are symptomatic). Water restriction is usually sufficient to control symptoms until systemic anticancer treatment is initiated, which typically leads to improvement or resolution of the hyponatremia. Saline infusion, furosemide, or demeclocycline is infrequently required.

Syndrome of ectopic adrenocorticotrophic hormone

Hyperadrenocorticism in association with ectopic adrenocorticotrophic hormone (ACTH) production (>200 pg/mL) is a frequently observed hormonal syndrome in lung cancer, particularly in SCLC. Serum ACTH levels are elevated in 30–72% of SCLC patients, and cortisol secretion is abnormally regulated in 51%, but only 3–7% of SCLC patients become symptomatic. Patients with ectopic ACTH syndrome generally fit the demographic characteristics of lung cancer patients and rarely exhibit the classic cushingoid features of centripetal obesity or moon facies. Ectopic ACTH syndrome was found to be associated with frequent complications from chemotherapy and shortened survival in patients with SCLC.⁵¹

Other hormone production

Other hormones elevated in lung cancer, particularly in patients with SCLC, include calcitonin, growth hormone, prolactin, serotonin, insulin, gastrin, and melanocyte stimulating factors. In most cases, however, these laboratory abnormalities bear minimal clinical significance.

Hypercalcemia of malignancy

It has long been known that cancer patients may have hypercalcemia even without demonstrable bone metastases. Hypercalcemia has been reported to occur in up to 30% of patients with cancer at some time during the course of their disease. This incidence may be falling owing to the wide use of bisphosphonates in patients with multiple myeloma or breast cancer, although data are lacking. Hypercalcemia leads to progressive mental impairment, including coma, as well as renal failure. These complications are particularly common terminal events among patients with cancer. The detection of hypercalcemia in a patient with cancer signifies a very poor prognosis; approximately 50% of such patients die within 30 days. A parathyroid hormone-related protein has been shown to be responsible for the majority of cases of hypercalcemia of malignancy. SCC is the lung cancer mostly associated with hypercalcemia, and SCLC is rarely involved. Hypercalcemia may be completely reversible with effective treatment of the underlying cancer, and bisphosphonates may be used as a specific therapeutic modality.⁵² Denosumab, a monoclonal antibody, which binds the bone resorption mediator RANKL, has recently been approved for hypercalcemia of malignancy refractory to bisphosphonate therapy.⁵³

Neurologic syndromes

Neurologic syndromes associated with lung cancer may occur through autoimmune mechanisms, mainly in patients with SCLC. Symptoms may precede diagnosis of the cancer by many months or may be the first sign of tumor recurrence. The severity of neurologic symptoms is unrelated to tumor bulk, and a primary malignant lesion may be undetected before death, despite disabling symptoms. Most of these conditions are not specific for malignancy.

Eaton–Lambert syndrome

A myasthenia gravis-like disorder that was originally linked to SCLC but was found in other cancers, this syndrome, characterized by proximal limb muscle weakness and fatigue, is caused by the formation of IgG antibodies directed at calcium channels present in both the tumor and the neuromuscular junction. A type-

1 antineuronal nuclear autoantibody (ANNA-1, also known as “anti-Hu”) has been identified as a marker of neurological autoimmunity that is highly associated with SCLC (97%) and other paraneoplastic neurologic disorders.⁵⁴

Subacute sensory neuropathy

This is the most characteristic peripheral neuropathy associated with SCLC. Clinical symptoms characterized by progressive impairment of all sensory modalities, with areflexia and marked sensory ataxia followed by stabilization after a period of weeks, may precede the diagnosis of SCLC by several months. It may be accompanied by more widespread evidence of paraneoplastic encephalitis, with cerebellar brainstem dysfunction and dementia.

Cutaneous and musculoskeletal syndromes

Digital clubbing and hypertrophic pulmonary osteoarthropathy (HPO) are the other major paraneoplastic syndromes associated with lung cancer, most commonly with NSCLC. Digital clubbing is more common than HPO, which often resembles rheumatoid arthritis. It is characterized by a symmetric polyarthritides (usually involving the ankles, wrists, and knees), proliferative periostitis of the long bones, and neurovascular changes of the hands and feet. Lung cancer accounts for more than 80% of cases of HPO in adults.⁵⁵ Radionuclide bone scans typically demonstrate increased uptake at the distal ends of the affected long bones, and the results may be confirmed by evidence of new bone formation on plain films; the spine is spared. The onset of HPO is often acute and may precede the diagnosis of cancer. A variety of underlying mechanisms have been suggested, including the release of platelet-derived growth factor by megakaryocytes or platelet clumps that bypass the pulmonary capillary network. The syndrome may resolve with response of the cancer to therapy. No effective form of treatment is recognized, including aspirin and nonsteroidal anti-inflammatory agents.

Cardiovascular and hematological manifestations

Arterial and, more commonly, venous thrombosis is a frequent complication of cancer and sometimes a harbinger of occult cancer. Moreover, the use of new and aggressive therapy for cancer increases the risk of thrombosis. The two most notable manifestations in lung cancer are nonbacterial thrombotic endocarditis (NBTE) and venous thromboembolism (VTE).

Diagnostic and staging techniques

Accurate clinical staging includes a combination of noninvasive and invasive procedures. Noninvasive studies include sputum cytology and imaging studies; most commonly used are chest radiography, computed tomography (CT) scanning, and positron emission tomography (PET) (usually PET–CT) scanning. For mediastinal or spinal lesions, magnetic resonance imaging (MRI) is considered. Invasive procedures include bronchoscopy, CT or ultrasound (US)-guided fine-needle aspiration (FNA) or biopsy, lymph node biopsy, and surgical (open) biopsy using mediastinoscopy or thoracoscopy. Patients who present with clinical or radiographic evidence of extensive disease (ED) usually require the least invasive procedure to establish both the diagnosis and disease stage. Cytologic or histologic confirmation through FNA or biopsy usually is sufficient to confirm suspicion of N3 or M1 disease. Thoracentesis or pericardiocentesis should be performed on associated effusions to assess malignant cytology. Tissue may be required for molecular assessment of the tumor to better select medical therapy. Therefore, in some cases repeated biopsy is needed.

Noninvasive studies

Sputum cytology

Cytologic evaluation of sputum, bronchial washings, bronchial brushings, and FNA specimens have high diagnostic yield, but the positive and negative predictive values of each and their accuracy of diagnosis certainly are dependent on sampling error, tissue preservation, processing quality, and observer experience. Sputum cytology is a simple test with a specificity rate of 99%. However, the sensitivity rate is approximately 70% for central tumors, and <50% for peripheral lesions. To increase the yield, three specimens are usually collected. In practice, more invasive measures to obtain a diagnosis are used in most cases.

Imaging

Lung cancer is generally first imaged by chest radiography. CT scan, PET/CT scan, and occasionally MRI are used to stage a known or suspected lung cancer and monitor response to therapy.

Chest radiography

Posterior–anterior and lateral chest radiographs remain the simplest method for identifying patients with lung cancer. It is widely available, has low cost and low radiation dose, but most cases are identified at an advanced stage. A standard chest radiograph can detect a lesion as small as 3 mm in diameter; however, unsuspected nodules generally are not seen unless larger than 5 mm in diameter. Associated atelectasis, postobstructive pneumonitis, abscess, bronchiolitis, pleural reaction, rib erosion, pleural effusion, or bulky mediastinal lymphadenopathy may be identified on radiographs, raising suspicions of a primary lung malignancy.

Plain chest radiography may identify abnormal pulmonary nodules. There are no absolute criteria to confirm a benign lesion on the basis of its radiographic appearance, but stability of size for 2 years and the presence of specific patterns of calcification (multipunctate foci, a dense central nidus, a popcorn ball, or laminated “bull's eye” appearance) are considered indicators of benignancy. However, some tumors such as AIS and typical carcinoids occasionally appear to be stable for 2 or more years.⁵⁶

Computed tomography

As a single comprehensive study, CT scan remains the most effective noninvasive technique for evaluating suspected or known lung cancer and the mediastinum, which may contain associated metastatic disease. However, the accuracy of CT scanning in identifying metastatic disease in mediastinal lymph nodes is highly variable and its sensitivity ranges from 51% to 95%. Such a wide range in accuracy is secondary to variations in the criteria for nodal abnormality, which are based on size and shape of a lymph node, CT scanner differences, and nonuniformity in nodal mapping. A lymph node size ≥ 1 cm in shortest diameter has been generally accepted as the criterion of abnormal nodal enlargement. Approximately 8–15% of patients considered to have a negative CT scan for mediastinal nodal enlargement, with lymph nodes ≤ 1 cm, will ultimately be found to have mediastinal nodal involvement at the time of operation. Mediastinal lymph nodes that are ≥ 2 cm in diameter contain metastatic disease in over 90% of cases. Lymph nodes that are 1.5–2 cm in size contain disease in over 50% of cases. Lymph nodes that are 1–1.5 cm in size harbor metastatic disease in 15–30% of cases. The negative predictive accuracy of CT scan is 85–92% for mediastinal lymph node metastases. For these reasons, many centers are now using PET–CT imaging.

Magnetic resonance imaging

MRI is not used for the routine evaluation of patients with lung cancer, but it does have specific advantages over CT scan. Because of its heightened ability to discern neurologic and vascular structures, tumors that reside in close proximity to neurovascular structures may be more accurately assessed by MRI than by CT scan. MRI is most useful in evaluating patients with superior sulcus tumors.

Positron emission tomography

Over the past several years, PET scanning with 2-[18F]fluoro-2-deoxy-D-glucose (FDG-PET) has been increasingly used in the diagnosis, staging, and therapeutic monitoring of lung cancer. This test identifies areas of increased glucose metabolism, which is a common trait in pulmonary tumors. As commercial PET scanners provide nominal spatial resolution of 4.5–6.0 mm in the center of the axial field of view, even lesions that are ≤ 1 cm in diameter can be detected on the basis of an increased uptake of FDG. Although initially heralded as a reliable noninvasive method of identifying and staging pulmonary neoplasms, a number of limitations have become apparent. Many inflammatory processes such as abscesses and active granulomatous diseases, as well as hypoxic conditions such as those that exist after radiotherapy, may cause high FDG uptake and lead to false-positive results. Treatment-induced hypermetabolic inflammatory changes also may lead to difficulty differentiating between treatment effects and those of the residual tumor. False-negative results have occurred primarily in tumors with low glucose metabolism (carcinoid and AIS) and in small tumors, owing to the limited spatial resolution of current PET scanners.⁵⁷

Integrated PET–CT

PET provides imprecise information on the exact location of focal abnormalities. Thus, even if the results of PET and CT scan are visually correlated, the precise location of lesions is sometimes difficult to determine. To overcome this limitation, integrated PET–CT was introduced.⁵⁸ Recent studies suggested that integrated PET–CT improved the diagnostic accuracy of NSCLC. Tumor staging was significantly more accurate with integrated PET–CT than with CT scan alone ($p = .001$), PET alone ($p < .001$), or visual correlation of PET and CT scan ($p = .013$); node staging was also significantly more accurate with integrated PET–CT than with PET alone ($p = .013$).⁵⁸ In patients with potentially resectable NSCLC, the accuracy of PET–CT is insufficient for mediastinal staging, and pathologic assessment of mediastinal lymph nodes remains the standard of care.⁵⁹ Randomized clinical trials (RCTs) suggest that PET–CT may help in the preoperative assessment of metastatic disease, potentially leading to the avoidance of unnecessary surgery.⁶⁰

Invasive studies

Tissue is collected for histopathological diagnosis, molecular studies, and genetic testing. In most cases, FNA for cytological assessment does not suffice and core biopsies are recommended. Endobronchial and centrally located tumors are usually diagnosed with bronchoscopy, whereas peripheral lesions with CT- (or US-) guided biopsies. In many cases, the biopsy is targeted to a lesion that would determine the diagnosis and the stage of the disease. For example, biopsy of a contralateral lymph node should be considered in cases where it would alter the disease stage (N stage) and a biopsy of a liver lesion would confirm the diagnosis of the primary tumor and the presence of a metastasis (M stage). In this regard, one has to consider the potential differences in the genetic expression between the primary tumor and its metastatic lesions and to avoid a biopsy of a lesion in a bone because decalcification processes could alter the genetic expression of the tumor.

