  - CT or MRI: Detection of neoplasms or abscesses
  - Radionuclide scans: Tumors, abscesses, osteomyelitis, localized pyogenic processes
  - MRI has the highest sensitivity and specificity for detecting osteomyelitis in children.

**Diagnostic Procedures/Other**

- Tuberculin skin testing is recommended for all patients with FUO without a recent skin test.
- Consider referral for laparoscopy, endoscopy, bronchoscopy, bone marrow exam, or biopsy (lymph node, muscle or skin).

**DIFFERENTIAL DIAGNOSIS**

See Etiology, History, and Physical Exam sections.

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

- Support ABCs.
- Initial treatment depends on the cause of FUO.

**MEDICATION**

See the respective topics for treatment of each of these causes.

**DISPOSITION**

**Admission Criteria**

If the patient is ill appearing or outpatient investigation fails to reveal a cause of the fever, inpatient admission may be necessary.

**Discharge Criteria**

- Normal or baseline vital signs
- Stable medical condition
- Follow-up ensured

**Issues for Referral**

- Refer to infectious diseases doctor if cause of FUO is undetermined.
- Connective tissue diseases, malignancy, and miscellaneous diseases (eg, IBD, diabetes insipidus, and periodic fever syndrome) should be referred to a subspecialist.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

No specific discharge instructions or activity limitations are warranted.

**PROGNOSIS**

- Children with FUO have a better prognosis than do adults.
- The outcome in a child is dependent on the primary disease process.
- In many cases, no diagnosis is established and fever abates spontaneously.
- In up to 25% of FUO in which fever persists, the cause is unclear after thorough evaluation.

**COMPLICATIONS**

Complications depend on the cause of FUO.

**REFERENCES**

1. Ingarfield SL, Celenza A, Jacobs IG, et al. Outcomes in patients with an emergency department diagnosis of fever of unknown origin. *Emerg Med Australas.* 2007;19(2):105–112.
2. Pasic S, Minic A, Djuric P, et al. Fever of unknown origin 185 pediatric patients: A single center experience. *Acta Paediatr.* 2006;95(4):463–466.
3. Badjatia N. Hyperthermia and fever control in brain injury. *Crit Care Med.* 2009;37(7 Suppl): S250–S257.

**ADDITIONAL READING**

- Barkin RM, Zukin DD. Pediatric fever. In Marx J, Adams J, Walls R, et al., eds. *Rosen's Emergency Medicine: Concepts and Clinical Practice.* 7th ed. St. Louis, MO: Mosby; 2009.

**CODES**

ICD9  
780.60 Fever, unspecified

**PEARLS AND PITFALLS**

- The cause of FUO is more often a common disease presenting in atypical fashion rather than a rare disease presenting in typical fashion.
- Careful and repeated history, physical exam, and review and interpretation of lab data usually help to determine the cause of FUO.

# FLAIL CHEST

Cathy E. Shin

## BASICS

### DESCRIPTION

- A flail chest occurs when a segment (at least 2 fractures per rib) of the chest wall is separated from the rest of the thoracic cavity:
  - Respiratory distress is identified with paradoxical movement of a segment of the chest wall (moving inward on inspiration and moving outward on expiration).
- Compared to adults, flail chest is far less common in infants and children.
- Due to the nature of the injury, the pediatric population is at higher risk for associated pulmonary injuries (1).
- Generally, the presence of a flail chest is associated with a mortality rate ranging from 10–35%.

### EPIDEMIOLOGY

#### Prevalence

Flail chest complicates ~5–13% of patients with blunt chest trauma in the general population (2,3).

### RISK FACTORS

- High-speed motor vehicle collisions
- Blunt trauma

### PATHOPHYSIOLOGY

- A transfer of significant kinetic energy in blunt trauma to the rib cage or a crushing rollover injury is the most frequent cause of flail chest.
- The paradoxical movement of the rib cage will adversely affect respiratory function via diminished ventilation, pulmonary contusions, and atelectasis from hypoventilation.
- The negative intrathoracic pressure generated under the flail segment during inspiration results in the flail segment being pulled inward. Similarly, the positive pressures with expiration cause the same segment to push outward, thus creating a paradoxical appearance.
- Respiratory distress can be caused by the dynamics of the chest wall or the underlying pulmonary injury.
- Derangement of chest wall mechanics results in reduced tidal volume, increased pulmonary secretions, atelectasis, and cough, which in turn increase the risk of pneumonia.
- In pediatric patients, the ribs are more pliable and less likely to fracture, although there may still be significant contusion of chest wall structures.
- In children, who have a more compliant chest wall, flail chest is observed with lower frequency than injury to the underlying structures, including the lungs, heart, and mediastinal structures (4).

### ETIOLOGY

- Blunt chest wall trauma:
  - Motor vehicle crashes (high speed)
  - Falls
- Nonaccidental trauma (5)

### COMMONLY ASSOCIATED CONDITIONS

- Pulmonary contusion
- Rib fractures
- Pneumothorax
- Hemothorax

## DIAGNOSIS

### HISTORY

- High-speed motor vehicular crashes involving blunt chest or upper abdominal trauma
- Falls involving blunt chest or upper abdominal trauma
- Conscious patients will complain of:
  - Pain on palpation of the chest wall or on inspiration
  - Shortness of breath
  - Difficulty with inspiration
  - Chest pain

### PHYSICAL EXAM

- Respiratory distress:
  - Tachypnea
  - Intercostal and substernal retractions
  - Air hunger
  - Nasal flaring
  - Grunting
  - Chest wall splinting
- Bruising, grazes, abrasions or seat belt signs are visible on inspection.
- Palpation may reveal the crepitus associated with broken ribs.
- Decreased pulse oximetry readings
- KEY EXAM: Paradoxical movement of a segment of the chest wall—moving inward on inspiration and moving outward on expiration:
  - This is often better appreciated by palpation than by inspection.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- No lab testing is necessary for the diagnosis of flail chest:
  - Consider obtaining a baseline arterial blood gas.
- The following may be helpful as part of the trauma evaluation:
  - CBC
  - PT, PTT, INR

### Imaging

- The AP CXR will identify most significant chest wall injuries but will not identify all rib fractures in the pediatric population. Lateral or anterior rib fractures will often be missed on the initial plain film.
- Chest films may also identify:
  - Subcutaneous emphysema
  - Broken ribs or other broken bones
  - Hemothorax
  - Pneumothorax
  - Pulmonary contusion
  - Diaphragmatic rupture
- There is no role for chest CT scans to diagnose flail chest, but CT may be helpful to identify associated injuries such as pulmonary contusion.

### DIFFERENTIAL DIAGNOSIS

Other clinical diagnoses with similar presentations include:

- Rib fractures: Clinically similar without paradoxical chest wall movement
- Pulmonary contusion: Respiratory distress without flail chest or rib fractures
- Chest wall muscular strain: Chest wall splinting may mimic flail chest

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation.
- All patients should initially be placed on 100% oxygen via a nonbreathing face mask.
- IV analgesia as noted below

### INITIAL STABILIZATION/THERAPY

- Management of chest wall injury is directed toward protecting the underlying lung and allowing adequate oxygenation, ventilation, and pulmonary toilet. This strategy is aimed at preventing the development of pneumonia, which is the most common complication of chest wall injury.
- Pain management, judicious fluid resuscitation, and excellent pulmonary toilet are essential to stabilizing the patient.
- Isolated flail chest may be successfully managed with aggressive pulmonary toilet including face mask oxygen, CPAP, and chest physiotherapy.
- Adequate analgesia is of paramount importance in patient recovery and may contribute to the return of normal respiratory mechanics.
- Early intubation and mechanical ventilation is important in patients with refractory respiratory failure or other serious traumatic injuries.

### MEDICATION

#### First Line

- Analgesia is the mainstay of therapy for rib fractures.
- IV opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN
  - Fentanyl 1–2  $\mu$ g/kg IV q2h PRN:
    - Initial dose of 1  $\mu$ g/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN

**Second Line**

- Once admitted, patient-controlled administration (PCA) is the best method for age-appropriate and cooperative patients.
- An alternative is a continuous epidural infusion of a local anesthetic agent (with or without an opioid analgesic).
  - This provides complete analgesia allowing normal inspiration and coughing without the risk of respiratory depression. These can be placed in the thoracic or high-lumbar positions.
- Regional anesthesia by rib block may provide tremendous pain relief.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Simple chest wall injury rarely requires intubation and mechanical ventilation.
- Where ventilation is necessary, it is usually for hypoxemia due to underlying pulmonary contusions. Positive pressure ventilation may be required for severe chest wall instability resulting in inadequate spontaneous ventilation.
- Prolonged mechanical ventilation is associated with the development of pneumonia and a poor outcome. Tracheotomy and frequent flexible bronchoscopy should be considered to provide effective pulmonary toilet.

**SURGERY/OTHER PROCEDURES**

- Chest tube placement: Patients with rib fractures who are intubated are at an increased risk of developing a pneumothorax or tension pneumothorax due to laceration of the lung by the sharp fracture end. In these cases, a prophylactic chest tube is recommended.
- In most cases, positive pressure ventilation (CPAP or intubation) allows for a nonoperative internal stabilization of the chest wall, and fixation is not necessary. This is the conservative approach and is applicable to most patients who have a flail chest.
- However, there is a small subgroup that may benefit from operative repair:
  - Internal fixation may:
    - Shorten duration of mechanical ventilation
    - Decrease the complication rate
    - Decrease the length of hospital stay
    - Be cost-effective (6–8)
  - Some indications for surgical repair include:
    - Failure to wean from the ventilator
    - Paradoxical movement visualized during weaning
    - Absence of pulmonary contusion
    - Absence of significant brain injury
    - Refractory pain despite narcotics or epidural pain catheter

- In several studies, the surgically repaired group demonstrated:
  - Significantly fewer days on the ventilator and in the ICU
  - Lower incidence of pneumonia
  - Better pulmonary function at 1 mo
  - Higher return to work percentage at 6 mo than the nonoperative group (7,8)
- In summary, most pediatric patients with flail chest may be treated successfully with intubation and pain management alone, but a small group may benefit from operative correction of the flail segment.

**DISPOSITION****Admission Criteria**

Critical care admission criteria:

- Inpatient management is necessary for patients with flail chest.
- Poor respiratory effort requires early intubation and mechanical ventilation.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications after inpatient admission:
  - Oral pain medications
- Activity:
  - Ad lib but no airplane travel if pneumothorax is present

**Patient Monitoring**

- Follow-up CXR 1 wk after the traumatic injury
- Pulmonary function testing

**PROGNOSIS**

- Overall, patients with flail chest have 5–10% reported mortality if they reach the hospital alive.
- Patients who do not need mechanical ventilation do better statistically, and overall mortality seems to increase with severity, age, and number of total rib fractures involved.

**COMPLICATIONS**

- Pneumonia
- Empyema
- Bronchial pleural fistula
- Chest wall deformity
- Chronic chest wall pain
- Dyspnea on exertion

**See Also (Topic, Algorithm, Electronic Media Element)**

<http://www.trauma.org>

**CODES**

**ICD9**  
807.4 Flail chest

**PEARLS AND PITFALLS**

- The diagnosis of flail chest is largely clinical.
  - Diagnosis: Observe paradoxical respirations while the examiner's hand is on the thorax (feel broken ribs and crepitus).
- Consider associated injuries, particularly intrathoracic injuries.
- Immediate treatment: Oxygen and pain management followed by possible intubation and chest tube

# FOOD POISONING

Nahar D. Alruwaili  
Brent W. Morgan

## BASICS

### DESCRIPTION

- There are many lay definitions of food poisoning. This topic will focus on illness created by microorganism-generated toxins contained in foods.
- The most common bacterial toxins causing foodborne illness will be discussed, including:
  - Staphylococcal enterotoxin B (SEB)
  - *Bacillus cereus* toxin
  - Scombroid toxin
  - Ciguatera toxin
  - Botulinum toxin is discussed briefly. Also see the Botulism topic.

### EPIDEMIOLOGY

- An estimated 76 million cases of foodborne disease occur each year in the U.S.
- 325,000 hospitalizations in the U.S. annually
- Estimated 5,000 deaths in the U.S. annually
- SEB, *B. cereus*, botulism, and scombroid occur throughout the U.S.
- Ciguatera poisoning occurs most frequently in Florida and Hawaii.

### RISK FACTORS

- Risk factors vary with specific etiology.
- Improper storage of food

### GENERAL PREVENTION

Proper cooking and storage of foods

### PATHOPHYSIOLOGY

- Toxins released by microorganisms into food may cause a variety of diseases.
- SEB: Heat-stable enterotoxin acts by stimulating release of cytokines from T cells in the intestines, leading to inflammatory reaction and cell destruction:
  - Enterotoxins also may act on receptors in the gut that transmit impulses to the emesis center in the brain.
  - In severe poisoning, SEB may cause systemic illness, shock, and multisystem organ failure.
- *B. cereus* toxin: 2 recognized types of illness are caused by 2 distinct toxins:
  - The vomiting (emetic) type of illness (short incubation and duration) is believed to be caused by a heat-stable toxin.
  - The diarrheal type of illness (long incubation and duration) is caused by heat-labile toxins that increase intestinal secretions by activation of adenylate cyclase in the intestinal epithelium.
- Scombroid: Results from improper refrigeration or preservation of large fish, which results in bacterial degradation of histidine to histamine:
  - *Scombrototoxin* is a term sometimes used to describe histamine in this scenario.
  - The histamine poisoning resembles an allergic reaction, with any combination of flushing, urticaria or other acute pruritic rash, vomiting, diarrhea, cough, wheezing, stridor, or diaphoresis.

- Ciguatera toxin: Produced by dinoflagellates that bioaccumulate, ultimately concentrating in reef fish. The mechanism of intoxication may involve increased sodium permeability in sodium channels and stimulation of central or ganglionic cholinergic receptors.

### ETIOLOGY

See Pathophysiology.

### COMMONLY ASSOCIATED CONDITIONS

- Vomiting
- Diarrhea

## DIAGNOSIS

### HISTORY

- Food poisoning most often presents as gastroenteritis with nausea, vomiting, diarrhea, and abdominal pain.
- Constitutional symptoms (fever, malaise, myalgias) may be suggestive of invasive bacteria or systemic disease.
- Oliguria may be suggestive of dehydration or renal failure.
- Ask about:
  - Timing of illness in relation to ingestions
  - Associated abdominal and systemic symptoms
  - History of similarly exposed persons with related symptoms
  - Type of food consumed:
    - Prepared foods: Meats, pastries, salads (SEB)
    - Contaminated fried rice (emetic *B. cereus* toxin) or meatballs (diarrheal *B. cereus* toxin)
    - Carnivorous reef fish such as mackerel, barracuda, amberjack, and grouper (ciguatera toxin)
    - Large fish—poorly refrigerated: Tuna, bonito, albacore, mackerel (scombrototoxin)
    - Home-canned foods
- SEB:
  - Characterized by the abrupt onset of vomiting within minutes to hours; vomiting is the most prominent finding. Severe abdominal cramps and diarrhea may occur. In severe illness, low-grade fever or mild hypothermia can occur.
- *B. cereus* toxin—2 clinical syndromes:
  - Emetic syndrome: Like staphylococcal foodborne illness with severe vomiting, but presentation may be delayed, occurring in several to 1–5 hr after ingestion.
  - Differentiation between the *B. cereus* emetic syndrome and SEB is difficult and may be based on the type of food involved.
  - Diarrhea syndrome has a slightly longer incubation period of 8–16 hr.
  - Both syndromes are mild and usually are not associated with fever.

- Botulism presents with impaired cranial nerve activity such as difficulty swallowing or handling oral secretions, constipation, hypotonia with progressive symmetric paralysis, absent deep tendon reflexes, and apnea.
- Patients with scombroid poisoning may present with skin flushing, urticaria, bronchospasm, tachycardia, and hypotension.
- Ciguatera toxin may present with myriad symptoms: Diarrhea; abdominal cramps and/or vomiting; CNS symptoms, including sensory changes such as blurred vision, change in temperature perception (temperature reversal, which is considered specific for ciguatoxin); sensation of teeth being painful or loose; paralysis; and respiratory arrest.

### PHYSICAL EXAM

- The most important element of the physical exam is the assessment of the patient's hydration status, signs of bacteremia, sepsis, or shock.
- Vital signs: Tachycardia, tachypnea, hypotension with dehydration, or toxin related
- The patient's general appearance: Well or ill or in shock
- HEENT: Presence or absence of tears; dry or moist mucous membranes; whether the eyes appear sunken; depressed or flat fontanelles
- Chest: Decrease of the air entry or wheezing (bronchospasm); dysrhythmia may occur with ciguatera.
- Skin: Skin turgor, capillary refill, skin flushing, urticaria
- CNS: Evaluate for neurologic involvement such as paresthesias, motor weakness, ataxia, visual disturbances, cranial nerve palsies, and temperature reversal.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

No lab testing is absolutely necessary, but consider the following:

- Bedside glucose: Hypoglycemia can occur in patients with inadequate oral intake.
- Serum electrolytes, BUN, creatinine
- CBC and C-reactive protein to evaluate inflammation
- Urinalysis
- Blood gas to evaluate oxygenation and perfusion
- Stool culture and WBC: For severe diarrhea, fever, persistently bloody stools, neurologic findings, severe abdominal pain, or if patient is immunocompromised or very young
- Blood culture: If the patient is notably febrile
- When epidemic poisoning is suspected, state public health departments or the CDC may be able to analyze suspect food for toxins.
- Botulinum: Stool sample for botulinum spores and toxin
- The health department may assay food for SEB, *B. cereus*, botulinum, ciguatoxin, and scombroid.

**Imaging**

Abdominal radiographs (flat and upright): If obstructive symptoms or perforation are suggested

**Diagnostic Procedures/Other**

ECG: In patients with any ciguatera poisoning

**DIFFERENTIAL DIAGNOSIS**

- SEB and *B. cereus*:
  - Infectious gastroenteritis is the main differential diagnosis.
  - Inflammatory bowel disease
  - Colitis
  - Irritable bowel syndrome
  - Surgical abdominal causes: Intestinal obstruction, appendicitis, intestinal malrotation or volvulus, intussusception
- Scombroid:
  - Allergic, anaphylactoid, and anaphylactic reactions are the main differential diagnoses for scombroid
  - Ethanol ingestion in aldehyde dehydrogenase-deficient patients such as Asians
- Botulism:
  - Guillain-Barré syndrome
  - Myasthenia gravis
  - Cerebrovascular accident
  - Transverse myelitis
- Ciguatera:
  - Organophosphate and carbamate toxicity
  - Scombroid
  - Botulism
  - Meningitis
  - Tetrodotoxin poisoning

**TREATMENT****PRE HOSPITAL**

Assess and stabilize airway, breathing, and circulation.

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Correct dehydration and/or hypoglycemia.

**MEDICATION****First Line**

- Antiemetics:
  - May be necessary for SEB, *B. cereus*, scombroid, or ciguatera
  - Ondansetron 0.15–0.2 mg/kg IV q6–8h PRN vomiting
  - Metoclopramide 0.1 mg/kg IV q6h PRN vomiting
- Scombroid:
  - Diphenhydramine: 1 mg/kg/dose PO/IV q6h PRN, max 300 mg/day
  - Cimetidine: PO/IV 5–10 mg/kg q6h
  - For severe histamine reaction/anaphylactoid reaction, epinephrine and/or albuterol may be necessary. See Anaphylaxis topic.
  - Corticosteroids are not indicated or useful in managing scombroid poisoning.
- Botulinum: Treatment is mainly supportive:
  - Baby BIG: A human-derived antitoxin is used to treat cases of infant botulism and is available from the California Department of Public Health.
  - Botulinum antitoxin: In cases of suspected foodborne botulism, it is most effective if administered early in the disease course. (Contact the local or state health department or the CDC.)
  - See the Botulism topic for more detailed dosing information.

**Second Line****Antidiarrheals:**

- Generally not used in children <5 yr of age
- Loperamide:
  - If <30 kg, 2 mg PO initially, then may repeat 1–2 times daily.
  - If >30 kg, 4 mg PO initially, then may repeat 2 mg PO after each loose stool to maximum of 12 mg/day.
- Bismuth subsalicylate (Kaopectate):
  - Children 100 mg/kg/day divided in 5 equal doses for maximum 3 days
  - Adolescent/adult: 2 tablets (262 mg each) or 30 mL of liquid q30–60min until symptoms are controlled, maximum 8 doses/day for maximum of 3 days.

**COMPLEMENTARY & ALTERNATIVE THERAPIES****Ciguatera:**

- Mannitol is sometimes used as therapy; clinical trials have not demonstrated effectiveness.
- Amitriptyline, given as a sodium channel blocker to counteract the sodium channel opening of the ciguatera toxin, may have some effectiveness, though clinical trials evaluating this therapy are lacking.

**DISPOSITION****Admission Criteria**

- Patients with intractable vomiting, diarrhea, dehydration, pain
- Severe illness, expected deterioration, or need for inpatient therapy/evaluation (eg, botulism)
- Critical care admission criteria:
  - Hypotension, dysrhythmia, unstable vital signs, paralysis, shock

**Discharge Criteria**

- Symptoms are controlled to a degree compatible with discharge.
- Patient not dehydrated
- No signs of toxicity or systemic disease

**Issues for Referral**

- Poison control center for additional information and patient care recommendations
- For suspected outbreaks of infective pathogens, call the local health department.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Because most cases of food poisoning are self-limited, prolonged follow-up care is not required.
- Discharge instructions and medications:
  - Antiemetics or antidiarrheals for 1–2 days
  - H1- and H2 blockers for 3–5 days

**DIET**

- Eliminate contaminated food.
- Dietary restrictions are not standard care.

**PROGNOSIS**

- Most gastroenteritis secondary to food poisoning is mild and self-limited.
- Recovery is complete in 2–5 days in most individuals.
- In the very young, the prognosis is more guarded because these patients can become dehydrated quickly.

- SEB: Onset 1–6 hr after exposure; duration on average 14 hr but as long as 24–48 hr. Usually self-limited to vomiting:
  - 20% of patients visiting emergency departments will require admission, and 4% of admitted patients are severely ill and die from multisystem organ failure, typically the elderly and young children.
- *B. cereus*: Emetic syndrome onset is 1–6 hr, diarrheal syndrome onset is 8–16 hr; resolves within 24–48 hr.
- Scombroid: Onset immediate, usually lasting several hours and resolves within 24–72 hr
- Ciguatera: Onset variable but <24 hr; long-lasting effects of weeks to months, sometimes with only partial resolution
- Botulinum: Onset hours to days; duration depends on treatment with IG. Resolution within days to weeks with IG. For patients not receiving IG treatment, convalescence may last months:
  - After the patient has survived the paralytic phase of botulism, the outlook for complete recovery is excellent.

**COMPLICATIONS**

- SEB: Shock, multisystem organ failure, death
- Botulism: Paralysis, pneumonia, sepsis, death
- Ciguatera: Persistence of neurologic and cognitive changes
- Dehydration secondary to vomiting or diarrhea
- Hypoglycemic secondary to vomiting

**ADDITIONAL READING**

- American Academy of Pediatrics. Appendix IX. Clinical syndromes associated with foodborne diseases. In Pickering LK, Baker CJ, Kimberlin DW, et al., eds. *Red Book: 2009 Report of the Committee on Infectious Diseases*. 28th ed. Elk Grove Village, IL: Author; 2009:860–863.
- CDC. *FoodNet 2007 Surveillance Report*. Atlanta, GA: U.S. Department of Health and Human Services; 2009.

**CODES****ICD9**

- 005.0 Staphylococcal food poisoning
- 005.89 Other bacterial food poisoning
- 005.9 Food poisoning, unspecified

**PEARLS AND PITFALLS**

- The main differential diagnosis of most food poisoning is gastroenteritis. General supportive care is similar for both.
- Antibiotic therapy is not indicated in most foodborne illnesses.
- Notify the health department for foodborne illnesses.

# FOREIGN BODY ASPIRATION

David D. Lowe  
Joshua Nagler

## BASICS

### DESCRIPTION

- Foreign body aspiration (FBA) is the inhalation of foreign matter that deposits within the airway, from the larynx to the distal bronchioles.
- Presentation varies from asymptomatic to airway obstruction and respiratory failure.
- Most cases occur in infants and toddlers.
- Most patients present after an acute choking event with symptoms including coughing and wheezing or respiratory findings.
- Delayed diagnosis can occur when the aspiration event is not witnessed or reported:
  - Initial presentation is often ascribed to an alternative diagnosis (eg, asthma).
  - Increased rates of postobstructive infection
- A careful history is the best diagnostic tool:
  - Physical exam and radiographic findings can provide supporting evidence.
- Bronchoscopy is the gold standard for diagnosis and management of solid object aspiration.

### EPIDEMIOLOGY

#### Incidence

- Peak incidence occurs between 1 and 2 yr of age.
- 80% of patients are <3 yr of age (1).
- Male to female ratio is 2:1.
- FBA is the most common cause of accidental death in children <1 yr of age.

### RISK FACTORS

- Younger age
- Absence of molars
- Developmental delay

### GENERAL PREVENTION

- Regulation of nonfood choking hazards
- Public education, including anticipatory guidance from primary care physicians
- Avoidance of high-risk foods in children with inadequate dentition or development

### PATHOPHYSIOLOGY

- Large objects in the proximal airway may cause complete airway obstruction and respiratory failure.
- Irritation of the larynx may cause laryngospasm.
- “Check valve” obstruction:
  - Diameter of bronchus increases during inspiration, allowing air passage, but recoil during expiration prevents airflow around foreign body (FB) (2).
  - Results in localized hyperinflation

- “Ball valve” obstruction:
  - FB dislodges during expiration and reimpacts during inspiration.
  - Results in atelectasis
- “Stop valve” obstruction:
  - Complete obstruction of air
  - Results in distal collapse or consolidation
- More distal FBAs cause less acute symptoms.
- Prolonged inability to clear secretions distal to the FB can lead to postobstructive pneumonia (often recurrent), lung abscess, or bronchiectasis.
- Aspiration of liquid or fine particulate substances, such as hydrocarbons or talc, do not result in obstruction but may result in pneumonitis with severe morbidity and potential mortality.

### ETIOLOGY

- Organic materials are the most frequently aspirated objects:
  - Nuts, popcorn, and seeds are most common (3).
- Inorganic objects are found more commonly in older children.

## DIAGNOSIS

### HISTORY

- A suggestive history is the most sensitive and specific means of diagnosis (1,4):
  - Requires high level of suspicion and directed questioning
  - Parents may otherwise forget a minor, self-resolving choking event.
- The most common symptoms are coughing, choking, or gagging (5).
- Other presenting symptoms may include:
  - Shortness of breath, chest pain, vomiting (often posttussive), fever, hemoptysis
- The constellation of a choking episode with cough and unilateral wheeze or decreased breath sounds is not found in most cases (3).
- Delayed diagnosis may present with:
  - Chronic cough, fever, hemoptysis

### PHYSICAL EXAM

- Findings depend on location, degree of obstruction, and time delay to presentation:
  - May be normal
- Vital signs:
  - Tachypnea
  - Hypoxemia

- Respiratory:
  - Cough very common
  - Varied respiratory distress depending on location of obstruction
  - Stridor with proximal airway obstruction
  - Abnormal auscultation in 75% of cases
  - Asymmetric breath sounds, wheeze, or both are the most common auscultatory findings.
- Negative exam cannot rule out FBA (3).

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- No specific lab testing for FBA
- WBC count and inflammatory markers may be elevated with retained FBA but are nonspecific.
- Blood gas analysis may be indicated to evaluate ventilatory function.

#### Imaging

- Patients with highly suggestive history and respiratory compromise may be taken directly to bronchoscopy without imaging.
- PA and lateral chest radiographs are the first-line imaging choice for stable patients.
- May reveal and localize radiopaque FB (10–20% of cases) (6)
- Nonradiopaque foreign bodies will not be seen directly on conventional films, making the radiographic diagnosis more challenging.
- Films may demonstrate indirect findings consistent with FBA (5):
  - Asymmetric hyperlucency and mediastinal shift suggests air trapping.
  - Atelectasis or consolidation can occur distal to the FB.
  - Sensitivity increases with:
    - Inspiratory and expiratory films taken sequentially OR
    - Decubitus views in young or noncooperative patients (5,7)
- Fluoroscopy is favored in some centers (2):
  - Abnormal movement of hemidiaphragm or mediastinal swing suggests air trapping.
- More proximal FBs (above the carina) are less likely to have abnormal radiographic findings.
- Lateral neck radiographs may be useful in patients with stridor or drooling when looking for FB or alternative diagnosis (prevertebral soft tissue swelling, abnormal epiglottis).

#### Diagnostic Procedures/Other

- Rigid bronchoscopy in the operating room (OR) is the definitive diagnostic and therapeutic procedure for FBA.
- Flexible bronchoscopy may be used; however, FB removal may be more difficult.

**DIFFERENTIAL DIAGNOSIS**

- Asthma
- Bronchiolitis
- Croup
- Epiglottitis
- Laryngotracheal malacia
- Pneumonia
- Tracheitis
- Vascular rings or slings

**TREATMENT****PRE HOSPITAL**

- Administer supplemental oxygen.
- Basic life support for airway obstruction

**INITIAL STABILIZATION/THERAPY**

- Complete airway obstruction per Basic Life Support guidelines:
  - Heimlich, chest thrusts may relieve complete obstruction.
  - Needle cricothyrotomy may be necessary pending surgical cricothyrotomy or tracheostomy.
  - High-flow oxygen and vascular access
  - Consult anesthesia or otolaryngology PRN.
  - Rapid transfer to OR for bronchoscopy
- Partial obstruction:
  - Keep patient comfortable, and avoid painful procedures.
  - High-flow oxygen
  - Anesthesia and otolaryngology consultation
- Stable patients with supportive history and/or exam:
  - Radiographic evaluation to help localize FB
  - Rigid bronchoscopy is diagnostic and therapeutic.
- Stable patients with low suspicion:
  - Screening CXR or fluoroscopy; if negative, consider close observation and repeat films in 24–48 hr.

**MEDICATION****First Line**

- No specific medications for FBA itself
- Nebulized racemic epinephrine 2.25% (0.5 mL in 2.5 mL normal saline):
  - May temporarily decrease swelling and obstruction in patients with stridor
- Antibiotics for associated pneumonia:
  - Ampicillin/Sulbactam 50 mg/kg IV q6h
  - Ceftriaxone 50–100 mg/kg IV q24h

**Second Line**

- Dexamethasone 0.15 mg/kg IV q6h for 24 hr:
  - If significant inflammation noted on bronchoscopy

**SURGERY/OTHER PROCEDURES**

- Rigid bronchoscopy is the gold standard and is 99% effective in removal of large solid FB.
- Thoracotomy is required for failed bronchoscopy.

**DISPOSITION****Admission Criteria**

- Patients being evaluated by bronchoscopy require admission.
- Persistent hypoxia, respiratory distress, or pneumonia
- Critical care admission criteria:
  - Patients with significant respiratory distress or airway inflammation after bronchoscopy
  - Endotracheal intubation

**Issues for Referral**

Patients with low suspicion for FB with negative exam and radiographs may follow up with their primary care providers, with referral to otolaryngology/surgery if symptoms recur or persist.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Patients discharged from the hospital are presumed not to have FBA and should follow up with primary care provider in 24–48 hr to ensure symptoms have improved or resolved.

**Patient Monitoring**

- All patients with possible FBA should be on continuous cardiopulmonary monitoring including pulse oximetry until definitive care is provided.
- Capnography may be a useful adjunct for impending respiratory failure.

**DIET**

Keep patient NPO for possible anesthesia.

**PROGNOSIS**

- Patients generally have a favorable prognosis.
- Worse prognosis with:
  - Complete airway obstruction
  - Missed aspiration

**COMPLICATIONS**

- Increased risk of complications with delayed diagnosis
- Due to FB:
  - Early:
    - Asphyxiation
    - Postobstructive pulmonary edema
  - Late:
    - Pneumonia
    - Lung abscess
    - Bronchiectasis
    - Erosion with airway perforation or hemoptysis
    - Fistula formation
- Due to bronchoscopy:
  - Anesthetic complications
  - Oral trauma
  - Laryngeal edema
  - Bronchospasm
  - Atelectasis
  - Retained fragments

**ICD9**

- 933.1 Foreign body in larynx
- 934.0 Foreign body in trachea
- 934.9 Foreign body in respiratory tree, unspecified

**PEARLS AND PITFALLS**

- Pearls:
  - A careful history is the most useful diagnostic evaluation for FBA.
  - Expiratory films may exaggerate localized hyperinflation on chest films and are more helpful than inspiratory films.
  - In young children, evaluating for persistent hyperinflation in the dependent hemithorax may suggest air trapping.
  - Radiographic changes evolve over time, so in the stable patient, follow-up films may provide an alternative to immediate bronchoscopy.
- Pitfalls:
  - A normal exam or negative radiographic studies cannot exclude FBA.

# FOREIGN BODY INGESTION

Cynthia Lodding  
Garth Meckler

## BASICS

### DESCRIPTION

- Foreign body (FB) ingestion is defined as a suspected or confirmed FB that has been swallowed and is located anywhere along the GI tract.
- The focus of this topic will be FBs that are objects rather than medications or toxic ingestions. Also, caustic ingestions are not discussed in this topic. Please see various topics on toxicologic ingestions and the Esophagitis and Burn, Chemical topics.

### EPIDEMIOLOGY

- Nearly 100,000 FB ingestions are reported annually in the U.S.
- 80% of FB ingestions occur in children, with a peak incidence between 6 mo and 3 yr of age.

### RISK FACTORS

- Young age
- Advancing food inappropriate for developmental age
- Inappropriate toys for developmental age (small, separate pieces)
- Developmental delay may increase the risk for older children compared to peers.
- Psychiatric disease may predispose adolescents to FB ingestion.

### GENERAL PREVENTION

- Close supervision during meals and while playing with toys may help prevent accidental ingestion of FBs.
- Careful inspection and storage of toys and batteries

### PATHOPHYSIOLOGY

The pathophysiology of FB ingestion and the potential for impaction depend on characteristics of the patient and the FB:

- Anatomic considerations include areas of physiologic narrowing:
  - Cricopharyngeus muscle and thoracic inlet in the upper 1/3 of esophagus
  - Aortic arch in the middle 1/3 of esophagus
  - Lower esophageal sphincter in the distal 1/3 of esophagus
  - Pylorus
  - FBs in the large intestine are likely to pass spontaneously without complication.
  - Rectal FBs may be the result of sexual activity and in prepubertal children may represent sexual abuse (see Foreign Body, Rectal topic).
- Underlying medical conditions such as congenital or acquired strictures of the GI tract may predispose to FB impaction.

- Characteristics of the FB are important to the risk of impaction or complications such as perforation:
  - Objects >2.5 cm have difficulty passing through the pylorus.
  - Sharp objects have a higher rate of perforation, especially in areas of angulation including the C loop of the duodenum, and the ileocecal valve.
  - Ingestion of multiple magnets may lead to impaction through attraction across adjacent loops of bowel leading to pressure necrosis (7).
  - Button batteries may cause local erosion and perforation if retained (6).

### ETIOLOGY

- Coins are the most commonly reported FB ingestions in the U.S. and Europe, comprising up to 76% of ingested FB (5), while 5–30% of FB ingestions are sharp objects (9,10).
- Fish bone ingestion is more common in Asia.
- Sharp and multiple metallic objects (eg, nails) are often associated with intentional ingestion in adolescents with psychiatric disease.

### COMMONLY ASSOCIATED CONDITIONS

Psychiatric disease in adolescents

## DIAGNOSIS

### HISTORY

- The majority (80%) of ingested FBs are witnessed.
- Younger patients (<2 yr of age) are more likely to have an unwitnessed ingestion and may present with symptoms such as coughing, drooling, or respiratory symptoms (8).
- 7–64% of FB ingestions are asymptomatic.
- Symptoms: Dysphagia/Odynophagia, FB sensation, drooling, vomiting, refusal to eat, gagging, choking, or respiratory symptoms (stridor, wheezing)

### PHYSICAL EXAM

Findings depend on site of the FB as well as its characteristics:

- Proximal pharyngeal or esophageal FBs may produce drooling, gagging, or coughing.
- Distal, blunt FBs are often associated with a normal physical exam.
- Rarely, resulting perforation may be associated with mediastinitis or peritonitis.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Routine lab testing for ingested FBs is not indicated.
- Leukocytosis associated with prolonged impaction of foreign bodies is associated with an increased incidence of complications (11).

#### Imaging

Plain radiographs of the chest and abdomen may demonstrate radiopaque foreign bodies:

- Lateral views may be helpful to distinguish esophageal from tracheal foreign bodies and to help define the anatomic location of FB if further along the GI tract.

### Diagnostic Procedures/Other

- Handheld metal detectors may be helpful in localizing ingested coins and metallic FBs and may obviate the need for x-rays when available (eg, metallic objects located below the diaphragm can be safely observed as outpatients) (5).
- Barium swallow may be useful for suspected FBs that are radiolucent.
- Endoscopy (flexible or rigid) may be indicated for symptomatic radiolucent FBs, impacted or sharp FBs, and retained button batteries or ingested multiple magnets.

### Pathological Findings

Mucosal edema, erosion, or perforation may be noted during endoscopy or open surgical exploration of impacted FBs.

### DIFFERENTIAL DIAGNOSIS

- The differential diagnosis of ingested FB presenting with respiratory symptoms includes:
  - Aspirated FB
  - Upper/Lower airway infections (eg, croup, bronchiolitis, pneumonia)
- The differential diagnosis of ingested FB presenting with drooling, dysphagia, dysphonia, and odynophagia includes:
  - Infections (eg, retropharyngeal or peritonsillar abscess, stomatitis)
  - Oropharyngeal trauma
  - Esophagitis (eg, viral, candidal)
  - Tear or other injury to esophageal or oropharyngeal mucosa may give the patient a sensation of a FB at the site of injury.

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation.
- Ingested FB associated with loss or severe limitation of airway patency should be treated with the Heimlich maneuver or abdominal thrust in toddlers and older children and back blows and chest compressions in infants.
- Support ABCs.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Oxygen and monitoring should be provided for patients with respiratory symptoms.
- Symptomatic patients should be kept NPO in anticipation of the potential need for anesthesia for procedural removal of the FB.
- Asymptomatic, blunt ingested FB below the diaphragm can be safely managed expectantly as an outpatient for spontaneous passage in 1–2 wk.

### MEDICATION

#### First Line

- Analgesia may be necessary.
- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.

- Fentanyl 1–2  $\mu\text{g}/\text{kg}$  IV q2h PRN:
  - Initial dose of 1  $\mu\text{g}/\text{kg}$  IV may be repeated q15–20min until pain is controlled, then q2h PRN.
- Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
- Hydrocodone/Acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN

### Second Line

Glucagon has not been demonstrated to increase the rate of spontaneous passage of esophageal coins in children and is not recommended (4).

### SURGERY/OTHER PROCEDURES

- Endoscopic removal may be necessary:
  - Sharp objects are a greater risk for complications, though there is no consensus on guidelines for endoscopic or surgical removal.
  - Button batteries are a risk for erosive complications that may occur within hours in the esophagus (6). When past the pylorus, they usually pass uneventfully; when retained in the esophagus or stomach > 12 hr, they usually require removal.
  - Magnets, when multiply ingested, are at risk for impaction and pressure necrosis across adjacent loops of bowel and should be endoscopically or surgically removed (7).
- No single strategy for the management of esophageal FBs exists, and several options can be considered (see Foreign Body, Esophagus topic):
  - A brief period (8–16 hr) of observation with maintenance of NPO status and repeat x-rays may be appropriate, as 25–30% of FBs will pass without complication (1).
  - Esophageal bougienage with or without sedation may be effective to push the esophageal FB into the stomach (2).
  - Removal using McGill forceps (for proximal FB) or a balloon-tipped catheter (usually under fluoroscopy, performed in the Trendelenberg position) may be effective in a minority of cases (3).
  - Endoscopy using a rigid or flexible endoscope is the mainstay of removal of most impacted esophageal FBs (4).
- Ingested FB with signs or symptoms of perforation or distal GI impaction may require surgical exploration and removal.

### DISPOSITION

#### Admission Criteria

- Symptomatic patients, patients with ingestion if multiple magnets, signs and symptoms of perforation
- Patients with ingested button batteries that have not passed the esophagus within 12 hr and stomach within 24 hr are at risk for erosive complications and should be admitted.
- Asymptomatic patients with impacted esophageal FBs who fail 8–16-hr observation should be admitted for endoscopic removal.
- Critical care admission criteria:
  - Signs and symptoms of GI perforation: Mediastinitis or peritonitis with unstable vital signs may require admission to an ICU.

### Discharge Criteria

- Asymptomatic patients with a blunt FB below the diaphragm (except multiple magnets) can be safely discharged with expectant outpatient management:
  - Patients in whom esophageal bougienage has successfully pushed the FB into the stomach
- Esophageal FB has been removed.