FNA biopsy

Transthoracic percutaneous needle biopsy (TPNB) has significantly heightened the ability to diagnose intrathoracic pathologic processes. With CT or US guidance, tissue samples can be obtained from poorly accessible sites in the lung, mediastinum, abdomen, and retroperitoneum. The procedure is performed under local anesthesia using a small-gauge needle to either aspirate or biopsy lesions. Aspirated material is immediately processed with optimal procedural coordination. Many centers use an on-site cytopathologist for interpretation. Should the material be inadequate, a repeat aspiration can be performed. TPNB has been shown to be over 90% effective in establishing a final diagnosis. The false-positive rate is low (1%) and the false-negative rate ranges from 23% to 29%.⁶¹

Fiberoptic bronchoscopy (FOB)

Fiberoptic bronchoscopy (FOB) is an essential and standard technique for the evaluation of patients with pulmonary neoplasms; it remains the most important procedure for determining the endobronchial extent of disease. FOB permits careful survey of the supraglottic, glottic, tracheal, and bronchial regions to the level of most subsegments. Tumor (T) status can be defined by measuring tumor proximity to the carina and various bronchi and by identifying unsuspected occult lesions that indicate multiplicity of disease. For lesions that are visible by endoscopy, an accurate histologic diagnosis can be achieved in over 90% of cases. For central lesions, cytologic studies via needle aspiration, washings, and brushings, coupled with biopsy, heighten the diagnostic yield to over 95%. Peripheral lesions not visible endoscopically may be approached by cytologic studies of brushings and bronchioloalveolar lavage (BAL), which yield a diagnosis in 50–60% of patients. Cytologic studies, coupled with transbronchial fine-needle aspiration (TBNA), greatly enhance diagnostic yield.

TBNA biopsy

TBNA biopsy was introduced by Wang and Terry⁶² using FOB. It has been used most widely to sample endobronchial and peripheral lesions and significantly improves the diagnostic yield when coupled with standard diagnostic measures (washings, brushings, and biopsies). TBNA is best performed in a suite that is equipped with fluoroscopy to enhance localization of the lesion. One of the most important applications of TBNA is the evaluation of mediastinal lymphadenopathy. The true sensitivity and specificity of TBNA appear to range from 14% to 50% and 96% to 100%, respectively. Thus, negative results require definitive operative confirmation, but the risk of a false-positive finding appears to be quite low.⁶³

Advances in bronchoscopy

The development of linear echo-endoscopes has opened up new diagnostic possibilities for patients with lung cancer. Transesophageal US-guided fine-needle aspiration (EUS-FNA) and transbronchial US-guided needle aspiration (EBUS-TBNA, endobronchial ultrasound transbronchial needle aspiration) are both minimally invasive diagnostic techniques that enable real-time controlled aspirations of mediastinal lymph nodes and centrally located lung tumors. Evolving reports using these technologies suggest that EBUS-FNA has higher sensitivity than TBNA and that EUS plus EBUS may allow near-complete minimally invasive mediastinal staging in patients with suspected lung cancer. These newer diagnostic technologies may serve as an alternative approach for mediastinal staging in patients with suspected lung cancer.⁶⁴ Electromagnetic registration and guidance combine virtual bronchoscopy, three-dimensional (3D) CT images, and a steerable probe to aid in the biopsy of lung lesions. The yield and safety of this technology are being tested in several centers.⁶⁵

Mediastinoscopy

Transcervical mediastinoscopy is the best method for invasive evaluation of the middle mediastinum to include the peritracheal and subcarinal lymph nodes. The indication remains preoperative mediastinal nodal assessment in patients with CT scan evidence of cross-sectional lymph node enlargement of ≥ 1 cm. In such patients who are proven to have lung cancer, the chance that these nodes contain metastasis is over 7%. If the nodes are enlarged to 1.5–2 cm or more, the risk of having metastatic involvement is over 30%. The accuracy of cervical mediastinoscopy ranges from 80% to 90%, and the false-negative rate ranges from 10% to 12%. The lymph node station most commonly missampled is the subcarinal region, which is difficult to access in some patients. The subaortic and aortopulmonary window regions are inaccessible by standard cervical mediastinoscopy.⁶⁶ Extended cervical mediastinoscopy, a variation of standard mediastinoscopy, has been useful for staging lesions in the left upper lobe. The standard mediastinoscopy incision is used, with the plane of dissection extending anterior to the innominate artery and aorta, anterolaterally to the level of the aortopulmonary window. “Anterior mediastinotomy,” originally described by McNeil and Chamberlain, permits direct visual access to the anterior mediastinum through the second, third, or fourth anterior interspace, with or without removal of a short portion of the adjacent cartilage. For right-sided lesions, the procedure provides access to the proximal pulmonary artery and SVC. The procedure is used on the left side to evaluate disease in the subaortic and lateral aortic regions.

Thoracoscopy

Thoracoscopy and video-assisted thoracoscopic surgery (VATS) are used in a broader range of applications, including resectional techniques. The VATS approach is used in many thoracic conditions, and its role continues to evolve regarding the evaluation and management of lung cancer. It is currently considered for the evaluation and treatment of pleural tumors and effusions and in the diagnosis of indeterminate pulmonary nodules, and has a complementary role to standard mediastinoscopy in the staging of mediastinal lymph nodes. It has also become an accepted approach for resection of peripheral early-stage lung cancer in many centers.⁶⁷

Operative staging

Operative staging provides the opportunity to verify histologically the extent of gross and microscopic diseases. The surgeon is responsible for performing a complete nodal dissection or nodal sampling as an integral part of the thoracotomy. Lymph nodes are removed and labeled according to the location of the station on the regional station map ([Figure 4](#)).

Figure 4 Regional lymph node stations for the staging of lung cancer. The location of the lymph nodes and assigned numbers are determined by the surgeon at the time of operation.

Cancer screening and early detection

Because symptoms of early-stage localized disease are insidious and nonspecific, they are frequently attributed to the effects of smoking. By the time the patient seeks medical attention, the disease is usually advanced so that complete surgical resection is possible in fewer than 30% of cases, and the overall 5-year survival rate is <17%. Clearly, screening and early detection of cancer at a more treatable stage is a

desirable goal.

In the 1970s, the National Cancer Institute (NCI) sponsored three separate RCTs to assess the efficacy of lung cancer screening in male smokers (aged 45 years or older who smoked at least one pack per day).⁶⁹ By 1978, a total of 31,360 patients had been enrolled, and the final results of all three studies were unable to demonstrate a disease-specific mortality reduction.⁷⁰

The introduction of low-radiation-dose spiral computed tomography (LDCT) renewed interest in screening high-risk individuals for early lung cancer.⁷¹ The NCI subsequently funded the National Lung Screening Trial (NLST), which enrolled 53,454 persons at high risk for lung cancer at 33 medical centers between 2002 and 2004. Eligible participants were between 55 and 74 years old, had a smoking history of at least 30 pack-years, and, if former smokers, had quit within the past 15 years and were randomly assigned to undergo three annual screenings with either LDCT or chest radiography. Subjects in the LDCT screening arm demonstrated a 20% reduction in lung cancer-specific mortality (95% CI, 6.8–26.7; $P = 0.004$).⁷² The current US Preventive Services Task Force (USPSTF) recommends lung cancer screening with annual LDCT for asymptomatic adults between 55 and 80 years old with at least a 30 pack-year smoking history.⁷³

Staging systems

Staging is the determination of the extent of disease, with the intent of grouping patients with similar levels of disease for analytical, therapeutic, and prognostic purposes. The staging of lung cancer provides a scale of relative disease, which can be assigned to all patients with primary lung malignancies. Accurate staging of lung cancer is essential for defining operability, for selecting treatment regimens, for predicting survival, and for reporting comparable end results.

The accuracy of staging depends on available clinical information and relies on preoperative and subsequent evaluations at different times during the course of the disease: clinical-diagnostic staging (*c*), surgical-evaluative staging (*s*), postsurgical resection-pathologic staging (*p*), retreatment staging (*r*), and autopsy staging (*a*).

Staging of NSCLC

The current seventh edition of the AJCC and UICC lung cancer staging system was updated in 2009 and is based on 67,725 cases treated from 1990 to 2000, derived from 46 sources in more than 19 countries.⁷⁴ This revision further improves the alignment of TNM (tumor, node, and metastasis) stage with prognosis and treatment ([Tables 7–9](#)).

Table 7 TNM descriptors

Primary tumor (T)	
TX	Primary tumor cannot be assessed, or tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma <i>in situ</i>
T1	Tumor ≤3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus ^a (i.e., not in the main bronchus) T1a tumor ≤2 cm ^a T1b tumor >2 cm but ≤ 3 cm

T2	<p>Tumor >3 cm but ≤7 cm; or tumor with any of the following features:</p> <ul style="list-style-type: none"> • Involves main bronchus, ≥2 cm distal to the carina • Invades the visceral pleura • Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung <p>T2a tumor >3 cm but ≤5 cm T2b tumor >5 cm but ≤7 cm</p>
T3	Tumor >7 cm or one that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, mediastinal pleura, parietal pericardium; or tumor in the main bronchus, ≤2 cm distal to the carina but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung
T4	Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, esophagus, vertebral body, carina; or tumor nodules in a different ipsilateral lobe to that of the primary
<i>Regional lymph nodes (N)</i>	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis to ipsilateral peribronchial and/or ipsilateral hilar lymph nodes, and intrapulmonary nodes involved by direct extension of the primary tumor
N2	Metastasis to ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis to contralateral mediastinal, contralateral hilar, ipsilateral, or contralateral scalene, or supraclavicular lymph node(s)
<i>Distant metastasis (M)</i>	
MX	Presence of distant metastasis cannot be assessed
M0	No distant metastasis
M1	<p>Distant metastasis present</p> <p>M1a separate tumor nodule(s) in a contralateral lobe; pleural nodules, or malignant pleural or pericardial effusion^b</p> <p>M1b distant mets</p>

^a The uncommon superficial tumor of any size with its invasive component limited to the bronchial wall, which may extend proximal to the main bronchus, is also classified T1a.

^b Most pleural effusions associated with lung cancer are due to tumor. However, there are a few patients in whom multiple cytopathologic examinations of pleural fluid show no tumor. In these cases, the fluid is nonbloody and is not an exudate. When these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging element, and the patient's disease should be staged M0.

Table 8 Stage grouping in lung cancer: TNM subsets.^a

Stage	TNM subset
0	Carcinoma <i>in situ</i>
IA	T1a–T1b N0 M0
IB	T2a N0 M0
IIA	T1a–T2a N1 M0
	T2b N0 M0
IIB	T2b N1 M0
	T3 N0 M0
IIIA	T1a–T3 N2 M0
	T3 N1 M0
	T4 N0–N1 M0
IIIB	T1a–T4 N3 M0
	T4 N2 M0
IV	Any T, Any N, M1a–M1b

^a Staging is not relevant for occult carcinoma, designated TX N0 M0.