### Issues for Referral

Asymptomatic ingested FBs that fail to pass spontaneously after 2–3 wk should be referred to a pediatric gastroenterologist or surgeon for possible endoscopic or surgical removal.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

#### Patient Monitoring

- Parents may be instructed to examine the stool for the ingested FB over the ensuing days to weeks.
- Discharged patients with ingested distal FBs should seek immediate medical care if there is fever, abdominal pain, vomiting, or bloody stools.

### DIET

No dietary restrictions

### PROGNOSIS

- >90% of ingested FBs pass spontaneously without complication.
- Prolonged impaction, ingested button batteries, sharp objects, and multiple magnets are associated with serious complications (3,9,10).

### COMPLICATIONS

- Esophageal perforation with abscess formation, mediastinitis, sepsis
- Arterial-esophageal fistula with hemorrhage
- Stricture formation
- GI perforation with peritonitis, sepsis

### ICD9

- 935.1 Foreign body in esophagus
- 935.2 Foreign body in stomach
- 938 Foreign body in digestive system, unspecified

### PEARLS AND PITFALLS

- Ingested button batteries in the esophagus can cause erosion or perforation within hours and should be emergently removed.
- Ingestion of multiple small magnets can lead to pressure necrosis of adjacent loops of bowel and require removal regardless of location within the GI tract.
- Though >50% of patients with ingested FB are asymptomatic, 75–90% will have a history of ingestion when specifically questioned.
- The rate of spontaneous passage of esophageal foreign bodies is highest for those located in the distal 1/3, followed by the middle 1/3, and finally the proximal 1/3; a brief period of observation may be warranted.

# FOREIGN BODY, CORNEA

Kimberly A. Giusto  
Joshua A. Rocker

## BASICS

### DESCRIPTION

- Corneal foreign bodies (FBs) commonly occur from workplace and environmental exposures.
- They can occur in any age group:
  - More common in school-age children and adolescents
- Signs and symptoms range from mild irritation to severe inflammatory reaction (1):
  - High-speed, smaller projectiles may not produce pain initially.
- If the FB penetrates the full layers of the cornea and enters the anterior chamber, it is considered an intraocular FB and should not be considered a corneal FB.

### EPIDEMIOLOGY

- One of the most common ophthalmologic reasons for emergency department visits:
  - FB may or may not still be present.
- Most common in young males

### RISK FACTORS

- Certain jobs and outdoor activities may increase a person's exposure to small projectile objects (1):
- Metal- and woodworkers fall into this group.

### GENERAL PREVENTION

Wearing protective eyewear during high-risk activities may reduce the likelihood of corneal FB.

### PATHOPHYSIOLOGY

- Occurs when a FB projected toward the eye lodges in the cornea:
  - An underlying corneal abrasion or laceration may be present.
  - An inflammatory response may cause vascular dilation, which may result in edema to the cornea, conjunctiva, or lids:
    - If the inflammatory response is not controlled or the FB is not removed, localized tissue necrosis may occur.
- If the FB penetrates beyond the cornea, it then becomes an intraocular FB, which has a much higher morbidity associated with it.

### ETIOLOGY

- Composition of the FB can affect the localized corneal inflammatory response (1):
  - Inert objects can cause minimal responses:
    - Nonoxidizing metals, glass, and plastic
    - However, larger-sized objects can cause a localized response.

- Organic and certain inorganic materials can cause significant localized response:
  - Organic materials:
    - Soil, plant materials, insect parts, and animal matter (fur)
    - Acids
    - Bases
  - Oxidizing materials:
    - Metals, such as iron and copper, can cause rust rings.

## DIAGNOSIS

### HISTORY

- Obtain history of exposure:
  - High-speed FBs have a greater risk of deeper penetration.
  - Important to note the FB material:
    - Rust rings can be created from retained iron pieces (2).
  - Patient may just complain of FB sensation without known exposure.
- Patient may complain of photophobia or blurry vision.
- Patient may complain of excessive lacrimation.
- Note reported visual acuity and pain.
- Note history of contact lens usage.

### PHYSICAL EXAM

- General:
  - Excessive tearing from affected eye
- Visual acuity:
  - Check visual acuity using Snellen chart (or equivalent) prior to further exam, and note whether or not corrective lenses are used.
- Slit lamp exam:
  - Important for complete ophthalmologic exam
- Lids:
  - Lid edema may be present.
  - The upper and lower lids should be everted to look for retained FB:
    - Presence of a linear vertical corneal abrasion may represent a retained FB in the upper eyelid.
- Conjunctiva:
  - May be a hyperemic, secondary to local irritation causing chemosis.
  - Corneal FB may be visualized during slit lamp exam or with a direct ophthalmoscope.
  - A rust ring, or a rusty stain at site of the FB, should be noted.
  - Fluorescein exam:
    - Use a fluorescein strip to perform a fluorescein exam to look for any disruption of the cornea.

- Pupil:
  - If significant irritation has occurred, signs of traumatic iritis or uveitis may be present. This may cause the pupil to have an abnormal shape.
- Anterior chamber:
  - Use a slit lamp to look for flare or cells in anterior chamber.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- Plain radiographs may be useful, especially if a metallic FB is suspected (3).
- If an intraocular FB is suspected, CT or US can be used for evaluation.
- MRI is not recommended because of the possibility of metallic FB.

#### Diagnostic Procedures/Other

- Slit lamp exam
- Fluorescein exam:
  - Seidel test:
    - A positive Seidel test is the appearance of dilution of the fluorescein at the site of the corneal injury. This will give the look of a waterfall or fluid moving from the site of the injury. This reveals the presence of an anterior chamber leak through the cornea and thus, by definition, is a globe rupture (2).

### DIFFERENTIAL DIAGNOSIS

- Corneal abrasion
- Corneal laceration or perforation
- Corneal ulcer
- Conjunctival FB
- Retained FB under the upper lid
- One also should consider more serious injuries such as globe rupture, hyphema, intraorbital FB, or keratitis secondary to prolonged inflammatory response.

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Any toxic exposure to the cornea requires immediate and copious irrigation:
  - Make sure the eye is anesthetized prior to attempted removal of a corneal FB.
  - It may be impossible to examine the eye secondary to the patient squinting or refusing to open the eye, so a topical anesthetic should be applied 1st:
    - If the patient has significant pain improvement with a topical anesthetic, the injury can be localized to the superficial layers of the eye, the cornea, or conjunctiva.
  - 1st attempt removal using normal saline with gentle jet stream irrigation.
  - A moist cotton swab can also be used:
    - Gently touch it to the corneal FB.

- If these methods are unsuccessful, a tuberculin syringe with a 25- or 27-gauge needle attached can be used while using the slit lamp for visual assistance:
  - The FB is approached with the needle tangential to the globe.
  - The FB is then pushed off the cornea using the beveled tip of the sterile needle, paying close attention not to penetrate the cornea.
  - Perform a Seidel test after attempting FB removal to look for any disruption in the cornea.
- If the FB is a metal, then a rust ring may remain after FB removal (3):
  - Ophthalmologic consultation is recommended, but a rust ring does not need to be removed emergently.
  - Removal of a rust ring is performed using an ophthalmic burr under a slit lamp (3).
- After FB removal, copiously irrigate the eye with normal saline and apply topical antibiotics:
  - Topical antibiotics should be applied until the corneal defect has completely healed (2).

## MEDICATION

### First Line

- Topical ophthalmologic antibiotics:
  - Choice of antibiotics include ophthalmic drops such as:
    - Polymyxin B sulfate/trimethoprim: 1 drop OP t.i.d.
    - Ofloxacin: 1 drop OP t.i.d.
    - Tobramycin: 1 drop OP t.i.d.
  - Consider ophthalmic ointment in younger children such as:
    - Bacitracin: 0.5-inch ribbon in subconjunctival sac q.i.d.
- Oral NSAIDs can be given for pain control (4).
- Topical anesthetics:
  - Proparacaine 0.5%: 1–2 drops OP once
  - Tetracaine 0.5%: 1–2 drops OP once

### Second Line

- Cycloplegic agents have not proved effective in studies but can be considered in cases of extreme pain or photophobia (5):
  - Homatropine 2–5%
- Check the tetanus status, and update if necessary.

## COMPLEMENTARY & ALTERNATIVE THERAPIES

Patching is not recommended but can be considered in cases of large defects.

## DISPOSITION

### Admission Criteria

Admission only needs to be considered if more serious ophthalmologic injuries are present.

### Discharge Criteria

Patients can be safely discharged home after removal.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Topical antibiotics should be continued until the corneal defect is completely healed.
- Patients can follow up with their primary care doctors in 1–2 days for re-examination.
- Large defects should follow up with ophthalmology within 24 hr (2).

### PROGNOSIS

- Prognosis is generally good, with no long-term effects.
- A prolonged delay in FB removal—days to weeks—increases the risk of serious inflammatory and infectious complication.
- Development of severe inflammation and infection worsens the prognosis.

### COMPLICATIONS

- Infection, scarring, corneal perforation, partial retained FB, traumatic iritis, hyphema, conjunctival hemorrhage, and conjunctivitis may occur secondary to corneal FB or its removal.
- Complications can occur if there is delayed removal of rust rings (2):
  - Iron decay causing staining
  - Chronic inflammation
  - Coats ring:
    - Circular scar in Bowman membrane of the cornea
  - Corneal vascularization or necrosis

- Eye, Visual Disturbance

## CODES

### ICD9

930.0 Corneal foreign body

## PEARLS AND PITFALLS

- Pearls:
  - Most corneal FBs can safely be removed by emergency medicine physicians. Antibiotics can be used to help prevent infection, and follow-up should occur in 1–2 days depending on the size of the defect.
  - Consider ophthalmologic consult in cases of larger defects or suspected intraocular FB.
  - A fundoscopic exam should always be attempted. At minimum, confirm the presence of bilateral red reflexes.
  - Always evert the eyelids to look for retained FBs.
- Pitfalls:
  - Corneal abrasions can give the sensation of FB.
  - Eye pain and clinical evidence of FB sensation should raise concern of corneal injury.
  - Reduction of visual acuity or visual fields should prompt immediate referral to an ophthalmologist.

# FOREIGN BODY, DISC BATTERY

Michelle J. Alletag  
Marc A. Auerbach

## BASICS

### DESCRIPTION

- Disc batteries are an exception to the benign nature of most ingested foreign bodies:
  - Found in watches, hearing aids, and other small electronics, these small round candy-sized objects can be enticing to small children.
- These batteries are often alkaline in composition (consisting of metal oxides—usually silver, mercury, or manganese) and can result in corrosive injuries.
- Older toys or those from other countries may have higher risk due to inadequate seal/coating.
- The increasingly popular lithium batteries contain several organic solvents and can also cause severe corrosive injuries.
- Ingestion is the most common cause of injury, but disc batteries can be inserted into other orifices such as the ear or nose.
- While generally benign once past the esophagus, disc or “button” batteries can result in rapid esophageal corrosion and/or hemorrhage and should be removed emergently when identified to be in the esophagus.

### EPIDEMIOLOGY

#### Incidence

- Disc batteries account for ~2% of foreign body ingestions (1).
- The American Association of Poison Control Centers reports thousands of disc battery ingestions per year (10,213 in 2007) (1).
- The overall incidence of nasal button batteries is unknown (2).
- 2 cases of severe corrosive burns to the skin have been reported when a button battery has been lodged under a hard cast (3).
- Button battery aspiration, with coagulation necrosis of the hypopharynx and respiratory mucosa, has also been reported:
  - May lead to the formation of tracheoesophageal fistulas (4).

### RISK FACTORS

- Age (preschool years most common):
  - Over half of reported ingestions in 2007 occurred in children <6 yr.
- Developmental delay in older children
- Ingestions often occur in a grandparent or elderly relative’s home.

### GENERAL PREVENTION

- Prevent toddlers from having access to button batteries. Avoid toys with button batteries.
- Make sure that a toy’s battery compartment is properly secured.

### PATHOPHYSIOLOGY

- Alkaline or lithium batteries cause corrosion and coagulation necrosis of esophageal or GI mucosa, skin, or nasal/ear mucosa.
- Less commonly, batteries may cause pressure necrosis, mucosal burns (from small electrical activity), or toxic metal absorption if corrosion occurs:
  - Disc batteries may contain lithium (Li), manganese (Mn), mercury (Hg), nickel (Ni), silver (Ag), or zinc (Zn).
- Ingested batteries with higher voltage or of larger size (sizes range from 8–23 mm) have a higher rate of complications:
  - Additionally, larger batteries are less likely to pass into the stomach.

### ETIOLOGY

- Placement of a disc battery into an orifice for curiosity or entertainment by a child given the semblance to candy or age-appropriate oral behavior
- Primarily unintentional ingestions:
  - Only 446 of 10,213 cases reported in 2007 were described as intentional.

## DIAGNOSIS

### HISTORY

- Note time of exposure or insertion of battery into the orifice.
- Most often asymptomatic after observed or reported ingestion
- Patients or their guardians may report history of drooling, vomiting or gagging, throat or chest pain, dysphagia, anorexia, abdominal pain or distension, hematemesis, or diarrhea.

### PHYSICAL EXAM

- Usually asymptomatic, though fever, tachycardia, and/or hypotension are suggestive of GI tract perforation
- Drooling may be a sign of pharyngeal or esophageal obstruction (more common with larger batteries) or represent late effects such as necrosis or perforation.
- Nasal bleeding or erythema
- Ear discharge or bleeding

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Unnecessary for uncomplicated cases
- For cases in which obstruction or perforation is suspected, CBC, serum electrolytes, BUN, and creatinine should be obtained.
- If the removed battery containing mercury or cadmium is not intact, mercury or cadmium levels may need to be assayed. However, cases of systemic toxicity have not been reported.

### Imaging

- Plain abdominal and chest radiographs to locate the battery should be obtained on any patient with potential ingestion:
  - In small children, it is often possible to include a significant portion of the abdomen with a chest radiograph.
- If these radiographs are negative, consider a lateral neck radiograph. This may locate a battery in the hypopharynx or nasopharynx.
- The structure of a disc battery gives it a double-ring appearance on plain radiographs. Coins appear as a homogeneous circle without a 2nd ring.

### Diagnostic Procedures/Other

Endoscopy can be used both for removal and to assess the extent of injury.

### Pathological Findings

Burns, coagulation necrosis, and mucosal sloughing may be seen on endoscopy.

### DIFFERENTIAL DIAGNOSIS

- Other foreign body ingestion
- Pill esophagitis
- Coin ingestion (coin is generally larger)
- Caustic ingestion

## TREATMENT

### PRE HOSPITAL

Children with airway compromise should be managed according to the Pediatric Advanced Life Support algorithm.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Batteries should be removed emergently, regardless of time of last oral intake:
  - Patients should be made NPO and prepared for surgery.
- Antibiotics should be given if there are concerns of GI tract perforation.
- Analgesic agents should be administered as needed for pain.
- Neutralizing agents have not been shown to decrease complications.
- Agents that increase GI motility also have not been shown to be effective (5).

### MEDICATION

#### First Line

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine/Acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN

- NSAIDs:
  - Relatively contraindicated in oral ingestions
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Ketorolac 0.5 mg/kg IV/IM q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

**Second Line**

Broad-spectrum antibiotics with anaerobic coverage for perforation:

- Cefoxitin:
  - 80–160 mg/kg/day IV divided q4–6h
  - Adult dose: 1–2 g IV q6–8h
- Clindamycin:
  - 30 mg/kg/day IV divided q8h, max single dose 900 mg IV q8h
- Piperacillin/Tazobactam (Zosyn):
  - <6 mo old: 150–300 mg/kg/24 hr IV div q6–8h
  - >6 mo old and children: 240–400 mg/kg/24 hr IV div q6–8h
  - Adult dose: 3 g IV q6h

**SURGERY/OTHER PROCEDURES**

- Removal techniques vary by institution:
  - Disc batteries in the esophagus should typically be removed promptly without delay:
    - Improvements in the sealing of such batteries, making them less prone to leak their caustic contents, has led some clinicians to allow a brief period of hours to see if battery will pass to the stomach.
    - We do not recommend this strategy.
  - Techniques include endoscopy under anesthesia, magnet extraction (orogastric tube with attached magnet) using fluoroscopy, and surgical removal.
- Nasal and ear foreign bodies require surgical removal if not easily extracted with an ear curette or other small hook in the emergency department:
  - Alligator forceps may rarely break or damage the cell, causing increased tissue damage and should not be routinely used. (See Foreign Body, Nose and Foreign Body, Ear topics for more details.)

**DISPOSITION**

**Admission Criteria**

- Patients with minor esophageal burns should be monitored in the hospital.
- NG tube feedings are recommended until wounds heal.
- Critical care admission criteria:
  - Known esophageal rupture or hemorrhage
  - Patients with respiratory difficulty or unstable vital signs

**Discharge Criteria**

- If a battery located in the ear, nose, nasopharynx, or esophagus has been removed without complication, the patient may be discharged after appropriate postsedation recovery.
- Hospitalized patients should demonstrate ability to tolerate feeds (either by mouth or by NG tube if wounds necessitate).
- Consider follow-up endoscopy prior to discharge to assess for any damage not seen on the initial evaluation.

**Issues for Referral**

- Any significant esophageal injury necessitates close follow-up with the surgeon for stricture formation and new or recurrent fistulas.
- ENT or pediatric surgery specialists should be contacted for operative removal of nasal or ear foreign bodies in the operating room under direct visualization and for follow-up if necrosis.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Return for respiratory distress, poor feeding, fever, or chest pain.
- Activity:
  - Regular activity as tolerated

**Patient Monitoring**

Children will need to be monitored as outpatients by the primary care provider, surgeon, or gastroenterologist for further complications.

**DIET**

In patients with esophageal injury, NG tube feeds or pureed foods may be necessary until wounds are fully healed.

**PROGNOSIS**

Patients with prompt removal (prior to any esophageal burns) of the foreign body have excellent prognosis.

**COMPLICATIONS**

- Esophageal perforation and tracheoesophageal fistula formation if the battery remains in the esophagus or stomach more than 3–4 hr
- Gastric hemorrhage and aorto-esophageal fistulas with hemorrhage have also been described.
- Children with esophageal injuries are at risk for developing esophageal strictures, feeding difficulties, or tracheoesophageal fistulas with resultant pulmonary complications.
- Nasal septal perforation and saddle-nose deformity are common complications when disc batteries are nasal foreign bodies.

**PEARLS AND PITFALLS**

- Pearls:
  - Esophageal disc batteries are highly concerning for their ability to cause caustic or electrical injury. Prompt removal is recommended.
  - Prompt recognition and treatment can prevent significant morbidity and mortality.
  - The frequent lack of initial symptoms and rapid onset of mucosal injury place children at high risk for potentially life-threatening esophageal injuries.
- Pitfalls:
  - Failure to appreciate the significant morbidity that may result from button battery ingestion, even in initially asymptomatic children, may be disastrous.

# FOREIGN BODY, EAR

James A. O'Donnell

## BASICS

### DESCRIPTION

- Ear foreign bodies (FBs) can be found anywhere in the external auditory canal.
- Common types of FBs include (1,2):
  - Food: Beans, seeds, corn kernels
  - Toys: Crayons, beads, play dough, toy parts
  - Miscellaneous: Sponge foam, Styrofoam, pebbles, buttons, pencil erasers, button batteries, cotton, insects, earrings

### EPIDEMIOLOGY

#### Incidence

0.05–0.45% emergency department visits (1,3)

#### Prevalence

Most cases are seen below the age of 8 yr. Can be seen in children as young as 1–2 yr. 43% of cases occur between the ages of 4 and 8 yr (4):

- No difference in occurrence in gender or right or left ear predilection
- Bilateral incidence is 0.8%.
- An incidental finding in 5%
- Most commonly seen in the summer months

### RISK FACTORS

- 45% of cases have a previous history of FB insertion.
- History of pica or developmental delay (1)

### GENERAL PREVENTION

- Keep small objects out of reach of children.
- Proper supervision of children
- Parental and child education

### PATHOPHYSIOLOGY

- The ear canal narrows at the junction of the cartilaginous and osseous portions. FBs deeper in the canal are more difficult to remove, as are those closer to the tympanic membrane (TM).
- Type of insult depends on nature of material placed in the ear canal:
  - Alkaline batteries (eg, button batteries) can cause alkaline burns and liquefaction necrosis.
  - Insects cause injury from movement or stinging. This can induce a local inflammatory or systemic anaphylactic response:
    - Have an increased incidence of damage to the ear canal or infection
  - Food items such as vegetable matter or breads can swell with moisture exposure and induce an inflammatory response.

- Delayed discovery of objects can result in inflammation as well as infection:
  - Necrotizing otitis externa (NOE):
    - Symptoms include severe tenderness around the auricle, headache, ear drainage, and granulation tissue at the junction of the osseous and cartilaginous portions of the external ear.
    - Facial nerve palsy, mastoiditis, sepsis, osteomyelitis, and sigmoid sinus thrombosis can be features (5).
    - Children have a higher incidence of facial nerve palsy earlier in the disease course than do adults (6).
    - Possible causes also include retained FB and button battery erosion (1).

### ETIOLOGY

- Most are self-inserted due to a child's curiosity (1):
  - Can be inserted accidentally or during play
- Insects can fly or crawl into the ear canal.
- Munchausen by proxy syndrome

## DIAGNOSIS

### HISTORY

- Local pain (47%)
- Verbal admission by child (33%)
- Insertion witnessed by caregiver (7%)
- Bleeding (4%)
- Discharge (0.9%)
- Foul odor coming from ear
- Rare: Cough, nausea, vomiting, excessive eye tearing, headache, hearing loss (2,4)

### PHYSICAL EXAM

- Assess both ear canals for FB:
  - Pulling the pinna superiorly and laterally will straighten the external auditory canal for adequate visualization.
- Note any drainage or discharge, bleeding, evidence of infection, or the presence of fever.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Usually no lab testing is required.
- Wound culture if infection is suspected

#### Imaging

Consider temporal bone CT scan if unable to visualize FB or liquefaction necrosis is suspected due to a button battery.

#### Diagnostic Procedures/Other

Visualization using otoscope with an instrumentation or operating head

### DIFFERENTIAL DIAGNOSIS

- Cerumen impaction, otitis externa (OE)/otitis media (OM)
- Abrasions to ear canal
- Bleeding secondary to traumatic damage to ear canal without FB
- TM perforation
- Cholesteatoma or tumor

## TREATMENT

### PRE HOSPITAL

- Comfort measures
- Keep patient NPO.

### INITIAL STABILIZATION/THERAPY

- Provide comfort measures and reassurance:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation.
  - Keep NPO in case procedural sedation is needed for removal or CT scan.
- Need to have a cooperative patient who will lie still to permit adequate visualization of the ear canal with magnification:
  - If patient is uncooperative, may need to consider the use of procedural sedation.
- Application of topical anesthesia to the ear canal is not effective due to the impermeable keratinized epithelial surface of the canal.
- The need for removal is more urgent if there is an infection, if a button battery is noted in the ear canal, or if vegetable matter has become wet.
- If an insect is the suspected FB, administer fluid to rapidly immobilize and kill the insect:
  - Microscope immersion oil agent has the most rapid onset of action against insects (2,7):
    - This is typically available only if microscopy is performed within the emergency department.
  - Mineral oil is also effective.
  - Benzocaine/Antipyrine has physical and pharmacologic properties that kill the insect and provide anesthesia to the ear canal and TM:
    - Of the viscous agents used, this is most likely to be readily available.
  - Lidocaine, tetracaine, proparacaine, or alcohol may also be used
  - Mineral oil or microscope immersion oil are more effective than alcohol or 1% lidocaine (1,7):
    - Lidocaine can make an insect exit an ear canal, but the movement can alarm your patient.
  - These agents may cause middle ear inflammation or nystagmus if the TM is not intact.

### MEDICATION

#### First Line

Antibiotics:

- Topical antibiotics:
  - A wide variety of these are available. A Cochrane review indicates that these agents are currently judged to be equally effective (8):
    - Polymyxin B/Neomycin solution: 4 drops b.i.d.
    - Ofloxacin 0.3%: 2 drops or 0.25 mL b.i.d. for 7 days if age > 1 yr

- Oral antibiotics:
  - Consider oral antibiotics for FBs that have been in place for >48 hr.
  - Oral antibiotics should be given if there is cellulitis of the face or neck, severe ear canal edema, or perforation of the TM or if an obstruction would prevent penetration of a topical antibiotic agent:
    - Amoxicillin 80 mg/kg/day divided b.i.d.–t.i.d.
    - Amoxicillin/Clavulanic acid 80 mg/kg/day divided b.i.d.–t.i.d.
    - Clindamycin 30 mg/kg/day divided t.i.d.
- Consider IV antibiotics for patients with:
  - Liquefaction necrosis, malignant OE, or NOE:
    - Cefepime 100 mg/kg/day divided q12h
    - Piperacillin 150–300 mg/kg/day divided q6–8h
    - Clindamycin 25–40 mg/kg/day divided q6–8h

### Second Line

Analgesic otic solution:

- Benzocaine/Antipyrine (Auralgan) otic drops

### SURGERY/OTHER PROCEDURES

- Surgical debridement and repair of necrotic tissues if NOE is present.
- Styrofoam beads can be dissolved by spraying them with ethyl chloride or acetone:
  - Avoid the use of either if the TM is not intact or the lining of the ear canal is abraded. This may increase the risk of systemic absorption of either agent.
- Cooperativity and/or restraint of the patient is paramount for safe removal of FBs.
- Irrigation of the ear canal:
  - Instill lukewarm water by means of flexible Silastic tubing attached to a syringe.
  - Irrigation is contraindicated if the TM is perforated or if the FB is suspected to be a button battery, bean, or other vegetable material.
- Suction:
  - Limited usefulness
  - Noise may frighten patient.
  - May push FB deeper into the canal
  - The Schuknecht FB suction catheter works best.
- Katz Extractor: A mini Foley catheter-like device inserted past the FB then inflated and withdrawn
- Right angle, nerve hook, or angled curette:
  - Insert past FB, rotate 90 degrees, and withdraw.
  - Can cause pain or damage to canal or TM if inserted improperly
- Alligator or Hartman forceps:
  - Most successful with small objects in the lateral 3rd of the canal
  - Can push FB deeper into the canal
  - Not best choice for removing a large or smooth FBs
- Cyanoacrylate (Super Glue) (3):
  - Place 1 drop of cyanoacrylate on the tip of a cotton swab or hollow plastic stick. Press this against the FB for 25–60 sec. Once adherent to the swab, remove the FB and stick from canal.
  - Best for smooth and dry FBs (eg, beads)
  - This technique is unsuitable for uncooperative patients or those with a tortuous canal, large tragus, or poorly visualized FBs.
  - Can result in glue stick being cemented to the ear canal or pushing the FB in deeper

### DISPOSITION

#### Admission Criteria

Admit patients with malignant OE, NOE, or necrotic tissue damage for IV antibiotics.

#### Discharge Criteria

- Discharge if FB is removed and there are no further FBs and TM is intact.
- If TM is perforated, recommend follow-up with ENT.

#### Issues for Referral

- ENT consultation or follow-up may be needed (48% of cases) (2,3)
- ENT follow-up may be needed if:
  - FB cannot be removed:
    - Patient will require sedation that cannot be accomplished in the emergency department
    - Round solid subjects
    - Object wedged in canal or up against TM
    - Glass or other sharp objects
      - Bleeding is an indication that the object may be sharp (1,2).
  - Damage to the TM has occurred.
- ENT consultation in the emergency department may be needed if:
  - There is an inordinate amount of bleeding.
  - FB is a button battery.
  - Liquefaction necrosis is suspected.

### FOLLOW-UP

#### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Patient needs to be rechecked by the primary care provider within 2–3 days post-discharge, especially if there are retained remnants of an insect or other organic matter, which can cause an inflammatory reaction or serve as a nidus for infection in the ear canal.
  - Always consider discharging on antibiotic drops.
  - Use oral antibiotics for OM or more serious cases of OE.
  - Consider analgesic agents for home use at discharge.
- Activity:
  - Avoid swimming and getting water into ear canal until the damage resulting from the aural FB has healed.

#### Patient Monitoring

Advise family to observe the patient for increased pain, foul-smelling discharge from the ear canal, swelling around the ear, persistent fevers, or altered mental status.

#### PROGNOSIS

Children do well if a timely diagnosis is made.

#### COMPLICATIONS

- Trauma to the canal
- Facial nerve palsy
- Ear canal laceration or hematoma
- OE
- Perforation of the tympanic membrane
- Auditory ossicle dislocation

931 Foreign body in ear

### PEARLS AND PITFALLS

- Pearls:
  - Examine the TM and ear canal before and after any attempted removal to look for additional FBs, remnants, or damage to the canal or TM.
  - Examine the opposite ear and nose, as children can place multiple FBs.
- Pitfalls:
  - Avoid cold water irrigation of the ear canal, as this can induce vertigo and nystagmus.
  - Almost 50% of aural FBs cannot be primarily removed. Repeated attempts lead to increased complications.
  - Unless the treating physician has a reasonable expectation that the FB can successfully be removed, it is preferable to have ENT attempt removal.

# FOREIGN BODY, ESOPHAGUS

Marc A. Auerbach  
Lilia Reyes

## BASICS

### DESCRIPTION

- Foreign bodies discussed here are coins, sharp foreign bodies, long or large objects, magnets and lead, and impacted food.
- Coins are the most common ingested foreign body in the U.S. and Europe.
- In Asia and other countries where fish is a large component of the diet, fish bone ingestion and impactions are common.
- Meat/Food impaction is common in adolescents and adults.

### EPIDEMIOLOGY

Data from the American Association of Poison Control Centers suggest that in 2007 there were more than 125,000 cases of foreign body ingestion by children <19 yr old:

- Incidence is highest in children ages 6 mo to 4 yr of age.
- 98% of foreign body ingestions in children are accidental (1).

### RISK FACTORS

- Foreign body entrapment and subsequent perforation are more likely at the site of a congenital malformation or at the site of prior surgery.
- 95% of meat impaction has underlying esophageal pathology that contributes to impaction:
  - Pathology includes peptic ulcers, caustic injury, or postoperative strictures.
  - A more recently recognized pathology is eosinophilic esophagitis.
- Food impaction may also be associated with underlying motility disorders.
- Mental retardation and psychiatric illness are associated with foreign body ingestion.

### GENERAL PREVENTION

- Parents should be advised to keep coins, sharp foreign bodies, long or large objects, magnets, and lead-based toys out of reach of small children.
- Education on cutting food into manageable proportions and complete mastication of food prior to swallowing

### PATHOPHYSIOLOGY

- 3 main locations: Esophagus, stomach, and lower GI tract
- Esophagus has 3 typical locations of impaction:
  - 60–70% impact at thoracic inlet, 10–20% lodge in the mid-esophagus at the level of the aortic notch, and 20% lie just above the lower esophageal sphincter:
    - The thoracic inlet is the area between the clavicles on CXR.
    - In the esophagus, there is an anatomic change from skeletal muscle to the smooth muscle.
    - The cricopharyngeus sling at C6 may provide an area of further entrapment of foreign body.

- Once a swallowed foreign body reaches the stomach within a normal GI tract, it is likely to pass through within 4–6 days and less likely to lead to complications:
  - Possible problem sites more distal include the pylorus, the fixed curves of the C loop of the duodenum (ie, secondary to its retroperitoneal location), and the ileocecal valve.

### ETIOLOGY

- Food boluses
- Esophageal abnormalities
- Oral behavior of younger children

### COMMONLY ASSOCIATED CONDITIONS

Esophageal abnormalities

## DIAGNOSIS

### HISTORY

- Children present after a caregiver witnesses the ingestion of a foreign body or after a child reports ingestion to a caregiver.
- Often presents asymptotically
- May have vague symptoms that do not promptly suggest foreign body ingestion
- The child may present with signs or symptoms of a complication of ingestion.
- Esophageal foreign body symptoms:
  - Dysphagia
  - Food refusal
  - Drooling
  - Emesis/Hematemesis
  - Foreign body sensation
  - Chest pain
  - Sore throat
  - Stridor
  - Cough
  - Unexplained fever
- Stomach/Lower GI tract foreign body symptoms:
  - Abdominal distention/pain
  - Vomiting
  - Hematochezia
  - Unexplained fever

### PHYSICAL EXAM

- Physical exam is usually normal.
- Signs mentioned in the History section may be present.
- Abrasions, blood streaks, or edema in the hypopharynx may be evidence of proximal swallowing-related trauma.
- Inspection of the oropharynx may reveal an impacted foreign body.
- Drooling or pooling of secretions suggests an esophageal foreign body but may be due to an esophageal abrasion.

- Physical findings may be due to complications of foreign body migration or esophageal perforation. In this situation, the following will be found:
  - Drooling, pooling of secretions
  - Rales, swelling or crepitus in neck, or peritonitis
  - Respiratory distress that can manifest as:
    - Stridor
    - Wheezing
    - Increased work of breathing

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- Chest/Abdominal radiography is most useful given that most foreign bodies ingested by children are radiopaque.
- Coins in the esophagus appear in an en face position on an AP view and the edge of the coin will be seen on the lateral view, while the opposite if the coin is in the trachea.
- If the swallowed object is below the diaphragm, further radiography is generally unnecessary since the object should pass through the GI tract in the setting of normal anatomy.
- Radiolucent objects in the esophagus may be better visualized if the study is done after having the patient drink a small amount of dilute contrast (ie, should not be done if endoscopy is planned).
- CT scan or MRI is rarely indicated.

#### Diagnostic Procedures/Other

Handheld metal detectors have been shown to have 100% sensitivity and 92.4% specificity in experienced hands in identifying the location of ingested metallic objects (2).

### DIFFERENTIAL DIAGNOSIS

- Esophagitis
- Viral or streptococcal pharyngitis
- Croup or retropharyngeal abscess
- Upper respiratory tract infection
- Psychological sensation or hysteria

## TREATMENT

### PRE HOSPITAL

Assess and stabilize airway, breathing, and circulation.

- Using abdominal thrusts to dislodge a foreign body in a spontaneously breathing patient without respiratory distress is not advised.

### INITIAL STABILIZATION/THERAPY

- Patients with drooling, marked emesis, or altered mental status may need supportive measures to protect the airway.
- Coin ingestion:
  - Emergent endoscopic removal of esophageal coins should be performed in symptomatic patients unable to swallow their secretions or who are experiencing acute respiratory symptoms.

- If asymptomatic, can delay to allow for appropriate fasting prior to endoscopy:
  - If the coin passes beyond the esophagus, routine removal is not indicated.
- Repeat radiograph to see if object has moved.
- Glucagon, benzodiazepines, and nifedipine have not been shown to be effective in the passage of esophageal foreign bodies in children.
- The majority of coins that pass asymptotically to the stomach or distally can be managed conservatively to see if they spontaneously pass through the GI tract.
- When multiple coins are ingested, they may adhere to each other, impairing transpyloric passage.
- Sharp foreign bodies: Safety pin ingestion is a fairly common sharp ingestion for children. Non-straight-pin sharps may require endoscopic or, in some cases, surgical removal.
- Long or large objects:
  - Primary sites of impaction are the esophagus, the pylorus (ie, may not allow passage of objects > 15 mm in diameter), and the duodenal C loop (ie, may not allow for passage of objects > 10 cm in length).
- Endoscopy may be performed on a patient who is asymptomatic after appropriate preanesthesia fasting.
- Urgent endoscopy is required in symptomatic patients despite the risk of aspiration or impaired visualization of the object.
- Magnets and lead:
  - Ingestion of > 1 magnet may be hazardous because magnets are able to attract each other, resulting in fistulization, obstruction, and/or perforation.
  - Early endoscopic removal is recommended if > 1 magnet is visualized on radiography.
  - Given that lead-based foreign bodies ingested can cause lead toxicity, early endoscopic removal is recommended.
- Food impaction:
  - Symptomatic patients unable to handle their secretions require urgent endoscopic disimpaction. Those who can handle their secretions require endoscopy within 12 hr.
  - Papain or “meat tenderizer” should not be used, as this may lead to hypernatremia and severe esophageal injury.
- Swallowed drug packages:
  - Children and adults swallow drug-filled balloons, condoms, finger cots, and plastic kitchen wrap in a variety of sizes:
    - The asymptomatic patient can be observed for passage with administration of activated charcoal to prevent further drug absorption followed by non-oil-based oral cathartic (ie, polyethylene glycol) (3).
    - Symptomatic patients with drug toxicity or obstruction require stabilization and surgical therapy for ruptured cocaine packets (4,5).
- Disc batteries should be removed emergently, regardless of time of last oral intake.
  - These pose risk of esophageal injury, including perforation from both conducted electrical current and caustic material that may leak.

## SURGERY/OTHER PROCEDURES

- Endoscopy by subspecialist
- Foley catheter method for removal of blunt esophageal foreign body:
  - Only experienced personnel should perform this procedure.
  - This procedure should be reserved for healthy children and those with a history of witnessed ingestion of blunt foreign body < 24 hr prior.
- Bougienage method for removal of blunt esophageal foreign body:
  - Only experienced personnel should perform this procedure.

## DISPOSITION

### Admission Criteria

- Children who require endoscopic foreign body removal usually require admission.
- Critical care admission:
  - Esophageal perforation and/or respiratory compromise

### Discharge Criteria

- Patient may be discharged soon after successful endoscopic removal foreign body without complications.
- Asymptomatic patients in whom the foreign body has been removed or has passed to the stomach

### Issues for Referral

- Surgery or GI specialists should be consulted for endoscopic removal of foreign bodies.
- A healthy child with repeated foreign body impaction should be evaluated for an underlying esophageal disorder.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- Return for any respiratory distress, chest pain, drooling, neck swelling, abdominal distension or pain, or inability to swallow.

### PROGNOSIS

Excellent

### COMPLICATIONS

- Intestinal perforation is a risk for battery or magnet ingestion.
- Esophageal rupture or perforation from attempted removal or displacement using Foley catheter method or bougienage

### See Also (Topic, Algorithm, Electronic Media Element)

- Foreign Body Aspiration
- Foreign Body Ingestion

### ICD9

935.1 Foreign body in esophagus

## PEARLS AND PITFALLS

- Children without symptoms may still have an esophageal foreign body that requires removal. When in doubt, obtain a radiograph.
- Consider foreign body ingestion in young children who present with their 1st episode of wheezing, stridor, or drooling.

# FOREIGN BODY, NOSE

Ee Tein Tay

## BASICS

### DESCRIPTION

- Nasal foreign bodies are most commonly found on floor of nasal passage, below the inferior turbinate.
- Common types of foreign bodies inserted:
  - Food: Corn kernels, seeds, beans
  - Toys: Crayons, beads, play dough, plastic toy parts
  - Miscellaneous: Paper, Styrofoam, magnets, rocks, buttons, erasers

### EPIDEMIOLOGY

#### Incidence

0.1% of pediatric emergency department visits

#### Prevalence

- Most common in children between 2 and 4 yr of age
- Gender ratio depends on type of foreign body:
  - Beads: Male to female ratio is 1:1.9.
  - Plastic toys: Male to female ratio is 1:1.

### GENERAL PREVENTION

- Keep small objects out of the reach of children.
- Parental and child education
- Proper child supervision

### PATHOPHYSIOLOGY

Pathophysiology depends on the composition of the foreign body:

- Battery corrosion may release alkaline material when in contact with moist mucosa, producing thermal burn.
- Nasal foreign bodies may exert a mass and pressure effect.
- Certain items such as food can cause a local and systemic inflammatory response that results in increased swelling.

### ETIOLOGY

Insertion of a foreign body for curiosity or entertainment by a child

### COMMONLY ASSOCIATED CONDITIONS

Foreign body in the opposite nasal passage or another body orifice

## DIAGNOSIS

### HISTORY

- Most nasal foreign bodies are often asymptomatic and incidentally noted by the caregiver or patient.
- Can often elicit a history of child placing a foreign body in the nose
- Foul chronic nasal discharge, usually unilateral
- Epistaxis
- Pain or discomfort
- Sneezing
- Snoring
- Mouth breathing

### PHYSICAL EXAM

- Foreign body visualized in nasal cavity
- Fever
- Nasal discharge
- Epistaxis
- May have septal laceration or perforation
- Enlarged nasal turbinate or mucosal edema
- Bony destruction
- Granulation tissue from chronic foreign body
- Requires a light source for visualization such as an otoscope, a nasal speculum, or an illuminated magnifying glass to fully examine the patient

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

CBC, ESR, C-reactive protein, and/or blood culture if infection is suspected

#### Imaging

Consider radiographic imaging of nasal bones if unable to visualize a radiopaque foreign body in the nasal cavity.