Table 9 Lymph node map definitions

Nodal station	Anatomic landmarks
N2 nodes: all N2 nodes lie within the mediastinal pleural envelope	
1. Highest mediastinal nodes	Nodes lying above a horizontal line at the upper rim of the brachiocephalic (left innominate) vein where it ascends to the left, crossing in front of the trachea at its midline
2. Upper paratracheal nodes	Nodes lying above a horizontal line drawn tangential to the upper margin of the aortic arch and below the inferior boundary of No. 1 nodes
3. Prevascular and retrotracheal nodes	Prevascular and retrotracheal nodes may be designated 3A and 3P; midline nodes are considered to be ipsilateral
4. Lower paratracheal nodes	The lower paratracheal nodes on the right lie to the right of the midline of the trachea between a horizontal line drawn tangential to the upper margin of the aortic arch and a line extending across the right main bronchus at the upper margin of the upper lobe bronchus, and contained within the mediastinal pleural envelope; the lower paratracheal nodes on the left lie to the left of the midline of the trachea between a horizontal line drawn tangential to the upper margin of the aortic arch and a line extending across the left main bronchus at the level of the upper margin of the left upper lobe bronchus, medial to the ligamentum arteriosum and contained within the

	mediastinal pleural envelope. Researchers may wish to designate the lower paratracheal nodes as No. 4s (superior) and No. 4i (inferior) subsets for study purposes; the No. 4s nodes may be defined by a horizontal line extending across the trachea and drawn tangential to the cephalic border of the azygos vein; the No. 4i nodes may be defined by the lower boundary of No. 4s
5. Subaortic (aortopulmonary window)	Subaortic nodes are lateral to the ligamentum arteriosum or the aorta or left pulmonary artery and proximal to the first branch of the left pulmonary artery and lie within the mediastinal pleural envelope
6. Para-aortic nodes (ascending aorta or phrenic)	Nodes lying anterior and lateral to the ascending aorta and the aortic arch or the innominate artery, beneath a line tangential to the upper margin of the aortic arch
7. Subcarinal nodes	Nodes lying caudal to the carina of the trachea, but not associated with the lower lobe bronchi or arteries within the lung
8. Paraesophageal nodes (below carina)	Nodes lying adjacent to the wall of the esophagus and to the right or left of the midline, excluding subcarinal nodes
9. Pulmonary ligament nodes	Nodes lying within the pulmonary ligament, including those in the posterior wall and lower part of the inferior pulmonary vein
N1 nodes: all N1 nodes lie distal to the mediastinal pleural reflection and within the visceral pleura	
10. Hilar nodes	The proximal lobar nodes, distal to the mediastinal pleural reflection and the nodes adjacent to the bronchus intermedius on the right; radiographically, the hilar shadow may be created by enlargement of both hilar and interlobar nodes
11. Interlobar nodes	Nodes lying between the lobar bronchi
12. Lobar nodes	Nodes adjacent to the distal lobar bronchi
13. Segmental nodes	Nodes adjacent to the segmental bronchi
14. Subsegmental nodes	Nodes around the subsegmental bronchi

Staging of SCLC

When the TNM system was first developed for NSCLC in the 1960s, it was not prognostic when applied to SCLC. This was most likely explained by the very low incidence of stage I or II SCLC and the fact that without chemotherapy, all patients with SCLC had very short survival. In a placebo-controlled trial of cyclophosphamide, the Veterans Administration Lung Group (VALG) developed a two-stage system for SCLC.⁷⁶ They separated patients into two groups, termed limited or extensive, based on whether or not their disease could be encompassed by a radiation port. The former group included those with malignant pleural effusion; the latter included all those with metastatic disease to distant sites. This classification was prognostic in patients on both arms of the trial, with median survival rates twice as long in limited stage patients. Through the past 20 years, the “limited” classification has been refined to identify those

who are candidates for curative-intent chemoradiation.

As in NSCLC, the process of staging SCLC is key to determining therapy and prognosis. The main goal of thorough staging is to identify patients who are candidates for curative-intent chemoradiation. Patients who have clinically evident metastatic disease (extensive stage) do not require thorough staging for all potential sites of spread. Because the major intent of staging is to determine therapy, the case can be made to image the brain in all patients as positive findings are an indication for eventual brain radiation.

General guidelines for lung cancer staging

Patients who present with a new lung lesion and no evidence of metastatic disease by history, physical examination, or chest radiography should undergo CT scanning of the chest, including the liver and adrenal glands. In some circumstances, when a clinical stage I malignancy is suspected, invasive diagnostic studies can be waived, and the patient can undergo resection for diagnosis and treatment. If a resection beyond a lobectomy is required or if the patient is a high surgical risk, it is best to attempt preoperative diagnosis of the lesion. If the patient requires pneumonectomy, a cancer diagnosis should be made before proceeding with the resection.

Asymptomatic patients who have no abnormal results on physical examination and who are potential surgical candidates with clinical stage I, stage II, or stage IIAN1 disease can undergo resection. Patients with chest CT scan evidence of metastatic disease, particularly N2 or N3 disease, should undergo invasive studies, which may include cervical mediastinoscopy. In some instances, FNA can be performed. For patients with potentially resectable stage III disease, the status of the mediastinal lymph nodes is the most important factor in determining therapy. If the lymph nodes are radiographically enlarged (>1 cm in cross-sectional diameter), histologic or cytologic evaluation is necessary before proceeding to thoracotomy.

If a diagnosis of SCLC is made, a thorough search for metastatic disease should be undertaken, followed by appropriate treatment with chemotherapy or chemoradiotherapy. In only 5% of cases can a patient with SCLC be considered for surgical intervention; these are cases of very early-stage disease, without evidence of nodal or metastatic disease.

If the history and physical examination are suggestive of metastatic disease, other noninvasive staging studies directed to the area of concern should be performed. In addition to a chest CT scan, these studies may include a PET/CT scan, a CT scan or MRI of the brain, bone scan, and a CT scan of the abdomen if the CT scan of the chest did not include the liver and adrenal glands.

Approximately 10% of all lung cancer patients have CNS metastases at the time of diagnosis. CNS metastases are more common in patients with SCLC. Occult brain metastases are present in approximately 3–6% of patients with NSCLC. CT scanning of the brain identified a 13% incidence of metastases in patients being evaluated for resection, although only 21% of these were unsuspected by virtue of unremarkable neurologic examination findings. Because of this low incidence of occult brain metastases, particularly in patients with early clinical stages of disease, routine MRI or CT scanning of the brain is not required. MRI is more sensitive than CT scans for identifying and diagnosing asymptomatic metastatic disease to the brain.^{77, 78}

Therapy for NSCLC

In patients with NSCLC, the most important prognostic factor is tumor stage.⁷⁹ Surgery is the standard mode of treatment for patients with stage I and II tumors. Selected patients with stage III tumors may be

candidates for surgical resection and may receive either preoperative chemotherapy (or chemoradiotherapy) or postoperative adjuvant chemotherapy and radiotherapy. The use of combined-modality therapy in locally advanced stage III NSCLC is an area of intense investigation, as discussed later in this chapter. Patients with stage IV disease are treated with chemotherapy, palliative radiation therapy, or with supportive therapy alone. Patients with unresectable or inoperable NSCLC are evaluated first for definitive, curative therapy with a combined chemoradiation therapy approach. If there are pressing symptomatic needs for palliation, such as complete obstruction of a major airway, hemoptysis, SVC obstruction, painful bony metastases in the weight-bearing areas, or symptomatic brain metastases, the initial treatment is radiotherapy with or without chemotherapy. If a patient has evidence of disseminated disease and there is no pressing need for radiotherapy, the approach includes consideration of systemic chemotherapy, or supportive therapy alone if the patient's general condition is not suitable for systemic chemotherapy. Each of the three main disciplines involved in the treatment of lung cancer—surgery, radiotherapy, and chemotherapy—is discussed individually. SCLC, whose treatment differs from that of NSCLC, is discussed as a separate section, albeit with similar organization.

Surgical treatment

Preoperative assessment

A patient who is considered for pulmonary resection should undergo preoperative evaluation by a thoracic surgeon. Lung cancer treatment outcomes are improved under the care of specialized thoracic surgeons.⁸⁰ There are many factors that influence patient selection for pulmonary resection, surgical approach, and the extent of surgical procedure. Known factors associated with increased perioperative morbidity and mortality include age, cigarette use, cardiac disease, restricted pulmonary function, and pneumonectomy. General PS graded by the Eastern Cooperative Oncology Group (ECOG) scale is another commonly quoted indicator of not only perioperative outcomes but also of the ability to tolerate any type of aggressive therapy.⁸¹

Surgical technique

Conduct of anesthesia

Pulmonary resections are conducted under general anesthesia with selective single-lung ventilation. FOB is generally performed first to ensure the correct placement of an endotracheal tube and to examine airways for the presence and extent of endobronchial disease or unexpected lesions.

Incisions

Several approaches and surgical techniques are used for the resection of pulmonary tumors. The decision about the approach and technique is based on the tumor size, location, and the relationship to other intrathoracic structures; patient's comorbidities and surgeon's experience are also taken into account. Options for surgical techniques include traditional open thoracotomy approach, video-assisted thoracic surgery (VATS), or robotic-assisted thoracic surgery (RATS).

Posterolateral thoracotomy with or without division of the latissimus dorsi muscle generally permits the best overall exposure to the pleural cavity and allows direct palpation of all structures within the hemithorax. Median sternotomy or clamshell incision can be used for resections of tumors located in the upper lobes or in cases of bilateral disease when exploration of both thoracic cavities is desired.

VATS has become a well-established tool in the armamentarium of thoracic surgeons.⁸² Multiple

investigators have shown the ability to perform anatomic lobectomies and even pneumonectomies using a VATS approach. There are sufficient data that the postoperative recovery is greatly shortened compared to standard rib spreading techniques. Other advantages include decreased postoperative air leaks, pneumonia, atrial fibrillation, length of stay, and mortality. These advantages have led some investigators to hypothesize that better tolerance of adjuvant chemotherapy will be seen following thoracoscopic lobectomy compared to open thoracotomy thus resulting in improved overall survival (OS). These claims have not been substantiated in an RCT.

The advent of robotic technology and RATS has further amplified the argument for performance of pulmonary resections without thoracotomy and rib spreading, and early outcomes of RATS lobectomy appear promising.⁸³ The cost of robotic technology is presently relatively high and it remains to be seen whether there is a demonstrable benefit of this technique over traditional VAT surgery.

Standard surgical procedures

Pneumonectomy, removal of the entire lung, is indicated for tumors that cannot be completely resected with a lesser procedure due to their central location and involvement of mainstem bronchus or main pulmonary artery, or due to transfissure involvement of multiple lobes. Adequate exposure for this procedure is generally obtained via posterolateral thoracotomy. Perioperative mortality after pneumonectomy is approximately 5%, with a range between 2% and 26% in some studies after neoadjuvant chemoradiation for locoregionally advanced disease. Right-sided pneumonectomy is regarded as the highest risk pulmonary procedure. Cardiopulmonary complications (pneumonia, acute respiratory distress syndrome, atelectasis, aspiration, atrial fibrillation, and myocardial infarction) are the most frequent morbidities associated with pulmonary resection and occur in approximately 20–30% of patients.^{84–87}

Lobectomy is the most common type of resection performed for lung cancer. It is regarded as an oncologic standard for the removal of lung cancer, as it extirpates the primary tumor with its lymphatic basins while sparing remaining functional lung parenchyma. Importantly, cancer survival is equivalent for patients undergoing lobectomy or pneumonectomy for all stages of disease when a complete resection is performed. Lobectomy requires isolation, ligation, and division of the individual arterial, venous, and bronchial branches supplying the lobe, along with the division of the interlobar fissure. Tumors that are close to the origin of a lobar bronchus require bronchial sleeve resection to obtain negative margin; this procedure spares functional lung parenchyma without compromising oncologic outcome ([Figure 5](#)). In selected patients, bronchial sleeve resection has proven to be a safe and effective method for pulmonary preservation, with cancer survival rates comparable to those following pneumonectomy.⁸⁸

Figure 5 A standard right upper lobectomy cannot be performed in this circumstance because residual tumor will remain in the bronchial stump. Rather than performing a pneumonectomy, a sleeve lobectomy is performed to ensure negative margins while still preserving the right middle and lower lobes.

Sublobar resections refer to segmentectomy, wedge resection, and lumpectomy. Lung segments are distinct anatomic regions supplied by a named artery, vein, and bronchus; although parenchymal borders of lung segments are not clearly visible. Each segment contributes approximately 5–6% of lung function so the loss of functional parenchyma is much less than with lobectomy. After isolation of bronchovascular structures, lung parenchyma of a given segment or segments is divided with a stapler. Segmentectomy is indicated in patients whose pulmonary function precludes lobar resection or in patients with tumors <2 cm in size. Whether segmentectomy is equivalent to lobectomy for T1A tumors is unclear, and this question is being addressed in two ongoing RCTs.

Wedge excision, in contrast, is performed without identifying bronchovascular anatomic landmarks. It is a simple and quick procedure for peripheral lesions. A stapling device is used to remove the lesion. The aim is to achieve a margin of normal tissue at least the same size as the tumor. Lesions that reside more deeply within the pulmonary tissue may be removed by precise local excision with laser or electrocautery assistance (lumpectomy). The pulmonary tissue is directly incised and the lesion is removed, with preservation of the surrounding lung. This technique is more applicable for benign lesions, or selected resection of metastases rather than lung cancer.

Positive margins (bronchial and parenchymal)

At the time of resection, the bronchial margin should be assessed by frozen section to ensure a complete resection. If the margin contains evidence of disease, all reasonable attempts to achieve a negative margin should be undertaken to minimize the risk of local recurrence. Several studies have shown that reasonable survival rates can be achieved in the face of a positive bronchial margin. When microscopic disease or CIS exists within the mucosa, 5-year survival rate can approach 24%.⁸⁹ Shields and colleagues⁹⁰ also showed a reasonable survival rate in patients with carcinoma in the bronchial mucosa. In this cohort of patients, however, survival was poor when disease was present outside of the bronchial mucosa or within the peribronchial lymphatics, a finding similar to those of other studies.^{89, 91}

Radiotherapy

Radiation therapy for lung cancer has changed rapidly in the past decade. Our ability to define target volumes and avoid normal structures has been aided by advancements in four-dimensional (4D) CT

technology and in FDG-PET scanning. It is now possible, moreover, to measure and account for individual variations in respiratory tumor motion. Treatment-planning algorithms can account for tissue heterogeneity and motion, which can improve dose distributions to target volumes. Three-dimensional conformal radiotherapy (3D CRT) is routinely achieved by using International Commission on Radiation Units and Measurements (ICRU) definitions of volumes and doses. Intensity-modulated radiotherapy (IMRT), including volumetric intensity-modulated arc therapy (VMAT) and stereotactic ablative radiotherapy (SABR), has been implemented clinically, and proton therapy has become a reality. We also look forward to the rational integration of new biologic therapies, including biomarker and pathway-targeted therapy and immunotherapy, into standard treatment.

More than 60% of lung cancer patients will receive radiotherapy at some point in their disease, 45% for initial treatment, and 17% for palliation.⁹² This means that over 100,000 US patients with lung cancer are irradiated yearly. Experienced teams are required to manage the care of these patients optimally, particularly when combined-modality therapy is used; outcomes are demonstrably better when patients are treated by experienced personnel.^{93, 94}

Radiation treatment techniques and volumes for lung cancer

The ICRU has defined several important volumes for the modern treatment of lung cancer: gross tumor volume (GTV), clinical target volume (CTV), planning target volume (PTV), and internal target volume (ITV).

Gross tumor volume

GTV is defined as visible tumor by any imaging modality. FDG-PET scanning is important for radiation treatment planning.⁹⁵ It reduces interobserver differences in GTV contouring⁹⁶ and helps to categorize suspect mediastinal/hilar lymphadenopathy as either benign or malignant; higher standardized uptake values (SUVs) are predictive of metastatic disease and local failure. It also helps to identify tumors within an atelectatic lobe and thereby decrease the amount of normal lung irradiated. Finally, because FDG-PET scans detect distant metastases in about 30% of patients with NSCLC (particularly those with otherwise advanced disease), it can help significantly with patient triage.⁹⁷

Clinical target volume

CTV is defined as the volume that is likely to contain gross and microscopic disease. To include the tumor within the CTV with 95% accuracy requires GTV to CTV expansions of 6 mm for squamous cancers and 8 mm for adenocarcinomas.⁹⁸ Expansions for other histologic types have not been determined, but a conservative approach would be to use 8 mm. Appropriate CTV for the mediastinum has not been rigorously determined. We empirically use 8-mm expansions around involved nodes (either gross involvement or FDG-PET positivity). Clinical editing of the CTV margin is needed to take anatomical boundaries and pattern of failure into consideration.

Planning target volume

PTV is defined as CTV with a margin to account for daily setup error and target motion. PTV takes setup uncertainty and motion into account. Setup uncertainty is likely both technique dependent and institution dependent and should be measured individually for each technique.

Accounting for respiratory-dependent tumor motion is similarly challenging and can be approached in several ways. It is clear, however, that two-dimensional (2D) measurement of tumor motion (e.g.,

fluoroscopy) is inadequate. Such motion is unpredictable and is independent of tumor size, location, and PFT (pulmonary function test) results.⁹⁹ Tumor motion should be assessed individually based on each patient's disease status, breath pattern, and other clinical conditions. 4D CT imaging showed that approximately 40% of lung cancers move more than 5 mm and 10% of lung cancers move more than 10 mm during the respiration. For patients with tumors moving <5 mm, simple expansion along the axis of motion is adequate. For patients with tumors moving more than 5 mm, particularly more than 10 mm, the treatment machine can be gated with respiration, the patient can use an assisted breath-hold technique, or an ITV-based approach can be used.

Internal target volume

ITV is an expansion of CTV in which target motion is explicitly measured and taken into account as defined by ICRU62. By using technologies such as multislice detectors and faster imaging reconstruction, we can image patients during real-time breathing and assess organ motion using 4D CT.¹⁰⁰ To determine the ITV from the 4D CT images, the tumor volume outlined on expiratory phase of the 4D images is registered on other phases of the images to create a union of target contours enclosing all possible positions of the target. The same principle can be applied to the images acquired with inspiration and expiration breath holds. Attention should be paid to irregular breathing and variation of breathing patterns over the course of the treatment and the effects of such on the ITV margin. Even with 4D CT, the free-breathing ITV is only a snapshot and a single stochastic sampling of the patient breathing during the 4D CT acquisitions. Thus, the true ITV margin should be enlarged on the basis of the uncertainty of patient's breathing during the treatment course.

Intensity-modulated radiation therapy (IMRT)

IMRT, including VMAT, can improve dose conformality and allow integrated dose escalation and dose “painting” within the PTV. Collectively, this leads to the delivery of higher radiation doses to high-risk areas of the tumor such as gross tumor, hypoxic areas, or areas showing high SUVs on PET–CT without increasing the number of treatment fractions and while minimizing exposure to normal tissues.^{101, 102} However, the application of IMRT to lung cancer has been delayed because of concerns that IMRT may deliver low yet damaging doses to larger volumes of normal lung tissue. Moreover, the possible movement of a tumor due to respiration introduces another level of complexity to both the IMRT dosimetry and the technique used.

Although IMRT may be effective in reducing normal tissue toxicity and improving tumor coverage, its high-dose gradient and conformity require a high level of precision in dose delivery and tumor localization. In the meantime, the complexity introduced by tumor motion must be recognized when using IMRT. Unlike 3D CRT, IMRT treats only a portion of the target volume at a particular time. Concern has been expressed as to whether target motion and collimator motion during IMRT delivery have a significant interplay effect, thus degrading the planned dose distributions. For IMRT to be feasible and more effective in treating NSCLC, motion reduction techniques should be explored further, such as breath holding and tumor tracking. Our clinical data indicate that IMRT may reduce toxic effects in normal tissue in selected cases and allow further dose escalation.¹⁰³ When used appropriately, IMRT is the preferred radiotherapy modality for dose-escalated radiotherapy in lung cancer.¹⁰⁴

Stereotactic ablative radiotherapy (SABR)

SABR, also called stereotactic body radiation therapy (SBRT), allows precise targeting and delivery of high doses of radiation therapy in <2 weeks. SABR for lung cancer uses elements of 3D CRT or

IMRT/VMAT, incorporates a variety of systems for taking tumor motion into consideration, and decreases setup uncertainty by using image-guided radiotherapy techniques. Use of SABR reduces treatment volumes, facilitating hypofractionation with markedly increased daily doses (>10 Gy) and significant reduction in overall treatment times. The combination of multiple beam angles or arc therapy to achieve sharp dose gradients, high-precision localization, and a high dose per fraction in extracranial locations is referred to as SABR. This approach delivers a high biological effective dose (BED) to the target while minimizing toxic effects to normal tissues, which may improve local control and survival rates.

Onishi et al.⁶⁸ reported on the use of SABR for stage I NSCLC in their retrospective evaluation of results from a Japanese multi-institutional study. Patients with stage I NSCLC ($n = 245$; median age, 76 years; T1 N0 M0, $n = 155$; T2 N0 M0, $n = 90$) were treated with hypofractionated high-dose SABR. Stereotactic 3D treatment was delivered with noncoplanar dynamic arcs or multiple static ports. A total dose of 18–75 Gy at the isocenter was administered in 1–22 fractions. The median calculated BED was 108 Gy (range, 57–180 Gy). During follow-up (median, 24 months; range, 7–78 months), pulmonary complications of grade 2 or higher (according to the NCI's common terminology criteria) were observed in only six patients (2.4%). Local progression occurred in 33 patients (14.5%), and the local recurrence rates were 8.1% for patients with a BED = 100 Gy and 26.4% for those with a BED < 100 Gy ($p < .05$). The 3-year OS rates for medically operable patients were 88.4% for those with BED = 100 Gy and 69.4% for those with <100 Gy ($p < .05$). This analysis showed that hypofractionated high-dose SABR with BED < 150 Gy was feasible and beneficial for curative treatment of patients with stage I NSCLC. For all treatment methods and schedules, local control and survival rates were better when the BED was 100 Gy than when it was less. Survival rates in selected patients (medically operable, BED = 100 Gy) were excellent and were potentially comparable to those of surgery.

The treatment of more than 2000 patients with imaging-guided SABR (4D CT simulation and daily CT-on-rails for tumor localization and setup accuracy) at doses of 50 Gy delivered in four fractions (daily treatment for 4 days) or 70 Gy in 10 fractions was associated with local control rates at the primary site of higher than 95% with minimal toxicity, even for centrally located lesions when normal tissue dose constraints were respected.¹⁰⁵

Proton therapy

The proton is a charged particle that, compared with the photon, possesses a well-defined range of penetration determined by both the beam's energy and the density of the tissue through which it passes. As the proton beam penetrates the body, the particles slow down and deposit the dose sharply near the end of its range, a phenomenon known as the Bragg peak. By modulating the Bragg peak across the target volume, proton beams can deliver a full, localized, uniform dose of energy to the treatment site while sparing the surrounding normal tissues. This therapy is ideal when organ preservation is paramount, such as in lung cancer. Clinical data using escalated/accelerated proton radiotherapy showed promising results comparable to those of surgical resection in stage IA cases.^{106, 107} The accuracy of target delineation and tumor motion consideration is critical for both proton and photon treatments. Proton treatment is more sensitive than photon therapy to anatomical motion, position uncertainties, and tissue inhomogeneity.¹⁰⁸

Primary radiation therapy for stage I and II NSCLC

Patients who have surgically resectable NSCLC but are medically inoperable or who decline surgery should be considered for curative radiotherapy. Primary radiotherapy for early-stage NSCLC is considered standard treatment, and several studies have reported a benefit from dose escalation with regard to survival and local control in early-stage NSCLC.^{109–112} Because early-stage NSCLC is not

inherently a systemic disease at diagnosis, and as local control is poor after conventional radiotherapy, research measures aimed at improving survival should put significant emphasis on improving local tumor obliteration.