#### Diagnostic Procedures/Other

- Visualization using an otoscope, an illuminated magnifying glass, or a nasal speculum
- Use of a fiberoptic scope either by an emergency department physician or an otolaryngologist

### DIFFERENTIAL DIAGNOSIS

- Nasal tumor or mass
- Nasal polyp
- Septal hematoma
- Foreign body that has already been removed or dislodged by the time of the emergency department visit

## TREATMENT

### PRE HOSPITAL

Assess and stabilize airway, breathing, and circulation.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Prevent child agitation to decrease the risk of airway aspiration.
- Patient may need to be appropriately restrained with a papoose or sedated to achieve optimal conditions to remove the object.

### MEDICATION

- 1% lidocaine without epinephrine drops to nasal cavity for local anesthesia, up to 5 mg/kg:
  - Consider using 2% viscous lidocaine as lubricant when using a Foley catheter for removal.
- 0.5% phenylephrine spray to decrease mucosal swelling, 1–2 sprays in affected nostril
- Antibiotics:
  - Consider Cephazolin if suspected facial cellulitis: 25–100 mg/kg/24 hr q6–8h IV.
  - Consider ampicillin/sulbactam if suspected sinus involvement: 100–200 mg/kg/24 hr q6h IV or IM.

**SURGERY/OTHER PROCEDURES**

- Use a light source and nasal speculum during foreign body removal.
- Techniques for removal:
  - “Parent’s kiss”:
  - Caretaker applies positive pressure through the child’s mouth and simultaneously occludes the contralateral nostril
  - Oral insufflations with a bag valve mask:
    - Positive pressure applied similar to “parent’s kiss”
  - Hooked probe or alligator forceps for foreign body close to anterior nares
  - Balloon catheter:
    - Insert a 5–8 French Foley or 4–6 Fogarty catheter past foreign body, inflate balloon 2–3 mL, then withdrawal catheter with foreign body.
  - Suction catheter for round, smooth object close to the anterior nares
  - Saline washout:
    - Use a high-pressure bulb syringe filled with isotonic sodium chloride to the contralateral nostril.
    - Saline can also cause objects to swell or change in consistency.
      - Organic matter/food
    - Forceful injection of saline can be a powerful choking stimulus.
  - Cyanoacrylate glue:
    - Apply a small amount on a cotton swab, press onto object for 60 sec, then attempt removal.
  - Magnet for use for retrieval of metallic objects

**DISPOSITION****Admission Criteria**

- Aspiration of foreign body resulting in airway compromise
- Removal requiring surgical intervention
- Infection requiring parenteral antibiotics

**Discharge Criteria**

- Well appearing with normal vital signs
- No airway compromise or concerns

**Issues for Referral**

Otolaryngology referral if removal is anticipated to be difficult, attempt at removal is unsuccessful, or perforation or mass is suspected

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Follow up with a primary care physician or return to the emergency department if there is prolonged epistaxis, respiratory difficulty, or signs and symptoms of infection.
  - Routine antibiotics are not recommended for patients without septal perforation or signs of bacterial infection.
- Activity:
  - May resume normal routine without activity restrictions

**PROGNOSIS**

Usually full recovery after retrieval of foreign body

**COMPLICATIONS**

- Nasal foreign body gets into trachea
- Epistaxis
- Nasal septal ulceration or perforation
- Nasal meatal stenosis
- Thermal burn with button batteries
- Pressure necrosis with magnets
- Pain and discomfort from removal
- Laceration
- Barotrauma from positive pressure
- Accidental adhesion of glue to mucosa
- Infection risks:
  - Acute otitis media
  - Sinusitis
  - Facial cellulitis
  - Periorbital cellulitis

**CODES****ICD9**

932 Foreign body in nose

**PEARLS AND PITFALLS**

- Pearls:
  - Sedation may reduce the cough or gag reflex if a foreign body is pushed into the pharynx, resulting in airway compromise.
  - Reinspect the nose and other orifices for a 2nd foreign body prior to discharge.
  - Consider using viscous lidocaine as a lubricant when using a Foley catheter for removal.
- Pitfalls:
  - Risk of aspiration or pushing object further into the nasal cavity, particularly if removal is attempted in an uncooperative child

# FOREIGN BODY, RECTUM

Mandisa A. McIver  
Robert F. Gochman

## BASICS

### DESCRIPTION

- The frequency of rectal foreign bodies encountered in the emergency department is increasing.
- Patients are reluctant to disclose their presence, which only delays their removal.
- The most serious complication is perforation of the rectum or colon.
- There is a high success rate for outpatient management.

### EPIDEMIOLOGY

#### Incidence

- Increasing incidence due to increasing popularity of anal eroticism
- 33% of patients with self-introduced rectal foreign bodies do not initially admit to the act (1).

#### Prevalence

Unknown

### RISK FACTORS

- Young children
- Psychiatric patients
- Victims of assault

### GENERAL PREVENTION

Careful insertion of rectal thermometers and enema tips

### PATHOPHYSIOLOGY

- Delay in presentation and multiple attempts at self-removal may lead to mucosal edema and injury as well as muscular spasm.
- Perforation of the rectal wall can lead to extension of injury into the peritoneum or perineum:
  - 2/3 of the rectum is extraperitoneal.

### ETIOLOGY

- Most objects found in children are self-introduced or placed iatrogenically (ie, tip of thermometer).
- They are also found in psychiatric patients, victims of assault, cases of concealment (ie, weapons or drug packets), patients with constipation, and from sex practices.
- It is possible to have an ingested foreign body lodged in the rectum (ie, toothpick, chicken bone).
- Sexual assault and child abuse must be considered.

### COMMONLY ASSOCIATED CONDITIONS

- Psychiatric disorder
- Constipation

## DIAGNOSIS

### HISTORY

- There may be a history of anal manipulation, foreign body insertion, or sexual abuse:
  - Ask how long the foreign body has been in the rectum.
  - Inquire as to how many attempts have been made to remove the object.
  - If self-introduced or concealing an object, the history is often vague or inconsistent.
- The patient may complain of anal or abdominal pain, constipation, rectal bleeding, difficulty voiding, or fever.

### PHYSICAL EXAM

- On external exam, look for signs of trauma.
- Attempt to palpate the foreign body on digital rectal exam (DRE) or anoscopy for better visualization, only if a sharp object is not suspected:
  - Low-lying objects are normally palpable by DRE and are often easily removed in the emergency department.
  - High-lying objects above the rectosigmoid junction are difficult to visualize and remove.
  - High-lying objects are 2.25 times more likely to require operative intervention (2).
- Abdominal exam may reveal tenderness to palpation or peritoneal signs if perforation or obstruction is present.
- There may be bloody discharge from the rectum or loose sphincter tone.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- No labs are required for emergency department management.
- CBC may reveal leukocytosis, which is suggestive of perforation.
- Preoperative labs may be indicated if the patient is requiring surgical removal of the object.

#### Imaging

- Plain abdominal radiographs can detect intra-abdominal free air:
  - An upright image can assist in looking for free air under the diaphragm.
- Radiographs are also used to determine the number of foreign bodies as well as the shape, surface outline, location, and direction (3).
- May need serial images to follow progress of object through rectum
- Radiographic study with contrast:
  - Use water-soluble contrast if perforation is suspected.

### Diagnostic Procedures/Other

- DRE
- Anoscopy
- Rigid sigmoidoscopy

### Pathological Findings

- Intra-abdominal free air
- Peritoneal signs on abdominal exam
- Rectal bleeding

### DIFFERENTIAL DIAGNOSIS

- Constipation
- Rectal tear
- Hemorrhoids
- Intestinal polyp
- Perirectal abscess

## TREATMENT

### PRE HOSPITAL

- Pain management
- NPO for possible sedation/general anesthesia
- Do not attempt to remove a rectal foreign body.

### INITIAL STABILIZATION/THERAPY

- Sphincter relaxation is mandatory for removal of large foreign bodies.
- In consultation with surgery, consider the following methods of analgesia and foreign body removal (4):
  - Local infiltrative anesthesia or IV sedation is useful.
  - For digital extraction, lubricate the area with lidocaine jelly and use the other hand to apply abdominal pressure.
  - Grasp the edge of the object with forceps and apply traction while the patient bears down to perform a Valsalva maneuver.
  - For anal block, inject local anesthetic with a 30-gauge needle. Raise an intradermal wheal at 6 and 12 o'clock positions. Then, with a larger needle, inject circumferentially along the internal sphincter muscles along the anal canal.
  - If the object has created a vacuumlike effect, pass a well-lubricated Foley catheter beyond the object and inflate a balloon to break the seal and aid in removal.
  - For removal, you may need to use a vaginal speculum, obstetric forceps, or an obstetric vacuum extractor.
- Limit time for attempts at removal to 30 min (4).
- In patients where multiple exams or attempts to remove the foreign body occur, admit the patient for a higher level of anesthesia and more invasive exam techniques.

- If there is concern for ischemic anorectal mucosa, more invasive exams should be performed in the operating room under general anesthesia.
- Consider broad-spectrum antibiotics (3rd-generation cephalosporins) for risk of perforation or if excessive manipulation has been performed.
- For suspected perforation/peritonitis, consider antibiotic combinations that cover gram-positive, gram-negative, and anaerobic organisms.

**MEDICATION**

**First Line**

Benzodiazepine to relax patient and anal sphincters:

- Diazepam 0.1–0.2 mg/kg/dose mg IM/IV/PO q1–2h as needed, max single dose 10 mg

**Second Line**

- Antibiotics:
  - For suspected perforation/peritonitis, consider the following antibiotic combinations for gram-positive, gram-negative, and anaerobic coverage.
- Single drug therapy might be accomplished by piperacillin/tazobactam (Zosyn) alone:
  - Piperacillin/Tazobactam (Zosyn):
    - >6 mo and children 240–400 mg/kg/day IV divided q6–8h; Adult: 3 g IV q6h
- Cefotaxime and metronidazole (Flagyl):
  - Cefotaxime:
    - Infants >30 days and children: 150 mg/kg/day IV divided q8h
    - Adult dose: 2 g IV q8h
  - Metronidazole:
    - Metronidazole 15–50 mg/kg/day IV divided q8h; Adult dose: 500–750 mg IV q8h
- Ciprofloxacin and clindamycin:
  - Ciprofloxacin:
    - 30 mg/kg/day IV divided q8h
    - Max single dose 1.2 g/day
  - Clindamycin:
    - 25–40 mg/kg/day IV divided q6–8h
    - Max single dose 900 mg IV q8h

**SURGERY/OTHER PROCEDURES**

Surgical consult should be obtained for (2,4,5):

- Large foreign body
- High-lying foreign body (above rectosigmoid junction)
- Foreign bodies in place >2 days with surrounding rectal edema
- Smooth objects without a natural lever
- Fragile objects
- Sharp objects
- Unsuccessful attempts in emergency department
- Peritonitis
- Intestinal perforation
- Postremoval sigmoidoscopy is recommended (2).

**DISPOSITION**

**Admission Criteria**

- Failed extraction attempts in the emergency department that require surgical removal in the operating room.
- May admit for observation for possible descension of high-lying object into rectum
- Critical care admission criteria:
  - Signs of perforation
  - Rectal laceration
  - Peritonitis/Sepsis
  - Obstruction

**Discharge Criteria**

- Stable after observation for 12 hr
- No signs of perforation, peritonitis, or sepsis
- Normal postextraction sigmoidoscopy

**Issues for Referral**

- Psychiatric counseling
- Social work if sexual abuse is suspected:
  - In this case, all children in the family should be evaluated.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Follow up with primary care physician in 24 hr.
  - Follow up with surgeon within 3 mo for loss of anal sphincter tone or fecal incontinence.
  - Return for abdominal pain or distension, fever, vomiting, or severe rectal bleeding.
  - Stool softeners
  - Pain medication
- Activity:
  - As tolerated

**Patient Monitoring**

After removal, watch the patient for any intestinal strictures, abdominal distension, obstruction, or inability to pass stools.

**DIET**

No restrictions

**PROGNOSIS**

- Most patients do well post extraction.
- Serious complications are rare.
- Operative repair may include colostomy.

**COMPLICATIONS**

- Failure to remove the foreign body
- Perforation (most serious)
- Deep mucosal tear
- Perianal infection (bacteremia/sepsis)

**See Also (Topic, Algorithm, Electronic Media Element)**

Trauma, Perineal

**ICD9**  
937 Foreign body in anus and rectum

**PEARLS AND PITFALLS**

- If the history suggests a foreign body with a sharp edge, the physician should forego the DRE.
- It is recommended to remove all mercury deposits from a broken mercury thermometer to prevent local mercury absorption (6).
- Use of enemas or cathartics may increase the risk of perforation (especially with sharp foreign bodies).
- Concomitant drug intoxication or moving battery-operated objects may require delay of surgery until conditions are safe.

# FOREIGN BODY, SOFT TISSUE

Jeranil Nunez

## BASICS

### DESCRIPTION

- Patients presenting with open wounds or where skin has been penetrated (eg, abrasions, lacerations, puncture wounds) have risk of retained foreign body (FB).
- FBs in soft tissue can cause:
  - Toxic or allergic reactions
  - Damage to vital structures such as nerves, tendons, vessels, or joints
  - Infection resistant to antibiotic therapy
  - Acute or chronic, recurrent inflammation
  - Destruction of surrounding soft tissue or bony abnormalities
- Some soft tissue FBs should or need to be removed immediately. The size, composition, location, and accessibility of the FB, potential tissue damage from wound exploration, difficulty of FB extraction, and risks of future complications should all be weighed against the benefits of removal.
- Indications for removing FBs (1):
  - Reactive material likely to cause:
    - Intense inflammation or infection (thorns, spines, vegetative material)
    - Allergic reaction
    - Toxicity (heavy metals, spines with venom)
  - Impingement on or damage to tendons, vessels, or nerves
  - Heavy bacterial contamination
  - Impairment of mechanical function
  - Intra-articular or intravascular location
  - Proximity to fractured bone
  - Potential for migration toward important anatomic structures (glass, metal, plastic)
  - Persistent pain
  - Established inflammation or infection
  - Cosmetic deformity or psychological distress
- FBs embedded in the thoracic cavity, abdominal cavity, or neck should be left in place and surgical consultation sought for wound exploration and FB removal under general anesthesia.
- High-pressure injection accidents (eg, paint guns) require urgent surgical consultation. Injected paint, grease, and hydrocarbons can lead to intense local inflammation, tissue destruction, and necrosis with possible need for amputation.

### EPIDEMIOLOGY

#### Incidence

In 1 prospective study, the most common complication of pediatric lacerations was retained FB (~2%) (2):

- Glass, wood, and metal accounted for the majority of the retained FBs.

### RISK FACTORS

- History of an object that has shattered (glass), splintered (wood, metal), or broken (teeth) on contact with open skin or has contaminated a wound (debris, gravel, chemicals)
- Deep wounds (>5 mm)
- Wounds whose depth is not visible
- Puncture wounds through clothing or shoes
- Prior attempt at removal (possible retention of fragments)

### GENERAL PREVENTION

Appropriate protective gear

### PATHOPHYSIOLOGY

- The body's normal transient inflammatory reaction in response to soft tissue injury is often prolonged in the presence of a retained FB, resulting in delayed wound healing. If excessive, there may be destruction of surrounding soft tissue.
- Increased granulocyte and macrophage proliferation with release of collagenases and proteases attempt to dissolve and extrude the foreign material.
- If unable to destroy the FB, macrophages that have ingested the foreign material coalesce into multinucleated giant cells that then become encased in a dense fibrous capsule (granuloma). Once encapsulated, the inflammatory response subsides but can recur with minor trauma to the area.
- Vegetative, organic foreign materials such as wood, thorns, and plant spines may trigger an intense inflammatory reaction and can lead to infection (usually fungal).
- In some instances, the inflammatory response can represent an allergic reaction (blackthorns, rose thorn, cactus spine) or a toxin-mediated reaction (sea urchin spines with venom, heavy metals). In very rare cases, systemic toxicity can result from exposure (lead, mercury) (3).

### ETIOLOGY

- FB embedded in soft tissue as sustained from direct trauma or a fall onto a dirty surface
- Penetration of skin by FBs with retention of material (thorns, splinters, cacti, branches, nails, needles, glass, fish hooks, etc.)

### COMMONLY ASSOCIATED CONDITIONS

- Lacerations
- Puncture wounds

## DIAGNOSIS

### HISTORY

- Detecting FB in soft tissue can be difficult.
- Detailed history of mechanism of injury is essential:
  - All elements listed in the Risk Factors section
  - Composition, size, and location of possible FB
  - Multiple wounds
  - Time elapsed from injury (Wounds >24 hr old are more difficult to examine and have increased risk of infection.)

- Complaint of FB sensation
- Pain with passive movement of the area
- In the preverbal child, a nonresolving infection refractory to antibiotic therapy (cellulitis, culture-negative abscess, persistent purulent drainage) or bony changes on radiographic studies may be the only clue to retained FB.

### PHYSICAL EXAM

- FBs may be visible to the naked eye either as a mass or discoloration in the epidermis.
- Suspicion for a retained FB when there is:
  - Pain with deep palpation over a puncture wound or a palpable, tender mass
  - Puncture wounds +/- signs of infection:
    - Surrounding erythema
    - Induration
    - Tenderness
    - Drainage
    - Abscess
- Patency of circulation and neurologic function (sensory, motor) should be carefully assessed in all patients with open wounds and FBs.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

Wound culture/fungal culture if there is purulent drainage or an abscess

#### Imaging

- Radiopaque FBs:
  - Plain radiographs (min 2 views):
    - Surface markers (paper clips, needles, grids) placed over the puncture wound can aid in localization.
    - Likely visible: Metal, glass >2 mm, gravel/stone, bone, aluminum, teeth, pencil graphite
  - Fluoroscopy: Most useful intraoperatively
- Radiolucent FBs:
  - US:
    - Best method to visualize wood, vegetative material, and rubber
  - CT or MRI are recommended in cases of:
    - Failed exploration or persistent infection with negative radiographic findings
    - Foreign material embedded in area
    - Need for 3-dimensional analysis for better surgical approach and exploration

#### Diagnostic Procedures/Other

All open wounds should be thoroughly irrigated and carefully inspected before and after attempted FB removal. If there are multiple FBs present, repeat imaging studies after removal are recommended.

### DIFFERENTIAL DIAGNOSIS

- Cellulitis
- Abscess
- Soft tissue mass
- Vascular thrombosis
- Septic or traumatic arthritis
- Bone cyst, tumor

## TREATMENT

### PRE HOSPITAL

- Hemostasis: Sterile dressings should be placed over exposed surface areas to minimize contamination of open wounds and control active bleeding.
- In cases of hypotension, IV fluid boluses
- Pain management as needed

### INITIAL STABILIZATION/THERAPY

- Hemostasis
- Superficial wound irrigation and exploration

### MEDICATION

#### First Line

- Pain management:
  - Local anesthetics:
    - Injected lidocaine with or without epinephrine SC
    - Lidocaine/Epinephrine/Tetracaine (LET) topically if minimal risk of infection
    - Not to be used in patients with high-pressure injection injuries
  - Opioids:
    - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
      - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
    - Fentanyl 1–2 µg/kg IV q2h PRN:
      - Initial dose of 1 µg/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
    - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
    - Hydrocodone/Acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- Tetanus prophylaxis and immune globulin as indicated (See Tetanus Prophylaxis topic.)

#### Second Line

Prophylactic antibiotics are not usually necessary but are recommended in wounds:

- With history of animal or human bites
- With heavy bacterial contamination (soil)
- Over sterile sites (tendons, joints, or bones)
- In immune-compromised patients
- With retained FBs

### SURGERY/OTHER PROCEDURES

- A time limit of 15 min should be set for wound exploration in the emergency department. Adequate anesthesia, hemostasis, and lighting are essential for successful exploration.
- Some wound margins may need to be extended in order to fully explore the area or to safely grasp and remove a foreign object:
  - In some cases, block excision of the tissue containing the FB may be necessary:
    - Superficial location but difficult to grasp
    - Contamination of tissue
    - Toxic reaction

- Cactus spines can be pulled out with careful traction along the axis of insertion:
  - If many cacti are present, depilatory wax or woodworking glue can be used for simultaneous extraction.
- FBs in the hand may be removed in the emergency department if:
  - Visible through the existing wound
  - No additional skin incisions are needed
  - Minimal bacterial contamination
  - No tendon or neurovascular injuries
  - Otherwise, consultation with a surgical hand specialist is recommended.
- Skin debridement of devitalized tissue
- Small, inert material (glass, metal, plastic) embedded in benign locations not readily accessible for removal can be left in place and removed electively if necessary.
- Wound closure as needed:
  - Delayed primary closure and prophylactic antibiotics are recommended for wounds >24 hr old or with heavy bacterial contamination.
- Surgery/Plastic surgery/Orthopedic surgery consultation as indicated based on location of FB

### DISPOSITION

#### Admission Criteria

- Inpatient ward admission criteria:
  - Need for parenteral antibiotics
  - FBs embedded in critical areas requiring surgical exploration and intervention (tendons, nerves, or vessels or those causing ischemia or hemorrhage)
- Critical care admission criteria:
  - Anaphylactic shock associated with a retained FB that cannot be removed immediately
  - Toxin-mediated reaction or systemic toxicity with significant end organ dysfunction (heavy metals, venomous spines) or tissue necrosis

#### Discharge Criteria

- Established hemostasis with appropriate wound irrigation and careful exploration
- Wound management and follow-up as needed

#### Issues for Referral

Outpatient surgical referral (general surgery, orthopedics, plastics) is recommended for any patient who is discharged from the emergency department with a retained FB (within 48–72 hr).

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- Antibiotic treatment as needed
- Wound care instructions

#### Patient Monitoring

Close follow-up is recommended for patients with a retained FB or for patients who had extensive wound exploration (within 48–72 hr).

### PROGNOSIS

- Most inflammatory responses resolve completely after FB extraction.
- Retained FBs that cause recurrent inflammation, infection, and tissue damage or migrate toward vital structures can cause significant morbidity.

### COMPLICATIONS

- Delayed wound healing with recurrent inflammation and scarring
- Infection: Cellulitis, culture-negative abscess, lymphangitis, bursitis, synovitis, arthritis, osteomyelitis
- Bony abnormalities: Periosteal thickening, bone pseudotumors, osteolytic lesions
- Migration of FB
- Vascular thrombosis
- Loss or limitation of function

### REFERENCES

ICD9

729.6 Residual foreign body in soft tissue

### PEARLS AND PITFALLS

- Chronic or recurrent infections resistant to antimicrobial therapy or wounds with persistent pain or limitation of function should raise suspicion for a retained FB.
- Superficial objects that are easily visible and located in benign locations can be safely removed in the emergency department or office.
- Retained, missed FBs are a common cause for malpractice claims against treating physicians (4).
- Careful, meticulous exam and documentation are crucial in all circumstances.

# FRACTURE, CERVICAL SPINE

Marc A. Auerbach  
Lawrence Siew

## BASICS

### DESCRIPTION

- Cervical spine fractures are rare in children.
- Injury can occur through flexion, extension, vertical compression, rotation, or a combination of these mechanisms.
- Age-related anatomic considerations account for differences in the types of injuries:
  - Younger children are more susceptible to fractures of the growth plate and ligamentous injuries involving the upper cervical spine.
  - Older children are more susceptible to vertebral and arch fractures involving the lower cervical spine.
- Most spinal cord injuries result from direct compression or disruption of the cord by fracture fragments or subluxed vertebrae:
  - Spinal cord injury without radiologic abnormality (SCIWORA) may occur, especially in children <8 yr of age.

### EPIDEMIOLOGY

#### Incidence

- 1–4% of children admitted to major trauma centers, 60–80% of all pediatric vertebral injuries:
- Male > female (teenagers)
- As high as 80% are bony spine injuries (1).

### RISK FACTORS

- Down syndrome:
  - 15% have atlantoaxial instability
- Klippel-Feil syndrome
- Morquio syndrome:
  - Mucopolysaccharidosis IV with associated hypoplasia of the odontoid
- Larsen syndrome:
  - Associated with cervical vertebrae hypoplasia
- Previous cervical spine surgery

### GENERAL PREVENTION

- Proper adult supervision
- Avoidance of high-risk activities such as trampolines, contact sports
- Age-appropriate restraints in motor vehicles

### PATHOPHYSIOLOGY

Children <8 yr of age are more susceptible to fractures of the growth plate and injuries of the upper cervical spine (C1-3):

- Growth centers are susceptible to sheer forces during rapid deceleration or hyperflexion-extension.
- Fulcrum of the cervical spine progresses caudally (C2-3 at birth to C5-6 at 8 yr of age).
- There is greater mobility of the cervical spine because of weaker cervical musculature and increased laxity of ligaments.
- Incomplete ossification of the odontoid process and relative larger head compared to body also contribute.
- Immature vertebral joints and facets allow more sliding (2).

### ETIOLOGY

- Majority of cervical spine fractures result from trauma to top of the head or back of the neck. Can occur from:
  - Motor vehicle and bike accidents
  - Pedestrian accidents
  - Falls
  - Diving injuries
  - Sports-related injuries
- Mechanism of injury can predict type of injury (2–4):
  - Hyperflexion (most common):
    - Wedge fractures:
      - Pure flexion injury with compression of the anterior vertebral body and without disruption of posterior elements
    - Teardrop:
      - Flexion with vertical compression causing anterior displacement of triangular bony fragment
    - Clay-Shoveler:
      - Abrupt flexion with lower neck muscular contraction resulting in oblique fracture at base of spine process, most commonly at C7-T1
  - Hyperextension:
    - Compression of posterior elements and disruption of anterior longitudinal ligament
    - Hangman fracture:
      - Affects the arch of C1 or the bilateral pedicles of C2
    - Axial loading:
      - Compressive downward forces that cause burst or comminuted fractures of the arches of C1 or vertebral bodies of lower cervical spine
      - Jefferson burst fracture:
        - Fractures of the arches of C1 and lateral displacement of C1 with respect to C2
    - Rotational injuries:
      - Fracture or dislocation of vertebral facets

### COMMONLY ASSOCIATED CONDITIONS

- Facial fractures
- Head injuries
- Spinal cord injuries

## DIAGNOSIS

### HISTORY

- Nature of trauma (fall, motor vehicle injury, sports injury, etc.):
  - Mechanism of injury
- Local pain, muscle spasm, or decreased range of motion
- Transient or persistent paresthesias
- Weakness
- Ask about signs of other types of neck trauma:
  - Changes in voice, hoarseness, dysphagia, odynophagia, tenderness, or hematemeses

### PHYSICAL EXAM

- Close monitoring of vital signs:
  - Apnea or hypotension may result from injuries at the level of diaphragmatic control.
  - Hypotension, bradycardia, or temperature instability may result from spinal shock.
- Neck exam:
  - Maintain in-line stabilization
  - Tenderness, muscle spasm, or deformity over spinous process
- Respiratory signs:
  - Diaphragmatic breathing
- Abdominal/Genitourinary signs:
  - Ileus
  - Fecal incontinence
  - No rectal tone with rectal exam
  - Urinary retention
- Neurologic signs:
  - Muscle tone:
    - Flaccid tone may indicate lower motor neuron lesion or spinal shock.
  - Muscle strength:
    - Focal weakness
    - Paralysis:
      - Partial cord syndromes (central cord, anterior cord, Brown-Sequard, and dorsal cord syndromes)
      - Complete cord syndrome (paraplegia, quadriplegia)
  - Sensation:
    - Isolated sensory deficit is the most common finding with cervical spine injury.
  - Deep tendon reflexes
  - Rectal exam

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- Children with suspected cervical spine injury must undergo radiologic evaluation.
- Radiologic imaging may be deferred if the suspicion of cervical spine injury is low. This may be guided by age of child (>8 yr), low risk mechanism of injury, no distracting pain or injuries, awake and able to cooperate with exam, no mental status changes, no neck pain or limitation of movement, and no neurologic deficits (5):
  - Preferred initial radiographs are cross-table lateral, anteroposterior, and odontoid. The series must include all 7 cervical vertebrae as well as odontoid and lateral masses.
  - Flexion-extension views may be required in the alert, cooperative patient who still complains of neck pain and there are concerns of ligamentous injury (6).
- Neck CT should be obtained for:
  - Inadequate 3-view plain radiographs
  - Suspicious plain radiographs
  - Fracture-displacement seen on plain radiographs
  - High index of suspicion for injury despite normal plain radiographs

- MRI is superior to CT for soft tissue and ligamentous injuries. It has limited utility in the emergent setting because of availability and accessibility.
- SCIWORA:
  - See objective signs of myelopathy as a result of trauma in the absence of findings on plain radiographs and CT.
  - 5–35% of patients with myelopathy may have SCIWORA (7)
  - MRI should be performed or CT myelography if MRI is unavailable.

**Diagnostic Procedures/Other**

- Somatosensory evoked potentials:
- Electrical impulse in response to stimuli

**DIFFERENTIAL DIAGNOSIS**

- Ligamentous injury
- Muscles strain
- Cauda equina syndrome
- Spinal cord infections, neoplasms
- Vertebral artery dissection

**TREATMENT**

**PRE HOSPITAL**

- Assess and stabilize airway, breathing, and circulation.
- Immobilization of spine with cervical collar and long spine board is necessary:
  - If properly fitting cervical collars are unavailable, splinting the head and body with towels or foam blocks and tape is a reasonable option.
  - Maintain the patient in a neutral position, and avoid head and neck movement while full spinal immobilization is being applied.

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation per Advanced Trauma Life Support (ATLS) and Pediatric Advanced Life Support guidelines:
  - If suspicion for cervical spine fracture, immobilize the patient with a rigid cervical collar and a long spine board if not done earlier.
  - Evaluate for associated injuries.
  - Perform serial neurologic exams.
- Control of pain, preventing further injury, and stabilize associated injuries
- Early, timely consultations with neurosurgery and/or orthopedic surgery:
  - If subspecialty care is not available, arrange transfer to trauma center.

**MEDICATION**

**First Line**

- Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
  - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
- Fentanyl 1–2 µg/kg IV q2h PRN:
  - Initial dose of 1 µg/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.

**Second Line**

Consider methylprednisolone: 30 mg/kg IV over 15 min, then 5.4 mg/kg/hr over the next 23 hr. (Caution: Dosage based on adult guidelines; lack of high-level pediatric evidence):

- Previously, steroids were recommended by the ATLS guidelines, but based on recent data this recommendation has been withdrawn.
- Routine use is institution dependent (8).

**SURGERY/OTHER PROCEDURES**

Surgical management is reserved for neurologic injury and/or unstable fractures:

- Conservative treatment includes skeletal traction and closed reduction (halo vest).
- Surgical treatment includes cervical spine decompression and fusion.

**DISPOSITION**

**Admission Criteria**

- Radiographic evidence of cervical spine fracture or dislocation
- Symptoms of spinal cord injury with negative radiographic imaging (SCIWORA)
- Critical care admission criteria:
  - All patients with proven or suspected spinal cord injuries and progressing neurologic exam or abnormal vital signs
  - Unstable fractures or dislocations at high risk for causing spinal cord injury

**Discharge Criteria**

- Resolution or improvement/stabilization of neurologic symptoms:
  - Disposition to physical rehabilitation facility as required
- Adequate pain control

**Issues for Referral**

Suspected spinal cord injury should have neurosurgery and/or orthopedic consultations.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Maintain cervical spine immobilization.
  - Adequate pain control
- Activity:
  - Restricted with no contact activities until cleared by physician

**Patient Monitoring**

- Monitor for any new neurologic deficits or progression of pre-existing deficits.
- Monitor for parathesias or inability to void or incontinence.

**PROGNOSIS**

- Related to associated spinal cord injury
- Mortality from spinal cord injury decreased 24% over past 30 yr; 80% of patients hospitalized for spinal cord injury survive (1).

**COMPLICATIONS**

- Spinal or neurogenic shock
- Paralysis
- Cord syndromes (complete, incomplete, anterior cord, Brown-Sequard)
- Horner syndrome

- Spinal Cord Compression
- Strangulation
- Trauma, Neck
- Trauma, Spinal Cord

**CODES**

**ICD9**

- 805.00 Closed fracture of cervical vertebra, unspecified level
- 805.01 Closed fracture of first cervical vertebra
- 805.02 Closed fracture of second cervical vertebra

**PEARLS AND PITFALLS**

- Pearls:
  - Younger children are more susceptible to upper cervical injuries, unlike older children who are more likely to have lower cervical spine involvement.
- Pitfalls:
  - Improper immobilization
  - Do not remove a cervical collar on a patient with abnormal mental status.

# FRACTURE, CLAVICLE

Louis A. Spina

## BASICS

### DESCRIPTION

- The clavicle connects the shoulder to the trunk and is one of the most commonly injured structures in the shoulder girdle.
- The clavicle is the most commonly fractured bone in the pediatric population.
- Clavicular fractures can be divided into fractures of the midshaft, the medial end (or medial 3rd), and the lateral end (or lateral 3rd).
- Most of the fractures (~90%) in the pediatric population occur in the midshaft of the clavicle. (1,2):
  - Greenstick fractures of the clavicle are common.

### EPIDEMIOLOGY

- Clavicular fractures are most common in children between 2 and 10 yr of age:
  - > 50% of all clavicular fractures occur in children < 10 yr of age.
- Clavicular fractures are also seen in the newborn period.
- Fractures of the medial aspect of the clavicle are rare in young children and raise the question of abuse.

### RISK FACTORS

- Participation in contact sports increases the risk of clavicular fracture.
- A difficult vaginal delivery can increase the risk of clavicular fracture in the neonatal population.

### PATHOPHYSIOLOGY

- Midshaft fractures of the clavicle are often greenstick fractures without significant angulation or displacement:
  - Associated neurovascular injury is rare but may be seen secondary to severe forces causing significant displacement.
- Lateral clavicular fractures usually occur through the physis, where the coracoclavicular and acromioclavicular ligaments anchor the clavicle and prevent dislocation.
- Medial clavicular fractures often occur through the medial physis with either posterior or anterior displacement of the distal fragment:
  - Posterior displacement can cause compression of the mediastinal vessels or the trachea.

### ETIOLOGY

- Mechanism of injury causing a fractured clavicle is typically a direct fall onto the affected shoulder during sports or play.
- Lateral compression during a crush injury, as can occur in some motor vehicle accidents, may also result in a fracture of the clavicle (2).
- Less commonly, clavicular fracture can be caused by a fall onto outstretched hand (FOOSH), with transmitted forces causing the fracture.

## DIAGNOSIS

### HISTORY

- Common presentation is pain in the affected area. Verbal children will spontaneously complain of pain, and younger children may cry, avoid use of affected arm, or cradle the affected arm with the opposite extremity.
- Often, there is an associated trauma reported by the patient or the caregiver:
  - However, there are times, especially in younger children, when there is no known mechanism of injury.
- In older children, a history of a sports-related injury (direct blow or FOOSH) may be present.

### PHYSICAL EXAM

- Exam of the clavicle will often reveal swelling due to a hematoma over the area of fracture with tenderness in this area:
  - Crepitus can sometimes be palpated at the site of fracture.
  - Medial clavicular fractures can have either anterior or posterior displacement, which is often palpable on exam.
  - Lateral fractures are infrequently displaced in children (1).
- Children often have limited active range of motion of the shoulder on the affected side. Limited abduction of the shoulder is usually present.
- Determine if the fracture is open or closed:
  - Open wounds should be apparent, but tenting of the skin overlying the fracture site should alert the examining physician for potential puncture of the skin at a later time.
- Examine the surrounding joints and bones for fractures, dislocations, and subluxations:
  - Sternal fractures or dislocation
  - Humeral fractures
  - Shoulder dislocations
- Evaluate the patient for associated life-threatening injuries:
  - Rib fractures
  - Cervical or thoracic spine fractures
  - Intrathoracic injuries
  - Pneumothorax

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- Routine radiographs of the affected clavicle are often obtained to confirm the diagnosis of a fracture:
  - Fractures are often not visible on every radiographic view.
  - Midshaft fractures are usually transverse or oblique, and displacements with comminution are common.
  - Medial fractures are at risk for displacement of the section lateral to the fracture:
    - Displacement can be either posterior or anterior.
    - Occasionally require further radiographs or CT scans to determine the direction of displacement if not readily apparent on physical exam.
- Some providers may defer radiographs on younger patients with midclavicular tenderness and make a clinical diagnosis.
- CT:
  - If there is concern about posterior displacement, chest CT scan with IV contrast can be helpful to determine if there is compression of the underlying vessels or the trachea.
- Angiography:
  - If there is a concern about vascular injury resulting from a displaced fracture, angiography may be necessary.

### DIFFERENTIAL DIAGNOSIS

- Humeral fractures
- Shoulder dislocation and contusion
- Acromioclavicular separation
- Sternoclavicular separation
- Sternal fractures
- Rotator cuff injury
- Muscular injuries to the shoulder and chest

## TREATMENT

### PRE HOSPITAL

- A sling should be utilized in the prehospital setting to help stabilize the affected extremity.
- Ice packs to the affected region
- Pain management

### INITIAL STABILIZATION/THERAPY

Most clavicle shaft fractures can be adequately stabilized using a figure-of-eight dressing or using a sling and swathe.

**MEDICATION**

**First Line**

- Once immobilized, most fractures will require over-the-counter medications to control associated pain:
  - NSAIDs:
    - Consider NSAID medication in anticipation of prolonged pain and inflammation.
    - Some clinicians prefer to avoid NSAIDs due to theoretical concern over influence on coagulation and callus formation.
    - Animal studies have raised concerns that NSAIDs may negatively influence bone healing; however, there is no clinical evidence in humans.
    - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
    - Ketorolac 0.5 mg/kg IV/IM q6h PRN
    - Naproxen 5 mg/kg PO q8h PRN
  - Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- Open fractures require prompt administration of antibiotics:
  - Initial treatment with cefazolin IV at a dose of 50–100 mg/kg/day divided into 3 doses per day (q8h) is preferred.

**Second Line**

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2 µg/kg IV q2h PRN:
    - Initial dose of 1 µg/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- For those requiring antibiotics and allergic to cephalosporins, clindamycin administered IV at dosing of 30 mg/kg/day divided q8h is an acceptable alternative.

**SURGERY/OTHER PROCEDURES**

- Most clavicular fractures in childhood do not require surgery due to excellent remodeling potential:
  - Only 15 patients during a 21-yr period required surgery in 1 review (3).
- Indications for surgery:
  - Open fractures
  - Neurovascular compromise
  - Irreducible fractures that carry the risk of becoming open fractures:
    - Often has tenting of the skin overlying the fracture site
  - Nonunion of fracture site (usually after 3 mo)

**DISPOSITION**

**Admission Criteria**

- Most clavicular fractures do not require admission unless surgical stabilization is necessary.
- Concerns about possible child abuse may necessitate admission to ensure the safety of the child.

**Discharge Criteria**

Stable patients with clavicular fracture that have been adequately immobilized may be safely discharged home.

**Issues for Referral**

- Most clavicular fractures do not require immediate orthopedic evaluation or follow-up. Most of these injuries can be managed by the primary care provider.
- Open fractures, unstable distal fractures, grossly displaced midshaft fractures, and posteriorly and severely anteriorly displaced medial fractures and any fracture with neurovascular compromise will require orthopedic consultation in the emergency department.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Sling should be worn for the initial 3 wk and then for comfort.
  - Parents should be warned that a lump in the area of the fracture might form during healing, which can take several months to resolve.
  - Ibuprofen is typically adequate for pain control.
- Activity:
  - Usually kept in sling for ~6 wk.
  - After 6 wk, the sling may be removed if patient’s pain allows.
  - Athletes should not return to sports until they have normal painfree range of motion and no tenderness to palpation over injured region.

**PROGNOSIS**

- Most clavicular fractures heal well due to the excellent remodeling capabilities of children.
- Very few clavicular fractures in children require surgical repair.

**COMPLICATIONS**

- Pneumothorax / hemothorax
- Brachial plexus injury
- Injuries to the subclavian artery or vein

**REFERENCES**

**ADDITIONAL READING**

**See Also (Topic, Algorithm, Electronic Media Element)**

- Fracture, Humerus
- Trauma, Chest
- Trauma, Shoulder

**ICD9**

- 810.00 Closed fracture of clavicle, unspecified part
- 810.01 Closed fracture of sternal end of clavicle
- 810.02 Closed fracture of shaft of clavicle

**PEARLS AND PITFALLS**

- Pearls:
  - Clavicular fracture is the most common fracture of childhood.
  - The majority of clavicular fractures may be treated conservatively with immobilization and do not need immediate orthopedic referral.
- Pitfalls:
  - Posterior displacement of a medial clavicular fracture may result in compression of the mediastinal vessels or the trachea.
  - In younger children (<2 yr of age) presenting with clavicular fractures and inconsistent histories, the possibility of an inflicted injury should be considered.

# FRACTURE, COCCYX

Nazreen Jamal  
Bruce L. Klein

## BASICS

### DESCRIPTION

- The coccyx, commonly called the tailbone, consists of up to 5 separate or fused vertebrae.
- Pain in and around the region of the coccyx is referred to as coccydynia (or coccygodynia).