It should be kept in mind that lung cancer in such patients is always staged clinically, which makes comparison with surgically treated patients difficult. Several surgical series demonstrate a 24–37% upstaging of cT1–T2 N0 disease, which partially explains the poorer results seen in clinically staged irradiated patients.¹¹³ As better screening tools for early-stage NSCLC are developed, however, the number of patients with small but medically inoperable tumors will increase.⁷¹

Postoperative radiotherapy (PORT)

PORT (postoperative radiotherapy) is currently contraindicated for patients with stage I completely resected disease on the basis of the PORT meta-analysis.¹¹⁴ Data for stage II and higher disease neither support nor refute the use of PORT (because the hazard ratio error bars include 1.0), although it clearly improves regional control.

The use of PORT for stage II and III NSCLC was first tested in a controlled trial by the Lung Cancer Study Group, which randomized 210 patients to receive either 50 Gy in 25 fractions or no treatment.¹¹⁵ Local recurrence rate was significantly reduced (3% vs 41%), but there was no effect on OS or disease-free survival (DFS) because of the high rate of distant failure. However, recent data from subgroup analyses of a phase III RCT examining surgical resection with/without adjuvant chemotherapy [ANITA (Adjuvant Navelbine International Trialist Association) trial] indicated that PORT may improve OS in patients with N2 disease.

In patients with resectable or marginally resectable NSCLC, 5-year survival rates and collective results of surgery alone for stage III (N2) ranged from 14% to 30%. Many patients who have clinical N0 disease are found to have occult mediastinal lymph node metastases. Approximately 15% of patients with resected T1 tumors have N2 disease, and 40–45% of patients with T2–T3 tumors will have N2 disease. Patients with incomplete resection, including positive margins, multiple levels of lymph node involvement, extracapsular extension, and N2 disease usually have poor local control, and PORT is usually indicated.

Preoperative chemotherapy and chemoradiotherapy

If N2 disease is bulky and the potential for complete resection is questionable, patients can be treated by neoadjuvant chemotherapy followed by surgery. Increasing numbers of patients with stage III disease undergo induction chemotherapy followed by surgery, based on the work of Rosell et al.¹¹⁶ and Roth et al.¹¹⁷ Findings from a phase II trial conducted by the Southwest Oncology Group (SWOG) found that concurrent induction chemoradiotherapy with etoposide and cisplatin (EP) in 74 patients with biopsy proven stage IIIA (N2) NSCLC may improve patient survival with reasonable toxicity.¹¹⁸ Following this, the NCI launched a phase III multicenter for patients with biopsy-proven N2 disease and potentially resectable NSCLC (NCI Protocol INT 139). Patients were stratified by PS and T status and were randomized to receive induction chemoradiotherapy followed by surgery or chemotherapy with definitive radiotherapy. Results showed no differences in OS but better progression-free survival (PFS) in the group treated with surgery. Subgroup analysis revealed better survival for patients who underwent a lobectomy ($p = .002$). However, trimodality therapy was not optimal when a pneumonectomy was required owing to the high mortality risk. Finally, N0 status at surgery significantly predicted a higher 5-year survival rate. The study concluded that chemotherapy plus radiotherapy with or without resection (preferably

lobectomy) are options for patients with stage IIIA (N2) NSCLC. Surgical resection after chemoradiation can be considered for fit patients if lobectomy is feasible.¹¹⁹

Radiation therapy for unresectable stage III NSCLC

For patients with unresectable stage III NSCLC, conventional radiotherapy alone resulted in a median survival time of 10 months and a 5-year survival rate of 5%. To improve outcomes, chemotherapy was added to radiotherapy. Chemotherapy and radiotherapy can be delivered sequentially or concurrently. The most well-known trial, reported by the Cancer and Leukemia Group B (CALGB), compared standard radiotherapy to 60 Gy to sequential cisplatin and vinblastine chemotherapy for two cycles followed by radiotherapy to 60 Gy. Median survival times and 5-year survival rates were superior for the chemoradiotherapy arm (13.8 months vs 9.7 months, 19% vs 7%, respectively).¹²⁰

The RTOG subsequently conducted a three-arm trial (RTOG 88-08) comparing standard radiotherapy, sequential chemoradiotherapy (CALGB regimen), and 69.6-Gy hyperfractionated radiotherapy. Sequential chemoradiotherapy was statistically superior to standard and hyperfractionated radiotherapy.¹²¹

Schaake-Koning et al.¹²² compared radiotherapy alone with radiotherapy plus daily cisplatin or weekly cisplatin. There was no difference in distant failure rates between the groups with or without cisplatin. However, the survival rate in the radiotherapy-plus-cisplatin group was 54% at 1 year, 26% at 2 years, and 16% at 3 years, compared with 46%, 13%, and 2% in the radiotherapy-alone group ($p = .009$). Therefore, this study showed that a gain in local tumor control seems to have translated into increased survival time.

Furuse and colleagues compared patients receiving two cycles of mitomycin, vindesine, and cisplatin given every 28 days concurrent with split-course radiotherapy (total dose of 56 Gy) with patients receiving two cycles of mitomycin, vindesine, and cisplatin followed by continuous radiotherapy (total dose of 56 Gy). The concurrent treatment yielded an improved 5-year survival rate compared with the sequential treatment.¹²³

The RTOG conducted a three-arm RCT (RTOG 9410) to analyze whether the concurrent delivery of cisplatin-based chemotherapy with thoracic radiotherapy (TRT) improves survival compared with the sequential delivery of these therapies for patients with locally advanced, unresected stage II–III NSCLC. The sequential therapy consisted of cisplatin and vinblastine followed by 60 Gy of radiation. The concurrent treatment used the same chemotherapy with 60 Gy of radiation beginning on day 1 of chemotherapy. The third treatment was concurrent cisplatin and oral etoposide with 69.6 Gy of radiation in 1.2-Gy BID fractions beginning on day 1. RTOG 9410 demonstrated that the concurrent delivery of cisplatin-based chemotherapy with TRT conferred a greater long-term survival benefit than did the sequential delivery of these therapies.¹²⁴

A third RCT comparing concurrent with sequential chemoradiotherapy also explored the use of consolidation chemotherapy.¹²⁵ In this phase III trial, patients were assigned to receive two cycles of cisplatin plus vinorelbine followed by 66 Gy of radiation or cisplatin/etoposide and concurrent radiation to 66 Gy followed by two cycles of consolidation chemotherapy with cisplatin and vinorelbine. Local control rates were improved with the concurrent regimen (40% vs 24%), and the median survival times and 4-year survival rates were numerically superior (but not statistically superior) in the concurrent arm of the trial (16.3 months vs 14.5 months and 21% vs 14%, respectively). However, the incidence of grade 3 esophagitis was significantly higher in the concurrent arm (32% vs 3%), and the toxic effects-related death rates were high in both arms (9.5% in the concurrent arm and 5.6% in the sequential arm).

These three phase III trials consistently demonstrated longer survival times for patients receiving concurrent chemoradiotherapy, and this difference was significant in two of the three trials. On the basis of these results, concurrent chemoradiotherapy has been the standard of care since 2001. It is important to note that toxic effects are significantly more common with concurrent chemoradiotherapy than with sequential chemoradiotherapy.

In RTOG 9410, the locoregional failure rate after concurrent chemoradiotherapy was still 34–43%. To improve the local control rate, three groups [RTOG, North Central Cancer Treatment Group (NCCTG), and the University of North Carolina (UNC)] have separately performed radiation dose-escalation trials for patients with inoperable stage III NSCLC and reported results supporting the safety of 74 Gy. UNC conducted a phase I/II dose-escalation clinical trial using high-dose 3D CRT (60–74 Gy) for inoperable stage IIIA/IIIB NSCLC with induction chemotherapy followed by concurrent chemoradiotherapy.¹²⁶ They reported a 3-year survival rate of 36% and a 13% locoregional relapse rate as the only site of failure. For patients who finished radiotherapy, the 3-year survival rate was 45%.

RTOG conducted a phase III study to compare conventional-dose (60 Gy) with escalated-dose (74 Gy) radiotherapy concurrently with weekly paclitaxel and carboplatin, with or without cetuximab, an antibody against EGFR, for patients with stage IIIA or IIIB NSCLC. Surprisingly, early analyses showed no improvement in OS with the higher radiation dose.¹²⁷ In fact, the high-dose arm had worse survival rates and greater toxicity. It is possible that 74 Gy is too toxic when delivered by the photon-based radiation technologies used in this trial. Further, the addition of cetuximab did not improve survival either.

Randomized trials have failed to identify an optimal concurrent chemotherapy doublet regimen. Several commonly used options include platinum (cisplatin or carboplatin) in combination with etoposide, paclitaxel, and pemetrexed.^{128–130}

Systemic therapy for incurable, advanced-stage NSCLC

For patients with stage IV NSCLC, or those with recurrent disease, which is not amenable to curative surgery or radiotherapy, the goals of systemic therapy are to palliate symptoms and prolong survival. In a meta-analysis of 2714 patients enrolled into 16 RCTs comparing chemotherapy to best supportive care (BSC), there was a significant benefit from chemotherapy with increased median OS from 4.5 to 6 months and 1-year OS from 20% to 29% (HR 0.77; 95% CI 0.71–0.83, $P < 0.0001$).¹³¹ Most trials included platinum-based doublets, which were the only chemotherapy regimens associated with a statistically significant improvement in OS.

First-line chemotherapy

Three large RCTs compared platinum-doublet to single-agent nonplatinum chemotherapy. The Swedish Lung Cancer Study Group randomized 334 patients with advanced NSCLC to gemcitabine plus cisplatin or as single agent.¹³² The platinum-doublet arm was associated with a significant improvement in overall response rate (30% vs 11%), median OS (10 months vs 8.6 months), and 1-year OS (40% vs 32%). Georgoulis et al.¹³³ compared docetaxel with cisplatin as single agent in 324 patients. Although the response rates were significantly higher in the combination arm (36% vs 22%), there were no significant differences in median OS (10.5 months vs 8 months) or 1-year OS (44% vs 43%). Similar results were observed in the CALGB 9730 study with 561 patients, where the combination of carboplatin plus paclitaxel was associated with increased response rates (30% vs 17%) but the median OS (8.8 months vs 6.7 months) and 1-year OS (37% vs 32%) did not reach statistical significance.¹³⁴ In contrast, two large studies showed a significant improvement in overall response rates, median OS, and 1-year OS for

cisplatin doublets, using either gemcitabine or vinorelbine, compared to cisplatin alone.^{135, 136} Three large meta-analyses comparing platinum doublets to single-agent chemotherapy showed increased response rates and OS for doublets.^{137–139} The addition of a third drug to the platinum regimen was associated with increased response rates but no improvement in OS.¹³⁷ With these data, the American Society of Clinical Oncology guidelines from 2009 recommended a platinum-based doublet as the initial treatment for patients with advanced NSCLC and ECOG PS of 0 or 1.¹⁴⁰

Multiple studies showed either no significant differences or a small improvement for a particular chemotherapy combination.^{141–143} In a large RCT, 1725 patients with previously untreated advanced-stage NSCLC were randomized to cisplatin plus gemcitabine or pemetrexed.¹⁴⁴ Similar to most previous studies comparing platinum-based doublets, there were no significant differences in median PFS or median OS. Nevertheless, this was the first study to show differences in outcomes for chemotherapy according to histology, with cisplatin plus pemetrexed associated with increased median OS in nonsquamous tumors (11.8 months vs 10.4 months, HR 0.84, $P = 0.005$) but not in squamous tumors (9.4 months vs 10.8 months, HR 1.23, $P = 0.05$). Histology also played a role in a phase III trial comparing carboplatin plus paclitaxel or nab-paclitaxel in 1052 patients.¹⁴⁵ This study showed increased response rates (33% vs 25%, $P = 0.05$) but similar median PFS and OS. The improvement in response rates was observed only in patients with squamous-cell histology (41% vs 24%, $P < 0.001$), with nearly identical responses in adenocarcinoma (26% vs 27%).

As carboplatin has a similar mechanism of action compared to cisplatin, two meta-analyses examined whether it would have equivalent efficacy in NSCLC. One meta-analysis included 2948 patients from eight RCTs, while the other included 2968 patients from nine RCTs. Although treatment with cisplatin-based doublets demonstrated longer OS, the results did not reach statistical significance.^{146, 147} In subset analyses, cisplatin doublets were associated with improved OS in patients with stage IIIB, nonsquamous histology and in those treated with third-generation chemotherapy including paclitaxel, docetaxel, and gemcitabine. Carboplatin was associated with increased incidence of thrombocytopenia whereas cisplatin was associated with increased risk of nausea, vomiting, and nephrotoxicity. Therefore, despite the superiority of cisplatin-based doublets, the small improvement in OS and increased toxicity compared to carboplatin led to the acceptance of both platinum drugs in a population of incurable patients treated with palliative intent.

Monoclonal antibodies

Bevacizumab

Bevacizumab is a recombinant humanized antibody against circulating vascular endothelial growth factor (VEGF). In a phase II study comparing first-line carboplatin plus paclitaxel with or without bevacizumab in patients with advanced NSCLC, treatment with bevacizumab was associated with increased response rates and median OS.¹⁴⁸ Six patients experienced life-threatening bleeding of which four were fatal. All six patients had centrally located tumors, five had cavitation in the tumor either at baseline or after treatment with bevacizumab, and four patients had squamous-cell histology. The ECOG 4599 trial randomized 878 patients with recurrent or advanced NSCLC with predominantly nonsquamous histology, hemoptysis of less than half teaspoon per event, and no brain metastases, to carboplatin plus paclitaxel with or without bevacizumab.¹⁴⁹ The bevacizumab arm was associated with increased response rates (35% vs 15%, $P < 0.001$), PFS (6.2 months vs 4.5 months, HR 0.66, $P < 0.001$), and median OS (12.3 months vs 10.3 months, HR 0.79, $P = 0.003$). The addition of bevacizumab increased the incidence of neutropenia, neutropenic fever, thrombocytopenia, hypertension, proteinuria, and bleeding. The avastin in

lung cancer (AVAiL) trial randomized 1043 patients to cisplatin plus gemcitabine alone or in combination with either low-dose (7.5 mg/kg) or high-dose bevacizumab (15 mg/kg).¹⁵⁰ The low-dose and high-dose bevacizumab arms demonstrated higher response rates (34.1% vs 30.4% vs 20.1%, $P = 0.003$), but there were no significant differences in median OS.¹⁵¹

Ramucirumab

Ramucirumab is a human monoclonal antibody against VEGF receptor 2. In a randomized trial comparing platinum plus pemetrexed with or without ramucirumab in 130 patients with previously untreated advanced-stage NSCLC, the addition of ramucirumab was associated with a nonsignificant increase in response rates (49.3% vs 38%, $P = 0.18$) and median PFS (7.2 months vs 5.6 months, HR 0.75, $P = 0.13$).¹⁵²

Cetuximab

Cetuximab is a chimeric monoclonal antibody against EGFR. The addition of cetuximab to chemotherapy was evaluated in two large RCTs. In BMS099, 676 previously untreated patients with advanced-stage NSCLC were randomized to chemotherapy (platinum combined with paclitaxel or docetaxel) with or without cetuximab.¹⁵³ Although the cetuximab arm was associated with increased response rates (25.7% vs 17.2%, $P = 0.007$), PFS and OS were not significantly improved. In the first-line erbitux (FLEX) trial, 1125 patients were randomized to cisplatin plus vinorelbine alone or in combination with cetuximab.¹⁵⁴ The cetuximab arm was associated with improved response rates (36% vs 19%, $P = 0.01$) but not median PFS (4.8 months for both arms). Nevertheless, the median OS was significantly increased in patients treated with cetuximab (11.3 months vs 10.1 months, HR 0.87, 95% CI 0.76–0.99, $P = 0.04$). Further analyses of the FLEX study showed that the benefit from the addition of cetuximab was seen only in patients with IHC H-score (calculated as the percentage of cells scoring weekly for EGFR X 1, plus percentage of cell scoring moderately X 2, plus percentage of cells scored strongly X 3, with the total ranging from 0 to 300) above 200 with a median OS of 12.2 months compared to 9.6 months in patients treated with chemotherapy alone.¹⁵⁵

Duration of chemotherapy

Patients with advanced NSCLC who achieve clinical benefit, defined as the absence of progressive disease (PD), and tolerate treatment without major toxicities, should receive no more than four to six cycles of platinum-based therapy. Clinical trials comparing three to four cycles of chemotherapy to six cycles of continuation of therapy until tumor progression showed no benefit from more prolonged therapy.^{156–158}

Maintenance therapy

Additional treatment after four to six cycles of platinum-based chemotherapy in patients without tumor progression is termed maintenance therapy. The main types of maintenance therapy include continuation of the nonplatinum drug alone, continuation of the monoclonal antibody alone, and switch therapy where a different nonplatinum drug is used. Several trials have evaluated the role of maintenance therapy in patients without tumor progression after four to six cycles of chemotherapy ([Table 10](#)).^{164–168} These trials were restricted to patients with nonsquamous histology where the two main drugs used during the maintenance phase, pemetrexed and bevacizumab, are more effective and safer, respectively. The median OS was improved for maintenance pemetrexed compared to observation and the role of bevacizumab, either alone or in combination with pemetrexed, remains unclear.

Table 10 Maintenance chemotherapy

Trial	Induction	Maintenance	PFS (months)	OS (months)
JMEN ¹⁵⁹	Platinum doublet	Pem versus Obs	4 versus 2 ($P < 0.001$)	13.4 versus 10.6 ($P = 0.01$)

Bev, bevacizumab; Carb, carboplatin; Cis, cisplatin; Pem, pemetrexed; Pac, paclitaxel; NR, not reached; Obs, observation.

Second-line chemotherapy

The benefit from second-line chemotherapy has been established by two randomized trials using docetaxel. In the TAX 320 study, 373 previously treated patients were randomized to docetaxel or a control regimen of ifosfamide or vinorelbine.¹⁶⁹ Docetaxel was administered as either 100 mg/m² (D100) or 75 mg/m² (D75) every 3 weeks. Response rates for D100, D75, and control arms were 10.8%, 6.7%, and 0.8%, respectively. The 1-year OS was significantly higher in the D75 arm compared to the control therapy (32% vs 19%, $P = 0.025$) but not in the D100 arm. Prior use of paclitaxel did not have an impact on the response or survival. The second trial had a similar design and randomized 203 previously treated patients with advanced NSCLC not previously exposed to paclitaxel, to docetaxel (D75 or D100) or BSC.¹⁷⁰ Similar to the TAX 320 study, D75 was associated with improved 1-year OS compared to D100 and BSC (37% vs 19% vs 19%) and less toxicity compared to D100. The second approved chemotherapy drug in the second-line setting was pemetrexed. A large RCT compared docetaxel 75 mg/m² to pemetrexed 500 mg/m², both administered every 3 weeks. Response rates and median PFS were similar, and there were no significant differences in median OS (8.3 months for pemetrexed vs 7.9 months for docetaxel) or 1-year OS.¹⁷¹ Patients treated with docetaxel were more likely to have grade 3 or 4 neutropenia, febrile neutropenia, and alopecia compared to pemetrexed. In the REVEL study, 1825 patients with advanced NSCLC progressing on first-line platinum-based chemotherapy were randomized to docetaxel alone or in combination with ramucirumab.¹⁷² The addition of ramucirumab was associated with increased median PFS and OS (10.5 months vs 9.1 months, HR 0.86, 95% CI 0.75–0.98, $P = 0.002$). Two EGFR tyrosine kinase inhibitors (TKIs) were compared to BSC in patients with previously treated NSCLC. In the Iressa survival evaluation in lung cancer (ISEL) trial, 1692 patients were randomized to gefitinib (Iressa) or placebo.¹⁷³ Gefitinib was not associated with a significant improvement in median OS (5.6 months vs 5.1 months, HR 0.89, 95% CI 0.77–1.02, $P = 0.08$). In contrast, the NCIC-BR21, which randomized 731 patients to erlotinib or placebo, showed a significant improvement in median

duration median OS (6.7 months vs 4.7 months, HR 0.70, 95% CI 0.58–0.85, $P < 0.0001$) in patients treated with erlotinib.¹⁷⁴ The currently approved regimens for previously treated advanced NSCLC currently include docetaxel, pemetrexed, erlotinib, and the combination of docetaxel plus ramucirumab.

Chemotherapy in the elderly

Approximately one-third of all patients with NSCLC are aged 70 years or older, and, although these patients are likely to have an increased risk of co-morbid conditions and impaired organ function, most studies have suggested that age alone should not be a factor in the decision to treat patients with chemotherapy. Retrospective studies of patients treated for advanced NSCLC found no major differences between patients older than and younger than 65 years of age,¹⁷⁵ and an analysis of age as a risk factor in chemotherapy trials found that the response, toxicity, and survival rates of elderly patients were similar to those of younger patients.¹⁷⁶ An international expert panel has published recommendations for elderly NSCLC patients. These include comprehensive geriatric assessment to better define prognosis and predict tolerance to treatment. The panel concluded that single-agent chemotherapy with a third-generation drug (vinorelbine, gemcitabine, or a taxane) is a reasonable option for nonselected elderly patients with advanced NSCLC and that platinum-based chemotherapy is a viable option for fit patients with adequate organ function.¹⁷⁷

Targeted therapy

Epidermal growth factor receptor

Gefitinib was the first EGFR TKI tested in patients with advanced NSCLC. In the Iressa dose evaluation in advanced lung cancer (IDEAL) trials, patients with advanced NSCLC progressing after previous chemotherapy were randomized to gefitinib 250 or 500 mg.^{178, 179} The studies showed a response rate of approximately 10–18%, without significant differences between the two doses of gefitinib and increased rash with the higher dose. Clinical predictors for response included good PS, adenocarcinoma histology, female gender, and Japanese ethnicity. The discovery of EGFR mutations, mostly deletions in exon 19 and the substitution of arginine for leucine at position 858 (L858R), provided the biological explanation for the clinical predictors of response to EGFR TKIs.^{180, 181} In one of the studies, eight of the nine patients responding to gefitinib had EGFR mutations, which were more common in never smokers with adenocarcinoma histology.¹⁸⁰ In a Spanish study evaluating 2105 patients with nonsquamous NSCLC, 350 patients (16.6%) had EGFR mutation.¹⁸² These mutations were most common in never smokers (37.7%). In the Memorial Sloan-Kettering Cancer Center experience, the presence of EGFR mutations in never smokers, former smokers, and current smokers with adenocarcinoma was 52%, 15%, and 6%, with the incidence of EGFR mutations inversely related to smoking burden.¹⁸³

In a pooled analysis of outcomes for patients treated with EGFR TKIs, 78% with an EGFR mutation responded to therapy compared to only 10% with wild-type EGFR.¹⁸⁴ In order to compare the two approaches in a large RCT, the Iressa Pan Asia Study (IPASS) was designed to compare gefitinib to carboplatin plus paclitaxel in chemo-naïve patients with advanced-stage NSCLC.¹⁸⁵ In patients with EGFR wild type, gefitinib was associated with decreased response rates (23.5% vs 1.1%) and median PFS (HR 2.85, 95% CI 2.05–3.98, $P < 0.001$). In contrast, in patients harboring EGFR mutations, response rates (71.2% vs 47.3%) and median PFS were higher for those treated with gefitinib (HR 0.48, 95% CI 0.36–0.64, $P < 0.001$). Several similar trials including only patients with EGFR mutant tumors have been conducted with similar results for patients treated with gefitinib^{186, 187} or erlotinib.^{188, 189}