### PATHOPHYSIOLOGY

- Trauma to the coccygeal region can cause a fracture of the coccyx and coccydynia.
- Coccydynia with or without a fracture can be a consequence of parturition.
- Coccydynia without a fracture can also result from nontraumatic etiologies:
  - Nearby septic arthritis
  - Malignant metastases
  - Idiopathic in origin

### ETIOLOGY

- Direct trauma to the coccygeal region:
  - A fall in the half-seated position, with the impact of the fall directed to the coccyx, is a common cause (1).
  - A kick to the buttocks can also result in a fracture of the coccyx.
- Coccyx fractures can be caused by obstetric or gynecologic maneuvers.

## DIAGNOSIS

### HISTORY

History of recent trauma to the coccygeal region, most commonly a direct fall onto the buttocks:

- Immediate pain in the coccygeal region following the event
- Worse pain while sitting or rising from the sitting position
- May also complain of pain on defecation

### PHYSICAL EXAM

- Pain on external palpation of the coccyx
- Rectal exam
  - Pain on internal palpation of the coccyx
- Abnormal mobility of the coccyx may be appreciated:
  - However, in normal adults, the tip of the coccyx can be moved up to 30 degrees anteriorly and 1 cm laterally (1).
- Perform a complete neurologic exam:
  - Isolated coccyx fractures should not have neurologic deficits.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- Lateral radiograph of the coccyx (with the hips flexed maximally):
  - Displaced fractures of the coccyx may be identified, but nondisplaced ones may be missed.
  - Interpretation can be difficult given the natural variations in coccygeal angulation.
  - If no fracture is visible radiographically, but the history and physical exam seem consistent with one, the injury should be treated as a fracture.

- MRI or CT scan should be reserved for select cases (2):
  - Each of these scans is more sensitive for diagnosing a coccyx fracture than the lateral radiograph.
  - Adjacent nonbony injury may be identified as well, but these associated injuries are rarely serious.
  - While an MRI or CT scan can be ordered when the lateral radiograph is normal or indeterminate, identifying a coccyx fracture usually does not change the initial management.

### DIFFERENTIAL DIAGNOSIS

- Contusion
- Sacrococcygeal dislocation
- Sacral fracture
- Pilonidal cyst
- Perirectal abscess
- Constipation
- Tumor

## TREATMENT

- If the history and physical exam suggest coccyx fracture, treat as such even if radiographs appear normal.
- Virtually all coccyx fractures are initially managed conservatively and in the same manner.
- Supportive care is recommended:
  - Analgesics
  - Sitz baths
  - Stool softeners
  - Inflated doughnut cushion to sit upon to relieve pressure off the coccyx
  - Activity restrictions
- Symptoms typically abate within 2–6 wk, although some patients, usually adults, will be refractory to conservative management.
- Manual reduction of an angulated or displaced fracture is rarely ever necessary, especially upon initial presentation.

**First Line**

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2  $\mu$ g/kg IV q2h PRN:
    - Initial fentanyl dose of 1  $\mu$ g/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4–6h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
    - Ketorolac 0.5 mg/kg IV/IM q6h PRN
    - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

**SURGERY/OTHER PROCEDURES**

Some adults with refractory coccydynia (from diverse etiologies, not just from fractures) have benefited from local anesthetic and steroid injections, manipulation of the coccyx under general anesthesia, or coccygectomy:

- These procedures are rarely, if ever, performed or necessary in pediatric patients with coccyx fractures (3,4).

**DISPOSITION**

Admission is usually not required.

**Discharge Criteria**

- Most patients can be discharged home with prescriptions for an analgesic and a stool softener as well as instructions regarding supportive care.
- Activity:
  - Avoid contact sports such as wrestling or football.

**Issues for Referral**

If the pain does not resolve in 4–6 wk, the patient should be referred to an orthopedic surgeon.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Follow up with the patient's primary care provider or an orthopedic surgeon if the pain persists after 4–6 wk of conservative therapy.

**PROGNOSIS**

Complete healing usually occurs in 6–12 wk.

**COMPLICATIONS**

- Isolated coccyx fractures should have no neurologic deficits.
- Rarely, chronic pain may result.

- Pilonidal Cyst
- Spinal Cord Compression
- Trauma, Perineal
- Trauma, Spinal Cord

**CODES****ICD9**

805.6 Closed fracture of sacrum and coccyx without mention of spinal cord injury

**PEARLS AND PITFALLS**

- Treat all patients with a history and physical exam consistent with coccyx fractures conservatively with supportive care regardless of the imaging results.
- If pain persists after 4–6 wk, the patient should be referred to an orthopedic surgeon.

# FRACTURE, FEMUR

Tara Webb

Marc Gorelick

## BASICS

### DESCRIPTION

Femur fractures are classified by level, pattern, open vs. closed, degree of displacement and angulation, and degree of comminution:

- Femoral shaft fractures are the most common, accounting for 70% of femur fractures.
- Subtrochanteric (1–2 cm below the lesser trochanter) and supracondylar fractures (just above the origin of the gastrocnemius) are less common and require unique management.
- Pattern types commonly include transverse, oblique, and spiral.
- Degree of comminution described by Winquist and Hansen:
  - Grade I: Fracture with small fragment <25% width of femoral shaft, stable in axial plane and rotational direction
  - Grade II: Fracture with 25–50% width of femoral shaft, stable in axial plane; possible rotational instability
  - Grade III: Fracture with >50% width of femoral shaft, unstable in axial plane and rotationally
  - Grade IV: Circumferential loss of cortex as well as instability in axial plane and rotationally

### EPIDEMIOLOGY

#### Incidence

Incidence of femoral shaft fractures in children is 19.15 per 100,000 (1):

- Peak incidence is during early childhood (<5 yr of age) and in adolescence.

### RISK FACTORS

- Patients who are male gender or black race have a higher incidence of femur fractures.
- Rickets or diet poor in vitamin D or calcium
- Osteogenesis imperfecta
- Presence of pre-existing bone cysts
- Physical abuse
- Motor vehicle accident

### GENERAL PREVENTION

Prevention may be accomplished by general injury prevention and child abuse prevention techniques.

### PATHOPHYSIOLOGY

- Direct force tends to produce a transverse fracture.
- Torsional force results in spiral fractures:
  - Spiral fractures are seen with falls from height.
  - Spiral fractures also strongly suggest nonaccidental trauma in younger children.
- Children rarely have open fractures due to increased bone elasticity.

### ETIOLOGY

- In premobile children, nonaccidental trauma is the most likely cause of a femur fracture.
- Ambulatory, small children can sustain femur fractures from relatively minor trauma, such as tripping or twisting a leg.
- School-age children are likely to sustain femur fractures when struck by motor vehicles.
- Adolescents can sustain femur fractures from high-velocity automobile collisions.
- Pathologic fracture secondary to tumors, osteogenesis imperfecta, bone cysts, or osteoporosis

### COMMONLY ASSOCIATED CONDITIONS

- In a pedestrian vs. auto collision, the Waddell triad refers to the constellation of femur fracture, thoracic or abdominal injury, and head injury.
- When a fracture of the femur is present, the joint above and below must be examined to rule out associated hip and tibial injuries.

## DIAGNOSIS

### HISTORY

- Thigh pain, swelling, and inability to ambulate are expected.
- Mechanism of the fracture
- Associated injuries during the event such as head, thoracic, or abdominal injuries that may be more immediately life threatening
- Screen for nonaccidental trauma risk factors or signs of systemic disease if mechanism of injury seems inconsistent with clinical findings.

### PHYSICAL EXAM

- Complete physical exam to evaluate hemodynamic stability and rule out other life-threatening injuries:
  - Patient could be tachycardic or hypotensive from hemorrhage into the affected thigh.
- In the affected limb:
  - Check skin overlying injury to classify fracture as open vs. closed.
  - Look for obvious deformity.
  - Assess neurovascular status distal to the injury to assess for vascular integrity and compartment syndrome.
- Determine if other injuries are present in the same limb (rarely, ipsilateral femoral neck fractures can occur) (2).

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- No lab tests are absolutely indicated for isolated femur fractures:
  - Consider CBC to assess for significant hemorrhage.
  - Although uncommon, hemodynamically significant bleeding may occur in these fractures (3).
- Lab testing should focus on evaluation for other suspected injuries based on mechanism of injury.

#### Imaging

- AP and lateral radiographs of the affected limb should include both the hip and the knee to check for other associated fractures or dislocations.
- Skeletal survey may be indicated if nonaccidental trauma is suspected.
- Other imaging as indicated by clinical suspicion of associated injuries

### DIFFERENTIAL DIAGNOSIS

- Hip fracture, dislocation, or contusion
- Thigh hematoma or contusion
- Knee fracture, dislocation, or contusion
- Overuse pain

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation.
- Consider cervical collar and spine board if necessary.
- Early immobilization using traction devices should be performed prior to hospital care:
  - Always ensure presence of distal lower extremity pulses.
  - Traction may be contraindicated with fractures close to the knee, hip, or pelvis.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Determination if any acute, life-threatening injuries are present.
- Adequate analgesia
- Placement of the affected limb into traction splint

### MEDICATION

#### First Line

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2  $\mu$ g/kg IV q2h PRN:
    - Initial fentanyl dose of 1  $\mu$ g/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN

- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Ibuprofen 10 mg/kg IV/PO q6h PRN
    - Ketorolac 0.5 mg/kg IV/IM q6h PRN
    - Naproxen 5 mg/kg PO q8h PRN
  - Some clinicians prefer to avoid due to theoretical concern over influence on coagulation and callus formation.

**Second Line**

Local anesthetic:

- Femoral nerve blockade with long-acting local anesthetic has been demonstrated to effect significant analgesia and reduce opioid requirement in adults.
  - May be considered in any patient, particularly if there is concern for hypotension due to opioid or preference to reduce opioid use.
  - Lidocaine max single dose 5 mg/kg
- Antibiotics as indicated for open fractures:
  - Cefazolin 25–100 mg/kg/day IV/IM divided q6–8h
  - Gentamicin 2.5 mg/kg/dose IV/IM q8h
- Tetanus prophylaxis as necessary:
  - Tetanus toxoid 0.5 mL IM for booster:
    - If unimmunized, combined antigen vaccine is recommended.
    - Tetanus Ig 250 IU IM all ages

**SURGERY/OTHER PROCEDURES**

All children with femur fractures should receive an orthopedic consult for definitive management:

- Femoral neck fractures have a high risk for hematoma formation, which can impair blood flow to the femoral head. Presence of a hematoma requires surgical drainage.
- Femoral neck fractures are repaired using either open reduction with fixation or closed reduction, followed by immobilization. Spica cast may be used in children <2 yr of age.
- Femoral shaft fractures in small children are managed conservatively, as they are usually relatively stable fractures. Pavlik harnesses are used in children 0–4 mo of age; spica casts are used in small children above this age with stable fractures.

- Children ages 6–10 yr are typically treated with closed reduction and flexible intramedullary rod fixation.
- Children > 11 yr of age are treated with either intramedullary fixation with rigid rods or casting with external fixation, depending on characteristics of the fracture.
- Distal femur fractures are close to the growth plate and therefore are managed using wire or screw fixation with careful avoidance of the growth plate (4).

**DISPOSITION**

**Admission Criteria**

- Most patients are initially admitted to the hospital:
  - Parents of patients who are placed in spica casts must receive training in how to care for the child in the cast.
  - Most patients are placed into traction until proper bone end apposition occurs to permit proper surgical repair.
- Patients who receive operative care must be admitted for monitoring and recovery.
- Critical care admission criteria:
  - Patients with significant hemorrhage, compartment syndrome or other complications, or multiple traumatic injuries may require ICU monitoring.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

**Patient Monitoring**

Patient and caregivers should monitor for evidence of compartment syndrome or other complications of casting.

**PROGNOSIS**

- Children have an increased femoral blood supply compared to adults, resulting in excellent prognosis for fracture healing and union.
- Most patients are able to bear weight by 6 wk and return to normal activity in 3 mo.

**COMPLICATIONS**

- Overgrowth of the affected limb and leg length discrepancy
- Thigh compartment syndrome
- Fat embolism
- Acute respiratory distress syndrome
- Avascular necrosis of the femoral head after femoral neck fractures
- Nonunion is very uncommon.

**ICD9**

- 820.00 Fracture of unspecified intracapsular section of neck of femur, closed
- 820.10 Fracture of unspecified intracapsular section of neck of femur, open
- 821.00 Fracture of unspecified part of femur, closed

**PEARLS AND PITFALLS**

- Pearls:
  - When a femoral shaft fracture is present, always obtain radiographs of the joint above and below the injury.
- Nonaccidental trauma must be strongly considered in the differential diagnosis of femur fractures in nonambulatory children.
- Pitfalls:
  - Failure to recognize and treat coexisting life-threatening injuries
  - Clinical presentation is usually very obvious; there is risk that the clinician may fail to recognize other injuries that may be more subtle.
  - Failure to recognize concomitant fractures in the pelvis or femoral neck when a femoral shaft fracture is present

# FRACTURE, FOOT

Bhawana Arora

Usha Sethuraman

## BASICS

### DESCRIPTION

- Fractures of the foot bones are common.
- Occur in all of the 26 bones of the foot:
  - 2 bones in the hindfoot (calcaneus, talus), 5 bones in the midfoot (navicular, cuboid, 3 cuneiforms), and 19 bones in the forefoot (5 metatarsals, 14 phalanges)

### EPIDEMIOLOGY

- Account for 5–8% of all pediatric fractures and for 7% of all physeal fractures (1)
- The incidence increases with age.
- Metatarsal physeal fractures are the most common fractures, accounting for 60% of pediatric foot fractures, with fractures of the base of the 5th metatarsal accounting for 22% (2,3).
- Phalangeal fractures account for as much as 18% of pediatric foot fractures (2).
- Talar and calcaneal fractures represent 2% each of all pediatric foot fractures (1).

### RISK FACTORS

- Congenital foot deformities
- Nutritional deficiencies
- Stress fractures due to change in activity
- High-impact or repetitive motion sports (eg, gymnastics, basketball, tennis, running)
- Improper foot wear or inadequate conditioning

### GENERAL PREVENTION

- Injury prevention and sports conditioning
- Wearing well-fitting, supportive athletic shoes

### PATHOPHYSIOLOGY

- Fractures can be localized to the forefoot, midfoot, and hindfoot. These regions are demarcated by 3 joints—Lisfranc, Chopart, and subtalar:
  - The Lisfranc (tarsometatarsal) joint separates the midfoot from the forefoot, which includes the 5 metatarsophalangeal joints:
    - The tarsometatarsal joints have intrinsic stability as a result of both the osseous architecture and the associated ligaments.
  - The Chopart joint separates the midfoot from the hindfoot and includes the joint between the calcaneus and the cuboid bone and the talus and navicular bone:
    - Supination and pronation occur at this joint.
  - The subtalar joint separates the talus and calcaneus. The 3 articulating facets of calcaneus form a complex subtalar joint with the corresponding talar facets:
    - The talus is unusual in that:
      - A large portion of its surface is articular cartilage.
      - Blood supply is limited, making it prone to osteonecrosis after a talar neck fracture:
- The calcaneus has numerous muscle and tendon attachments.

### ETIOLOGY

- Simple falls/accidents
- Fall from heights, especially calcaneal fractures
- Twisting injuries and stress fractures
- Objects falling onto the foot or stubbing of toe
- Crush injuries (eg, lawn mower injuries)

### COMMONLY ASSOCIATED CONDITIONS

- Ligament injuries, as with Lisfranc injuries
- Compartment syndrome seen with crush injuries
- Ankle fractures
- Lower spine fractures (5% of calcaneal fractures)
- Other injuries in multisystem/high-energy trauma

## DIAGNOSIS

### HISTORY

- Description of pain characteristics:
  - Onset, location, character, duration
  - Change with activity or rest
  - Aggravating factors
- Trauma (new or repetitive):
  - Time between injury and the onset of pain
- Mechanical symptoms (locking, clicking)
- Neurologic symptoms (eg, altered sensation, numbness, discoloration of foot)
- Gait and current function
- Effect of previous treatment.
- Usual mechanisms of fractures are:
  - Talar fractures: Forceful dorsiflexion of ankle
  - Calcaneal fractures:
    - Occur with high velocity, axial loading, with the talus being driven into the calcaneus
  - Tarsometatarsal complex injuries:
    - Athletes with these injuries tend to have subtle clinical and radiographic findings.
    - Can be from low- or high-force injuries due to flexion or abduction.
    - Include Lisfranc fractures:
      - Forceful plantarflexion of the foot with axial loading, or a direct crush injury
      - Commonly missed diagnosis
  - Metatarsal fractures (indirect or direct injuries):
    - Indirect injuries result from axial loading, inversion, or rotation
    - Direct injuries often result from the impact of falling objects.
  - Phalangeal fractures result from objects falling onto the foot or stubbing of toe:
    - Proximal phalangeal fractures are more common than distal phalangeal fractures.
    - Hallux injuries are more common than those of the lesser toes.
  - Stress fractures occur in adolescents who are involved in repetitive intense training.

### PHYSICAL EXAM

- Inspect the injured foot for swelling, bruises, deformity, and open wounds.
- Palpation along the foot will show point tenderness at the fracture site.
- With displaced fractures and dislocations, a deformity of the foot is usually apparent.
  - Rotational deformity is present if the nail bed does not lie in the same plane as that of the corresponding toe on the opposite foot.
- Test range of motion and joint function.
- Conduct a careful neurologic exam of the foot, including both motor and sensory functions.
- Palpate for pulses and assess capillary refill.
- Look for compartment syndrome with crush injuries of the midfoot:
  - Hallmark of compartment syndrome is excessive pain on passive flexion of toes.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- Plain film radiography—AP, lateral, and oblique:
  - Ottawa foot rules predict need for radiography for midfoot fractures. Need to obtain radiograph if there is pain in the midfoot zone and any of the following 3 findings (4):
    - Point tenderness over the base of 5th metatarsal
    - Point tenderness over the navicular bone
    - Inability to take 4 steps, both immediately after injury and in the emergency department
  - Although the Ottawa rules were designed for those > 18 yr of age, studies have shown they may be used in adolescents  $\geq 10$  yr (5).
  - Jones fracture:
    - Involves the proximal diaphysis of the 5th metatarsal and has a high incidence of nonunion/delayed union
    - Pseudo Jones fracture:
      - Avulsion of 5th metatarsal base, usually a pull by peroneus brevis
  - Nondisplaced fractures of the phalanx are common:
    - Usually Salter-Harris I or II types
- Special plain film imaging views may be needed for the diagnosis of specific fractures:
  - Lisfranc fractures require a high index of suspicion because spontaneous reduction may occur masking the true extent of injury:
    - Need stress views with weight bearing
  - Calcaneal fracture requirements:
    - Lateral view is important because it allows measurement of the Böhler's angle, which is measured at the intersection of 2 lines on superior surface of calcaneus:
      - Böhler's angle normally measures 20–40 degrees but is reduced in fractures
    - Need to also consider lumbosacral spine films
  - Talar fractures require 45-degree internal oblique films.
- Other imaging modalities such as bone scanning, CT scanning, MRI, and US may help diagnose occult foot fractures:
  - CT scan:
    - Many bones are not ossified, so this is useful.
    - Bony tarsal coalitions not seen on radiographs may be seen on CT.
    - Useful for assessing for tarsometatarsal complex injury
  - MRI:
    - Permits increased soft tissue contrast
    - Better visualization of muscles, ligaments, cartilage, periosteum, and subchondral bone

### DIFFERENTIAL DIAGNOSIS

- Osteochondroses: Kohler, Freiberg disease
- Calcaneal apophysitis: Sever disease
- Tarsal coalition, infections
- Pathologic fractures through a neoplasm
- Accessory bones or sesamoids may mimic

## TREATMENT

### PRE HOSPITAL

Ice application, splint immobilization, elevation

### INITIAL STABILIZATION/THERAPY

- Immobilization: Posterior/Stirrup splint
- Pain control
- Nondisplaced talar fractures: Immobilization in a non-weight-bearing long leg cast for 6–8 wk
- Calcaneal fractures: Extra-articular fractures can be treated with immobilization for 5–6 wk.
- Lisfranc injuries:
  - Nondisplaced fractures at the level of the tarsometatarsal joint complex may actually be injuries that were initially displaced but then spontaneously reduced.
  - Patients with such injuries may be treated with a posterior plaster splint for up to 1 wk, followed by a non-weight-bearing short leg cast for a month and then a short walking cast for an additional 2 wk.
- Tarsal fractures: Avulsion or stress fractures can be treated in a short walking cast for 2–3 wk.
- Metatarsal fractures: If fracture is not proximal, they can be treated with weight bearing as tolerated in a short walking cast or a cast shoe for 3 wk:
  - In proximal, 1st through 4th metatarsal fractures, consider possibility of a Lisfranc injury.
  - If Lisfranc injury is ruled out, treat with a non-weight-bearing short leg cast for 4 wk.
- Pseudo Jones fracture: 6 wk walking cast
- Jones fractures are more recalcitrant to treatment. These fractures should be treated with at least 6 wk in a non-weight-bearing cast (6).
- Toe fractures: Immobilization by taping the injured toe to the adjacent toe (buddy taping):
  - A piece of cotton or felt should be placed between the toes to avoid maceration.
  - A rigid-soled shoe or surgical cast shoe aids in immobilization and comfort.
  - Immobilize injured toe until point tenderness has resolved, which usually requires 3–4 wk.

### MEDICATION

#### First Line

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2 µg/kg IV q2h PRN:
    - Initial dose of 1 µg/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine/Acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Some clinicians prefer to avoid NSAIDs due to theoretical concern over influence on coagulation and callus formation.
    - Animal studies have raised concerns that NSAIDs may negatively influence bone healing; however, there is no clinical evidence in humans.

- Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
- Ketorolac 0.5 mg/kg IV/IM q6h PRN
- Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- Antibiotics for open fractures:
  - Cefazolin 25–100 mg/kg/day IV divided q6–8h, max 12 g/day
- If open fracture, give tetanus toxoid if not current.

### SURGERY/OTHER PROCEDURES

- Nail bed injuries involving the germinal matrix should be repaired, and significant subungual hematomas (>40% of nail bed) should be drained.
- Operative management is suggested for:
  - Unstable displaced talar fractures
  - Displaced intra-articular calcaneal fractures
  - Tarsometatarsal complex injuries
  - Markedly angulated fractures or displaced intra-articular fractures of the proximal phalanx of the great toe
  - Open fractures require irrigation and debridement and IV antibiotic therapy.

### DISPOSITION

#### Admission Criteria

- Children who sustain Lisfranc injuries due to high-energy trauma have significant soft tissue injury and should be observed for compartment syndrome.
- Need for open reduction and internal fixation
- Other significant nonorthopedic injuries

#### Discharge Criteria

- Stabilization of fracture
- Adequate pain control
- Good follow-up

#### Issues for Referral

- Complex open fractures
- Unstable fractures
- Displaced intra-articular fractures
- Lisfranc injuries
- Compartment syndrome
- Need for open reduction and internal fixation

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Rest, ice, and elevation
- Adequate analgesia
- Proper instruction in crutch walking
- Resume normal activity when pain free after assessment by a physician.
- Follow up with orthopedics/primary care physician depending on nature of fracture.
- Follow up initially after 1 wk and then regularly until patient has a well-healed fracture and is pain free.

#### Patient Monitoring

Watch for signs of compartment syndrome.

### PROGNOSIS

Prognosis is generally excellent with appropriate and timely treatment.

### COMPLICATIONS

- Osteonecrosis, especially with talar fractures
- Compartment syndrome
- Arthritis with intra-articular toe fractures
- Infection in open fractures
- Nonunion/Delayed union as with Jones fractures
- Growth arrest from great toe fractures
- Residual pain after tarsometatarsal complex injuries (eg, Lisfranc fractures)

### CODES

#### ICD9

- 825.0 Fracture of calcaneus, closed
- 825.1 Fracture of calcaneus, open
- 825.20 Fracture of unspecified bone(s) of foot (except toes), closed

### PEARLS AND PITFALLS

- Foot fractures in children usually have a good prognosis and usually are treated nonoperatively.
- A high index of suspicion is needed to diagnose tarsometatarsal complex injuries.
- Watch for compartment syndrome in children with crush injuries and high-energy foot injuries.

# FRACTURE, FOREARM/WRIST

Dante Pappano  
Darshan Patel

## BASICS

### DESCRIPTION

- The bones of the forearm and wrist are at risk for traumatic injury as part of reflexive attempts at deceleration of the body when falling (sometimes called *FOOSH*, or “fall on outstretched hand”) (1).
- In adolescents, fatigue-type stress fractures (especially those related to sports activities) while less common than in the lower extremity, may also occur (2).

### EPIDEMIOLOGY

- Upper extremity fractures are the most common fractures in children. After clavicle fractures, forearm fractures are the most common, comprising 10–45% of all pediatric fractures (3).
- Wrist injuries make up 2.5% of all emergency department visits:
  - 60–70% of these are scaphoid fractures (1), while all other carpal fractures are rare.
- The National Electronic Injury Surveillance System estimates that >250,000 pediatric forearm and wrist fractures occurred in 2008 (4):
  - Most occur during biking, football, snowboarding, skateboarding, roller skating, other sports, and playground/slides/swings/trampolines (4)

### RISK FACTORS

- Underlying bone weakness due to osteogenesis imperfecta, osteoporosis, unicameral bone cysts, or neoplasms
- Stress fractures of the forearm and wrist related to specific sports (2):
  - Olecranon: Javelin, baseball, weight lifting
  - Ulnar shaft: Softball, tennis, volleyball, bowling
  - Distal radius: Gymnastics
  - Wrist: Gymnastics, shot put, tennis

### GENERAL PREVENTION

- Adult supervision of high-risk play activities
- Safety equipment, wrist protectors
- Graduated training schedules and interruption of activity at the earliest signs of injury

### PATHOPHYSIOLOGY

- Children’s process of skeletal maturation (3):
  - Increased porosity
  - Thicker periosteum
  - Presence of growth plates
- The above pediatric physiology allows for (2):
  - Plastic deformity:
    - Less prone to comminution
  - Buckle/Torus fracture
  - Greenstick injuries
  - Growth plate injuries
  - Standard “complete” or adult-type fractures
  - Greater remodeling potential:
    - Nonunion is more rare than in adults.

### ETIOLOGY

- Acute accidental trauma related to play and sports activity, especially FOOSH
- Acute trauma of other types: Major multitrauma, penetrating missile, electrical injury (5)
- Nonaccidental trauma
- Repetitive stress
- Pathologic fractures

### COMMONLY ASSOCIATED CONDITIONS

- Fracture/Dislocations:
  - Monteggia
  - Galeazzi
- Sprains/Soft tissue injury
- Lacerations
- Head/Neck injury

## DIAGNOSIS

### HISTORY

- Context and mechanism
- Screen for associated trauma.
- If reported mechanism and actual injury do not seem to agree, consider nonaccidental trauma.

### PHYSICAL EXAM

- Primary trauma survey and management of ABCs when appropriate
- Bone: Note deformity, overlying soft tissue swelling, tenderness, erythema:
  - For scaphoid fractures, note snuffbox tenderness or pain on compression of the thumb along the longitudinal axis.
- Joint: Note effusion, range of motion, swelling, tenderness
- Skin integrity
- Vascular integrity, Doppler exam if needed
- Neurologic (sensory and motor) exam

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- Plain radiography:
  - Study of choice for forearm fractures
  - Can perform contralateral comparison views
- MRI or bone scan:
  - Studies of choice for stress fractures and suspected wrist fractures, however, after splinting may be performed nonemergently.
- CT scan:
  - When necessary, can show improved anatomic definition over plain films, especially for suspected wrist fractures

#### Diagnostic Procedures/Other

US performed by the emergency department physician (6)

#### Pathological Findings

- Forearm fractures have overt cortical disruption or plastic deformity on plain films.
- Monteggia fracture: Fracture of the proximal ulna with radial head dislocation
- Galeazzi fracture: Fracture of the radius with disruption of the radioulnar joint and ulnar luxation

- For all fractures, note the following:
  - Involved portion of bone(s): Diaphysis, metaphysis, or epiphysis
  - Type of fracture: Buckle, plastic deformity, greenstick, oblique, spiral, or complete
  - Physeal involvement and grading according to Salter-Harris/Ogden classification system
  - Angulation: Degree and direction
  - Displacement: Percentage and direction
  - Measurement of overlap or shortening
  - Presence of fragments
- Gustilo and Anderson (GA) grading system for open fractures (7):
  - Type I: Laceration <1 cm, minimal soft tissue damage or contamination
  - Type II: Laceration >1 cm, minimal soft tissue damage or contamination
  - Type III: Extensive soft tissue damage

### DIFFERENTIAL DIAGNOSIS

- Normal variant radiographic findings
- Sprains and soft tissue injury

## TREATMENT

### PRE HOSPITAL

- Temporary splint in position of comfort with easily removable splinting material:
  - Check pulses pre- and post splinting.
- Pain medication
- Ice and elevation

### INITIAL STABILIZATION/THERAPY

- Elevate and rest the affected extremity.
- Apply ice and administer analgesics.
- Immobilization:
  - Most forearm fractures: Apply sugar tong splint.
  - Scaphoid fracture (or clinically suspected fracture): Apply thumb spica splint.
  - Buckle fracture: Removable splint and even prefabricated splint may be options.
  - Ulnar styloid: None
- Open fracture: IV antibiotics, cover with sterile or anti-infective (eg, betadine) impregnated gauze (7):
  - GA type I:
    - In consultation with an orthopedic surgeon, option of irrigation in the emergency department, admission, and observation on IV antibiotics (7)
  - GA types II and III:
    - Administer IV antibiotics.
    - Will need operative management

### MEDICATION

#### First Line

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2 µg/kg IV q2h PRN:
    - Initial dose of 1 µg/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN

- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Some clinicians prefer to avoid NSAIDs due to theoretical concern over influence on coagulation and callus formation.
    - Animal studies have raised concerns that NSAIDs may negatively influence bone healing; however, there is no clinical evidence in humans.
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Ketorolac 0.5 mg/kg IV/IM q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

**Second Line**

Open fracture infection prophylaxis (7):

- Tetanus immunoprophylaxis as indicated
- GA type I: Cefazolin 25–100 mg/kg/day IV divide q6–8h
- GA types II and III: Cefazolin dosing as above and gentamicin 2.5 mg/kg/dose IV q8h

**SURGERY/OTHER PROCEDURES**

- Regional anesthesia may significantly or completely eliminate need for other analgesics:
  - Ulnar nerve block, radian nerve block, hematoma block
- Closed reduction in the emergency department or close outpatient orthopedic follow-up for diaphyseal and metaphyseal forearm fractures with:
  - > 15-degree angulation
  - Overlapping ends or significant displacement
- Urgent orthopedic consultation for:
  - Monteggia and Galeazzi fracture/dislocations
  - Neurovascular compromise
  - Open fracture
  - Physeal or displaced intra-articular injury
- Operative management (namely, closed reduction in the operating room, open reduction, or internal or external fixation) anticipated for (3,7):
  - Difficult to reduce fractures
  - Unstable fractures
  - Displaced scaphoid fracture
  - GA types II and III open fractures
  - Discretionary operative management if severe angulation/displacement and skeletally mature

**DISPOSITION**

**Admission Criteria**

- Open fracture
- Anticipated surgery (relative indication)
- Increased risk of compartment syndrome
- Suspected nonaccidental trauma

**Discharge Criteria**

- Skin intact (no open fractures)
- Displacement/Angulation is effectively reduced or close orthopedic follow-up is assured
- Documentation of satisfactory neurovascular exam post immobilization
- Recovery from sedation (if provided)

**Issues for Referral**

- Acute traumatic fractures need orthopedic follow-up.
- Stress fractures need sports medicine or orthopedic follow-up.
- Report suspected nonaccidental trauma.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Orthopedic surgery follow-up within 1 wk
  - Always wear splint (except for torus fracture).
  - Wear sling only while up and awake.
  - Apply ice, and elevate affected extremity.
  - Pain medications
- Activity:
  - Rest the affected extremity.
  - Avoid activities that could result in reinjury.

**Patient Monitoring**

Advise patients to return for inadequate pain control, additional trauma to the injured area, numbness, or discoloration of fingers/thumb.

**PROGNOSIS**

- Forearm fracture: Excellent healing and functional outcome is expected.
- Scaphoid fractures carry moderate risk of nonunion and avascular necrosis.

**COMPLICATIONS**

- Complications of general forearm fracture care are rare but include the following (3):
  - Compartment syndrome
  - Neurovascular compromise from immobilization (casting or splinting)
  - Refracture
  - Nonunion
  - Synostosis
  - Physeal injury with growth arrest
  - Angulation with unacceptable functional outcome
- Scaphoid fractures are at higher risk of complications:
  - Moderate risk of nonunion (1)
  - Avascular necrosis complicates 5–10%, with risk of subsequent collapse or “SLAC wrist” (1).
- Complications of fracture reduction:
  - Completion of greenstick fracture or iatrogenic fracture of nonfractured bone
  - Secondary displacement
  - Iatrogenic neurovascular injury
  - Risk of infection with open fracture

**ADDITIONAL READING**

**See Also (Topic, Algorithm, Electronic Media Element)**

- Fracture, Hand
- Fracture, Scaphoid
- Fracture, Torus
- Trauma, Elbow

**ICD9**

- 813.00 Closed fracture of upper end of forearm, unspecified
- 813.10 Open fracture of upper end of forearm, unspecified
- 813.80 Closed fracture of unspecified part of forearm

**PEARLS AND PITFALLS**

- Pearls:
  - When only a single forearm bone is fractured, look for dislocation of the nonfractured bone.
  - Salter-Harris type I fracture of the distal radial physis is the most common growth plate injury and may have a normal radiograph.
- Pitfalls:
  - Failure to screen for compartment syndrome and document the neurovascular exam

# FRACTURES, GREENSTICK/BOWING

Rasha Dorothy Sawaya  
Cindy Ganis Roskind

## BASICS

### DESCRIPTION

- Bowing and greenstick fractures are incomplete fractures involving the diaphyses or metaphyses of the long bones, most commonly of the forearm:
  - Usually caused by trauma
- Both are often associated with a complete fracture of another adjacent bone.
- Both can angulate further without adequate therapy.
- Bowing fractures:
  - Plastic deformation without any cortical defect
  - Most commonly involve the radius, ulna, and occasionally the fibula.
- Greenstick fractures:
  - An extension of a bowing fracture, with a cortical and periosteal defect on the convex side of the bone
  - Most commonly involve the radius and ulna

### EPIDEMIOLOGY

#### Incidence

- Greenstick fractures are common:
  - Highest incidence between 7 and 12 yr of age (1)
- Bowing fractures are relatively rare:
  - Occur in children 28 mo to 16 yr
  - Highest incidence between 4 and 10 yr (2)

### RISK FACTORS

- Rickets
- Diet deficient in vitamin D or calcium
- Osteogenesis imperfecta

### GENERAL PREVENTION

- Fall prevention
- Playing on playgrounds with safe surfaces
- Proper adult supervision

### PATHOPHYSIOLOGY

- Long bones have an “elastic limit” and a “plastic limit.”
- Bowing fracture:
  - An axial compression force applied to a long bone in an amount exceeding its elasticity results in a bowing deformity maintained after the force is removed.
  - Multiple microfractures seen on histopathology without evidence of hematoma or callus formation (3)
- Greenstick fracture:
  - An axial compression force with a twisting force applied to a long bone in an amount exceeding its plasticity results in a classic fracture with cortical and periosteal disruption of the convex surface.
  - The cortex and periosteum of the inner curvature remains intact though deformed.
  - Hematoma and callus formation
- Case reports of transverse forces causing bowing (2,4)

### ETIOLOGY

Usually secondary to a fall on outstretched hand (FOOSH) with or without a rotator movement

### COMMONLY ASSOCIATED CONDITIONS

- Bowing or greenstick fractures of one bone are frequently associated with injury to an adjacent bone or joint:
  - Supracondylar fractures: Frequently associated with diaphyseal greenstick fractures of the radius/ulna
  - Monteggia fracture-dislocation: Dislocation of the proximal radius with greenstick or bowing fracture of the proximal ulna
  - Galeazzi fracture: Fracture of distal radius with distal radioulnar joint injury
- Nerve injury:
  - Case reports of median or ulnar nerve injury with greenstick fractures (5,6)

## DIAGNOSIS

### HISTORY

- FOOSH
- History of axial or transverse trauma to the site of injury
- Symptoms:
  - Pain, decreased movement, or use of affected limb
  - Tenderness of affected limb
  - Visible deformity
- Past medical history of metabolic bone disease

### PHYSICAL EXAM

- Affected limb:
  - Deformity
  - Greenstick fractures: Usually rotational and visually dramatic with skin-line changes at the level of the fracture
  - Swelling
  - Tenderness
  - Pain
  - Limitation of motion, especially pronation and supination
- Neurovascular exam:
  - Sensation and movement distal to the site of injury
  - Pulse and capillary refill distal to the site of injury
- Evaluate the other bones and joints of the injured limb.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- Plain radiographs of affected limb:
  - At least 2 views: AP and lateral
  - Always include the joints above and below the suspected fracture.
- A certain degree of bowing may be “normal” for a child:
  - Comparison films of the unaffected limb may be helpful to assess the degree of abnormal (excess) bowing.

### DIFFERENTIAL DIAGNOSIS

- Nonpathologic bowing
- Pediatric growth plates have nutrient vessels that may be mistaken for fracture lines.
- Rickets
- Osteogenesis imperfecta
- Other metabolic bone disease
- Pathologic fractures

## TREATMENT

### PRE HOSPITAL

- Immobilization of the injured limb with a splint:
  - Ensure intact distal pulses pre- and post-immobilization.
- Ice, elevate, and administer analgesic.

### INITIAL STABILIZATION/THERAPY

- Pain management as needed (see below)
- Procedural sedation for fracture reduction as needed
- Bowing fracture:
  - No consensus on management of bowing fractures. Early pediatric orthopedic involvement during the emergency department course is highly recommended for all bowing fractures (2).
  - Decision to immobilize with sugar tong splint or a long arm cast or to perform a closed reduction depends on several factors. Older age is a significant factor for reduction:
    - Age of the child:
      - Children <4 yr old remodel well and reduction may not be required.
      - Children 4–10 yr old: No consensus
      - Children >10 yr old: Closed reduction is generally advised (4).
    - Degree of bowing:
      - >10–20-degree bowing and >6 yr old: Closed reduction is recommended (1,2).
    - Associated fractures or dislocations:
      - Lack of reduction of a bowing fracture associated with a fracture or dislocation of a second bone impedes appropriate healing of the latter (2,4).
    - Amount of functional limitation upon initial exam:
      - Significant loss of supination or pronation or clinical deformity requires reduction (4,7).
- Greenstick fracture:
  - Angular deformity remodels well, however rotational deformity (most common) often requires closed reduction.
  - 2 types of reduction techniques: Rotational method of reduction and fracture method of reduction:
    - Rotational method: Rotating the bone in the direction opposite to the deforming force (1):
      - Easier and less painful
      - Most commonly used
    - Fracturing method: Completing the fracture:
      - Has lower refracture rate
      - Risk of reangulation if not adequately rotated
      - More painful and traumatic (8)
    - Associated complete fracture may require completing the greenstick fracture for better outcome of closed reduction and alignment of now both completely fractured bones.

**MEDICATION**

**First Line**

- Oral opioids:
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- Oral NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Some clinicians prefer to avoid NSAIDs due to theoretical concern over influence on coagulation and callus formation.
    - Animal studies have raised concerns that NSAIDs may negatively influence bone healing; however, there is no clinical evidence in humans (9).
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

**Second Line**

IV pain management:

- Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
  - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
- Fentanyl 1–2 µg/kg IV q2h PRN:
  - Initial dose of 1 µg/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
- Ketorolac 0.5 mg/kg IV/IM q6h PRN

**SURGERY/OTHER PROCEDURES**

- When possible, pediatric orthopedic consultation in the emergency department is suggested prior to splinting/casting or reduction.
- Closed reduction depending on significance of bowing (see above) and other associated fractures
- Rarely, open reduction may be required.

**DISPOSITION**

**Admission Criteria**

- Open fractures
- Fractures with compartment syndrome or neurovascular compromise
- Suspected nonaccidental trauma

**Discharge Criteria**

- Stable vital signs and no other associated injuries that may require hospitalization
- Intact neurovascular exam
- Pain adequately controlled with oral medications
- Adequate reduction and immobilization of affected bone with a double sugar tong splint or long arm cast
- Ability to follow-up with pediatric orthopedic surgeon:
  - Document intact neurovascular function after emergency department therapy and casting.

**Issues for Referral**

- Transfer to a center with a pediatric orthopedic specialist if:
  - Nerve impingement
  - Vascular supply injury
  - Compartment syndrome
- Associated supracondylar fractures or joint dislocation
- Refer all bowing and greenstick fractures to a pediatric orthopedic specialist for follow-up.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Timely orthopedic follow-up within 5–10 days, depending on initial management
- Oral pain management: Ibuprofen as first-line therapy in the 1st 72 hr (10)
- Rest, ice, and elevation of cast or splint for at least 48 hr post cast/splint to avoid compartment syndrome

**ACTIVITY**

No physical activity until further recommendation by a pediatric orthopedic surgeon.

**PROGNOSIS**

- Generally favorable
- Children have good remodeling potential of the forearm.
- Depends on age, degree of angulation, and supination/pronation of the affected area

**COMPLICATIONS**

- Bowing fractures if untreated or incompletely treated:
  - Limitation of motion:
    - Loss of complete supination, pronation, and especially rotator motion
  - May prevent proper healing of concurrent fractures (7)
- Greenstick fractures if incomplete reduction/rotation or immobilization:
  - 10–20% redisplacement rate with volar angulation (1)
  - Refracture
- Medullary cyst formation
- Posttraumatic cortical cysts

**See Also (Topic, Algorithm, Electronic Media Element)**

- Fracture, Forearm/Wrist
- Fracture, Supracondylar
- Fracture, Torus

**CODES**

- ICD9**
- 813.04 Other and unspecified closed fractures of proximal end of ulna (alone)
  - 813.07 Other and unspecified closed fractures of proximal end of radius (alone)
  - 813.14 Other and unspecified open fractures of proximal end of ulna (alone)

**PEARLS AND PITFALLS**

- Pearls:
  - A 2nd adjacent bone is often involved.
  - Greenstick fractures have been described in patients with vitamin D deficiency.
- Pitfalls:
  - Bowing fractures may be subtle on radiographs.
  - Injuries to the proximal or distal joint must be ruled out when the radius or ulna are fractured or bowed.
  - Consider child abuse if the history does not fit the injury.
  - Inadequate rotation during reduction of greenstick fractures

# FRACTURE, HUMERUS

Donna M. Simmons

## BASICS

### DESCRIPTION

- The humerus is the largest bone in the upper extremity and is an important component of the shoulder.
- The proximal humerus has 2 ossification centers:
  - The medial ossification center may be present at birth but generally appears by 2 mo of age.
  - The lateral ossification center generally appears by 9 mo of age in girls and by 14 mo in boys.
  - The ossification centers fuse by 5–7 yr of age.
- Closure of the proximal humeral epiphysis does not occur until 16–19 yr of age.
- The proximal humeral epiphysis accounts for 80% of the longitudinal growth of the humerus.
- Proximal physeal fractures most commonly occur in children 11–17 yr of age and are usually Salter-Harris type II.
- In the younger child, proximal humerus fractures are typically Salter-Harris type I.
- Humeral shaft fractures occur in all ages but are more common in children ages <3 yr and >12 yr (1).
- Supracondylar humeral fractures are discussed in a separate topic.

### EPIDEMIOLOGY

#### Incidence

The incidence of proximal humeral fractures is 1–3 cases/1,000 population per year.

#### Prevalence

- Shaft fractures are not common, representing <10% of all fractures in children (2).
- Humerus fractures are the 2nd most common fractures in neonates.

### RISK FACTORS

- Unicameral bone cyst or tumor of humerus
- Obesity
- Malignancy, metastasis to bone
- Prior radiation treatment
- Osteoporosis
- Contact sports

### GENERAL PREVENTION

- Proper parental supervision
- Proper education of sports safety
- Athletic protective equipment
- Correction of osteoporosis

### PATHOPHYSIOLOGY

- Fractures of the proximal humeral physis are most common in adolescents during the period of rapid growth when the physis is weakest.
- The axillary and radial nerves are at risk for injury with displaced proximal humeral head and midshaft humeral fractures, respectively:
  - Fortunately, these injuries are rare.
  - Usually just see temporary loss of function (neurapraxia) without a physical nerve disruption
- The thick periosteum of the humerus limits displacement, and the growth potential of the proximal epiphysis allows for significant remodeling of proximal and shaft fractures with minimal deformity.

### ETIOLOGY

- Direct blow to shoulder on the lateral aspect of the arm.
- Fall on outstretched hand (FOOSH)
- High-energy trauma, motor vehicle accidents, contact sports, falls
- Birth trauma
- Consider child abuse when shaft fractures occur in children <3 yr of age.
- Electrical shock, seizures

### COMMONLY ASSOCIATED CONDITIONS

Shaft fractures are commonly pathologic in children 3–12 yr of age and are associated with bone cyst or tumor.

## DIAGNOSIS

### HISTORY

- Typically, there is a FOOSH or other significant trauma.
- Shoulder or arm pain with and without movement
- Irritability in a neonate when upper extremity is moved or decreased movement of upper extremity (pseudoparalysis)

### PHYSICAL EXAM

- Swelling of the proximal, midshaft, or distal humerus
- Shortening of the upper extremity suggests displacement.
- Pain on palpation
- Ask young children to point with 1 finger to locate the injury.
- Decreased range of movement of shoulder or elbow
- Perform a detailed neurovascular exam:
  - Brachial plexus injury can cause decreased sensation or pain in the affected arm.
  - Axillary nerve injury:
    - Numbness over the deltoid
    - Shoulder weakness
    - Inability to raise or abduct shoulder

– Radial nerve injury:

- Numbness over the dorsum of the hand between the 1st/2nd metacarpals
- Decreased thumb and wrist extension
- Decreased forearm supination/wrist drop
- Assess motor function by having the patient make a “thumb’s up” (radial nerve), tight fist over the thumb (median nerve), and an “OK” sign (anterior interosseous nerve).
- Presence of radial, ulnar, and brachial pulses and capillary refill in all digits

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- AP and lateral radiographic views of humerus:
  - Must include shoulder and elbow joints
- Obtain dedicated shoulder and elbow radiographs for concerns of injury of those joints.
- Assess fracture location, fracture pattern, and the presence of displacement or angulation:
  - Suspect Salter-Harris type I fracture if there is tenderness over the proximal humeral physis despite normal radiographs.
  - Comparison views may show widening of the physis.
- US or MRI may be helpful in diagnosing fractures in neonates.

### DIFFERENTIAL DIAGNOSIS

- Clavicle fracture
- Shoulder dislocation/rotator cuff injury
- Brachial plexus palsy
- Shoulder joint infection
- Osteomyelitis of humerus
- Tumor
- “Little league” shoulder or osteochondrosis of proximal humeral epiphysis
- Tendinitis
- Bursitis

## TREATMENT

### PRE HOSPITAL

- Immobilize the fracture
- Manage the patient with multiple trauma according to Advanced Trauma Life Support (ATLS) principles.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation per ATLS guidelines, and identify all injuries.
- Immobilization:
  - Sling or shoulder immobilizer
  - Check neurovascular status before and after placement.
- Administration of adequate analgesia facilitates exam and eases pain during imaging.
- Application of ice

- Nonoperative treatment for most despite angulation and displacement:
  - Sling and swathe for infants and young children with proximal and humeral shaft fractures with arm wrapped close to trunk for 3–4 wk
  - Adolescents may also use sling/swathe or can use shoulder immobilizer for proximal and shaft fractures if there is no significant displacement.
- Acceptable angulation and displacement is as follows (without need for reduction):
  - For proximal fractures:
    - <5 yr of age: ≤70-degree angulation, minimal apposition
    - 5–12 yr: <45-degree angulation, <50% apposition
    - Adolescents: ≤25-degree angulation, <30% apposition
  - For shaft fractures:
    - <5 yr of age: Up to 70-degree angulation, 100% displacement
    - 5–12 yr: 40–70-degree angulation
    - >12 yr: Up to 40-degree angulation, 50% displacement (3)
  - Bayonet apposition of 1–1.5 cm is acceptable:
    - Traction may be required if bone segments are overriding too much.
    - Rotational deformity may require correction.
- For complete or moderately displaced fractures, coaptation splint, modified Velpeau bandage, and functional bracing are options.
- Long arm cast for distal 3rd fractures
- Hanging arm casting for humeral shaft fractures require upright position during sleep and may not be effective.
- Open humeral fractures require sterile dressings, tetanus prophylaxis, parenteral antibiotics, and surgical repair.

**MEDICATION**

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2 μg/kg IV q2h PRN:
    - Initial dose of 1 μg/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine/Acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Some clinicians prefer to avoid NSAIDs due to theoretical concern over influence on coagulation and callus formation.
    - Animal studies have raised concerns that NSAIDs may negatively influence bone healing; however, there is no clinical evidence in humans.
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Ketorolac 0.5 mg/kg IV/IM q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

**SURGERY/OTHER PROCEDURES**

- Open fractures and fractures with associated neurovascular injury may require surgical repair. Most neurapraxias will resolve spontaneously.
- Displaced or angulated fractures for which alignment cannot be maintained with closed reduction may undergo percutaneous pinning or open reduction with internal fixation.

**DISPOSITION**

**Admission Criteria**

- Patients requiring surgery
- Trauma victims with multisystem injuries
- Children who are victims of abuse
- Neurovascular compromise

**Discharge Criteria**

- Patients with fractures amenable to nonoperative management
- May discharge if there is no suspicion of nonaccidental injury

**Issues for Referral**

- Refer to an orthopedic surgeon immediately for:
  - Open fractures
  - Neurovascular injury
  - Significantly displaced/angulated fractures
  - Intra-articular fractures
  - Compartment syndrome
  - Multisystem trauma
- Child protective services for nonaccidental injury. Transverse and spiral fractures may be associated with abuse.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Refer to an orthopedic surgeon in 7–10 days.
  - See Medication section.
- Activity:
  - For fractures treated nonoperatively, patients can usually resume light activities and active range of motion after 4–6 wk. They should have followed up with their orthopedic surgeon before this and received their advice to progress.
  - Resume vigorous activities gradually.
  - No contact sports until 6 mo following the humeral shaft fracture

**Patient Monitoring**

- Neurapraxia usually resolves by 3 mo. If not, refer to an orthopedic surgeon for possible surgical exploration (2).
- Patients requiring pinning for unstable fractures are followed weekly with radiographs to determine when pins can be removed.

**PROGNOSIS**

- Usually full recovery without loss of function
- Nearly all cases of radial nerve palsy fully resolve.
- Complete recovery of brachial plexus injury in neonates in 9 mo (4)

**COMPLICATIONS**

- Radial nerve palsy with shaft fractures
- Deltoid nerve injury with proximal fractures
- Growth retardation without functional limitation and usually not clinically significant
- Nonunion is rare.
- Avascular necrosis is rare.

**ADDITIONAL READING**

**See Also (Topic, Algorithm, Electronic Media Element)**

- Fracture, Clavicle
- Fracture, Forearm/Wrist
- Fracture, Scapula
- Fracture, Supracondylar
- Trauma, Shoulder

**ICD9**

- 812.00 Fracture of unspecified part of upper end of humerus, closed
- 812.10 Fracture of unspecified part of upper end of humerus, open
- 812.20 Fracture of unspecified part of humerus, closed

**PEARLS AND PITFALLS**

- Pearls:
  - Always consider nonaccidental trauma with spiral fractures of the humerus, especially for children <3 yr of age.
- Pitfalls:
  - Failing to evaluate for neurovascular injury
  - Failing to consider nonaccidental injury if the mechanism of injury is inconsistent with level of development in a healthy child <3 yr of age.

# FRACTURE, MANDIBULAR

Hnin Khine

## BASICS

### DESCRIPTION

- The mandible makes up the lower jaw of the face and houses the lower teeth.
- It is the largest and strongest bone of the face.
- The mandible is composed of 2 hemimandibles fused at midline by a vertical symphysis.
- Facial fractures are rare in children for the following reasons:
  - Underdeveloped facial skeleton and paranasal sinuses
  - Unerupted teeth provide additional strength.
  - Lower center of gravity during falls with less resultant force on impact (1)
- Many patients with mandibular fractures (30–60%) have serious associated injuries:
  - Strong forces are required to break the mandible (2):
    - This is especially true for the mandibular symphysis, which is rarely fractured due to its thickness.
- Among the hospitalized trauma patients, mandibular fractures are the most common type of facial fracture (1).

### EPIDEMIOLOGY

- Very rare in children <5 yr of age
- Incidence increases with increasing age
- Mandibular fractures were found in 1.5% of all hospitalized trauma patients (1).
- Male to female ratio of 3:1

### RISK FACTORS

- Lack of proper restraints in motor vehicles
- Participating in sports without proper protective gear
- Interpersonal violence
- Use of substances that impair mental abilities

### GENERAL PREVENTION

- Use of appropriate protective equipment during sports
- Use of proper restraints in motor vehicles
- Appropriate use of child safety precautions at each developmental stage
- Proper adult supervision of children during play

### PATHOPHYSIOLOGY

- Fractures can occur along any part of mandible:
  - Greenstick fractures are common in the younger age group due to the high elasticity of bone with thick medullary spaces and thin bony cortices.
- Pediatric fractures are less likely to be comminuted.
- The site of fracture is dependent on the mechanism of injury:
  - Forces directed to the chin can cause fractures of the condyles or symphysis.
  - Direct assaults usually result in a fracture of the body or angle of the mandible at the point of impact.

- Condylar fractures are common in younger children and decrease with increasing age.
- Multiple fracture sites along the mandible can be found in 40–60% of the cases. This is especially more common in older children.

### ETIOLOGY

- In younger children, most mandibular fractures are the result of motor vehicle accidents (MVs) or falls.
- With increasing age, altercations (35%), MVAs (28%), bicycle accidents (12%), and falls (7%) cause the majority of mandibular fractures (2).

### COMMONLY ASSOCIATED CONDITIONS

- Among hospitalized trauma patients, facial fractures are associated with:
  - Higher injury severity score
  - Longer ICU stays
  - Longer hospital stays (1)
- Can see concomitant thoracoabdominal, intracranial, spine, extremity, and other facial injuries.
- Chin lacerations or contusions should raise suspicion for mandibular fractures (3).
- Mandibular dislocations

## DIAGNOSIS

### HISTORY

- Obtain the mechanism of injury, including the time of injury and circumstances surrounding the injury:
  - Mechanism of injury will help determine the possible site of fracture.
- Symptoms of mandibular fracture include:
  - Facial swelling with localized pain
  - Pain and difficulty with mouth opening and closing
  - Dental pain or abnormal bite
  - Numbness of the lip and chin

### ALERT

- Important to correlate the history with physical findings
- Suspect child abuse if there are inconsistencies in the history or physical exam.

### PHYSICAL EXAM

- General exam using Advanced Trauma Life Support (ATLS) protocols to exclude life-threatening injuries
- Maintain cervical spine immobilization until significant spine injuries are excluded.
- Assess for associated injuries focusing on the CNS, spine, airway, and other facial injuries.
- Inspection:
  - Deformity or swelling
  - Ecchymosis: External or inner mucosa of mouth
  - Lacerations: External or intraoral
  - Any tooth trauma, including dental avulsion; dental luxation, subluxation, concussion, intrusion, and extrusion; or enamel, crown, root, and alveolar bone fractures
- Palpation:
  - Palpate along the entire mandible to look for step-off, bony disruption, or point tenderness.
  - Palpate each tooth for pain and stability.

- Assess the difficulty of mouth opening, range of motion, and stability of the temporomandibular joint (TMJ):
  - Place a finger into the external auditory canal and locate the TMJ. Then, ask the patient to move his or her jaw to assess its stability.
  - Place a wooden tongue blade laterally between the teeth on either side and assess for the patient's ability to hold the blade in place without pain while the examiner attempts to pull the blade with twisting motions.
  - Assess the bite status (normal or abnormal).
- Paresthesia of the lower lip or gums suggests damage to the inferior alveolar nerve, which also provides sensation to the teeth.

### DIAGNOSTIC TESTS & INTERPRETATION Imaging

- Dental panoramic views (Panorex)
  - 86–92% sensitive
  - Require the patient's cooperation
  - Useful in isolated mandibular injury
- A series of plain radiographs may be more useful in patients who are unable to cooperate to take panoramic views:
  - Lateral oblique view: To view the condyle, coronoid process, body, ramus, and angle of mandible
  - PA view: To view the ramus, angle, and body of mandible
  - Towne view: To view the condyles
  - Mandibular occlusal views: To view a symphyseal fracture
  - Dental radiograph: To view alveolar or dental root fractures
- Computerized tomogram (CT):
  - 100% sensitive
  - May be useful when other facial fractures are suspected as well.
  - CXR to look for unaccounted teeth

### DIFFERENTIAL DIAGNOSIS

- Mandibular dislocations or contusions
- Traumatic hemarthrosis of TMJ
- Dental trauma resulting in referred pain
- Related skull fractures

## TREATMENT

### PRE HOSPITAL

- Assess ABCs per ATLS and Pediatric Advanced Life Support (PALS) guidelines:
  - Cervical spine immobilization if necessary
- Collect and preserve any avulsed teeth:
  - See Trauma, Dental topic for proper technique for preservation of teeth.

### INITIAL STABILIZATION/THERAPY

- Address ABCs per ATLS and PALS guidelines:
  - Look for other life-threatening injuries.
  - Recognize that mandible fractures may make orotracheal intubation difficult.
- Ensure a patent airway by removing any material that could obstruct the airway, such as blood, vomitus, bone fragments, and foreign bodies.
- Control bleeding locally with pressure. Consider nasal packing if there is persistent epistaxis.

- Consider use of an antiemetic (eg, ondansetron) to prevent vomiting.
- Judicious pain therapy
- Use of routine antibiotic prophylaxis is controversial.
- Consider prophylactic antibiotics in:
  - Heavily contaminated wounds
  - Severely comminuted fractures
  - Severely macerated soft tissues
  - Delayed fracture treatment
  - Prolonged operative time
  - Uncomplicated fractures in patients with valvular heart disease

**MEDICATION**

**First Line**

- Pain therapy is guided by severity:
  - Mild pain:
    - Acetaminophen 15 mg/kg PO q4h PRN
  - Moderate to severe pain:
    - Codeine/Acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
    - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
    - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
      - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
- Ondansetron:
  - 0.15 mg/kg IV/PO q4–8h, max single dose 8 mg

**Second Line**

- Consider tetanus prophylaxis:
  - Td 0.5 mL IM or DTaP 0.5 mL IM
- If antibiotics are considered, use:
  - Penicillin G sodium aqueous:
    - 100,000–400,000 units/kg/day IV divided q4–6h, max single dose 24 million units/day, OR
  - Amoxicillin:
    - 25–50 mg/kg/day PO divided b.i.d. or t.i.d. orally for 3–5 days
  - For penicillin-allergic patients, clindamycin:
    - 10–30 mg/kg/24 hr PO or IV divided q6–8h for 3–5 days, max single dose 2.7 g/day PO/IV

**SURGERY/OTHER PROCEDURES**

- Definitive repair of a mandibular fracture is not a surgical emergency.
- Wide range of management available:
  - Analgesia alone
  - Physiotherapy
  - Mandibulomaxillary fixation
  - Open reduction with internal fixation
- Most pediatric mandibular fractures can be managed with closed reduction.
- Every attempt should be made to manage prepubertal children with mandibular fractures conservatively to minimize trauma to permanent dentition.

**DISPOSITION**

**Admission Criteria**

- Patients with significant dental or mandibular trauma who cannot tolerate PO intake
- Other associated system trauma requiring admission
- Critical care admission criteria:
  - As determined by the injury severity score
  - Unstable fracture with potential airway compromise

**Discharge Criteria**

- Stable vital signs
- Adequate pain control achieved
- No respiratory difficulties and associated CNS issues
- Reliable family for follow-up

**Issues for Referral**

Follow up with the surgical service that initiated initial therapy.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Soft or liquid diet
  - Pain control as needed
  - Antibiotics to be taken as prescribed
  - Consider antiemetic agent as needed
- Activity:
  - Avoid rigorous activity.
  - No contact sports until the treating surgeon clears the patient

**Patient Monitoring**

Return sooner for re-evaluation if:

- Worsening pain
- Difficulty breathing or swallowing
- Severe headache, drowsiness, or weakness
- Fever or other serious complaints

**DIET**

Soft or liquid diet

**PROGNOSIS**

- Dysfunction resulting from condylar fractures increases with increasing age at the time of trauma (4).
- If occlusion is normal after swelling has resolved, early mobilization is associated with excellent results (5).

**COMPLICATIONS**

- Immediate:
  - Wound infection or sepsis
- Delayed:
  - Growth disturbance with facial asymmetry
  - Malocclusion or trismus
  - Nonunion or malunion
  - Tooth loss or ankylosis
- Paresthesias
- TMJ dysfunction

**ICD9**

- 802.20 Closed fracture of unspecified site of mandible
- 802.30 Open fracture of unspecified site of mandible

**PEARLS AND PITFALLS**

- Pearls:
  - Remember to assess for associated injuries since patients admitted with facial fractures have a higher injury severity score than those without facial fractures.
  - Remember to assess for mandibular injuries in patients with chin lacerations.
- Pitfalls:
  - Beware that bilateral mandibular fractures may be present.

# FRACTURE, NASAL

Hnin Khine

## BASICS

### DESCRIPTION

- The nose is made up of bone and cartilage.
- The upper 1/3 is made up of paired nasal bones that articulate:
  - Superiorly with nasal process of frontal bone
  - Laterally with frontal process of maxillary bones
  - Medially with each other (thicker above than below) and spine of frontal and the perpendicular plate of the ethmoid to form the bony septum
  - Inferiorly with the cartilaginous framework
- The lower 2/3 consists of a cartilaginous framework.
- The middle 1/3 is made up of septal and lateral cartilaginous structures in the shape of a triangle.
- The lower lateral cartilage is paired and joined in the middle to form the tip of the nose.
- The nose has an abundant blood supply from both the internal and external carotid arteries.
- Facial fractures are rare in children for the following reasons:
  - Underdeveloped facial skeleton and paranasal sinuses
  - Additional strength of the maxilla and mandible from unerupted teeth
  - Lower center of gravity during falls with resultant less force on impact (1)

### EPIDEMIOLOGY

- Nasal fractures are the most common pediatric facial fractures.
- Nasal fractures are more common in young toddlers than adolescents.

### RISK FACTORS

- Sport, especially without protective gear
- Improper use of restraints in motor vehicles

### GENERAL PREVENTION

- Use of appropriate protective gear during sport activities
- Proper use of restraints in motor vehicles
- Child safety precautions

### PATHOPHYSIOLOGY

- Fracture can occur in both bony and cartilaginous structures.
- The Kiesselbach plexus at the anterior septum is a common site of nosebleed.
- Septal hematoma occurs when blood collects between septal cartilage and mucoperichondrium:
  - May grow acutely or subacutely
  - Can be bilateral with nasal fractures
  - Complications associated with septal hematoma include:
    - Septal abscess may extend to CNS (meningitis, intracranial abscess, orbital cellulitis, or cavernous sinus thrombosis).
    - Avascular necrosis of nasal septal cartilage with subsequent “saddle nose” deformity
    - Functional nasal obstruction due to scar tissue and cartilage overgrowth (2)

- Naso-orbito-ethmoid fractures:
  - Occur as a result of a direct blow to the mid face
  - Seen as complete separation of nasal bones and medial orbital bones from frontal bone and the infraorbital rim

### ETIOLOGY

A majority results from direct trauma:

- In younger children, falls or motor vehicle accidents (MVAs)
- In older children and adolescents, MVAs, falls, sport-related trauma, and assault

### COMMONLY ASSOCIATED CONDITIONS

- Among hospitalized trauma patients, facial fractures are associated with:
  - Higher injury severity score (ISS)
  - Longer ICU stay
  - Longer hospital stay (1)
- It is important to look for other concomitant intracranial, spinal, and facial injuries.

## DIAGNOSIS

### HISTORY

- Assess for associated injuries, mainly CNS, spine, ocular, and other facial injuries.
- Mechanism of injury can suggest the likelihood of associated injuries or symptoms:
  - Symptoms include pain, bleeding, nasal obstruction, anosmia, and deformity.
  - Symptoms associated with septal hematoma include severe localized nasal pain, tenderness on palpation of nasal tip, and significant nasal obstruction:
    - Symptoms of septal hematoma can be delayed.
    - Septal hematoma may occur even after minor trauma (3).
  - Patients with septal abscess usually can have fever in addition to the symptoms of a septal hematoma.

### PHYSICAL EXAM

- General exam to rule out severe life-threatening injuries
- Inspection of nose and face:
  - Deformity and swelling
  - Ecchymosis
  - Epistaxis
  - Shape of nose: Pugnacious nose with loss of anterior projection on lateral view with increased intercanthal distance suggest naso-orbital-ethmoid fracture
- Palpation:
  - Tenderness:
    - At nasal tip: Suggests septal hematoma
    - Over the frontal sinus: May indicate a frontal sinus fracture
  - Deformity
  - Crepitus

- Exam of nares:
  - Elevate the tip of the nose to maximize the view.
  - Use an otoscope with an ear or nasal speculum to aid the exam:
    - Remove any blood clots.
- Swelling of the septum with a blue to purple intranasal mass is suggestive of septal hematoma:
- Useful aids to help differentiate septal hematoma from edema
  - Application of topical vasoconstrictor:
    - Application of phenylephrine hydrochloride or oxymetazoline
    - No change in size seen with septal hematoma
  - Palpate the septum with a cotton-tipped applicator: Doughy consistency suggests septal hematoma or abscess.
- The presence of clear fluid may indicate a CSF leak from an associated skull fracture.
- Mid-face instability or dental malocclusion is indicative of a midfacial Le Fort fracture.

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

Consider coagulation studies for hemorrhage.

### Imaging

- Plain radiographs are rarely needed emergently.
- Consider a CT scan if suspecting skull, naso-orbito-ethmoid, or other facial fractures.

### DIFFERENTIAL DIAGNOSIS

Other facial fractures such as orbital, maxillary sinus, ethmoid sinus, and cribriform plate fractures

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation per Advanced Trauma Life Support (ATLS) and Pediatric Advanced Life Support (PALS) guidelines:
  - Administer supplemental oxygen, preferably by nonrebreather mask, if necessary.
  - Consider a cervical collar, if necessary.
- Control epistaxis:
  - Application of pressure usually is effective:
    - Pinch nares together.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation per ATLS and PALS guidelines:
  - Administer supplemental oxygen, preferably by nonrebreather mask, if necessary.
  - Assess nasal passage patency:
    - Nasal intubation is contraindicated if the nasal passage is compromised or if a septal hematoma is present.
  - Consider a cervical collar, if necessary.
  - Displaced nasal fractures do not require reduction in the emergency department unless they compromise the airway.

- Control epistaxis:
  - Use pressure or a vasoconstricting agent.
  - Pack nares with gauze if necessary:
    - Antibiotics may be prescribed if the patient is discharged home with packing.

**MEDICATION**

**First Line**

- Pain therapy: Guided by the severity of injuries
- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- NSAIDs:
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- Vasoconstricting agents:
  - Phenylephrine hydrochloride nasal spray:
    - Children 2–5 yr: Use 1–2 sprays or drops of 0.25% solution in each nostril q4h.
    - Adults and children >6 yr of age: Use 2 sprays or drops of 0.5% solution in each nostril q4h.
  - Oxymetazoline nasal spray:
    - Children 2–5 yr: Use 1–2 sprays or drops of 0.025% solution in each nostril q12h.
    - Adults and children >6 yr of age: Use 2 sprays or drops of 0.05% solution in each nostril q12h.
  - Prolonged use of vasoconstricting agents will cause rebound congestion with chronic swelling of nasal mucosa.
  - Cocaine 4% solution, max single dose 1 mg/kg topically to septum, max single dose 8 mL in adult:
    - Preferred for closed reduction, as it provides vasoconstriction and anesthesia

**Second Line**

- Consider tetanus prophylaxis.
- Use of antibiotics with nasal packing is controversial (4):
  - If considered, use amoxicillin/clavulanate:
    - 25–50 mg/kg/day dosed as amoxicillin divided b.i.d. or t.i.d. for 3–5 days
  - For penicillin-allergic patients, clindamycin:
    - 10–30 mg/kg/24 hr PO divided q6–8h for 3–5 days

**SURGERY/OTHER PROCEDURES**

- Most nasal fractures require closed reduction at a later date when the swelling has subsided.
- If swelling has not yet occurred, immediate closed reduction is preferred:
  - Averts need for delay and potential use of general anesthesia
  - Useful if ability to follow up with subspecialist is uncertain
  - Procedure is painful but brief, and the goal is to produce a symmetrical appearance.
- Nasal packing is needed if epistaxis is not controlled by pressure.

- Septal hematomas must be drained in the emergency department:
  - After drainage, pack with petroleum jelly gauze to prevent reaccumulation.
- Consult otolaryngologist if:
  - Uncontrolled epistaxis
  - Significant deviation of external nares with nasal obstruction
  - Suspicion for septal hematoma/abscess
  - Naso-orbital-ethmoid fracture

**DISPOSITION**

**Admission Criteria**

- Most nasal fractures do not require admission.
- Admit patients with significant craniofacial injuries (eg, nasoethmoid fractures).
- Critical care admission criteria:
  - Unstable vital signs due to injury severity, altered mental status, or respiratory compromise
  - Airway obstruction
  - Nasal obstruction in neonates requires immediate intervention since they are obligate nose breathers.

**Discharge Criteria**

- Stable vital signs and epistaxis controlled
- Adequate patent airway assured
- No evidence of significant head, face, neck, or other injuries
- Adequate pain control
- Reliable caregiver

**Issues for Referral**

- Otolaryngologist referral for patients with any significant amount of nasal swelling
- Follow-up should be within 48–72 hr:
  - Patients with septal hematoma should follow up within 24 hr after emergency department septal hematoma drainage.
- Bring a few recent photos of the patient to compare the shape of the nose before and after the trauma.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Apply ice (1st 24 hr) and then heat/warm compress (after 24 hr) to the affected area to minimize swelling.
  - Avoid nose blowing.
  - Pain medications as needed
- Activity:
  - Minimize activities until follow-up with otolaryngologist.
  - No contact sports until approved by treating otolaryngologist or plastic surgeon

**Patient Monitoring**

Return sooner for re-evaluation if:

- Difficulty breathing
- Pain increases
- Worsening nasal obstruction
- Fever develops
- Recurrence of uncontrolled epistaxis
- Signs of increased intracranial pressure develop

**PROGNOSIS**

Full recovery is typical unless complications from associated injury or infection occur.

**COMPLICATIONS**

- Acute:
  - Septal hematoma or abscess
- Chronic:
  - Cosmetic deformity: Saddle nose or bump
  - Structural deformity: Septal deviation, deviation of osseous and cartilaginous pyramid
- Functional:
  - Nasal obstruction
  - Obstructive sleep apnea

**ADDITIONAL READING**

**See Also (Topic, Algorithm, Electronic Media Element)**

- Fracture, Orbital
- Trauma, Head
- Trauma, Facial

**CODES**

- ICD9
- 802.0 Closed fracture of nasal bones
- 802.1 Open fracture of nasal bones

**PEARLS AND PITFALLS**

- Remember to assess for associated injuries since patients admitted with facial fractures have higher ISS score than those without facial fractures.
- Have a high vigilance for septal hematomas. Consult otolaryngologist early for septal hematomas.
- Septal hematoma can occur even with minor trauma.
- Consider prophylactic antibiotics, particularly those with fracture reduction in ED.

# FRACTURE, ORBITAL

Victoria Shulman

## BASICS

### DESCRIPTION

- The orbit is made up of several facial bones:
  - The frontal bone makes up the superior and upper medial orbital ridge.
  - The zygoma makes up the lateral orbital rim.
  - The maxilla comprises the inferior and lower medial rims and floor of the orbit.
  - The ethmoid bone forms the medial and part of its posterior walls.
  - The sphenoid, lacrimal, and palatine bones form the remainder of the posterior orbit.
- The weakest parts of the orbit are the thin bones overlying the maxillary and ethmoid sinuses along the orbital floor and medial wall:
  - However, these bones tend to be thicker in the pediatric population than in adults until the sinuses are fully aerated.
- Orbital roof fractures occur in younger children. This relates to the proportionally larger head and lack of pneumatization of the frontal sinuses (1).
- Orbital floor fractures occur primarily in older children (1).

### EPIDEMIOLOGY

- Trauma to the eye represents between 0.3% and 3% of all emergency department visits in the U.S. (2,3).
- Facial fractures are rare in young children:
  - The face of a child is small relative to the head, so the majority of injuries involve the upper face and skull.
  - Nasal, mandibular, and orbital fractures are the most common types seen.
- The age distribution of orbital fractures has 2 peaks: 10–40 yr of age and >70 yr.
- Male to female ratio of 9:1 (4)

### RISK FACTORS

- Unrestrained car accident victims
- Certain sports, especially baseball or softball
- Male gender (4)

### GENERAL PREVENTION

- Protective eyewear during sports activities
- Proper use of motor vehicle restraints

### PATHOPHYSIOLOGY

- Significant force is required to produce orbital fractures.
- Orbital roof fractures, which are more common in younger children, have a higher association with intracranial injury:
  - Dural tears are associated with CSF leakage.
  - Ptosis and vertical ocular motility problems can be seen due to injury to the levator–superior rectus muscle complex.
- Orbital rim fractures are usually the result of a direct blow to the superior or lateral orbit.

- Orbital floor fractures, also known as “blowout fractures,” occur when an object strikes the eye. The force of the object displaces the globe posteriorly and increases intraorbital pressure. This causes the weakest portion of the orbit (floor) to rupture. Several consequences can occur:
  - Entrapment of the inferior rectus muscle and orbital fat leading to pain with or restriction of movement of the eye and diplopia
  - Injury to the infraorbital nerve with the associated decreased sensation of the cheek or upper teeth
  - Globe malpositioning such as enophthalmos or orbital dystopia
- “Trapdoor blowout fractures” are most common in the pediatric population:
  - Similar to a greenstick fracture, because of the elastic nature of pediatric bones, the orbital floor, instead of rupturing, may trap orbital fat and muscle as the bones snap back into place potentially resulting in severe, restrictive ophthalmoplegias.
  - There may be few periocular signs of trauma, and this is known as the white-eyed blowout fracture:
    - In addition to the relative lack of external signs of trauma, there is also a decreased sensitivity of CT in identifying entrapment of the soft tissues; therefore, a comprehensive evaluation of the patient’s ocular motion and visual acuity must be performed.
  - The recovery period in children who undergo surgery within the 1st 5 days after trauma is significantly shorter (5).

### ETIOLOGY

- In younger children, motor vehicle accidents, falls, and nonaccidental trauma are common causes of orbital fractures.
- In older children and adolescents, sports-related injuries and assaults become more common.
- Domestic violence should be considered as a cause in adolescent and older females.

### COMMONLY ASSOCIATED CONDITIONS

Since orbital fractures occur from significant trauma to the face and eye, other associated injuries may be seen:

- Hyphema, vitreous hemorrhage
- Ruptured globe, orbital hematoma
- Retinal detachment
- Traumatic optic neuropathy
- Corneal abrasion or laceration
- Intracranial injury
- Related facial or cervical spine fractures

## DIAGNOSIS

### HISTORY

- When and how did injury occur?
  - Suspect underlying fracture when the mechanism of injury indicates that a great force was applied to the face even in the absence of significant physical findings.
- Blurry vision or decreased vision?
  - Hyphema, vitreous hemorrhage
  - Retinal detachment
- Double vision?
  - Entrapment
  - Lens dislocation (causes monocular diplopia)
- Pain with eye movement?
- Difficulty with eye movement in a specific direction?
- Diplopia with eye movement in a specific direction (especially lateral or upward gaze)?
- Sensitivity to light?
  - Suggests traumatic iritis or iridocyclitis
- Numbness of a region of the face?
  - Forehead: Suspect superior orbital rim or roof fracture
  - Cheek or upper teeth: Suspect orbital floor fracture
- Nausea or vomiting?
  - May indicate intraocular injury
  - Can also indicate muscle entrapment via the oculocardiac reflex
  - Also may indicate intracranial injury

### PHYSICAL EXAM

- Since orbital fractures are the result of trauma, primary survey and attention to ABCs take priority per Advanced Trauma Life Support (ATLS) guidelines:
  - Maintain cervical spine immobilization if indicated.
- After life-threatening injuries have been stabilized, a more specific exam of the face and orbits should occur:
- Inspect:
  - Face for asymmetry while looking down from the head of the bed, as this allows for easier evaluation of enophthalmos or exophthalmos
  - Eyelids for lacerations:
    - May represent globe penetration
  - Pupils for roundness and reactivity
  - Cornea for abrasions or lacerations
  - Anterior chamber for hyphema
  - Interorbital distance:
    - Widening may indicate disruption of the medial canthal ligament.
  - Nares for septal hematoma
- Palpate:
  - Supraorbital ridge and frontal bone for step-off fractures
  - Zygoma along its arch and at its frontal, temporal, and maxillary articulations
  - Mandible for swelling, tenderness, or step-off
  - Teeth for stability and/or malocclusion
- Check:
  - Ocular movements:
    - Make sure that eyes are symmetric and do not cause pain with movement, especially with upward and lateral gaze.
  - Visual acuity and presence of diplopia
  - Sensation to face
  - Orbital emphysema (soft tissue crepitation)

**DIAGNOSTIC TESTS & INTERPRETATION**

**Imaging**

- Since orbital fractures are often associated with other traumatic injuries, routine radiographs for trauma surveys should be considered.
- Plain radiographs have poor sensitivity in diagnosing orbital fractures. However, they may be indicated when:
  - CT is unavailable or there is low suspicion of orbital fractures
  - Consider the Waters view when ordering plain radiographs:
    - This view best shows the inferior orbital rims, nasoethmoid bones, and maxillary sinuses.
    - An air-fluid level in the maxillary sinus when the patient is upright may indicate an orbital floor fracture.
    - The teardrop sign is an opacification in the upper maxillary sinus representing orbital fat or an entrapped muscle. This may indicate an orbital floor fracture.
  - The Caldwell view best displays the lateral orbital rim and ethmoid bone.
- CT scan of the orbits is usually considered the test of choice to diagnose orbital or other facial fractures:
  - Has increased sensitivity
  - Useful in diagnosing associated injuries
  - Helpful in diagnosing orbital nerve involvement in the fracture or intracranial injury
  - Obtain a CT scan for severe pain, decreased visual acuity, limitation of ocular movements, or suspicion for orbital fracture.
  - Consider including CT of the brain for suspected intracranial injury.

**DIFFERENTIAL DIAGNOSIS**

- Coincidental facial infections
- Other facial fractures, including Le Fort fractures
- Contusions to the face
- Dental trauma, including fractures

 **TREATMENT**

**PRE HOSPITAL**

- Assess and stabilize airway, breathing, and circulation.
- Placement of metal shield if suspected globe injury

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Any suspicion of globe injuries should prompt immediate evaluation by an ophthalmologist.

**ALERT**

Orbital fractures in children are associated with a high prevalence of ocular injury necessitating full ophthalmologic evaluation (6).

**MEDICATION**

**First Line**

- Ibuprofen 10 mg/kg/dose PO q6h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- Codeine/Acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
- IV fluids and antiemetics may be indicated if severe nausea or vomiting occurs.

**Second Line**

- Administer tetanus toxoid if appropriate.
- Oral antibiotics:
  - Controversial, limited data (7)
  - Consider if orbital fracture extends into a sinus
  - Amoxicillin 80 mg/kg/day PO divided b.i.d.–t.i.d.
  - Amoxicillin/Clavulanic acid 80 mg/kg/day PO divided b.i.d.–t.i.d.
  - Clindamycin 30 mg/kg/day PO divided t.i.d.
- Corticosteroids:
  - May play a role in treatment of patients with limitation of ocular motility by differentiating between edema-induced restriction of ocular movement (should resolve within a week) and entrapment (will not resolve) (8)
  - May decrease time of resolution of diplopia and improve surgical outcome (8)
  - Dosing recommended by consulting ophthalmologist

**SURGERY/OTHER PROCEDURES**

- The goal of surgical intervention is to prevent visual loss and minimize late problems such as persistent diplopia and globe malpositioning (6).
- Isolated orbital floor fractures generally require surgical repair if there is alteration of extraocular motility or orbital volume
- The timing of surgery is still debated. Many surgeons will allow a few days for the orbital and periorbital edema to resolve.
- A “trapdoor fracture” has the potential for ischemia to occur in the entrapped tissues, so these fractures are generally repaired within 24 hr of the injury.