More recent studies compared the second-generation EGFR TKI afatinib to chemotherapy. Second-generation EGFR TKIs are characterized by irreversible binding to the HER family including HER-2 and HER-4. In the Lux-Lung 3 and 6 studies of patients with previously untreated advanced-stage lung adenocarcinoma, afatinib was associated with improved PFS versus cisplatin plus pemetrexed or cisplatin plus gemcitabine, respectively.^{190, 191} Although combined analysis of the two trials showed no difference in OS between afatinib and chemo, a subset analysis showed that median OS was significantly higher in patients harboring the EGFR deletion 19 mutation, but not those with the L858R mutation.¹⁹²

Despite the initial responses to EGFR-TKI therapy and prolonged median PFS compared to standard chemotherapy, virtually all EGFR mutant patients eventually developed acquired resistance to therapy.¹⁹³ The most common cause of acquired resistance to EGFR TKIs is the development of a secondary mutation in exon 20 (T790M).¹⁹⁴ Other potential causes include Met amplification, PIK3CA mutations, HER-2 amplification, BRAF mutations, and SCLC transformation.^{195, 196} Third-generation EGFR TKIs are potent inhibitors of T790M tumors. Two drugs are in advanced stage of development. Early results from trials with CO-1686 in patients with T790M mutation showed 58% response rate and an estimated median PFS >12 months.¹⁹⁷ Similarly, impressive results were observed with AZD-9291 in such patients, where response rates and overall disease control were 64% and 94%, respectively.¹⁹⁸ Another approach in patients with acquired resistance to EGFR TKIs is the combination of afatinib and cetuximab. In a phase IB study, this combination was tested in 126 patients with acquired resistance to erlotinib or gefitinib.¹⁹⁹ The overall response rate was 29% with no significant differences between T790M positive and negative patients (32% and 25% respectively, $P = 0.34$).

Anaplastic lymphoma kinase

Anaplastic lymphoma kinase (ALK) fusions with EML4, KIF5B, TFG, and KLC1, among others, result in constitutive activation of ALK and its downstream signaling pathways.²⁰⁰ Crizotinib is an oral ATP-competitive inhibitor of ALK, MET, and ROS1 tyrosine kinases. In an expanded cohort from a phase 1 trial including 82 patients with ALK fusion, response rate was 57% with an additional 33% of patients achieving stable disease (SD).²⁰¹ At the time of cutoff, the median PFS was not reached and the estimated probability of PFS at 6 months was 72%. In patients with ALK fusion, first-line crizotinib was associated with improved median PFS compared to platinum plus pemetrexed (10.7 months vs 7 months; HR 0.45, 95% CI 0.35–0.60, $P < 0.001$) without significant changes in median OS.²⁰² Similar findings were observed in the second-line setting where crizotinib was associated with increased median PFS compared to docetaxel or pemetrexed but no changes in median OS.²⁰³ One option for patients who develop acquired resistance to crizotinib is the use of second-generation ALK inhibitors. In the dose escalation part of a phase 1 study, ceritinib was associated with a 58% response rate and a median PFS of 7 months, ranging from 6.9 months in patients previously treated with crizotinib to 10.4 months in those who had not received previous ALK directed therapy.²⁰⁴

Other targets

Several potentially targetable gene abnormalities have been described in NSCLC and are currently being investigated in clinical trials.²⁰⁵ Among them, there has been recent data suggesting benefit from crizotinib in patients with ROS1 fusions.²⁰⁶ In a phase II trial enrolling 50 patients with ROS1 fusions, the response rate was 72% with a median PFS of 19.2 months.²⁰⁷ Although there are no direct inhibitors for KRAS mutations, downstream blockage with MEK inhibitors may play a role in the treatment of this patient population. In a phase 2 study randomizing 87 previously treated patients with advanced KRAS mutant

NSCLC to docetaxel alone or in combination with selumetinib, the latter was associated with increased median PFS (5.3 months vs 2.1 months, $P = 0.01$) and a numerically superior median OS (9.4 months vs 5.2 months, $P = 0.21$).²⁰⁸

Immunotherapy

Immune check point pathways play a key role in regulating T-cell responses. Programmed cell death (PD1) is an inhibitory T-cell receptor that binds to its ligand PD-L1 in tumors. Preclinical studies have shown that inhibition of the PD-1/PD-L1 interaction may increase T-cell responses and induce an anti-tumor effect. Several drugs designed to block this pathway are under development including the anti-PD1 antibodies BMS-936558 (nivolumab) and MK-3475 (pembrolizumab) and the anti-PDL1 antibodies MPDL-3280A and MEDI-4736.²⁰⁹ In a phase 1 study evaluating the role of nivolumab in patients with NSCLC, renal cell carcinoma, and melanoma, there were 14 responses among the 122 patients with NSCLC.²¹⁰ All the responses occurred in patients treated with 3 or 10 mg/kg, including 6 out of 13 patients with squamous histology and 7 out of 44 patients with nonsquamous histology. In a study evaluating MPDL-3280A in multiple malignancies, the response rate in 53 patients with NSCLC was 34% with SD lasting 24 weeks or more in 17% of patients.²¹¹ Treatment with PD-1/PD-L1 checkpoint inhibitors was well tolerated in both studies and the presence of PD-L1 expression in tumors was associated with responses.

Systemic therapy for potentially curable NSCLC

Adjuvant chemotherapy

The administration of chemotherapy after curative NSCLC surgical resection in order to improve OS is termed adjuvant chemotherapy. Despite undergoing resection, the majority of lung cancer patients experience recurrent and/or metastatic disease; two-thirds of these recurrences and metastases occur systemically. Therefore, supplementing surgery with chemotherapy is a rational treatment strategy.²¹² A meta-analysis in 1995 compared surgery alone with surgery followed by cisplatin-based chemotherapy. This study included eight trials and 1394 patients and showed a 13% reduction in the risk of death, suggesting that adjuvant chemotherapy afforded an absolute benefit of 5% at 5 years ($p = .08$).²¹³ Subsequent randomized trials have demonstrated a modest benefit with adjuvant chemotherapy.^{214–217} A pooled analysis of the five largest randomized trials conducted after the 1995 meta-analysis included 4584 patients. Improved survival was observed in stage II and III disease.²¹⁸ Current ASCO guidelines indicate that adjuvant cisplatin-based chemotherapy is recommended for routine use in patients with stage IIA, IIB, and IIIA disease, including selected patients older than 65 years. Although there has been a statistically significant OS benefit seen in several RCTs enrolling a range of people with completely resected NSCLC, results of subset analyses for patient populations with stage IB disease were not significant, and adjuvant chemotherapy in stage IB disease is not currently recommended for routine use. To date, very few patients with stage IA NSCLC have been enrolled onto RCTs of adjuvant therapy, and adjuvant chemotherapy is not recommended for this stage group.²¹⁹

Neoadjuvant chemotherapy

The delivery of chemotherapy before surgical resection is termed neoadjuvant or induction chemotherapy. Potential advantages to neoadjuvant chemotherapy compared with adjuvant chemotherapy include improved chemotherapy compliance, lower pneumonectomy rates, and the ability to assess tumor responsiveness to chemotherapy. Although adjuvant chemotherapy remains the current standard of care for

resectable NSCLC, clinical trial data indicate that neoadjuvant chemotherapy may confer a similar level of benefit.^{220–223} A meta-analysis of 13 trials that randomized a total of 3224 patients demonstrated improved survival with neoadjuvant chemotherapy (HR 0.84, $P = 0.0001$).²²⁴ Although these data indicate that neoadjuvant chemotherapy may be a reasonable approach for resectable NSCLC patients, few studies provide guidance regarding how to select patients for adjuvant versus neoadjuvant therapy.

Therapy for SCLC

SCLC differs from NSCLC in its rapid growth rate, propensity for early systemic spread, and short natural history. With the general acceptance of SCLC as a systemic disorder and recognition of the superiority of multimodal regimens over local therapy alone, chemotherapy became the cornerstone of SCLC management.²²⁵

Surgical treatment

Although it has been established that surgical resection does not customarily play a role in the treatment of SCLC, there are some clinical settings in which surgery may be of potential benefit, such as in the case of peripheral SCLC. Although two-thirds of patients have ED at the time of presentation, fewer than 5% present with the tumor confined to the lung, with or without N1 lymph node metastases. These patients commonly present with a solitary pulmonary nodule on an incidental chest radiograph. Overall 5-year survival rate for patients who have undergone surgery followed by adjuvant chemotherapy has been shown to range from 28% to 60% for patients with stage I disease and 20 to 35% for patients with T1 N1 disease.²²⁶ A recent retrospective study showed a 5-year OS of 52.6% for all patients undergoing surgery and 45–51% for T1 N1 disease.²²⁷ Isolated reports have described 5-year survival rates as high as 70–80% for some patients with very limited stage disease. The great disparity between the survival rates of these patients and those of the more common central SCLC has led to several hypotheses. Some investigators believe that these tumors represent a variant of SCLC with altered biology; however, others believe that these tumors are inaccurately diagnosed and may in fact be well or moderately differentiated neuroendocrine carcinomas (typical or atypical carcinoids).²²⁸

Although most patients with peripheral SCLC have the diagnosis made at the time of thoracotomy, a minority are diagnosed preoperatively with FNA. The rare but established presentation of SCLC as a peripheral lesion, along with the fact that NSCLC and carcinoids can be misdiagnosed as SCLC on FNA, should prompt the clinician to continue to consider the patient for surgical treatment rather than refer immediately for chemotherapy. In light of this preoperative diagnosis, staging should be even more thorough than usual to reflect the high incidence of occult mediastinal and systemic metastasis associated with SCLC. Thorough radiographic staging and mediastinoscopy are employed before consideration of surgery. The presence of mediastinal involvement would obviate the role of surgery, but the presence of hilar adenopathy on radiographic staging is not an absolute contraindication to surgery. These patients may still undergo exploration as a means of establishing the presence of disease within the hilar nodes and, in good candidates, resection can still be offered if a complete resection is possible. All patients with surgically treated SCLC should receive postoperative chemotherapy. In trials reported by the Veterans Administration Surgical Adjuvant Group, patients who received postoperative chemotherapy did better than those who did not. When the timing of chemotherapy was examined, there appeared to be no advantage to giving chemotherapy preoperatively.²²⁵

Radiotherapy

Surgical local control is applicable to a very small subset of patients with SCLC. The remainder requires some form of local control as part of their treatment, and radiotherapy fulfills this role. Two meta-analyses employing different methods confirmed the value of thoracic irradiation to decrease local recurrence and prolong survival. The first study, based on results from 11 trials, showed an absolute increase in OS rate of 5.4% at 2 years.²²⁹ The second study collected data on 2140 patients from 13 RCTs comparing chemotherapy alone with chemotherapy plus thoracic irradiation and found an improvement in absolute survival rate of 5.4%, from 15% to 20.4%, at 3 years.²³⁰ Of note, the trials included in these meta-analyses were not recent studies, and none of them employed EP, the current standard chemotherapy regimen. In addition, these trials included both sequential and concurrent chemoradiotherapy.