**DISPOSITION**

**Admission Criteria**

- Severe herniation of orbital contents or similar injury that threatens vision
- Associated injuries that require admission
- Critical care admission criteria:
  - Associated injuries, especially intracranial

**Discharge Criteria**

- Normal vital signs and adequate pain control
- Reliable caregiver and follow-up assured

 **FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Follow up as per surgical specialty service.
- All patients should have follow-up with an appropriate subspecialist within 1 wk.
- Discharge instructions and medications:
  - Cold packs to the eye to reduce swelling
  - Elevate head of bed, and avoid nose blowing.
  - Medications to reduce coughing, sneezing, and vomiting may be helpful.
  - Pain medications as needed

**Patient Monitoring**

Patient should return promptly for:

- Any change in visual acuity, worsening pain
- Fever, headache, facial tenderness

**COMPLICATIONS**

- Visual loss from associated ocular injuries
- Cosmetic defects such as enophthalmos or orbital dystopia may occur.
- Persistent diplopia, especially in extreme excursions of gaze

**ADDITIONAL READING**

See Also (Topic, Algorithm, Electronic Media Element)

Globe Rupture

**ICD9**

- 802.6 Closed fracture of orbital floor (blow-out)
- 802.7 Open fracture of orbital floor (blow-out)
- 802.8 Closed fracture of other facial bones

**PEARLS AND PITFALLS**

- Pearls:
  - Always check visual acuity in an age-appropriate manner since decreased visual acuity may be a sign of optic nerve injury, retrobulbar hemorrhage, or other eye injury.
- Pitfalls:
  - Failure to identify nonaccidental injury
  - Failure to diagnose associated intracranial, cervical, or intraocular injuries
  - Failure to consult an ophthalmologist in the emergency department if the patient has a significant loss in visual acuity, signs of entrapment, or ocular hematomas

# FRACTURE, PATELLA

Sara Ahmed

Michele M. Nypaver

## BASICS

### DESCRIPTION

- The patella is the largest sesamoid bone in the body.
- It is enveloped within the quadriceps tendon and receives an excellent blood supply from the geniculate branches (inferior, middle, and superior) of the popliteal artery.
- There are 3 types of patellar fracture:
  - Traumatic fracture
  - Stress fracture (insufficiency/fatigue fracture) (1,2)
  - Avulsion fracture (sleeve fracture): Superior, inferior, medial, and lateral

### EPIDEMIOLOGY

Patellar fractures are rare (<5% of all fractures).

### RISK FACTORS

- Traumatic fractures:
  - Occur in younger athletes (3,4)
- Stress fractures (3,5):
  - Young athletes due to overuse
  - Children with osteoporosis or osteomalacia
- Avulsion fractures:
  - Those who perform high-impact jumping activities

### PATHOPHYSIOLOGY

Fractures typically caused by:

- Direct blow AND/OR
- Sudden contraction of quadriceps

### ETIOLOGY

- Motor vehicle accident
- Direct blow/fall
- Sports related:
  - Weight lifting
  - Jumping and landing sports

## COMMONLY ASSOCIATED CONDITIONS

- Patellar dislocation
- Patellar tendinitis
- Patellar tendon rupture

## DIAGNOSIS

### HISTORY

- Hearing a crack or feeling a popping sensation when injured
- Pain, swelling, and tenderness at the knee:
  - Inability to bear weight
  - Pain decreasing with rest but resuming with movement
  - Pain in the anterior knee
  - Pain with weight bearing and extension of the knee

### PHYSICAL EXAM

- Localized tenderness and a joint effusion are typically present:
  - Inability to bear weight
- Joint effusion
- High-riding patella:
  - Refers to situation when the patella does not rest well within the trochlear sulcus with the knee extended
- With a displaced fracture, a gap between the 2 fracture fragments may be palpated.
- The integrity of the extensor mechanism needs to be evaluated:
  - For this, joint aspiration and lidocaine injection may be needed to differentiate limitation of extension based on pain or extensor injury:
    - Continued limitation of extension despite reduction of joint effusion and injection of lidocaine suggests extensor injury.

## DIAGNOSTIC TESTS & INTERPRETATION

### Imaging

- Plain x-rays are the initial imaging choice with AP, lateral, and sunrise views:
  - Traumatic fractures:
    - Occur at the middle 1/3
    - Often comminuted with a high-riding patella
  - Stress fractures:
    - Occur at the junction of the middle and distal 1/3 of the patella
    - Have sclerotic edges
    - If initial radiographs are negative, diagnosis may require serial radiographs over time or a bone scan (6).
  - Avulsion:
    - Small bone fragment
    - High-riding patella in contrast to the contralateral side
- MRI:
  - May be indicated to identify osteochondral fractures from the patella

### Diagnostic Procedures/Other

With significant mechanism or diminished distal pulses, may need to consider an arteriogram to assess the integrity of the vessels.

## DIFFERENTIAL DIAGNOSIS

- Knee sprain
- Ligament injury
- Patellar displacement
- Meniscus injury
- Femur, tibia, and/or fibula fracture
- Quadriceps tendon rupture
- Traumatic bursitis
- Bipartite patella
- Vascular injury

## TREATMENT

### PRE HOSPITAL

- Immobilization
- Non-weight bearing
- Analgesia
- Ice

### INITIAL STABILIZATION/THERAPY

- Immobilization: Casting from groin to ankle or knee bracing with the knee in extension
- Analgesia

### MEDICATION

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2 μg/kg IV q2h PRN:
    - Initial dose of 1 μg/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Some clinicians prefer to avoid NSAIDs due to theoretical concern over influence on coagulation and callus formation.
    - Animal studies have raised concerns that NSAIDs may negatively influence bone healing; however, there is no clinical evidence in humans.
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Ketorolac 0.5 mg/kg IV/IM q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
  - Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

### COMPLEMENTARY & ALTERNATIVE THERAPIES

Physical therapy once healing is complete

### SURGERY/OTHER PROCEDURES

Consultation with orthopedic surgery indicated for:

- Open fractures requiring debridement:
  - Disruption of extensor mechanism
  - >2-mm displacement
  - >3-mm fragment separation
  - Dislocation with fracture
  - Associated patellar tendon rupture

### DISPOSITION

#### Admission Criteria

Admission may be required if the patient requires surgery.

#### Discharge Criteria

- Intact lower extremity neurovascular status
- Adequate pain control with oral medications

#### Issues for Referral

Children with patellar fractures should be referred to an orthopedic specialist.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Rest, ice, elevation
  - Follow-up with orthopedics
  - Follow-up with physical therapy
  - Complete immobilization for 4–6 wk
  - Crutch walking to keep affected extremity non-weight bearing
  - Pain control
- Activity:
  - Complete immobilization for 4–6 wk followed by:
    - Physical therapy involving passive range of motion and quadriceps strengthening

### Patient Monitoring

Check for distal extremity perfusion and presence of adequate pulses.

### PROGNOSIS

Good prognosis for full recovery

### COMPLICATIONS

- Infection
- Loss of reduction
- Failure of fixation
- Avascular necrosis
- Delayed union or nonunion/malunion
- Chondromalacia
- Traumatic arthritis
- Quadriceps weakness
- Extensor lag

### CODES

#### ICD9

- 822.0 Closed fracture of patella
- 822.1 Open fracture of patella

## PEARLS AND PITFALLS

- Pearls:
  - Bipartite patella can mimic patellar fracture on radiographs.
  - Physical therapy will improve outcome.
- Pitfalls:
  - Assuming that weight bearing on the affected leg excludes a patellar fracture
  - Prolonged immobilization will result in muscle atrophy.

# FRACTURE, PELVIC AVULSION

Deirdre D. Ryan  
Robert M. Kay

## BASICS

### DESCRIPTION

- Avulsion fractures are typically caused by a powerful contraction of the attached muscle on a developing apophysis, or less commonly due to repetitive traction of a muscle on a developing apophysis (1).
- Muscle/Apophysis associations:
  - Sartorius muscle/anterior superior iliac spine (ASIS)
  - Direct head rectus femoris muscle/anterior inferior iliac spine (AIIS)
  - Hamstring muscles/ischial tuberosity
  - Adductor muscles/ischial tuberosity
  - Iliopsoas muscle/lesser trochanter
  - Transversus abdominis muscle/iliac crest
  - Rectus abdominis muscle/pubis ramus

### EPIDEMIOLOGY

#### Prevalence

- Occurs in 16.4% overall in patients who report pelvic pain after sporting activity (2)
- Pelvic avulsion fractures breakdown (2):
  - 54% ischial
  - 22% AIIS
  - 19% ASIS
  - 3% superior corner pubic ramus
  - 1% iliac crest

### RISK FACTORS

- Active adolescent and young adult athletes
- Sports such as soccer, gymnastics, sprinting/hurdles, basketball, and tennis

### GENERAL PREVENTION

- Thorough warm-up and stretching of affected muscles prior to participation in sports
- Sitting out of play if experiencing pain

### PATHOPHYSIOLOGY

Sudden eccentric or concentric muscle force avulses bone through the cartilaginous apophysis.

### ETIOLOGY

- ASIS: Overpull of the sartorius muscle with the hip in extension and the knee flexed
- AIIS: Avulsion by the direct head of the rectus femoris muscle most often occurs when the hip is hyperextended and the knee is flexed in kicking sports (eg, soccer, rugby, football).
- Ischial tuberosity: Due to maximal exertion of the hamstring muscles (eg, gymnastics, football, track)
- Lesser trochanter: Due to overpull of the iliopsoas muscle during hip flexion

## DIAGNOSIS

### HISTORY

- Patient will complain of pain at the site of the avulsion fracture.
- Acute fractures: Sudden pain and a popping sound
- Chronic fractures: Slowly developing pain with repetitive activity that increases over time
- Pain may be mild or marked.
- Motion is limited.
- Loss of muscular function
- Patients will complain of pain when sitting or moving on the involved tuberosity.

### PHYSICAL EXAM

- Palpate for area of tenderness.
- Range of motion of the hip and knee will elicit pain in the localized area.
- Contraction or stretching of involved muscle will elicit pain.
- Ischial tuberosity fractures: Flexing the hip and extending the knee elicit pain. Abducting the hip at this point will increase the pain.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- AP/Frog-leg pelvis x-rays will demonstrate most fractures. This is helpful because it provides a view of the contralateral side for comparison (1).
- Oblique/Axial pelvis x-rays can be performed if there is any difficulty seeing the fracture on the routine pelvis x-rays (1).

### DIFFERENTIAL DIAGNOSIS

- Muscle strain
- Exuberant callus formation can mimic an osteosarcoma if the x-ray is obtained more than 7–10 days post-injury.

## TREATMENT

### PRE HOSPITAL

- Rest
- Positioning the hip and knee in a position of comfort

### INITIAL STABILIZATION/THERAPY

Crutch use until pain resolves

### MEDICATION

Oral or parenteral pain medication:

- Ibuprofen 10 mg/kg PO q6h PRN
- Naproxen 5 mg/kg PO q12h PRN
- Acetaminophen 15 mg/kg PO q4h PRN
- Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
  - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.

### COMPLEMENTARY & ALTERNATIVE THERAPIES

Physical therapy after pain resolves

**SURGERY/OTHER PROCEDURES**

- Operative fixation is rarely indicated but is recommended by some for fragments displaced > 2 cm (3).
- Occasionally, patients will require removal of excessive callus formation at the ischial tuberosity if it leads to chronic pain and disability.

**DISPOSITION**

**Admission Criteria**

Admit if pain is not controlled by oral pain medications (rarely necessary).

**Issues for Referral**

Refer to orthopaedist as an outpatient.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Weight bearing as tolerated with crutches
- Oral pain medications PRN
- No sports participation until released for it by an orthopaedist

**Patient Monitoring**

Orthopaedist will order follow-up x-rays at 4–6 wk.

**PROGNOSIS**

- Overall very good
- Some patients may develop chronic pain due to abundant callus formation that may need to be addressed.

**COMPLICATIONS**

- Pain due to abundant callus formation
- Nonunion and persistent pain at the fracture site requiring operative intervention

**REFERENCES**

1. Sundar M, Carty H. Avulsion fractures of the pelvis in children: A report of 32 fractures and their outcome. *Skeletal Radiol.* 1994;23:85–90.
2. Rossi F, Dragoni S. Acute avulsion fractures of the pelvis in adolescent competitive athletes: Prevalence, location, and sports distribution. *Skeletal Radiol.* 2001;30:127–131.

**ADDITIONAL READING**

**See Also (Topic, Algorithm, Electronic Media Element)**

- Dislocation, Hip
- Pain, Abdomen
- Trauma, Abdominal

**CODES**

**ICD9**

- 808.2 Closed fracture of pubis
- 808.3 Open fracture of pubis
- 808.41 Closed fracture of ilium

**PEARLS AND PITFALLS**

- Oblique/Axial pelvis x-ray will show avulsions difficult to see on AP pelvis x-ray.
- Most fractures are successfully treated conservatively.
- Abundant callus formation can be mistaken for osteosarcoma; therefore, the history should be carefully reviewed.

# FRACTURE, RIB

Kristin McAdams Kim  
Michele M. Nypaver

## BASICS

### DESCRIPTION

- Rib fractures can occur as a result of both major and minor trauma with and without concurrent intrathoracic injury:
  - Involves the fracture of  $\geq 1$  rib
- 2 causes:
  - Acute trauma
  - Stress fractures
- Stable fractures are minimally displaced and do not involve  $>2$  consecutive segments.

### RISK FACTORS

- Thoracic trauma
- Vigorous force such as rowing, weight lifting
- Osteopenia
- Osteogenesis imperfecta

### PATHOPHYSIOLOGY

- Fractures are due to significant force:
  - Elastic chest wall makes rib fractures rare in younger children.
- Mortality and morbidity are usually due to associated internal injuries (1).

### ETIOLOGY

- Multiple trauma
- Blunt trauma to chest
- Stress fracture in athlete (2)
- Nonaccidental trauma, especially in those  $<3$  yr of age (3):
  - Need to correlate injury with reported mechanism and make sure that there are not any inconsistencies

### COMMONLY ASSOCIATED CONDITIONS

- Pneumothorax
- Hemothorax
- Pulmonary contusion
- Injury to trachea, large neck vessels, brachial plexus, or spine is seen with fractures of 1st, 2nd, or 3rd ribs.
- Splenic and liver injuries are seen with injuries to lower ribs.
- Flail chest:
  - Flail chest occurs when  $\geq 3$  consecutive ribs are fractured in 2 places.

## DIAGNOSIS

### HISTORY

- Multisystem trauma
- Severe blow to chest with blunt object
- Nonaccidental trauma, especially with posterior rib fractures
- Difficulty breathing
- Abdominal pain with trauma

### PHYSICAL EXAM

- Expose the body to assess the nature of injury and other associated injuries as outlined in the Advanced Trauma Life Support (ATLS) recommendations.
- Pain with palpation of chest wall
- Flail chest wall/unstable chest wall
- Chest wall hematoma (due to intercostal vessel laceration)
- May have shallow or rapid respirations
- Evaluate for any crepitus, bony deformity, or decreased breath sounds.
- Muffled heart sounds may indicate associated pericardial effusion.
- Distended neck veins may suggest cardiac tamponade or tension pneumothorax.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- CXR (PA and lateral):
  - To assess for pneumothorax or hemothorax
  - To assess heart size and width of mediastinum
  - Very difficult to detect fracture on plain radiograph:
    - Rib plain film series with oblique views
- Consider bone scan for high suspicion and negative plain films.
- Consider CT or MRI for suspected costochondral injury or internal thoracic injuries.
- If concerned about abdominal injury, consider FAST (Focused Assessment with Sonography for Trauma) and/or abdominal CT.
- Consider skeletal survey for child abuse.

## DIFFERENTIAL DIAGNOSIS

- Pathologic fracture
- Chest wall contusion
- Pneumothorax
- Sternal fracture or dislocation
- Nontraumatic causes of chest pain:
  - Cardiac injury or compromise
  - Pulmonary embolus
  - Pneumonia
  - Musculoskeletal chest wall strain
- GI:
  - GERD
  - Esophagitis
- Dermatologic:
  - Herpes zoster

## TREATMENT

### PRE HOSPITAL

Assess and stabilize airway, breathing, and circulation:

- Administer supplemental oxygen, preferably by nonrebreather mask.
- Provide pain control.
- Consider possible tension pneumothorax if clinically evident.

### INITIAL STABILIZATION/THERAPY

Assess and stabilize airway, breathing, and circulation as per ATLS and Pediatric Advanced Life Support (PALS) guidelines:

- Administer supplemental oxygen, preferably by nonrebreather mask.
- Pain control
- Treat pneumothorax/hemothorax.
- Evaluate for flail chest.
- Look for paradoxical chest wall movement.
- Look for other associated injuries during secondary survey.

**MEDICATION****First Line**

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2  $\mu$ g/kg IV q2h PRN:
    - Initial fentanyl dose of 1  $\mu$ g/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
    - Ketorolac 0.5 mg/kg IV/IM q6h PRN
    - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

**Second Line**

## Local anesthetics:

- Intercostal nerve block may be highly effective for treatment of rib fracture pain.
- Lidocaine, max single dose 5 mg/kg
- Exercise care to avoid deep needle insertion that violates the pleura.

**SURGERY/OTHER PROCEDURES**

- Will depend on other injuries
- May need thoracostomy tube

**DISPOSITION****Admission Criteria**

- Parenteral analgesia requirement
- Respiratory compromise
- Concern for child abuse
- Fracture of  $\geq 3$  ribs
- Nature of other associated injuries
- Patients with underlying lung or cardiac disease or other concerning comorbidities
- Critical care admission criteria:
  - Pulmonary contusion, cardiac contusion, respiratory distress, respiratory compromise, or associated injuries may necessitate critical care admission.

**Discharge Criteria**

- No underlying lung injury or compromise to pulmonary function
- No concern for child abuse
- Simple rib fractures and no concerning concurrent intrathoracic or intra-abdominal injuries
- Pain well controlled with oral medications

**Issues for Referral**

May need orthopedic follow-up

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Outpatient pain control with NSAIDs or oral narcotics as needed
  - Return to medical care if any respiratory difficulty/distress, worsening chest or abdominal pain, pain with swallowing, inadequate pain control, or activity intolerance.
- Activity:
  - Incentive spirometry may be helpful to prevent pneumonia.
  - Several weeks of light activity
  - Limit risk for reinjury.
  - No contact sports until well healed and pain free

**Patient Monitoring**

- Follow up with primary care provider in 2–3 days.
- May need serial chest radiographs to find healing fractures

**PROGNOSIS**

- Simple rib fractures heal well.
- Pain may continue for several weeks.
- Primarily determined by associated injuries

**COMPLICATIONS**

- Pneumothorax
- Hemothorax
- Pulmonary contusion:
  - Flail chest has high mortality due to pulmonary contusion.
- Pneumonia
- Nonunion or improper union of rib fracture
- Chronic pain
- Splenic laceration

**See Also (Topic, Algorithm, Electronic Media Element)**

- Child abuse
- Hemothorax
- Pneumothorax/Pneumomediastinum
- Trauma, Chest

**ICD9**

- 807.00 Closed fracture of rib(s), unspecified
- 807.01 Closed fracture of one rib
- 807.02 Closed fracture of two ribs

**PEARLS AND PITFALLS**

- Perform a thorough exam to look for other associated injuries.
- Rib fractures in infants are very rare. Perform a thorough investigation for nonaccidental trauma in these situations.
- Consider nonaccidental injury with posterior rib fractures in infants and toddlers.
- Flail chest can result in significant mortality from the underlying pulmonary contusions.
- Fracture of the 1st, 2nd, or 3rd rib is associated with high morbidity and mortality due to the protected location of these bones and degree of force required to fracture them.
- Conduct a thorough evaluation with 1st rib fractures, and strongly consider a trauma team evaluation.

# FRACTURE, SCAPHOID

Mark X. Cicero

## BASICS

### DESCRIPTION

- *Scaphoid*, the name of the most commonly injured carpal bone, comes from the Greek *skapos*, meaning “boat.”
- The scaphoid is alternately referred to as the navicular in some texts.
- Its articulations include the distal radius, trapezium, and capitate bones.
- Blood supply is from a branch of the radial artery and enters the bone distally:
  - Blood vessels enter at the distal tubercle and the waist of the scaphoid.
  - The proximal portion of the bone has tenuous arterial blood flow and is prone to ischemia, nonunion, and avascular necrosis with fracture.

### EPIDEMIOLOGY

#### Incidence

- ~350,000 new scaphoid fractures occur annually in the U.S. (1).
- The scaphoid is the most commonly fractured carpal bone across all age groups.
- Among pediatric patients, males in late adolescence most frequently sustain scaphoid fractures.

### RISK FACTORS

Gymnastics, skateboarding, and other activities increase the risk for a forceful fall onto outstretched hand (FOOSH); as a result, a scaphoid fracture occurs.

### GENERAL PREVENTION

Wrist guards prevent hyperextension during skating and cycling-related falls.

### PATHOPHYSIOLOGY

- Momentum of the fall determines the likelihood of wrist fracture.
- Wrist hyperextension determines whether the scaphoid is at risk for fracture.
- Wrist flexion or extension <90 degrees is protective. The force of the fall is transmitted proximally along the upper extremity in these situations.

### ETIOLOGY

- FOOSH is the etiology. The forearm is prone during the fall.
- There are rare reports of scaphoid stress fractures in athletes who compete in diving and racquet sports.

### COMMONLY ASSOCIATED CONDITIONS

Infrequently (5–12% of the time), there are concurrent fractures of another carpal bone or the distal radius.

## DIAGNOSIS

### HISTORY

- FOOSH, as noted previously, is almost always present and followed by deep dull pain in the wrist.
- Alternately, there may be a history of activity or sports with repeated hyperextension and flexion, such as tennis, gymnastics, or wood chopping.
- The pain worsens with gripping or squeezing.

### PHYSICAL EXAM

- Snuffbox tenderness (100% sensitive, 80% specific) (2)
- Pain with supination against resistance, gripping, or squeezing is sensitive but not specific.
- Scaphoid tubercle tenderness while the wrist is in extension has greater positive predictive value than snuffbox tenderness (2).
- Pain with axial compression of the thumb is suggestive of scaphoid fracture.
- Contusion, swelling, or snuffbox fullness are seen infrequently:
  - A recent series suggested that 3 findings are highly suggestive of scaphoid fracture (3):
    - Volar scaphoid tenderness
    - Pain with radial deviation of the hand
    - Pain with active wrist range of motion

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- Obtain AP, lateral, and oblique radiographs of the wrist.
- Additionally, a dedicated scaphoid view, in which the wrist is ulnarly deviated, is useful.
- Initial radiography has 70–90% sensitivity for fracture.
- If radiographs are negative and occult fracture is suspected, there are 3 options (listed below). The wrist should be immobilized if occult fracture is suspected (see Initial Stabilization/Therapy):
  - Bone scintigraphy (bone scan) is a cost-effective option, either during the emergency department evaluation or soon after.
  - MRI is an excellent choice for detecting occult fractures of the scaphoid and adjacent bones as well as ligamentous injuries.
  - Follow-up radiographs performed 2 wk after the injury. Fractures should then be evident due to remodeling and periosteal elevation.
- The role of ultrasound is unclear.

### DIFFERENTIAL DIAGNOSIS

- Scapholunate dissociation:
  - An increased gap between these bones is evident on radiograph.
- Fractures of other metacarpals
- Fracture of the distal radius, including the radial styloid
- Radioulnar joint injuries
- De Quervain tenosynovitis:
  - Lateral wrist pain and tenderness over radial styloid:
    - The tendons of the abductor pollicis longus and extensor pollicis brevis are affected.
  - Perform the Finklestein test where the examining physician grasps the thumb while the hand is ulnarly deviated:
    - If there is a sharp pain along the distal radius, then De Quervain tenosynovitis is likely.

## TREATMENT

### PRE HOSPITAL

- Immobilization with a simple splint
- Compression, such as an elastic bandage
- Pain management
- Ice
- Elevation

### INITIAL STABILIZATION/THERAPY

- When a radiographically proven nondisplaced fracture is present, a short arm thumb spica cast is applied with the wrist in neutral position. There is no added benefit to long arm casting.
- Clinically suspected fractures with no radiographic evidence or nondisplaced fractures are managed with the thumb spica splint or casting.
- Scaphoid fractures with displacement are splinted until operative management occurs.
- Pain control will be necessary.

### MEDICATION

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2  $\mu$ g/kg IV q2h PRN:
    - Initial dose of 1  $\mu$ g/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine/Acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN

- Oral NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Some clinicians prefer to avoid NSAIDs due to theoretical concern over influence on coagulation and callus formation.
    - Animal studies have raised concerns that NSAIDs may negatively influence bone healing; however, there is no clinical evidence in humans.
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

**SURGERY/OTHER PROCEDURES**

- Displaced fractures require stabilization to prevent mal- or nonunion (see Complications). Orthopedic surgery needs to be consulted for these cases.
- Orthopedic interventions include:
  - Percutaneous pin fixation
  - Internal fixation with Kirschner wires or a screw
  - Nonunions may require excision of the avascular proximal portion of the scaphoid, bone grafting, or radial stylectomy.

**DISPOSITION**

**Admission Criteria**

- Even displaced fractures are not routine grounds for admission. Internal fixation is done as an outpatient operative procedure.
- Open fractures or the presence of other serious injuries will require admission.
- Patients with chronic fractures or malunion may be admitted after surgical repair, especially if bone grafting is involved.

**Discharge Criteria**

- Appropriate immobilization
- Adequate pain control
- Caretaker understands discharge instructions
- Follow-up with a pediatric or general orthopedist is arranged.

**Issues for Referral**

- Refer all patients with scaphoid fractures to orthopedic surgery. In some centers, scaphoid fractures are managed by hand-specific services:
  - Displaced fractures are grounds for urgent referral.
- Advise patients about the concerns of scaphoid malunion and avascular necrosis.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Patients with a clinical suspicion for a displaced or nondisplaced fracture should be re-evaluated in 1–2 wk by an orthopedic surgeon.
  - Displaced fractures are prone to mal- or nonunion and are managed with operative fixation. Patients need to be seen promptly by orthopedic surgery.
  - Patients and their families are given instructions using the PRICE mnemonic:
    - Pain control
    - Rest
    - Ice, especially in the 1st 24 hr after the injury
    - Compression, achieved with the splint or cast
    - Elevation: A sling can assist this goal.
- Activity:
  - Activities that risk reinjury during the healing process are to be avoided.
- Immobilization precludes wrist range of motion:
  - Later management of scaphoid injuries includes rehabilitation with an occupational therapist or physical therapist.

**Patient Monitoring**

- Caregivers are instructed to monitor the patient for:
  - Worsening pain in the wrist
  - Numbness or paresthesias in the ipsilateral fingers
  - Cold, discolored, or swollen digits
- These findings should prompt a speedy return to the emergency department or a call to the primary care doctor or managing orthopedist.

**PROGNOSIS**

- Nondisplaced scaphoid fractures have an excellent rate of union (95%), but the limb may be casted for up to 10 wk when the fracture is through the scaphoid waist or more proximal.
- Displaced fractures are more prone to mal- or nonunion and have a more guarded prognosis.
- Even with good union of the bony fragments, patients may suffer chronic pain and limitation of range of motion.

**COMPLICATIONS**

- Fractures through the middle (waist) of the scaphoid and the proximal 3rd of the bone are prone to avascular necrosis and chronic wrist dysfunction.
- As noted previously, malunion of the scaphoid is of particular risk when there is displacement. Nonunion may occur even with nondisplacement:
  - Degenerative joint disease and osteoarthritis may result.

Fracture, Hand

**ICD9**

- 814.01 Closed fracture of navicular (scaphoid) bone of wrist
- 814.11 Open fracture of navicular (scaphoid) bone of wrist

**PEARLS AND PITFALLS**

- Missed and misdiagnosed scaphoid fractures may result in a lawsuit for malpractice.
- Displaced fractures are prone to mal- or nonunion and are managed with operative fixation. The emergency physician should arrange prompt consultation.
- All clinically suspected scaphoid fractures should prompt thumb spica immobilization and referral to an orthopedic surgeon.

# FRACTURE, SCAPULA

Asha S. Payne  
Bruce L. Klein

## BASICS

### DESCRIPTION

- The scapula is a triangular-shaped bone that is responsible for providing a stable anchor for the movement of the arm:
  - The scapula is flat, is relatively translucent at its center, and has thickened borders and ridges that serve as sites for multiple muscle attachments.
  - Attaches to the clavicle via the acromioclavicular and coracoclavicular ligaments
  - Articulates with the humerus
  - Protected by the supraspinatus, infraspinatus, and subscapularis muscles
- Scapula fractures can involve the:
  - Scapular body
  - Scapular spine
  - Scapular (glenoid) neck
  - Glenoid body/rim (intra-articular)
  - Acromion process and/or
  - Coracoid process

### EPIDEMIOLOGY

- Scapular fractures are uncommon, as the scapula is a mobile bone and is mostly protected by thick muscles:
  - ≤1% of all fractures (1–3)
  - 3–5% of shoulder girdle fractures
- Occurs predominantly in young and middle-aged men:
  - Rare in children

### RISK FACTORS

- High-speed activities, such as motorcycle riding
- Contact sports
- Mountain climbing (due to falls)
- Child abuse

### GENERAL PREVENTION

Standard protective equipment specific to the various sports may help prevent fractures.

### PATHOPHYSIOLOGY

Usually caused by high-energy trauma:

- Strong forces overwhelm the protection of the soft tissues and the normal mobility of the scapula and shoulder, resulting in fracture.

### ETIOLOGY

- Scapular body, spine, and/or neck fractures, sometimes with extension into the intra-articular glenoid:
  - Usually caused by high-energy trauma
  - Most commonly, direct blunt trauma to the posterolateral or lateral aspect of the forequarter or shoulder:
    - From a significant fall, motor vehicle crash, motorcycle accident, or contact sport injury (such as football or hockey)
  - There are reports of scapula fractures following a seizure or electric shock, without direct blunt trauma.
- Glenoid fractures:
  - Can be caused by lower-energy forces:
    - From a fall on an outstretched hand with transmitted force
  - Anterior glenoid rim fracture:
    - Can result from a glenohumeral shoulder dislocation
- Acromion or coracoid avulsion fracture:
  - Can be caused by traction to the upper extremity

### COMMONLY ASSOCIATED CONDITIONS

- When the mechanism is a high-energy trauma, there very frequently are other, sometimes life-threatening, injuries (1–6):
  - Thoracic (eg, clavicle and rib fractures, hemo-/pneumothorax, pulmonary contusion)
  - Upper extremity (including brachial plexus and vascular [eg, axillary, brachial, and subclavian arteries] injuries and fractures)
  - Skull/Intracranial (eg, skull fracture, closed head injury)
  - Spinal (eg, vertebral fracture, spinal cord injury)
  - Intra-abdominal
  - Pelvic (eg, fractures), among others
- Traction to the upper extremity can result in brachial plexus and vascular injuries.

## DIAGNOSIS

### HISTORY

- History of a direct blow to the scapula
- Pain in the scapula or shoulder area following trauma to the ipsilateral forequarter or upper extremity

### PHYSICAL EXAM

- Visualization of the scapula and shoulder:
  - Abrasions, contusions, and/or edema may be present.
  - The shoulder sometimes appears deformed or flattened.
  - The arm is typically held in adduction.
- Palpation over the fracture site elicits tenderness.

- Movement of the scapula and shoulder:
  - Shoulder movement, especially abduction, causes pain.
  - Deep inspiration can be painful (due to scapular movement).
  - With some combinations of fractures and ligamentous injuries, the shoulder can become unstable.
- Must perform careful neurologic and vascular exams of the adjacent thorax and upper extremity to assess:
  - Brachial plexus
  - Axillary, brachial, and subclavian artery function

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

Lab tests would only be needed for associated injuries:

- CBC in situations with considerable hemorrhage

#### Imaging

- Scapular fractures can be subtle and may be missed on the initial trauma AP CXR.
- Standard radiographic series for the evaluation of a scapula fracture includes:
  - AP view of the scapula/glenohumeral joint
  - Axillary view:
    - Velpeau axillary lateral view may be more comfortable for the patient.
  - Scapular Y view
- CT scan of the scapula with 3-dimensional reconstruction can help to more accurately define the extent of the fracture and assist with surgical planning:
  - Particularly useful when a fracture of the glenoid neck or intra-articular body/rim is suspected on conventional x-rays as well as for angulated or comminuted fractures
- Often additional imaging studies (eg, CXR or CT scan, angiogram/CT angiogram) are needed to rule out associated injuries.

### DIFFERENTIAL DIAGNOSIS

- A normal growth center in a child may be confused as a fracture:
  - Fractures of the coracoid and acromion can be distinguished from their normal physes based on the patient's age and the usual locations of these physes.
- Os acromiale, a failure of the acromion ossification centers to ever close, occurs in a small percentage of patients and is frequently bilateral:
  - X-ray of the contralateral scapula may help distinguish an os acromiale from a true fracture.
- Adjacent soft tissue (eg, ligamentous) injury
- Clavicle, rib, or proximal humerus fracture

## TREATMENT

### PRE HOSPITAL

- Immobilize the spine, including the cervical spine, when injury is due to a high-energy force or if there is concern for spinal injury.
- Immobilize the ipsilateral upper extremity with a sling and swathe.

### INITIAL STABILIZATION/THERAPY

- Defer the scapula and shoulder exam and treat other, more life-threatening injuries 1st.
- Stabilize airway, breathing, and circulation per Advanced Trauma Life Support and Pediatric Advanced Life Support guidelines:
  - Immediately evaluate for and treat any life-threatening conditions (eg, severe pulmonary contusion, tension pneumothorax).

### MEDICATION

#### First Line

- Analgesia for comfort as well as to enable a good exam
- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4–6h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN

#### Second Line

- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Some clinicians prefer to avoid NSAIDs due to theoretical concern over influence on coagulation and callus formation.
    - Animal studies have raised concerns that NSAIDs may negatively influence bone healing; however, there is no clinical evidence in humans.
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Ketorolac 0.5 mg/kg IV/IM q6h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

### SURGERY/OTHER PROCEDURES

- Nondisplaced, minimally displaced, or minimally angulated scapular fractures are usually treated nonoperatively.
- Significantly displaced or angulated fractures of the glenoid neck, intra-articular glenoid, acromion process, or coracoid process are usually repaired via open reduction with internal fixation.
- Open fractures are generally irrigated and debrided in the operating room.

### DISPOSITION

#### Admission Criteria

- For surgical repair or irrigation/debridement
- When there is inadequate pain control with immobilization (sling and swathe) and oral analgesia
- For other associated injuries
- Critical care admission criteria:
  - For associated life-threatening injuries necessitating mechanical ventilation or inotropic support
  - A scapula fracture alone usually does not require intensive care admission.

#### Discharge Criteria

- No need for surgical repair or irrigation/debridement
- Pain is well controlled.
- No associated injuries that require admission

#### Issues for Referral

- Consult an orthopedic surgeon, ideally one with expertise in scapular fractures:
  - Consult emergently or urgently for:
    - Neurologic or vascular compromise
    - Open fracture
    - Intra-articular fracture
    - Fracture/Dislocation
    - Significantly displaced or angulated fracture
- Physical therapy eventually:
  - Passive range of motion exercises as pain abates
  - Active range of motion exercises later

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions:

- Rest the shoulder.
- Wear a sling and swathe.
- Take an oral analgesic for pain.
- Make follow-up appointments with the orthopedic surgeon and, eventually, a physical therapist.

#### Patient Monitoring

Follow-up immediately for:

- New-onset numbness, tingling, or weakness
- Uncontrolled pain

#### DIET

No dietary limitations

#### PROGNOSIS

Well-aligned scapular fractures tend to heal well:

- Nonunion is rare.

#### COMPLICATIONS

Potential complications of intra-articular fractures include:

- Chronic shoulder pain
- Decreased range of motion
- Premature arthritis

### CODES

#### ICD9

- 811.00 Closed fracture of scapula, unspecified part
- 811.01 Closed fracture of acromion process of scapula
- 811.02 Closed fracture of coracoid process of scapula

### PEARLS AND PITFALLS

- Pearls:
  - Concern for a scapula fracture should prompt a thorough evaluation for more life-threatening injuries.
  - If necessary, CT scan of the scapula with 3-dimensional reconstruction can better define the extent of injury.
- Pitfalls:
  - An acromion, coracoid, or scapular tip ossification center (in a pediatric patient) or an os acromiale (in an older individual) may be confused with a fracture.

# FRACTURE, SKULL

Antonio Riera

David M. Walker

## BASICS

### DESCRIPTION

- A skull fracture is a break in the bone usually caused by direct impact to the calvaria:
  - Can be associated with intracranial injuries
- Skull fractures and intracranial injury are often related to high-impact closed head injuries.
- Infants are the exception, as there is increased risk of skull fracture in setting of minor trauma (1).
- 4 major types:
  - Linear, depressed, open, basilar

### EPIDEMIOLOGY

#### Incidence

- Overall incidence of skull fracture during outpatient evaluations of head trauma: 6–30% (2):
  - Children <2 yr of age (2):
    - Incidence of skull fracture in children with intracranial injury: 70–80%
    - Incidence of intracranial injury in children with skull fracture: 15–30%
- Incidence of clinical deterioration for isolated linear skull fracture not requiring initial intervention: 0% (2)

### RISK FACTORS

- Direct blunt trauma
- Age <2 yr
- Highest risk for age <3 mo
- Nonfrontal scalp hematoma (3)
- Diseases of bone fragility (eg, osteogenesis imperfecta)

### GENERAL PREVENTION

- Fall prevention (stair gates, etc.)
- Helmet use
- Car seats with appropriate restraints

### PATHOPHYSIOLOGY

- A direct blunt force over the affected calvarial bone may cause a parietal, occipital, temporal, frontal, or basilar skull fracture.
- Linear skull fracture:
  - A single fracture line that involves the thickness of the skull:
    - Most common type (75%)
    - Most common site: Parietal bone
    - May disrupt underlying vascular structures
    - Comminuted describes multiple linear fractures causing a shattered appearance
- Depressed skull fracture:
  - An uneven fracture that projects downward onto the dura and brain tissue
  - Often caused by a forceful blow to a small area (eg, hammer)
  - Increased risk of intracranial injury, seizures, and infection
- Open skull fracture:
  - A skull fracture that communicates with injured skin or mucosa:
    - Fracture with overlying scalp laceration
    - Fracture with sinus or middle ear involvement
  - Increased risk of CNS infection
- Basilar skull fracture:
  - A skull fracture that involves base of the skull
  - Often associated with hearing loss, cranial nerve injury (VI, VII, VIII), and CSF leaks

### ETIOLOGY

- Falls
- Sporting activities
- Motor vehicle accidents
- Nonaccidental trauma

### COMMONLY ASSOCIATED CONDITIONS

- Intracranial injuries with possible increased intracranial pressure (ICP):
  - Subdural hematoma
  - Subarachnoid hemorrhage
  - Epidural hemorrhage
- Pneumocephaly
- Cervical spine injuries
- Facial fractures and lacerations
- Retinal hemorrhage:
  - Especially with nonaccidental trauma
- Cutaneous, skeletal, and visceral injuries

## DIAGNOSIS

### HISTORY

- History of head trauma
- Loss of consciousness
- Symptoms may include:
  - Abnormal neurologic exam
  - Seizures
  - Depressed mental status
  - Prolonged loss of consciousness
  - Persistent vomiting
  - Headache
- For children <2 yr of age, symptoms may also include irritability, change in feeding patterns, or level of alertness:
  - May be asymptomatic, especially in infants
- Suspected nonaccidental trauma

### PHYSICAL EXAM

- The following features may be compatible with the presence of an underlying skull fracture:
  - Scalp hematoma
  - Bony step-off
  - Subcutaneous crepitus
- For basilar skull fractures:
  - Battle sign (ecchymosis over mastoid)
  - Raccoon eyes (periorbital ecchymoses)
  - Hemotympanum
  - CSF rhinorrhea, CSF otorrhea
  - Cranial nerve deficits
- Cushing triad (HTN, bradycardia, irregular respirations) if associated ICP
- Evaluate bony cranium and cervical spine for evidence of injury:
  - Extraocular eye movement
  - Orbital step-off
  - Mobility of zygoma
  - Palpation of temporomandibular joint in neutral position and through full range of motion
  - Cervical spine tenderness
- Neurologic exam:
  - Glasgow Coma Scale
  - Mental status
  - Full exam of cranial nerves, strength, tone, coordination, reflexes

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- No lab testing is routinely necessary.
- If institution uses preoperative lab tests, consider sending if intracranial bleed is suspected.

#### Imaging

- CT indications (3):
  - Age <2 yr:
    - Altered mental status
    - Nonfrontal scalp hematoma
    - Loss of consciousness >5 sec
    - Severe mechanism of injury
    - Palpable step-off on exam
    - Not acting normally per parent
  - Age >2 yr:
    - Altered mental status
    - Vomiting
    - Loss of consciousness
    - Severe mechanism of injury
    - Signs of basilar skull fracture
    - Severe headache
  - Noncontrast head CT is preferred to detect intracranial injury and skull fractures:
    - Young children may require sedation.
    - Benefit of diagnosis of injury must be weighed against risk of radiation (4) and sedation.
- Skull radiography:
  - Limited sensitivity (59%) and specificity (88%) as diagnostic test in 1 meta-analysis (5)
  - Can detect skull fracture but not intracranial injury/hemorrhage
- US:
  - Only studied in children with open fontanelles
  - Shown to detect dural tears (6) and intracranial hemorrhage (7)
  - Possible role as screening tool, but prospective data are lacking

### DIFFERENTIAL DIAGNOSIS

- Diastasis
- Hematoma
- Concussion
- Contusion

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation.
- Administer supplemental oxygen.
- Consider cervical spine immobilization for suspected cervical spine injury or a trauma patient with altered mental status.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation using Advanced Trauma Life Support and Pediatric Advanced Life Support guidelines.
- Administer supplemental oxygen.
- Consider cervical spine immobilization as suggested previously if not already performed.

**MEDICATION**

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2  $\mu$ g/kg IV q2h PRN:
    - Initial dose of 1  $\mu$ g/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine/Acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
    - Ketorolac 0.5 mg/kg IV/IM q6h PRN
    - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- Prophylactic antibiotics:
  - For open skull fractures to prevent osteomyelitis:
    - Cefazolin 25 mg/kg/dose IV q6h
    - If allergic, clindamycin 10 mg/kg/dose IV q8h
  - Tetanus prophylaxis 0.5 mL IM if necessary

**SURGERY/OTHER PROCEDURES**

- Depressed and open skull fractures:
  - Usually require operative management
- Basilar skull fractures:
  - May require operative management
- See Trauma, Head topic for management of intracranial injuries.

**DISPOSITION****Admission Criteria**

- Ill-appearing children with persistent emesis
- Symptoms suggesting neurologic injury:
  - Disorientation
  - Repetitive questioning
  - Agitation or other mental status change
- Intracranial injury
- High suspicion of nonaccidental trauma

## Critical care admission criteria:

- Admission to a critical care unit is recommended for the following situations:
  - Depressed skull fractures
  - Open skull fractures
  - Basilar skull fractures
  - Linear skull fractures associated with:
    - Intracranial injury
    - Cervical spine injury
    - Depressed mental status
    - Abnormal neurologic exam
    - Abnormal vital signs, especially development of Cushing triad

**Discharge Criteria**

- Discharge from the emergency department if patient meets following criteria:
  - Nondepressed linear skull fracture and >6 mo of age
  - Isolated injury
  - Normal neurologic exam
  - Neurosurgical consultation, if obtained, agrees
  - Reliable follow-up
  - Child can tolerate PO intake without vomiting
- Possibility of nonaccidental injury reliably excluded

**Issues for Referral**

- Skull fractures diagnosed on head CT should be managed in consultation with a pediatric neurosurgeon.
- Child protection specialists if concern for nonaccidental trauma
- Neuropsychiatric testing if prolonged concussion symptoms

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- 24-hr follow-up with primary care provider
- Discharge instructions and medications:
  - Pain control
  - Keep child at home for 24 hr after injury.
  - For children <2 yr of age:
    - Watch for poor feeding, lethargy, persistent vomiting, irritability, seizures
  - For older children and adolescents:
    - Watch for worsening headache, persistent vomiting, changes in mental status, seizures, visual complaints, problems with balance

**DIET**

Resume a regular diet.

**PROGNOSIS**

- Excellent for isolated, linear, nondepressed skull fractures without intracranial involvement
- Prognosis for other skull fractures depends on the degree and extent of associated intracranial injuries.

**COMPLICATIONS**

- Growing skull fractures due to a tear of the underlying dura and subsequent bone remodeling can be seen in a small number of cases of linear skull fractures. Can present months to years after initial injury as a skull defect or swelling.
- Depressed skull fractures:
  - Intracranial hemorrhage, dural laceration, parenchymal injury, seizures
- Basilar skull fractures:
  - CSF leak, meningitis, hearing loss, cranial nerve impairment
- Open skull fractures:
  - Nonunion, infection/meningitis
- Developmental delay/persistent neurologic deficits can result from all fractures.

**ADDITIONAL READING****See Also (Topic, Algorithm, Electronic Media Element)**

- Trauma, Head
- Traumatic Brain Injury

**CODES****ICD9**

- 803.00 Other closed skull fracture without mention of intracranial injury, with state of consciousness unspecified
- 803.10 Other closed skull fracture with cerebral laceration and contusion, with state of consciousness unspecified
- 803.20 Other closed skull fracture with subarachnoid, subdural, and extradural hemorrhage, with state of consciousness unspecified

**PEARLS AND PITFALLS**

- Linear skull fractures are the most common injury after blunt injury to the head.
- The presence of a skull fracture is associated with an intracranial injury in 15–30% of cases.
- Isolated, linear, nondisplaced skull fractures may be managed as outpatients after consultation with a pediatric neurosurgeon.
- Depressed, open, or basilar skull fractures should be managed in an inpatient setting, as they often require neurosurgical intervention.
- High index of suspicion for nonaccidental trauma, especially in nonmobile younger children

# FRACTURE, SUPRACONDYLAR

Louis A. Spina  
Lana Friedman

## BASICS

### DESCRIPTION

- A supracondylar fracture is a transverse fracture of the distal humerus above the joint capsule in which the diaphysis of the humerus dissociates from the condyles.
- Supracondylar fractures are subdivided based on the position of the distal humeral segment:
  - Extension type (posterior displacement)
  - Flexion type (anterior displacement)

### EPIDEMIOLOGY

- Supracondylar fractures account for 60% of pediatric elbow fractures (1):
  - The vast majority (95%) of displaced supracondylar fractures are of the extension type (2).
  - 25% of supracondylar fractures are of the greenstick type.
- Supracondylar fractures occur most frequently in children between 5 and 10 yr of age.
- The nondominant extremity is most commonly affected.

### RISK FACTORS

- Participation in certain sports such as football, hockey, and gymnastics increases the risk of supracondylar fractures.
- Home trampolines and playgrounds

### GENERAL PREVENTION

Wearing protective equipment such as elbow guards and pads can help reduce the risk of sustaining a supracondylar fracture.

### PATHOPHYSIOLOGY

- In children, the supracondylar region encompasses an area of thin, weak bone located in the distal humerus:
  - This region is bordered posteriorly by the olecranon fossa and anteriorly by the coronoid fossa.
  - The medial and lateral aspects of the supracondylar region extend distally to the developing medial and lateral condyles and epicondyles.
- When a child falls onto an outstretched arm with the elbow in hyperextension, the force of the fall is transmitted through the olecranon to the weak supracondylar region, causing a supracondylar fracture.
- Depending on the severity of the fracture, posterior displacement of the distal fracture fragment or anterior displacement of the proximal fracture fragment may occur.
- The fracture line typically propagates transversely across the distal humerus through the center of the olecranon fossa.

### COMMONLY ASSOCIATED CONDITIONS

Distal humeral fractures are frequently associated with neurovascular complications, even in the absence of displacement:

- The most commonly injured structures are the median nerve and the brachial artery.

## DIAGNOSIS

### HISTORY

- The typical history is a fall on an outstretched arm with hyperextension at the elbow and resultant injury to the distal humerus.
- A 2nd mechanism involves a direct blow to the elbow (direct mechanism).

### PHYSICAL EXAM

- Recent injuries typically demonstrate mild swelling with severe pain.
- The displaced distal humeral fragment can often be palpated posteriorly and superiorly because of the pull of the triceps muscle.
- The involved forearm may appear shorter when compared with the uninvolved side.
- Always assume that there is neurovascular compromise until a physical exam has excluded this threat:
  - Initially document the presence and strength of the radial, ulnar, and brachial pulses.
  - Examine and document the motor and sensory components of the radial, ulnar, and median nerves:
    - Assess motor function by having the patient make a “thumb’s up” (radial nerve), a tight fist over the thumb (median nerve), and an “OK” sign (anterior interosseous nerve).

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- Routine views should include AP and lateral projections with comparison to the uninvolved extremity, if necessary.
- AP and lateral views of the affected elbow are necessary to evaluate thoroughly for injury:
  - Have the patient’s elbow flexed at 90 degrees on the lateral projection for correct interpretation.
- For suspected vascular insult, arteriography, Doppler US, or CT angiography may evaluate arterial flow and anatomy and guide treatment. Utility of these studies is controversial (2).

#### Pathological Findings

- Subtle changes, such as the presence of a posterior fat pad or an abnormal anterior humeral line, may be the only radiographic clues to the presence of a fracture:
  - The anterior humeral line is a line drawn on the lateral radiograph along the anterior surface of the humerus through the elbow:
    - Normally, this line transects the middle 3rd of the capitellum.
    - With a supracondylar extension fracture, this line will transect the anterior 3rd of the capitellum or pass entirely anterior to it.

- Gartland distinguished 3 types of supracondylar fractures (1):
  - Type I: Nondisplaced or minimal displacement
  - Type II: Moderate displacement with intact posterior cortex
  - Type III: Complete displacement with fractures of both cortices
- Another diagnostic aid in evaluating radiographs of suspected supracondylar fractures is to determine the carrying angle:
  - The intersection of a line drawn through the midshaft of the humerus and a line through the midshaft of the ulna on the AP extension view determines the carrying angle.
  - Normally the carrying angle is between 0 and 12 degrees.
  - Traumatic or asymmetric carrying angles of > 12 degrees are often associated with fractures.

### DIFFERENTIAL DIAGNOSIS

- As the swelling increases, the injury can easily be confused with a posterior dislocation of the elbow resulting from the prominence of the olecranon and the presence of a posterior concavity.
- Nursemaid elbow and inter- or transcondylar fractures should also be considered.
- Bursitis
- Contusion/Sprain/Strain
- Effusion

## TREATMENT

### PRE HOSPITAL

- Immobilization for transport in a long posterior splint without any attempt at reduction is essential after initial triage:
  - Assess for adequate distal pulses.
- The involved extremity should be iced and elevated to reduce swelling.
- Pain control

### INITIAL STABILIZATION/THERAPY

- Appropriate trauma exam to ensure that no other life-threatening injuries are present
- Good neurovascular exam
- Ice and elevation of affected extremity with administration of good pain control
- Emergent reduction by the emergency specialist is indicated only when the displaced fracture is associated with vascular compromise, which immediately threatens the viability of the extremity:
  - Traction is applied with the elbow in extension and the forearm in supination.
  - After traction has been applied and the length regained, the fracture is hyperextended to obtain apposition of the fragments.
  - With traction being maintained, the varus or valgus angulation along with the rotation of the distal fragment is corrected.

**MEDICATION**

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2 µg/kg IV q2h PRN:
    - Initial dose of 1 µg/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Some clinicians prefer to avoid NSAIDs due to theoretical concern over influence on coagulation and callus formation.
    - Animal studies have raised concerns that NSAIDs may negatively influence bone healing; however, there is no clinical evidence in humans.
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Ketorolac 0.5 mg/kg IV/IM q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

**SURGERY/OTHER PROCEDURES**

- Gartland type I fractures are treated with closed reduction and casting.
- Gartland type II fractures require closed reduction and percutaneous fixation if a long arm cast does not adequately hold the reduction.
- Gartland type III fractures are managed by closed reduction and percutaneous fixation followed by 3 wk of immobilization in a long arm cast.
- Extension-type supracondylar fractures that are nondisplaced and are of <20-degree angulation are immobilized in a posterior long arm splint extending from the axilla to a point just proximal to the metacarpal heads with the elbow in >90 degrees of flexion:
  - The splint should encircle 3/4 of the circumference of the extremity.
  - The distal pulses should be checked; if absent, the elbow should be extended 5–15 degrees or until the pulses return.
- For nondisplaced extension fractures with >20-degree angulation, the emergency management includes immobilization in a posterior long arm splint and emergent orthopedic referral for reduction under anesthesia.
- Flexion-type supracondylar fractures are also immobilized in a posterior long arm splint with the elbow positioned at 35 degrees short of full extension to avoid the development of delayed elbow stiffness.
- Open reduction with internal fixation is indicated under the following circumstances:
  - Inability to achieve a satisfactory closed reduction
  - Complicating fractures to the forearm
  - Inability to maintain a closed reduction
  - Vascular compromise

**DISPOSITION**

**Admission Criteria**

All displaced supracondylar fractures require admission for neurovascular monitoring.

**Discharge Criteria**

Only stable fractures with minimal swelling (usually type I) can be safely discharged.

**Issues for Referral**

All displaced fractures require emergent consultation with an experienced orthopedic surgeon.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - The affected elbow and hand should be iced and kept elevated for the 1st 2–3 days.
  - The cast should be kept clean and dry.
  - Adequate pain control
- Activity:
  - The child should avoid any activities that increase the risk of tripping or falling.

**Patient Monitoring**

- The child’s fingers should be monitored often for restriction in movement and circulation and sensory changes for the 1st few days following surgery and/or cast placement.
- Monitor for signs of pin-tract infection, including increasing elbow pain, fever, and drainage from the cast:
  - ~3% of patients develop pin-tract infection, usually at 1–4 wk post-pin placement.

**COMPLICATIONS**

Complications of supracondylar fractures include:

- Vascular injury:
  - Occurs with posterior displacement of the distal fragment stretching the brachial artery across the fractured surface of the proximal fragment
  - Vascular insufficiency or swelling may lead to Volkmann ischemic contracture of the forearm, markedly limiting function of the extremity.
- Neurologic injury:
  - Occurs in up to 8% of supracondylar humeral fractures and most frequently involves the anterior interosseous branch of the median nerve:
    - When the anterior interosseous nerve is injured, there is loss of thumb interphalangeal joint flexion and index distal interphalangeal joint flexion.
  - Can also see ulnar nerve palsy
- Compartment syndrome
- Joint stiffness:
  - Diminished range of motion may be secondary to inadequate reduction or callus formation within the joint.
- Cubitus varus and valgus deformities (due to malposition of the distal humeral fragment after reduction)

Trauma, Elbow

- ICD9**
- 812.41 Supracondylar fracture of humerus, closed
  - 812.51 Supracondylar fracture of humerus, open

**PEARLS AND PITFALLS**

- Pearls:
  - Immediate therapy consisting of pain management and application of a splint for comfort with expedited imaging and definitive therapy
  - Emergent consultation with an experienced orthopedic surgeon is recommended.
- Pitfalls:
  - Neurovascular injuries must be a consideration since key structures pass through the elbow, including the anterior interosseous nerve, ulnar and radial nerves, and brachial artery.
  - Neurovascular status must be assessed both prior to and after splinting.

# FRACTURE, TIBIAL AVULSION

Deirdre D. Ryan

Robert M. Kay

## BASICS

### DESCRIPTION

- Tibial avulsion occurs when a fragment of the tibial tubercle is avulsed by the patellar tendon and is displaced upward.
- Watson-Jones described a classification with 3 fracture types, but this has been modified to 5 types:
  - Type I: A small fracture through the distal portion of the tibial tubercle that extends proximally through the secondary ossification center of the tubercle
  - Type II: The fracture extends proximally and anteriorly, exiting through the area joining the tibial tubercle ossification center and the proximal tibial epiphysis.
  - Type III: The fracture extends upward through the tibial epiphysis and into the knee joint.
  - Type IV: The fracture extends from the tubercle up to the proximal tibial physis, then traverses it posteriorly.
  - Type V: Not a true physeal fracture, this occurs when the periosteal sleeve of the patellar tendon avulses from the tibia.

### EPIDEMIOLOGY

#### Prevalence

0.4–2.7% of all epiphyseal injuries

### RISK FACTORS

- Male gender
- Adolescents:
  - Tibial tuberosity apophysis is made of cartilage at this age.
- Sporting activity, especially jumping activities such as basketball (1)
- Patella baja
- Tight hamstrings

### GENERAL PREVENTION

- Warming up well prior to sports participation
- Quadriceps stretching
- Resting if pain is experienced at the tibial tuberosity with play

### PATHOPHYSIOLOGY

Avulsion of the tuberosity occurs when patellar tendon traction exceeds the combined strength of the apophysis underlying the tubercle, the surrounding perichondrium, and periosteum.

### ETIOLOGY

- Most occur during sporting or play activity
- Occurs with sudden acceleration or deceleration of the knee extensor mechanism

### COMMONLY ASSOCIATED CONDITIONS

- Osgood-Schlatter disease
- Extensor mechanism disruption (2)

## DIAGNOSIS

### HISTORY

- Patients report a popping sensation.
- Localized pain and swelling at the tuberosity

### PHYSICAL EXAM

- Swelling and tenderness at the tibial tuberosity
- Knee joint effusion/hemarthrosis
- Can palpate a freely moving fragment of bone at the anterior proximal tibia
- Knee is held flexed at 20–40 degrees.
- Patella alta: Degree correlates with the amount of displacement of the tibial tuberosity

- Assess if patient can actively extend the leg:
  - Type I: Patients may be able to actively extend the knee (usually not completely).
  - Types II–V: Patients will not be able to actively extend the knee.
- Rule out compartment syndrome (3):
  - Palpate compartments for compressibility.
  - Check circulation and neurologic status.
  - Assess pain with passive flexion/extension of the toes.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

AP/Lateral knee x-rays:

- Diagnosis is made on the lateral view.
- Note the size of the fragment and the degree of displacement.

### DIFFERENTIAL DIAGNOSIS

- Osgood-Schlatter disease
- Extensor mechanism disruption (2):
  - Patellar tendon avulsion
  - Quadriceps tear

## TREATMENT

### PRE HOSPITAL

- Immobilization
- Application of a cold compress to the anterior knee

### MEDICATION

#### First Line

- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
    - Ketorolac 0.5 mg/kg IV/IM q6h PRN
    - Naproxen 5 mg/kg PO q8h PRN
  - Animal studies have raised concerns that NSAIDs may negatively influence bone healing; however, there is no clinical evidence in humans.

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/IM may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN

**SURGERY/OTHER PROCEDURES**

- The vast majority of these fractures require open reduction and internal fixation followed by long leg cast application (1,2).
- Closed treatment (with closed reduction and a long leg cast) may be undertaken for those with fractures displaced <2 mm and with full active knee extension. Follow-up x-rays are needed to confirm anatomic reduction (1,2).

**DISPOSITION**

**Admission Criteria**

- Patients with severe swelling and tense hemarthrosis should be admitted for observation to rule out compartment syndrome.
- Patients with displaced fractures should be admitted to orthopedics for surgery.

**Discharge Criteria**

- Adequate pain control
- No neurovascular compromise

**Issues for Referral**

Follow up with an orthopedic surgeon.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Keep leg elevated.
  - Monitor the color, warmth, motion, and sensation of the toes.
  - Keep the cast dry.
  - Patient should return for:
    - Increasing pain
    - Numbness or tingling in the toes
    - Inability to move the toes
- Activity:
  - Non–weight bearing for 6 wk or until radiographic and clinical healing occurs
  - Quadriceps exercises can be started after 6 wk.
  - Return to sports:
    - After radiographically and clinically healed
    - When quadriceps strength is equal
    - When there is full range of motion of the knee

**PROGNOSIS**

Good (2)

**COMPLICATIONS**

- Compartment syndrome (3)
- Genu recurvatum can result in skeletally immature children <11 yr of age due to premature anterior physeal closure.
- Pain can develop at screw heads after fracture fixation.

**REFERENCES**

1. Hosalkar FS, Cameron DB, Cameron DB, et al. Tibial tuberosity fractures in adolescents. *Child Orthop.* 2008;6:469–474.
2. Mosier SM, Stanitski CL. Acute tibial tubercle avulsion fractures. *J Pediatr Orthop.* 2004;24:181–184.
3. Pape JM, Goulet JM, Hensinger RN. Compartment syndrome complicating tibial tubercle avulsion. *Clin Orthop Rel Res.* 1993;295:201–204.

**CODES**

**ICD9**

823.00 Closed fracture of upper end of tibia

**PEARLS AND PITFALLS**

- Patients should be taught to sit out of any activity that elicits pain at the tibial tuberosity.
- If x-rays do not show a tibial tuberosity fracture but the patient is unable to extend the knee, refer for MRI to look at the extensor mechanism.

# FRACTURE, TODDLER'S

Louis A. Spina

## BASICS

### DESCRIPTION

- Toddler's fracture was originally described as an oblique spiral fracture occurring in the distal tibia of young children (1).
- Initially thought to be a unique type of fracture, toddler's fractures are now felt to be a subset of a more common group of injuries—childhood accidental spiral tibial (CAST) fractures (2).

### EPIDEMIOLOGY

The mean age for CAST fractures is ~50 mo, with a range of 12–94 mo (2).

- Toddler's fractures occur more commonly in children between the ages of 9 mo and 3 yr.

### GENERAL PREVENTION

Avoidance of these injuries begins with general childhood injury prevention strategies. These can include appropriate adult supervision, avoidance of dangerous activities, and adequate home safety measures.

### PATHOPHYSIOLOGY

- External force transmitted through the tibia is the common factor involved.
- Some fractures appear to involve only axial loading, while others may involve torque.
- The fracture remains nondisplaced due to the relatively strong periosteum in young children.

### ETIOLOGY

- Toddler's fractures usually occur after low-energy trauma:
  - Tripping, twisting of the ankle, or falling from a low height can all cause a toddler's fracture.
- These low-energy actions can cause a sudden twisting of the tibia, creating the spiral component of the fracture.

## DIAGNOSIS

### HISTORY

- Patients will usually present with history of an acute injury, inability to bear weight, and no signs or symptoms of infection.
- Fever should not be present, but if present, it should be unrelated to leg pain or altered gait:
  - Due to the mild clinical presentation, many children present >24 hr after the development of pain, limp, or altered gait.
  - At times, there is history of trauma given by the caregivers. In these cases, the trauma was likely unwitnessed or thought to be so minor that it went unnoticed.

### PHYSICAL EXAM

- Assess vital signs with attention to temperature.
- Physical exam findings may be subtle, or the physical exam may be normal.
  - Pain, tenderness, limp, or inability to bear weight on the affected extremity are findings that most commonly accompany a toddler's fracture.
  - Other notable findings are tenderness, mild swelling, and mild warmth over the affected region.
  - Pain may be elicited by:
    - Dorsiflexion of the ipsilateral ankle
    - Transmitting force through the tibia, by applying compressive force simultaneously through ankle and knee
    - With knee flexed 90 degrees and foot flat on the floor, apply compressive force to the knee.
  - There is usually no sign of bruising or deformity with a toddler's fracture.
- Thorough exam is necessary to exclude other diagnoses that may have similar presentations, including hip disorders such as polyarthritis, slipped capital femoral epiphysis (SCFE), Legg-Calvé-Perthes disease, or foreign body in the sole of the foot.
- Examine for a skin rash, which may suggest an alternate diagnoses.

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- Lab testing is unhelpful in diagnosis of toddler's fracture.
- Lab assays may be indicated if an infectious etiology such as osteomyelitis or septic arthritis is suspected.

### Imaging

- Radiographs of the tibia (both AP and lateral views) should be obtained if there is suspicion for a toddler's fracture:
  - Findings are often subtle but may reveal an oblique or spiral fracture in the distal 3rd of the tibia extending distally.
  - If initial views are normal, an internal oblique view of the tibia may be diagnostic.
- If all initial imaging is normal and there is still strong clinical suspicion, a bone scan can be used to elicit a diagnosis. However, it is also reasonable to repeat a tibial film in 10 days when a fracture, if present, is likely to be more apparent secondary to the developing periosteal reaction.
- If there is concern that the patient's refusal to bear weight is due to an injury in another part of the extremity, those areas should be imaged as well.

### DIFFERENTIAL DIAGNOSIS

- Fractures of other bones:
  - Femur fracture
  - Tibia and fibula fracture
  - Pelvic fracture
  - Foot and ankle fracture
- Sprains:
  - Knee sprain
  - Ankle sprain
  - Foot sprain
- Hip disorders:
  - Transient synovitis of the hip
  - SCFE
  - Legg-Calvé-Perthes disease
  - Septic hip

- Rheumatologic disease
- Bone tumor
- Contusions of the lower extremity
- Muscular injuries
- Infectious etiologies:
  - Septic arthritis
  - Osteomyelitis
  - Cellulitis
- Trauma secondary to physical abuse

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation.
- Determination if any acute, life-threatening injuries are present.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Determination if any acute, life-threatening injuries are present.
- Administer analgesics as needed:
  - Though parenteral opioids are routinely necessary for management of other fractures, toddler's fractures often may be managed with NSAIDs or oral opioids such as codeine.
- Splinting:
  - Always assess neurovasculature exam pre- and post-splinting.

### MEDICATION

- Ibuprofen 10 mg/kg/dose PO/IV q6h PRN:
  - Some clinicians prefer to avoid due to concern over influence of callus formation.
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- Codeine/Acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
- Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
  - Initial dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.

### SURGERY/OTHER PROCEDURES

- Toddler's fractures are typically treated by casting.
- Clinician and institutional practice typically dictate whether a short or long leg cast is chosen:
  - It is unclear if there is any difference in the benefit of short leg vs. long leg casting.
  - Short leg weight-bearing cast
  - Long leg cast for up to 5–6 wk (2)
  - Patients with a limp or a history strongly suggestive of toddler's fracture and who have no fracture evident on tibial radiography may have a cast or splint placed and follow-up radiographs.

## DISPOSITION

### Admission Criteria

- Admission is not medically necessary.
- If there is concern about possible physical abuse and there is no safe place to discharge the patient, admission may be the only alternative.

### Discharge Criteria

- Once the cast has been applied and the patient's caregivers have been instructed on proper care and follow-up, the patient may be discharged home.
- If there are concerns about possible child nonaccidental trauma, this should be explored and resolved prior to discharging the patient.

### Issues for Referral

Consider referral to a pediatric orthopedist for patients with confirmed or presumptive toddler's fractures.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Parents should be instructed on proper cast maintenance and instructed to seek medical care if the cast breaks or appears too tight:
    - Poor circulation in the toes noted by color changes (cyanosis) and being cool to the touch are signs parents can look out for.
  - Adequate analgesia
- Activity:
  - Activity is obviously limited due to the presence of a cast.
  - Children should remain non–weight bearing on the affected extremity:
    - Most children who suffer toddler's fractures are too young to use crutches or a cane effectively and should not be given these, as the risk for further injury is high.

### PROGNOSIS

Prognosis with proper treatment is excellent.

### COMPLICATIONS

Casting may rarely be associated with heel ulcers and prolonged limping after cast removal, but these are relatively uncommon (3).

## ICD9 CODES

### ICD9

823.80 Closed fracture of unspecified part of tibia

## PEARLS AND PITFALLS

- Toddler's fracture is a common cause of limp, and often no history of trauma is elicited.
- Some specialists recommend casting of presumed toddler's fractures even with negative radiographs so as not to mistreat an occult fracture.
- Any CAST fracture found in a child who is not yet ambulating should raise the concern about possible physical abuse.

# FRACTURE, TORUS (BUCKLE)

Kevin Ching

## BASICS

### DESCRIPTION

Torus fractures are stable, nondisplaced fractures that commonly are sustained when axial compression of a long bone causes it to “buckle” on itself:

- Typically involve the distal radius or ulna after a fall on outstretched hand (FOOSH)
- Less commonly involves the distal tibia, fibula, scaphoid, humerus, or femur

### GENERAL PREVENTION

Wrist guards may provide some protection against wrist fractures when in-line skating, skateboarding, or roller skating (1).

### PATHOPHYSIOLOGY

Longitudinal forces cause the trabeculae in the transitional zone (junction between the metaphysis and diaphysis) to buckle:

- The cortex on 1 or both sides is compressed and “bulges” outward.
- If unilateral cortical buckling occurs, there may be angulation but often no appreciable deformity since the periosteum and cortex on the side opposite to the fracture are intact.
  - This is in contrast to a greenstick fracture, where a fracture through the cortex on 1 side extends incompletely through to the opposite side, producing a plastic deformity with convex angulation on the side of fracture.

### ETIOLOGY

- Sports activities (in-line skating, skateboarding, roller skating, biking, and scooters)
- Wrist torus fractures result from pure axial loading (bilateral bulging) or axial loading with hyperextension, hyperflexion, valgus, or varus stress (unilateral bulging with angulation).

## DIAGNOSIS

### HISTORY

- Trauma resulting in longitudinal axial compression on a long bone:
  - Usually FOOSH
- Torus fractures may occur in cases of very minor trauma or in cases with no known trauma.
- Degree of pain and disability associated with torus fractures is typically much less severe than with other fractures:
  - As a result, patients with torus fractures often present later than those with other fractures, which typically are brought to medical care immediately.

### PHYSICAL EXAM

- Localized pain, swelling, tenderness, and decreased range of motion around site of fracture
- Assess vascular integrity of extremity.
- Examine motor and sensory function.
- Search for concomitant injuries.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

Radiographs:

- Multiple views in different planes
- Standard evaluation includes 2–3 views (depending on site of fracture):
  - Commonly an AP and lateral view
- Bilateral or unilateral outward bulging of cortex (with or without angulation)
- Identify concomitant injuries (eg, Salter-Harris type II fracture) accompanying an angulated distal radius torus fracture:
  - Consider radiographic assessment of the joint above and below the site of injury.
- When evaluating distal forearm fractures, consider AP and lateral views of the wrist, forearm, and elbow.

### DIFFERENTIAL DIAGNOSIS

- Greenstick fracture
- Bowing fracture
- Growth plate (physeal) fracture:
  - Salter-Harris I–IV fractures

## TREATMENT

### PRE HOSPITAL

- Immobilize the injured extremity.
- Ice and elevation

### INITIAL STABILIZATION/THERAPY

- Immobilize the injured extremity.
- Provide appropriate analgesia.
- Casting:
  - Distal radial torus fractures are traditionally managed with plaster or fiberglass short arm casting (below the elbow) for 2–4 wk.
  - Casting practices vary by institution, but placement of short arm and short leg casts is within the scope of pediatric emergency medicine and emergency medicine practice.
- Splinting:
  - Recent literature suggests that 3 wk of continuous immobilization with a removable splint is equally safe and effective as a cast for distal radius torus fractures (2,3):
    - No significant difference in clinical or radiologic outcomes
    - Better physical functioning
    - Less difficulty with daily activities
    - Earlier return to sports
    - No significant difference in pain experienced
    - Reduces the need for follow-up (4)
  - Commercially available or individually fitted (plaster or fiberglass) splints:
    - Volar or sugar tong splint for distal radial torus fracture

**MEDICATION**

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2 µg/kg IV q2h PRN:
    - Initial dose of 1 µg/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine/Acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Some clinicians prefer to avoid NSAIDs due to theoretical concern over influence on coagulation and callus formation.
    - Animal studies have raised concerns that NSAIDs may negatively influence bone healing; however, there is no clinical evidence in humans.
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Ketorolac 0.5 mg/kg IV/IM q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

**DISPOSITION**

**Discharge Criteria**

- No evidence of more serious injury
- Normal neurovascular exam
- Provision of appropriate short arm cast or removable splint

**Issues for Referral**

- Uncertainty or concern for greenstick, bowing, or physeal fractures requires orthopedic consultation.
- Require immediate orthopedic consultation for:
  - Open reduction with internal fixation
  - Compound fracture
  - Compartment syndrome

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Rest, ice, and elevation.
  - Adequate pain control
  - Educate about the signs of tight casts/splints.
  - Follow up with orthopedics as necessary:
    - Review of the literature supports the safe discharge of distal radius torus fractures in removable splints without orthopedic follow-up (4).
- Activity:
  - As tolerated, but restrict use of affected extremity

**Patient Monitoring**

- Neurovascular exam
- Uncontrollable pain

**PROGNOSIS**

Excellent if appropriately immobilized

**COMPLICATIONS**

- Torus fractures are generally considered stable (refracture rate < 1% [2,5]):
  - Torus fractures may share a similar radiographic appearance with nondisplaced greenstick fractures.
  - In 1 study, 15 children managed as torus fractures in the emergency department were later rediagnosed with greenstick fractures (3).
  - Greenstick fractures are unstable (with a high refracture rate), necessitating closed reduction and casting.
- Potential for unscheduled return emergency department visits for cast-related problems (eg, broken or wet cast)

**See Also (Topic, Algorithm, Electronic Media Element)**

- All fracture/trauma of the extremity topics
- Fracture, Greenstick/Bowing

- ICD9**
- 813.45 Torus fracture of radius (alone)
  - 813.46 Torus fracture of ulna (alone)

**PEARLS AND PITFALLS**

- Pearls:
  - Unless reinjury occurs, torus fractures are expected to heal fully without complication.
  - Casting or splinting is to provide support to prevent a complete fracture from occurring in the event of further trauma.
- Pitfall:
  - Although a torus and greenstick fracture may share similar radiographic features, their management is different (splinting vs. reduction and casting).

# FRACTURE, ZYGOMA

Usha Sethuraman

## BASICS

### DESCRIPTION

- The zygoma's integrity is critical to maintaining normal facial width and cheek structure.
- The zygoma consists of a body and an arch.
- The following muscles attach to it: Zygomaticus major and minor, masseter, and orbicularis oculi.
- The zygoma articulates with 4 bones: Frontal, sphenoid, temporal, and maxilla:
  - A fracture here may involve all 4 bones:
    - It may extend to involve the floor of the orbit.
- Fractures occur in the following places:
  - Orbital floor and lateral orbital wall superiorly
  - Posterior maxillary buttress inferiorly
  - Arch attachment to temporal bone laterally
  - The fractured bone rotates medially and downward into the maxillary sinus.
- Le Fort fractures occur in the midface and may include the zygoma:
  - Le Fort fractures never occur at <2 yr of age.
- Direct trauma to the zygoma can cause a fracture of the orbital floor with intact rims.
- This is a true "orbital blowout fracture."

### EPIDEMIOLOGY

#### Incidence

- Pediatric facial fractures generally result from severe trauma:
  - Overall frequency is lower in children due to:
    - Retruded position of the face relative to the skull
    - Increased structural stability due to lack of pneumatization
    - Structural strength provided by the presence of tooth buds
- Midface fractures have the lowest incidence (10%) of all maxillofacial fractures in the general population:
  - Of these, zygoma fractures are the most common, with an incidence of 28.6% among all facial trauma and 52% among midfacial fractures (1–3).
  - Le Fort fractures occur in 2.7% of cases.

#### Prevalence

- Lowest in infants and increases with age
- Zygoma fractures following trauma occur only after pneumatization of the maxillary sinus has been completed, usually by age 7 yr.
- Usually result from lateral trauma, while Le Fort fractures occur from anterior trauma:
  - Highest frequency is in the adolescent age.

### RISK FACTORS

- Overall risk is lower in children.
- Males are at higher risk than females at all ages (3:1) (4).
- Alcohol consumption
- Motor vehicle accidents (MVAs), sports and falls, and interpersonal violence among teenagers

### GENERAL PREVENTION

- Since the most common cause of zygoma fractures is MVAs, effective child seat restraints are important in preventing these injuries.
- Use of any protective device such as an airbag, seat belts, or a car seat is associated with a decreased incidence of facial injuries (5).

### PATHOPHYSIOLOGY

- Structure of the facial bones is different in children:
  - More cartilage and higher proportion of cancellous to cortical bone
  - Irregular fractures due to indistinct medullocortical junction
- Bones are less mineralized and more elastic:
  - Hence, greenstick fractures are more common.
  - Minimally displaced due to thicker adipose tissue, elastic bones, and flexible sutures (6)
- High rate of bone metabolism causes quicker healing to occur.

### ETIOLOGY

- MVAs are most common, followed by sports-related activity and falls:
  - MVAs double the risk of facial fractures (2).
- Facial fractures occur in 2.5% of abuse cases (2).

### COMMONLY ASSOCIATED CONDITIONS

- Associated with other injuries 50–60% of the time
- Head injuries are most common, followed by extremity injuries.
- Associated facial soft tissue injuries occur in >50% of cases (2).

## DIAGNOSIS

### HISTORY

- Details of the major trauma, violence, abuse, or fall should be obtained.
- History of pain and numbness in the distribution of the infraorbital nerve (upper lip and side of the nose) may be elicited.
- Trismus may occur due to an impacted zygoma impinging on the temporalis muscle.
- Ipsilateral epistaxis may occur.

### PHYSICAL EXAM

- Inspection:
  - Look for asymmetry, swelling, or bruising.
  - Features suggestive of zygomatic fractures:
    - Periorbital hematoma
    - Flat cheek bone (malar depression)
    - Downward appearance of globe
    - Subconjunctival hemorrhage
    - Inferior displacement of lateral canthus
    - Enophthalmos
  - Facial edema may obscure above signs.
  - In isolated fractures of the zygomatic arch, a decreased temporal width may be seen.
  - Inspect for signs of nerve deficit.
  - Eyebrows that cannot be raised and eyelids that cannot be closed indicate injury to the temporal and zygomatic branch of the facial nerve.

- Palpation:
  - Feel for tenderness and crepitus.
  - Cheek and upper lip numbness
  - Gently grasp the maxilla intraorally and rock back and forth. Movement indicates Le Fort fracture.
- LeFort type I fracture:
  - Involves only the maxilla
  - Extends through the zygomaticomaxillary junction
  - Causes the teeth and alveolar bone to be mobile
- Le Fort type II fracture:
  - Extends superiorly through the infraorbital rim and to the nasofrontal sutures
  - Causes mobility of nose and upper jaw
  - Zygoma is stable.
- Le Fort type III fracture:
  - Extends through the zygomatic arch, zygomaticofrontal region, orbital floor, and nasofrontal sutures
  - Separates midface from skull base (craniofacial disassociation)
  - The entire midface or zygoma moves when the nose or upper jaw is moved.
  - Rare and asymmetric injuries
  - Usually, impact is on 1 side.
- With true orbital blowout fractures, orbital dystopia (asymmetry of the horizontal level of the eyes) may occur:
  - Decreased sensation of the cheek, upper gums, and upper lip may occur due to involvement of the infraorbital nerve.
  - Limitation of upward gaze due to trapping of the inferior rectus may occur.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

In case of multisystem trauma:

- Hemoglobin
- Liver enzymes
- Urinalysis
- Blood group and type

##### Imaging

- Plain radiographs are often ineffective due to incomplete calcification and dentition.
- CT is the gold standard for facial injuries (6):
  - Sagittal and coronal views are recommended.
  - 3-dimensional reconstruction helps define complex injuries.
- Head CT may be required if associated with head injury.

### DIFFERENTIAL DIAGNOSIS

- Severe swelling may mask orbital injuries.
- Mandibular fractures may often present with trismus.

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Assess and maintain airway and breathing per Advanced Trauma Life Support protocols.
- Control of any hemorrhage
- Observation with a soft diet for:
  - Fractures without displacements or functional defects (eg, diplopia) (6)
  - Minimally displaced arch fragments that may be reduced intraorally and remain stable (7)

- Displaced fractures require open fixation (8).
- Analgesia may need to be given.
- Tetanus status needs to be updated, especially for open fractures.
- Antibiotics for open wounds and animal bites

**MEDICATION**

**First Line**

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2 μg/kg IV q2h PRN:
    - Initial dose of 1 μg/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine/Acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Some clinicians prefer to avoid NSAIDs due to theoretical concern over influence on coagulation and callus formation.
    - Animal studies have raised concerns that NSAIDs may negatively influence bone healing; however, there is no clinical evidence in humans.
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Ketorolac 0.5 mg/kg IV/IM q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN:
    - Some clinicians prefer to avoid due to theoretical concern over influence on coagulation and callus formation.
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

**Second Line**

Antibiotics for open fractures:

- Cefazolin 25–50 mg/kg IV q8h

**SURGERY/OTHER PROCEDURES**

- Only 25% of children need operative repair (3):
  - Comminuted fractures need open reduction and fixation (6).
  - In the absence of orbital entrapment, treatment is done after the edema has resolved, usually in 3–5 days.
  - Delay in orbital repair may result in higher rates of posttraumatic enophthalmos and the need for additional surgery.
- Zygomatic arch fractures, once reduced, are stable and require no further fixation.
- Displaced Le Fort fractures are treated by open reduction with rigid internal fixation.

**DISPOSITION**

**Admission Criteria**

- Zygoma fractures associated with other severe cranial and extremity injuries
- Critical care admission criteria:
  - Severe head injuries
  - Hemorrhage
  - Tenuous airway

**Discharge Criteria**

- Undisplaced or greenstick fractures of the zygoma
- Absence of functional defects (eg, diplopia)
- Absence of other associated injuries (eg, head injury)

**Issues for Referral**

- All nondisplaced stable fractures should be referred to an oral and maxillofacial surgeon within 72 hr.
- Displaced fractures require urgent referrals.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Pain control is important in children.
  - Soft diet
  - Most need follow-up with surgeon.
  - Close follow-up and exam every 3 days for 2–4 wk for nondisplaced, greenstick fractures is recommended.
- Activity:
  - Refrain from contact sports during recuperation.

**Patient Monitoring**

Patients should be monitored at home for increasing pain, diplopia, CSF rhinorrhea, and malocclusion.

**PROGNOSIS**

- Bony facial injuries are associated with significant morbidity.
- Children with facial fractures have a 3 times longer ICU stay, 2 times longer hospital stay, and 63% higher mortality:
  - This is due to higher association with head injuries (2).
- However, prognosis for isolated zygoma fractures is good.
- Postoperative complications are unusual.
- Infections, malunions, and nonunions are less common in children.