Timing of thoracic radiotherapy relative to chemotherapy

The optimal schedule of chemoradiotherapy for limited disease (LD) SCLC continues to evolve. Earlier data from randomized trials, including meta-analyses, favored concurrent chemoradiotherapy and the administration of radiotherapy earlier in the course of treatment (i.e., during cycles 1–3 of chemotherapy).^{231–237}

Fractionation of thoracic radiotherapy with concurrent chemotherapy

Because SCLC is radiosensitive, without a shoulder in the radiation dose–response curve, and has a rapid doubling time, the use of multiple reduced-dose fractions in theory may increase efficacy. This approach is also hypothesized to protect normal tissues from late effects, especially those with a shoulder in their dose response.²³⁸ Several phase II trials of hyperfractionated and accelerated chemoradiation in LD SCLC patients yielded encouraging 2-year survival outcomes compared to historical controls with conventionally fractionated radiation.^{239, 240} Standard daily fractionation (1.8 Gy per fraction × 25 fractions in 5 weeks) and accelerated fractionation (1.5 Gy twice-daily × 30 fractions in 3 weeks) were compared in a pivotal intergroup phase III trial (INT-0096) of 417 patients with LD SCLC.²⁴¹ Concurrent chemotherapy consisted of cisplatin 60 mg/m² IV on day 1 and etoposide 120 mg/m² IV on days 1–3 for four cycles. The accelerated radiation was associated with prolonged median (23 months vs 19 months) and 5-year (26% vs 16%) survival compared with concurrent once-daily radiotherapy ($p = .04$). The only significant difference in toxicity between the arms was in grade 3 esophagitis, which was more frequent with twice-daily TRT (27% vs 11%, $p < .001$). Despite these favorable results, this approach has not been widely adopted in the community, possibly because of the difficulty of scheduling and the increased rate of esophagitis.²⁴²

Total tolerable dose

Radiation dose to the thorax is another controversial area.²⁴³ A study by the National Cancer Institute of Canada (NCIC) clearly demonstrated a dose response in the thorax: thoracic PFS was prolonged by giving 37.5 Gy in 15 fractions over 3 weeks rather than 25 Gy in 10 fractions over 2 weeks as consolidation after completion of induction chemotherapy.²⁴⁴ Arriagada and colleagues published a report of 173 patients with LD SCLC treated in three consecutive trials. The total dose of TRT ranged from 45 to 65 Gy, administered by split courses interdigitating with chemotherapy. Dose of radiotherapy did not significantly impact local control or survival.²⁴⁵ Strategies were considered that might increase the local control rate for concurrent chemotherapy and radiation therapy without increasing the esophageal toxicity rate to unacceptable levels. One strategy was to increase the total dose by administering daily thoracic radiation therapy at higher levels. Considering the value demonstrated by accelerated fractionation even to a total dose of just 45 Gy in 3 weeks, there was concern that a greater overall duration of thoracic

radiation therapy might be disadvantageous.

Accelerated fractionation via concomitant boost is associated with improved locoregional control in patients with head and neck cancer compared to conventional daily fractionation.²⁴⁶ This strategy uses once-daily irradiation through approximately 4–5 weeks of treatment and then twice-daily irradiation in approximately the last 2 weeks of treatment, delivering one daily fraction to the large field and one fraction to boost the dose to the small field. Thus, it is termed concomitant boost. Taking a lead from its success in head and neck cancer, the RTOG evaluated a similar strategy in phase I and II trials (RTOG 9712 and RTOG 0239, respectively) of concomitant boost radiation with concurrent EP in SCLC. The results showed an 18% rate of severe acute esophagitis (lower than the 27% previously noted in INT 0096) and a 2-year survival rate of 36.6% (lower than the 47% seen in INT 0096).^{247, 248}

Theorizing that daily radiation to a dose >45 Gy might be as efficacious as 45 Gy given twice-daily in 3 weeks, the CALGB compared the MTDs (maximum tolerated doses) of once-daily and twice-daily radiotherapy in LD SCLC patients.²⁴⁹ Radiotherapy was started with the fourth cycle of chemotherapy, and the recommended phase II dose in the once-daily arm was 70 Gy. Not surprisingly, the MTD of the accelerated therapy was 45 Gy. A subsequent phase II trial (CALGB 39808) demonstrated that 70 Gy in daily fractions was feasible with carboplatin and etoposide after induction chemotherapy with paclitaxel and topotecan.²⁵⁰ The median survival of 22.4 months reflects the best outcome reported for conventional daily fractionation in LD SCLC. The rate of grade 3–4 esophagitis was 21%, compared to 17% in RTOG 0239, and estimated in a much larger number of patients, 32% in INT-0096. A pooled analysis of patients treated on 3 CALGB trials (39808, 30002, 30206) using high-dose (70Gy) daily radiotherapy with concurrent chemotherapy following two cycles of induction chemotherapy showed a median survival of 19.9 months, with 2- and 5-year OS rates of 37% (95% CI: 31–44%) and 21% (95% CI: 16–27%), respectively.²⁵¹

Given the reduced esophageal toxicity and predicted maintained efficacy of the radiation regimens in CALGB 39808 and RTOG 0239, a pivotal phase III trial is ongoing, comparing two experimental arms with a control arm of 45 Gy administered twice-daily, all with early concurrent EP (cycle 1).

Prophylactic cranial irradiation in SCLC

Symptomatic brain metastases are detected in approximately 10% of SCLC patients at initial presentation, and an additional 10% may have occult metastases on MRI or CT imaging, with the likelihood of new brain metastases developing increasingly with lengthening survival.²⁵² In the absence of specific therapy to the CNS, the actuarial cumulative probability reached 80% at 28 months of follow-up when the cases of CNS metastasis found at autopsy were included and 58% at 24 months when only clinical brain metastases were counted. At postmortem examination, much higher incidences were reported, ranging up to 65%. With the hope that the CNS would be the only site of residual disease, prophylactic cranial irradiation (PCI) was incorporated as an initial part of treatment of SCLC in the early 1970s.²²⁵ A meta-analysis concluded that PCI prolongs both OS and DFS among SCLC patients in complete remission.²⁵³ When patients with LD SCLC were evaluated before and after PCI, 83% (25/30 patients) were found to have minor cognitive dysfunction before PCI, and no significant differences were found in the comparison of pretreatment and post-treatment neuropsychological results.²⁵⁴ An RCT comparing PCI at 25 or 35 Gy in 720 patients evaluated neurocognitive function and quality of life and found no significant differences between the two groups.²⁵⁵ These data indicate that concerns over PCI-associated neurotoxicity should not deter patients from receiving PCI.

PCI may improve outcomes for patients with extensive stage disease (ED) that have responded to therapy.

An RCT for patients with extensive SCLC who achieved a response to chemotherapy has shown that PCI reduced the incidence of symptomatic brain metastases and prolonged DFS and OS. PCI increased median survival from 5.4 to 6.7 months ($p = .003$), and 1-year survival rates were 27.1% in the PCI group compared to 13.3% in the control group ($p = .003$). This difference in survival in the PCI patients may be attributed in part to increased treatment for extra-CNS progression in that group (68% vs 45%) and a low rate of brain radiation for patients with brain recurrence on the control arm (59%). Effects of PCI on health-related quality of life were collected, with short-term results at 3 months showing a negative impact of PCI, especially on hair loss and fatigue, but similar cognitive and emotional functioning. Long-term results were unable to be assessed due to noncompletion of forms and small numbers.²⁵⁶

Chemotherapy

In its initial presentation, SCLC is sensitive to a variety of cytotoxins in the following drug classes: alkylators, anthracyclines, camptothecin derivatives, epipodophyllotoxins, platinating agents, vinca alkaloids, and taxanes. While the nitrogen mustard derivatives, methotrexate, vinorelbine, and gemcitabine, do have activity, they are less active than other drugs and not commonly utilized. Drugs considered active are associated with single-agent response rates generally >30%.

The combination of EP, first studied as a salvage regimen in the 1980s, has over the past 25 years become the standard of care for initial therapy of both LD and ED patients. RCTs have generally shown equivalent efficacy for EP and other more toxic regimens in patients with ED; thus, it is the standard based on higher therapeutic index.²⁵⁷ In patients with LD, in combination with concurrent thoracic radiation, it was associated with survival impact when compared to cyclophosphamide, epirubicin, and vincristine.²⁵⁸ This may relate to the ability to deliver full doses of EP in this setting without prohibitive midline, lung parenchymal, and bone marrow toxicity, that is observed with anthracycline-alkylator regimens.

Combination chemotherapy

The standard regimen for initial therapy in North America is the combination of EP. A minimum of four courses of EP is recommended based on a Southeastern Cancer Study Group phase III trial, which randomized patients to receive four courses of EP, six courses of cyclophosphamide, doxorubicin, and vincristine (CAV), or alternating EP and CAV.²⁵⁷

The Japanese Clinical Oncology Group (JCOG) trial 9511 randomized patients with ED to either EP or irinotecan and cisplatin (IP).²⁵⁹ Patients in the IP arm had improved median and long-term survival, compared to patients on etoposide (median survival: 12.8 months vs 9.4 months, $p = .002$, 2-year survival: 20% vs 5%). The experimental arm in this study consisted of IP given at 4-week cycles. A slight modification of this schedule was used in a subsequent trial in North America, which attempted to confirm these findings.²⁶⁰ However, this trial, in a predominantly Caucasian population, demonstrated no benefit for patients in the IP arm. Toxicities were different with more diarrhea due to irinotecan, and more myelosuppression in the EP arm. The results of SWOG 0124, replicating the dose and schedule of IP from JCOG 9511, also failed to confirm the benefit for IP over EP for patients with ED.²⁶¹ Interestingly, subsequent pooled analyses of JCOG 9511 and SWOG 0124 patients showed significant differences in response rates and survival for the IP arms across trials, but not for the EP arms. These data suggest that polymorphisms in genes involved in irinotecan metabolism may explain differences in toxicity and possibly efficacy between the Japanese and American patients.²⁶²

Carboplatin substitution for cisplatin in combination with etoposide has been studied in multiple RCTs and several meta-analyses.²⁶³ The most recent meta-analysis analyzed 4 RCTs, including 663 LD and ED

SCLC patients, and showed no difference between cisplatin and carboplatin with respect to OS, PFS, and response rate.²⁶⁴ The median OS was 9.6 and 9.4 months for cisplatin and carboplatin, respectively (HR 1.08; $p = .37$). Further, carboplatin was substantially less toxic as regards emesis, nephrotoxicity, and neurotoxicity, while hematologic toxicity was higher. Current practice standards hold that carboplatin with etoposide is reasonable therapy for patients with ED and, based on favorable toxicity profile, is preferred in those with poor PS and/or significant comorbidities.

Carboplatin and irinotecan are other first-line options for ED SCLC patients. A randomized phase II trial found improvement in PFS with carboplatin and irinotecan versus carboplatin and etoposide.²⁶⁵ A subsequent phase III trial comparing carboplatin and oral etoposide with carboplatin and irinotecan showed improvement in OS from 7.1 to 8.5 months ($p = .04$).²⁶⁶ Other regimens including carboplatin with pemetrexed have been found to be inferior to carboplatin and etoposide.²⁶⁷

Management of the elderly

Currently representing more than one-third of patients with SCLC, the proportion of those aged >70 years will continue to increase in the future as our population ages. Although the heterogeneity in this group is substantial, there is general agreement that they represent a population at higher risk for treatment-related morbidity and mortality. Although RCTs are few in number, reducing the intensity of therapy in this group by using single agents or low-dose chemotherapy has been associated with inferior efficacy and shortened survival and is not recommended.^{268, 269} Multiple phase II trials of etoposide and carboplatin in this population have revealed good tolerance and reasonable efficacy.^{270, 271} In a phase II randomized trial, EP was safely given to elderly patients with granulocyte-colony stimulating factor (G-CSF) support and resulted in efficacy similar to outcomes in younger patients.²⁷²

Regarding management of the elderly patient with LD, an analysis of patients >70 years in INT-0096 reported an increased death rate in the first 6 months after randomization, with a 10% treatment-related death rate compared to the 1% rate in those <70 years.²⁷³ Severe myelosuppressive toxicity was greater in the elderly compared to younger patients. Other toxicities were similar. Median (21.6 months vs 14.4 months) and 5-year (22% vs 16%) survival rates were worse in the elderly, reflecting, at least in part, the increased death rate during treatment and early in follow-up. These data suggest that the elderly with LD and retained performance status benefit from standard chemoradiation. However, this group should be carefully selected with respect to PS and deserve greater use of supportive care measures. Chemoradiation is recommended.

Special clinical situations

Brain metastases