**COMPLICATIONS**

- Trismus
- Paresthesias
- Enophthalmos
- Facial asymmetry
- Ocular dystopia

- Fracture, Orbital
- Fracture, Skull
- Globe Rupture
- Trauma, Dental
- Trauma, Head
- Trauma, Facial

**ICD9**  
802.4 Closed fracture of malar and maxillary bones

**PEARLS AND PITFALLS**

- Pearls:
  - Zygoma fractures are less common in children than adults.
  - Nondisplaced zygoma fractures can be managed conservatively.
  - Complications are rare.
- Pitfalls:
  - Zygoma fractures have a high association with other major trauma.
  - Fractures of the zygoma may involve the orbital floor.

# FROSTBITE

Cara Bornstein  
William I. Krief

## BASICS

### DESCRIPTION

- Frostbite is a cold-related injury resulting from a variety of mechanisms.
- Severity of frostbite injury is related to ambient temperature and duration of exposure.

### RISK FACTORS

- Prolonged exposure to cold
- Alcohol or drug intoxication
- Use of nicotine or vasoconstrictive drugs
- Psychiatric disorders
- Altered mental status
- Peripheral vascular disease, diabetes mellitus
- High altitude
- Wet and windy conditions
- Homelessness
- Malnutrition
- Infancy or advanced age

### GENERAL PREVENTION

- Dress appropriately:
  - Protect hands and feet (waterproof shoes).
  - Cover head and all parts of the face.
  - Avoid restrictive or wet clothing.
- Avoid smoking and alcohol use.
- Avoid remaining in the same position for prolonged periods of time.

### PATHOPHYSIOLOGY

2 components to frostbite injury:

- During the cooling process, initial freeze injury occurs:
  - Extracellular ice crystals form, causing an osmotic gradient, intracellular dehydration, enzymatic destruction, and cell death.
  - Vascular endothelial damage leads to intravascular damage and reduced blood flow.
  - Vasoconstriction and arteriovenous shunting occur at the capillary level, compounding end organ damage.
- During rewarming, reperfusion injury occurs:
  - Intracellular swelling due to the influx of fluid
  - Red cell, platelet, and leukocyte aggregation causes thrombosis of the microcirculation.
  - Release of free radicals and arachidonic acid metabolites (prostaglandin and thromboxane), which then exacerbate vasoconstriction

### ETIOLOGY

- Prolonged exposure to cold of underprotected areas of the body
- Refreezing of thawed extremities

### COMMONLY ASSOCIATED CONDITIONS

- Hypothermia:
  - Children are especially susceptible due to a larger body surface area to weight ratio.
- Alcohol and drug use
- Homelessness

## DIAGNOSIS

### HISTORY

- Progression of symptoms may be seen:
  - Patient may complain of feeling cold, then burning or throbbing in the affected region
  - Numbness followed by complete loss of sensation
  - Loss of muscle dexterity
  - Severe joint pain
- Sites most susceptible include hands, feet, ears, nose, and lips

### PHYSICAL EXAM

- During the initial evaluation, most frostbite injuries appear similar:
  - Need to perform a careful exam that assesses for presence of necrotic tissue or compartment syndrome:
    - With compartment syndrome, will see extraordinary pain, paresthesia, pallor, poor pulses and perfusion, and paralysis
      - Paresthesia is a late symptom.
  - Classification of frostbites is applied after rewarming and can be categorized by either degree of injury or by superficial (1st and 2nd degree) and deep (3rd and 4th degree).
    - 1st degree:
      - Erythema and swelling, usually no blisters
      - Patient may complain of throbbing or burning pain.
    - 2nd degree:
      - Skin is red and usually has large, clear blisters.
      - Pain often resolves, and the patient is numb in the affected area.
    - 3rd degree:
      - Full-thickness skin injury:
        - Skin is waxy and hard. There may be subcutaneous edema.
      - Patient may complain of numbness, throbbing, or burning pain.
      - Hemorrhagic vesicles may be present.
    - 4th degree:
      - Tissue necrosis and gangrene

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Lab tests are not necessary for diagnosis but may aid in management.
- Urinalysis is performed to detect myoglobinuria.
- Gram stain and cultures from suspected frostbite wound infections

#### Imaging

- Several modalities may be effective in revealing tissue perfusion and the extent of deep-tissue injury and predicting tissue viability:
  - Technetium-99m scintigraphy can also show effects of treatment.
  - MRI may be helpful in predicting nonviable tissue and guiding debridement.
  - Laser Doppler flowmetry can measure microvascular RBC perfusion.
  - Angiography
- Radiography for suspected fractures in the acute setting, and osteomyelitis and growth plate injury on future presentations

#### Diagnostic Procedures/Other

Consider ECG in any patient with hypothermia.

### DIFFERENTIAL DIAGNOSIS

- Pernio (chilblains/cold sores) are localized inflammatory skin lesions due to chronic repeated exposure to non-freezing-cold temperatures.
- Cold immersion foot (trench foot) is a peripheral neurovascular injury due to prolonged exposure to a damp nonfreezing environment.
- Frostnip is a mild cold injury that manifests as redness, numbness, and swelling to affected areas.
- Raynaud phenomenon

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation.
- Remove wet clothing.
- Rewarm only if refreezing will not occur in transit.
- Protect affected areas from mechanical trauma:
  - Extremities can be padded and splinted for protection.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Attend to life-threatening conditions first. Address ABCs per Advanced Trauma Life Support and Pediatric Advanced Life Support guidelines:
  - Frostbite is primarily a condition of morbidity.
- The goal of wound care with frostbite is the preservation of viable tissue, prevention of infection, and return of function:
  - Correct hypothermia with passive and active rewarming:
    - Rapid rewarming in a bath of circulating hot water between 40°C and 42°C for 20–60 min with a mild antibacterial agent (hexachlorophene or povidone/iodine).
    - Continue until distal extremity is flushed, supple, and pliable.
    - Active motion may be useful.

- Use sterile cotton between fingers and toes to prevent skin maceration.
- Keep affected extremities elevated, with splinting as indicated.
- Anti-inflammatory agents such as ibuprofen can reduce inflammation and pain.
- Pain control to address pain associated with rewarming of affected areas
- Systemic antibiotics should be reserved for identified infections and wound sepsis. Antibiotics should not be used for prophylaxis.

## MEDICATION

- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
    - Ketorolac 0.5 mg/kg IV/IM q6h PRN
    - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- Aloe vera (thromboxane inhibitor) topically q6h
- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2  $\mu$ g/kg IV q2h PRN:
    - Initial fentanyl dose of 1  $\mu$ g/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- Tetanus prophylaxis as indicated

## COMPLEMENTARY & ALTERNATIVE THERAPIES

- Tissue plasminogen activator (tPA) may improve tissue perfusion and reduce amputations if administered within 24 hr (1,2):
  - Pediatric dosing has not been established.
  - Administered in conjunction with heparin infusion
  - Precaution: Potential for catastrophic hemorrhage if risk factors of bleeding, stroke, or gastric ulcers
- Numerous medical treatments have been suggested but remain investigational and should be administered during inpatient management:
  - IV heparin to prevent microthrombosis (1–3)
  - Reserpine may reduce associated vasospasm (4).
- Daily hydrotherapy for 30–45 min followed by debridement
- Hyperbaric oxygen therapy (5)

## SURGERY/OTHER PROCEDURES

- Use debridement of clear blisters; hemorrhagic blisters should be left intact.
- Potential for compartment syndrome:
  - Measurement of compartment pressure
  - Emergent fasciotomy
- Amputation and surgical debridement are often delayed for 2–3 mo unless wound infection with sepsis is refractory to treatment.
- Surgical sympathectomy for alleviation vasospasm-related pain.

## DISPOSITION

### Admission Criteria

Critical care admission criteria:

- Admission recommended for deep frostbites (3rd and 4th degree)
- Consider transfer of patient if medical personnel not familiar with frostbite care:
  - Burn centers can often serve as the referral center for severe frostbites.

### Issues for Referral

Superficial frostbites (1st and 2nd degree) can be followed by primary care physicians or surgeons for development of complications:

- The hospital course will dictate follow-up of deep frostbites.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Anti-inflammatory medication as noted in Medication section
  - Tobacco and vasoconstrictive medications must be withheld.
  - No weight bearing until edema has resolved
  - May experience cold insensitivity, neuropathy, and/or decreased hair and nail growth
  - Affected tissue at increased risk for reinjury
  - Discuss with patient methods to avoid cold-weather injuries (see General Prevention section).
- Activity:
  - Encourage activity of affected extremities as soon as possible:
    - Physical therapy is recommended.

## DIET

A high-calorie, high-protein diet will promote wound healing.

## PROGNOSIS

- Favorable prognostic factors are early sensation to pinprick, clear blebs, and normal skin color after rewarming.
- Poor prognostic factors are nonblanching skin, persistent cyanotic hue, hemorrhagic blebs, and frozen-appearing tissue.

## COMPLICATIONS

- Wound infections, tetanus, gangrene, and septicemia
- Tissue loss
- Compartment syndrome
- Hyperhidrosis
- Neuropathy and reflex sympathetic dystrophy
- Decreased nail or hair growth
- Premature closure of epiphyses
- Persistent Raynaud phenomenon
- Squamous cell carcinoma development over areas previously frostbitten

Hypothermia

## CODES

### ICD9

- 991.0 Frostbite of face
- 991.1 Frostbite of hand
- 991.2 Frostbite of foot

## PEARLS AND PITFALLS

- Pearls:
  - Avoid rewarming with dry heat, since temperature cannot be regulated and can cause further tissue injury.
  - Always consider tetanus prophylaxis.
- Pitfalls:
  - Refreezing after rewarming may worsen outcome.
  - Compartment syndrome may develop during rewarming.
  - Rubbing or exercising the affected tissue does not increase blood flow and may lead to mechanical trauma.
  - A common error is premature termination of rewarming process due to reperfusion pain.
  - External rewarming of extremities in a hypothermic patient may lead to peripheral vasodilation and intravascular volume redistribution (“rewarming shock”) and a subsequent fall in core temperature (“afterdrop”).

# GANGLION CYST

P. Micky Heinrichs  
Alan L. Nager

## BASICS

### DESCRIPTION

- A ganglion cyst is a benign, generally painless, fluid-filled mass mainly found at the dorsum of the wrist near the radiocarpal joint or the volar radial aspect of the wrist (1).
- Ganglion cysts may occur at any tendon sheath throughout the musculoskeletal system, such as the foot or the ankle (2).
- 70% are located at the dorsal wrist, and 75% of these are connected with the scapholunate joint (3).
- While common in adults, wrist ganglia are unusual and rare in children (4).
- Colloquial term: "Bible Cyst" due to the use of the Bible (commonly being the heaviest book in a household) for forceful destruction of the cyst:
  - Due to the high recurrence rate and the increased likelihood of trauma to adjacent structures, this is not a recommended procedure.

### EPIDEMIOLOGY

- Estimated incidence of 10% in patients <20 yr of age and 2% in patients <2 yr (1).
- Pediatric population: Proportion of affected females to males has been reported as ranging from 1.6:1–4.7:1 (1,2,4).

### PATHOPHYSIOLOGY

- Defect in 1 of the joint capsules allowing accumulation of synovial fluid in an outpouching of a tendon sheath or joint capsule (1)
- Depending on the location of the ganglion, pain, sensory changes, or nerve palsy may occur when nerves or branches of nerves are compressed by the ganglion (3):
  - Dorsal ganglions can cause pain because of pressure on the branches of the posterior interosseous nerve.

- If larger, it can compress branches of the superficial radial nerve (3).
- Volar ganglions can present with sensory or motor nerve palsy involving the palmar cutaneous branch of the median nerve, the median nerve itself, the ulnar nerve, or the deep ulnar motor branch (3).
- A high percentage of ganglions resolve spontaneously between 1.5 and 12 mo after appearance. Ganglions rarely persist >2 yr (4,5).

### ETIOLOGY

Unknown

## DIAGNOSIS

### HISTORY

- Complaints about a spontaneously appearing, usually painless, cystic growth almost always located near a joint capsule or tendon sheath of the wrist, the foot, or any other location in the musculoskeletal system
- Occasionally, a specific traumatic event can be recalled, but usually there is none (3).
- The patient may complain of pain secondary to pressure on the branches of nerves (depending on location) (3).
- Pain can also occur in ganglia of the feet or ankles when external pressure is applied (eg, wearing shoes) (2).
- Questioning the parent or child should reveal no fever, erythema, pulsation, bleeding, or drainage.

### PHYSICAL EXAM

- Firm or fluctuant, well-defined, <3 cm mass near a joint capsule or tendon sheath without skin changes, such as redness, warmth, or drainage
- Most commonly found over the dorsal or volar aspect of the wrist (3):
  - Volar ganglia have the highest occurrence rate (4) with a general tendency to develop on the radial side.

- Small dorsal ganglions, which may be tender, may be only palpable in full wrist extension.
- Occult ganglions may not be palpable but are tender (3).
- Transillumination will confirm that there is clear fluid in the ganglion cyst, unless the ganglion is very small and deep or the patient is dark skinned.

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

No lab tests are needed for a ganglion cyst.

### Imaging

- A ganglion cyst is a clinical diagnosis, and, in general, no imaging is required.
- Imaging may be helpful in ambiguous cases, especially when ganglions cannot be easily palpated or patients present with pain (3). US should be the initial imaging modality of choice for suspected ganglia. It is equally effective as MRI (3) but can be obtained more readily (although it is more operator dependent).

## DIFFERENTIAL DIAGNOSIS

- Any mobile mass that moves with excursion of the extensor tendons:
  - Ganglion of tendon sheath
  - Tenosynovitis of inflammatory, rheumatoid, or infectious origin
  - Extensor digitorum brevis manus muscle belly
- Firm mass more radial and slightly more distal: Osteophyte (more common in adult patients)
- Compressible mass: Venous aneurysm
- Pulsating mass: Arterial aneurysms of the radial or ulnar artery
- Other types of tumors: Lipoma, posterior interosseous neuroma, hamartoma, sarcoma

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Treatment is generally not necessary for cysts with minimal symptoms.
- Pain usually suggests pressure on a nerve and suggests the need for further workup.
- If other structures are involved, further evaluation should be pursued (3).

### MEDICATION

- NSAIDs:
  - Ibuprofen 10 mg/kg/dose PO q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

### COMPLEMENTARY & ALTERNATIVE THERAPIES

Injection of triamcinolone acetonide as an outpatient has been found to reduce recurrence.

### SURGERY/OTHER PROCEDURES

- Surgery, in general, is not required with initial ganglion cyst presentation.
- Surgical referral can be considered for:
  - Atypical ganglions
  - Ganglions that cause pain
  - Ganglions that do not resolve within 1 yr (6)
- Upon referral:
  - Surgical aspiration of the fluid can be helpful in the short term (1), but there is a high risk of recurrence (up to 43%) after aspiration (1,2). There is an additional risk of injury to the underlying structures (radial artery or palmar cutaneous branch of the median nerve) (4,5).
  - Excision surgery accompanied by removal of the tract that extends into the joint is curative.

## DISPOSITION

### Admission Criteria

Generally, no admission is needed.

### Issues for Referral

Consider referral to a surgeon.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Follow up with a primary care physician for further care.

### PROGNOSIS

Most ganglions resolve spontaneously within 1 yr (4,5).

### COMPLICATIONS

Closed rupture, either by firm massage or trauma to the area, often leads to recurrence of the ganglia.

## CODES

### ICD9

- 727.41 Ganglion of joint
- 727.42 Ganglion of tendon sheath
- 727.43 Ganglion, unspecified

## PEARLS AND PITFALLS

- Pearls:
  - Testing is generally not necessary for diagnosis.
  - Any painful swelling that does not fit the description of a ganglion should trigger a more extensive evaluation.
  - US is the study of choice for further evaluation.
- Pitfall:
  - Ganglion cyst in a patient who has fever, erythema, pulsation, bleeding, or drainage is highly unlikely.

# GASTRITIS

Sabina Zavolkovskaya  
Barbara M. Garcia Peña

## BASICS

### DESCRIPTION

- Gastritis is best defined as injury-induced inflammation of the gastric mucosa leading to epithelial cell damage and regeneration.
- Gastritis is often used loosely to describe epigastric pain, dyspepsia, mucosal irregularity, or swelling on radiograph images:
  - Gastritis is neither a clinical nor a radiologic diagnosis.
  - Gastritis is most accurately a histologic diagnosis characterized by the presence of inflammatory cells.
- Gastritis is often confused with “gastropathy,” which is epithelial damage and regeneration of the gastric mucosa without associated inflammation (1,2).

### EPIDEMIOLOGY

One of most common GI diagnoses

#### Incidence

- True incidence is unknown.
- Accounts for ~1.8–2.1 million visits to physician offices each year
- More common in adults than in children

#### Prevalence

- 8 in 1,000 people
- Increases with age (2,3)
- *Helicobacter pylori* (as one of the causes of gastritis):
  - In developed countries: Isolated in <10% in children <10 yr of age
  - In developing countries: As high as 80% in children <10 yr of age

### RISK FACTORS

- Infectious: Poor hygiene, developing nations, immunocompromised states
- *H. pylori*: Poor socioeconomic conditions, bed sharing, large sibships (3)

### GENERAL PREVENTION

- Improving hygiene
- Stress reduction
- Avoidance of NSAIDs, caffeine, alcohol

### PATHOPHYSIOLOGY

Imbalance between cytotoxic (acid, pepsin, certain medications, bile acids, and infection) and cytoprotective factors (the mucous layer, local bicarbonate secretion, and mucosal bloodflow) in the upper GI tract leads to injury to the gastric mucosa with associated inflammation (4):

- May result from local effects at the gastric mucosa or from systemic diseases or processes

### ETIOLOGY

- Infectious:
  - Bacterial (most common—*H. pylori*)
  - Viral
  - Mycobacterial
  - Syphilitic
  - Parasitic
  - Fungal

- Physiologic stress:
  - Sepsis
  - Major trauma, head injury (Cushing ulcer), surgery
  - Organ failure
  - Severe burns (Curling ulcer)
- Drug induced:
  - Aspirin
  - NSAIDs
  - Steroids
  - Antibiotics
  - Valproate
  - Iron
- Ethanol
- Caffeine
- Allergic:
  - Allergic enteropathy
  - Milk protein allergy
- Crohn disease
- Less common causes:
  - Radiation
  - Eosinophilic gastritis
  - Ingestion of corrosive agents
  - Ménétrier disease (hypertrophic gastritis)
  - Autoimmune (atrophic) gastritis
  - Collagenous gastritis
  - Zollinger-Ellison syndrome
  - Vascular injury
  - Direct trauma (eg, NG tube)
- Idiopathic

### COMMONLY ASSOCIATED CONDITIONS

- *H. pylori*
- Autoimmune diseases:
  - Crohn disease

## DIAGNOSIS

### HISTORY

- Epigastric pain or discomfort, often postprandial
- Decreased appetite
- Weight loss
- Bloating
- Irritability
- Nausea
- Vomiting, often postprandial
- Coffee-ground emesis or hematemesis
- Diarrhea
- Melena
- Midsternal chest pain

### PHYSICAL EXAM

- Epigastric tenderness
- Normal bowel sounds
- Melena or hematochezia
- Heme-positive stool
- Pallor

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

Testing is usually not necessary. Consider the following selectively:

- Stool testing for blood
- Hemoglobin or CBC to rule out anemia
- *H. pylori* identification (4–6):
  - Noninvasive:
    - Urea breath test
    - Stool antigen testing
    - Serum IgG antibody
  - Invasive:
    - Biopsy urease test
    - Brush cytology
    - Histologic staining with a Warthin-Starry silver stain, a modified Giemsa or a Cresyl violet stain
    - Culture (recommended for refractory disease to identify antibiotic susceptibility)

#### Imaging

- Imaging is generally not necessary.
- Abdominal upright or cross-table lateral radiographs to detect free abdominal air (if perforation is suspected)

#### Diagnostic Procedures/Other

Upper GI endoscopy with biopsies from different gastric topographic zones

- Gold standard for diagnosis
- Most sensitive test
- Provides histologic evidence of mucosal inflammation

#### Pathological Findings

- Erythematous mucosa
- Atopic mucosa
- Ulcers or erosions
- Mucosal petechiae or hemorrhage
- Enlarged gastric rugae
- Nodules
- Inflammatory cells on histologic evaluation

### DIFFERENTIAL DIAGNOSIS

- GERD
- Peptic ulcer disease
- Idiopathic (nonulcer dyspepsia)
- Functional abdominal pain
- Inflammatory bowel disease
- Biliary tract disorders
- Pancreatitis
- Genitourinary pathology (eg, renal stones, infection)

## TREATMENT

General goals of treatment:

- Stabilization of patient
- Elimination of offending agents
- Symptomatic treatment
- Etiology-specific treatment (eg, Crohn disease, *H. pylori*, fungal)

### PRE HOSPITAL

Assess and stabilize airway, breathing, and circulation.

### INITIAL STABILIZATION/THERAPY

- Fluid resuscitation in case of upper GI hemorrhage
- Pain management
- NPO
- Withdrawal of offending agent

### MEDICATION

#### First Line

- *H. pylori* gastritis (5,6):
  - Triple therapy (7–14 day course):
    - Proton pump inhibitor (PPI) plus amoxicillin (50 mg/kg/day up to 1 g b.i.d.) plus clarithromycin (15 mg/kg/day up to 500 mg b.i.d.)
    - PPI plus amoxicillin plus metronidazole (20 mg/kg/day up to 500 mg b.i.d.)
    - PPI plus clarithromycin plus metronidazole
- Other gastritis:
  - H<sub>2</sub> antagonists:
    - Cimetidine 20–40 mg/kg/day up to 400 mg b.i.d.
    - Famotidine 1–1.2 mg/kg/day up to 20 mg b.i.d.
    - Ranitidine 2–4 mg/kg/day up to 150 mg b.i.d.

#### Second Line

- *H. pylori* gastritis (4,6):
  - Quadruple therapy:
    - Bismuth subsalicylate 1 tablet (262 mg) or 15 mL (17.6 mg/mL) q.i.d. plus PPI plus metronidazole plus amoxicillin or clarithromycin or tetracycline (for children  $\geq$  12 yr of age: 50 mg/kg/day up to 1 g b.i.d.)
    - Ranitidine bismuth/citrate 1 tablet q.i.d. plus clarithromycin plus metronidazole
- Other gastritis:
  - PPIs:
    - Lansoprazole 0.8–1.5 mg/kg/day up to 30 mg b.i.d.
    - Omeprazole 0.8–1 mg/kg/day up to 20 mg b.i.d.
  - Cytoprotective agent:
    - Sucralfate 40–80 mg/kg/day up to 1 g q.i.d.

### DISPOSITION

#### Admission Criteria

- Inadequately controlled pain in the outpatient setting
- Persistent vomiting
- Inability to tolerate PO
- Critical care admission criteria:
  - Active upper GI bleeding with unstable vital signs (eg, hypotension)

### Discharge Criteria

- Normal hemoglobin or CBC if obtained
- Heme-positive stool with stable vital signs
- Adequate pain control
- Adequate PO intake
- Adequate hydration status

### Issues for Referral

Gastroenterology referral for suspected *H. pylori* infection or significant/persistent symptoms

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions:

- Avoidance of inciting agent (eg, NSAIDs, ethanol, etc.)
- Take medications as prescribed.
- Return if persistence or worsening of symptoms.

### Patient Monitoring

- Compliance with treatment regimen
- Symptom resolution

### DIET

- Avoidance of ethanol, caffeine, tobacco
- Bland diet with milk is no longer recommended.

### PROGNOSIS

- There are significant relapse rates for children who remain infected with *H. pylori* or are inadequately treated.
- Reinfection rate is 2–2.4% in children  $>$ 5 yr of age

### COMPLICATIONS

- Bleeding
- Anemia
- Failure to thrive
- Gastric carcinoma
- Mucosa-associated lymphoid tissue (MALT) lymphoma
- Corrosive gastritis:
  - Latent strictures and outlet obstruction

### Pregnancy Considerations

- Treatment for *H. pylori* gastritis should be initiated after pregnancy and breast-feeding because some of the recommended medications are relatively contraindicated.
  - Some antimicrobials (clarithromycin, tetracycline) have harmful effects on the fetus.
- H<sub>2</sub> receptor antagonists (eg, cimetidine, ranitidine, famotidine) and lansoprazole are safe for use in pregnancy.

- Gastroesophageal Reflux
- Pain, Abdomen

## CODES

### ICD9

- 041.86 *H. pylori* infection
- 535.00 Acute gastritis (without mention of hemorrhage)
- 535.50 Unspecified gastritis and gastroduodenitis (without mention of hemorrhage)

## PEARLS AND PITFALLS

- *H. pylori* infects at least 50% of the world's human population, but most people are asymptomatic.
- In most children, the presence of *H. pylori* infection does not lead to clinically apparent disease, even when the organism colonizing the gastric mucosa causes chronic active gastritis.
- The decision to treat *H. pylori*-associated gastritis without duodenal or gastric ulcer is subject to the judgment of the clinician and deliberations with the patient and family.
- Antibiotic resistance is a growing problem that interferes with eradication of *H. pylori*.
- Noncompliance is a major cause for eradication failure of *H. pylori*.

# GASTROENTERITIS

Carla Maria P. Alcid

## BASICS

### DESCRIPTION

- Gastroenteritis (GE) refers to:
  - Infections of the GI tract caused by bacteria, viruses, or parasites
  - Noninfectious causes of inflammation of the GI tract secondary to drugs and toxins
- The majority are foodborne illnesses.
- GE most commonly manifests as nausea, vomiting, diarrhea, abdominal pain, and cramping.
- Usually the presence of vomiting and diarrhea, together with a detailed history and physical exam excluding other serious illnesses, constitute a diagnosis of acute GE.

### EPIDEMIOLOGY

#### Incidence

- In the U.S., GE accounts for > 1.5 million pediatric outpatient visits and 200,000 hospitalizations annually:
  - There are ~300 deaths per year.
- Worldwide, the WHO estimates > 700 million episodes of diarrhea annually in children <5 yr of age in developing countries (1):
  - Globally, death estimates are 1.8 million deaths per year.

#### Prevalence

- Accounts for ~3% pediatric office visits and 10% hospitalizations in children <5 yr of age
- Attack rate ranges from 0.5–1.9 illnesses per person annually and is higher in the 1st 2–3 yr of life:
  - 2.5–5 illnesses per child in day care

### RISK FACTORS

- Poor hygiene
- Young age (<6 mo)
- Prematurity
- Presence of an immunodeficiency
- Malnutrition
- Coexisting infection
- Lack of exclusive or predominant breast-feeding in small infants

### GENERAL PREVENTION

- Strict hand hygiene with improvement in water and sanitation facilities
- Contact tracing and source identification to prevent outbreaks from occurring
- Immunization may prevent rotavirus, some salmonella, and hepatitis A
- Proper cleaning and complete cooking of all meals, especially meats and vegetables

### PATHOPHYSIOLOGY

- Infection acquired through the fecal–oral route by direct person-to-person contact or by ingestion of contaminated food and water:
  - Presence of preformed toxins (*Bacillus cereus*)
  - Production of enterotoxins: Enteroinvasive *Escherichia coli* (EIEC), enterotoxigenic *Escherichia coli* (ETEC)
  - Direct invasion of intestinal mucosa (villi surface destruction by viruses; wall adherence by parasites)
- Noninfectious:
  - Chemical toxins most often found in food (especially seafood), heavy metals, antibiotics, and other medications
  - Toxins adhere to the intestinal wall, causing irritation and swelling, which leads to water, mucus, or blood to leak from the wall of the intestine.

### ETIOLOGY

- Viruses cause the majority of GE:
  - Rotavirus
  - Noroviruses and other caliciviruses
  - Hepatitis A
  - Astroviruses, adenoviruses, parvoviruses
- Bacterial infections:
  - *Salmonella* species, *Shigella*, *Yersinia enterocolitica*, *Campylobacter* species, *Staphylococcus aureus*, *Bacillus*—acute food poisoning
  - EIEC, ETEC
  - Less commonly: *Listeria*, *Clostridium* species
  - *Vibrio cholera*: Most common etiology in developing countries
- Parasitic infections:
  - *Giardia lamblia*, *Entamoeba histolytica*: Mostly from uncooked foods
  - Toxoplasma; *Cryptosporidium*, *Trichinella* species: Less common
- Noninfectious agents:
  - Heavy metals
  - Mushrooms (toxins)
  - Nitrites and pesticides
  - Fish and shellfish poisoning (scombroid, ciguatera toxins, tetrodotoxins)
  - Antibiotics and other medications

### COMMONLY ASSOCIATED CONDITIONS

- Poverty
- Poor environmental hygiene
- Child's delayed developmental status

## DIAGNOSIS

### HISTORY

- Clinical spectrum ranges from asymptomatic to severe symptoms, dehydration, and death.
- Assess the onset, frequency, and quantity of both vomiting and diarrhea.
- Determine the character, such as the presence of bile, blood, or mucus.
- Note most recent oral intake, including quantifying breast milk and other food or fluids.
- Elicit a most recent preillness weight and amount of urine output.
- Note presence of other associated symptoms such as fever, mental status changes, and presence of rashes, as it may signify more serious disease.
- Past medical history should include any underlying illnesses or recent medical problems.
- Include a list of medications and presence of any immunodeficiency (HIV).
- Social history should include day care exposures and presence of outbreaks in the community.
- Recent travel should also be documented, including travel on cruise ships (noroviruses).

### PHYSICAL EXAM

- Body weight and vital signs:
  - Tachycardia is an early sign of dehydration.
  - Deep respirations suggest metabolic acidosis.
- Assess mental status for listlessness or inconsolability.
- Note presence or absence of tears, sunken eyes, or dry mucous membranes and the appearance of the lips, mouth, and tongue.
- Absence of bowel sounds can indicate an ileus, signifying hypokalemia.
- Severe abdominal pain and tenesmus indicate involvement of the large intestines and rectum.
- Periumbilical pain with watery diarrhea indicates small bowel involvement.
- General perfusion of the extremities helps assess the level of dehydration.
- Delayed capillary refill and prolonged skin tenting may be helpful clues to assess hydration.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Not necessary for diagnosis but may be helpful to assess dehydration and identify etiology or complications
- Assess serum electrolytes if there is possibility of dehydration or oral intake suggests potential abnormalities.
- Consider stool studies selectively:
  - If there is concern for acute bacterial diarrhea, stool for WBCs may reveal >5 WBC/hpf.
  - Rotavirus is identified on electron microscopy or rapid ELISA.
  - Stool for ova and parasites
- CBC, urine studies, and blood cultures may be indicated in the context of sepsis.
- *Clostridium difficile* testing for patients with recent antibiotic use

- Procalcitonin has been suggested as a diagnostic marker for bacterial GE but has not been helpful (2).
- C-reactive protein (CRP) has also been studied as a biologic marker (CRP >95 mg/L in 1st 48 hr suggests bacterial disease) and may serve as a useful predictor of bacterial GE in children (3).

### Imaging

Not generally warranted unless the possibility of a surgical abdomen exists (obstruction, appendicitis, volvulus, or intussusception)

### DIFFERENTIAL DIAGNOSIS

- Non-GI illnesses, including meningitis, sepsis, pneumonia, otitis media, and urinary tract infections
- Isolated vomiting can be the initial manifestation of a metabolic disorder, CHF, toxic ingestions, intracranial injury, or trauma.

## TREATMENT

Most GE can be effectively managed at home with oral rehydration solutions.

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation.
- Administer fluid bolus as necessary for dehydration.

### INITIAL STABILIZATION/THERAPY

- Initial assessment must focus on hydration status and presence of any toxicity.
- IV rehydration with isotonic fluids boluses (20 mL/kg)
- See Dehydration topic for further management.

### MEDICATION

#### First Line

- Expired American Academy of Pediatrics practice guideline previously recommended no antiemetic/antidiarrheal use in children <5 yr of age.
- Ondansetron (antiemetic) (4):
  - 0.15 mg/kg PO or IV
- Antibiotics not typically useful but may be useful for specific pathogens:
  - Shigellosis: Trimethoprim/Sulfamethoxazole at 8–10 mg/kg trimethoprim dosing PO divided b.i.d., if susceptible
  - Campylobacter—if severe:
    - Erythromycin 30–50 mg/kg/day PO divided b.i.d.–q.i.d. for 5 days OR
    - Ciprofloxacin 20–30 mg/kg/day PO divided b.i.d.
  - *G. lamblia* or *E. histolytica*:
    - Metronidazole 15 mg/kg/day PO divided t.i.d. AND
    - Iodoquinol 35–50 mg/kg/day PO divided t.i.d. to prevent spread of the disease
  - Rotavirus GE has sometimes been effectively controlled with nitazoxanide (5).

#### Second Line

- Metoclopramide (antiemetic):
  - 0.1 mg/kg IV/PO, max single dose 10 mg
  - If metoclopramide is given IV, administer as piggy back with normal saline over >30 min to prevent akathisia.
- Loperamide (antidiarrheal):
  - 6–8 yr (20–30 kg): 2 mg PO b.i.d.
  - 9–12 yr (>30 kg): 2 mg PO t.i.d.
  - Adolescent/Adult (>45 kg): 4 mg PO initial dose, then 2 mg/dose each stool, max single dose 16 mg/day

- Bismuth subsalicylate (Kaopectate) (antiemetic and antidiarrheal):
  - 100 mg/kg/day divided in 5 equal doses, max single dose 4 g/day

### COMPLEMENTARY & ALTERNATIVE THERAPIES

- Zinc supplementation reduces the incidence, duration, and recurrence of diarrhea:
  - <6 mo of age: 10 mg/day
  - >6 mo: 20 mg/day
- Probiotic (*Lactobacillus*, *Bifidobacterium*) bacteria to prevent/reduce diarrhea

### DISPOSITION

#### Admission Criteria

- Severely dehydrated patients
- Moderately dehydrated patients unable to take adequate oral rehydration fluids
- Consider admission for the following:
  - Severe metabolic acidosis
  - Abnormal serum sodium (high or low)
  - Abnormal or changing mental status

#### Discharge Criteria

- Normal vital signs
- Ability to tolerate oral fluids
- Follow up with the primary care provider.
- Reliable caregivers who can provide adequate care at home

#### Issues for Referral

- If concern exists for other possible illnesses that may complicate the clinical course
- Any social concerns that might prevent returning for evaluation

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Early feeding with age-appropriate diet
- Activity:
  - No restrictions once able to tolerate oral feeds

#### Patient Monitoring

If patient is discharged home, strict instructions on criteria to return, such as inability to tolerate oral feeds or decreased urine output

### DIET

- Overly restricted diets should be avoided.
- Lactose-free formulas can be used in infants if lactose malabsorption is of concern.
- Avoid carbonated drinks or juices with a high concentration of simple carbohydrates.
- Breast-fed infants should nurse ad libitum.

### PROGNOSIS

Good prognosis when early therapy is instituted and no concurrent illnesses are present

### COMPLICATIONS

- Bacteremia, urinary tract infection, vaginitis, endocarditis, meningitis, pneumonia, hepatitis, soft tissue infections (especially *Salmonella*)
- Guillain-Barré syndrome from *Campylobacter* infection
- Hemolytic uremic syndrome (HUS) from *Shigella dysenteriae* 1 or *E. coli* O157:H7
- Hemolytic anemia from *Campylobacter* and *Yersinia*
- Reactive arthritis and glomerulonephritis from *Shigella*, *Campylobacter*, and *Yersinia*

## CODES

### ICD9

- 005.9 Food poisoning, unspecified
- 009.0 Infectious colitis, enteritis, and gastroenteritis
- 558.9 Other and unspecified noninfectious gastroenteritis and colitis

## PEARLS AND PITFALLS

- Obtain appropriate stool cultures early in the course of the disease in children with bloody diarrhea and suspected HUS.
- Early nutritional support is key in successful management of the majority of cases of GE.
- Lower osmolality oral rehydration fluids are more effective in reducing stool output.
- The practice of withholding food for >24 hours should be avoided.

# GASTROESOPHAGEAL REFLUX

Sandra L. Grossman  
Barbara M. Garcia Peña

## BASICS

### DESCRIPTION

- Gastroesophageal reflux (GER) is the retrograde passage of gastric contents into the esophagus.
- GER is a normal physiologic process, occurring several times per day in healthy infants, children, and adults.
- In healthy people, most episodes of GER occur in the postprandial period, last <3 min, and cause few or no symptoms.
- Gastroesophageal reflux disease (GERD) occurs when clinical symptoms result from GER.
- GERD is usually minimally symptomatic but must be distinguished from life-threatening causes of vomiting.

### EPIDEMIOLOGY

#### Incidence

- 40–67% of healthy full-term infants (1)
- >50% of children with moderate to severe neurologic disorders/developmental delay

#### Prevalence

- 50% of infants 0–3 mo of age (2)
- 67% of infants 4 mo of age
- 5% of infants 10–12 mo of age
- 1.4–8.2% of children 3–17 yr of age

### RISK FACTORS

- Asthma
- Neurologic disorders (eg, cerebral palsy)
- Obesity
- Smoking
- Caffeine use
- Pregnancy
- Cystic fibrosis
- Repaired esophageal atresia or achalasia
- Other congenital esophageal disease
- Chronic lung disease
- Premature birth
- Lung transplant
- Hiatal hernia
- Family history of GERD, Barrett esophagus, or esophageal adenocarcinoma

### PATHOPHYSIOLOGY

- Multifactorial process that involves airway responsiveness, acidity, frequency of reflux events, and esophageal clearing mechanisms (2,3)
- Occurs during the spontaneous transient relaxation of the lower esophageal sphincter (LES) unaccompanied by swallowing
- Increased intra-abdominal pressure may contribute
- Vomiting associated with GER is due to stimulation of pharyngeal sensory afferents by refluxed gastric contents.

- GER becomes GERD when there are disturbances in protective mechanisms:
  - Delayed gastric emptying
  - Abnormal epithelial repair
  - Insufficient clearance and buffering of refluxate
  - Decreased neural protective reflexes of aerodigestive tract

### ETIOLOGY

- GER is a normal physiologic process.
- GERD is due to LES incompetence as a result of loss of tone or recurrent inappropriate transient relaxation.

## DIAGNOSIS

- In the infant presenting before 6 mo of age with uncomplicated emesis, a thorough history and physical should be adequate to make the diagnosis.
- This is also true for verbal older children presenting with typical heartburn symptoms (substernal, burning chest pain) and regurgitation.
- There is no symptom or symptom complex in infants and toddlers that is diagnostic of GERD or predicts response to therapy:
  - However, the presence of the bothersome signs/symptoms associated with GER often leads to the clinical diagnosis of GERD in infants and children.

### HISTORY

- Effortless, painless vomiting is the most common historical feature in healthy-appearing infants/children.
- Vomiting, recurrent abdominal pain, and/or chest pain are more common features in adolescents and adults.
- Signs and symptoms associated with GER are nonspecific. Not all children with GER have these symptoms, which can be caused by conditions other than GER.
- Signs/Symptoms associated with GER:
  - Recurrent regurgitation with or without vomiting
  - Weight loss and poor weight gain
  - Choking, gagging, arching during or after feeds
  - Feeding refusal
  - Irritability (infants)
  - Chest pain or heartburn
  - Dysphagia, odynophagia
  - Cough, wheezing, stridor, or hoarseness
  - Apnea spells
  - Apparent life-threatening event (ALTE)
- Other historical features associated with GER:
  - Past history of prematurity, surgery, asphyxia, neurologic/respiratory disease, atopic dermatitis/other allergy symptoms
  - Tobacco, alcohol use
  - Family history of GERD

- Consider causes other than GER when the following occur in the vomiting infant (2):
  - Forceful vomiting
  - Billious vomiting
  - Onset of vomiting after 6 mo of life (GER most commonly manifests prior to this age.)
  - GI bleeding (hematochezia, hematemesis)
  - Failure to thrive
  - Diarrhea
  - Constipation
  - Lethargy
  - Hepatosplenomegaly
  - Seizures
  - Fever
  - Genetic/Metabolic disorders
  - Micro-/Macrocephaly
  - Bulging fontanelle
  - Abdominal distension/tenderness

### PHYSICAL EXAM

- Normal physical exam
- Significant GERD may lead to dental erosions.
- Dystonic torso/head posturing (Sandifer syndrome) is a specific manifestation of GERD.
- Unlikely GERD if the following are present:
  - Appears malnourished
  - Decreased activity level
  - Evidence of dehydration
  - Hypotonia
  - Abnormal respiratory or abdominal exam

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

Indicated to investigate other sources of vomiting, based on history and physical exam

### DIFFERENTIAL DIAGNOSIS

- Other sources of vomiting (2):
  - GI obstruction (pyloric stenosis, foreign body, malrotation/volvulus, intermittent intussusception, gastric outlet obstruction)
  - Other GI (pancreatitis, cholelithiasis, appendicitis, gastritis/peptic ulcer disease)
  - Toxins (iron, lead, caffeine, theophylline, medications)
  - Infection (gastroenteritis, *Helicobacter pylori*, urinary tract infection, pneumonia, hepatitis, meningitis, sepsis)
  - Neurologic (intracranial bleed or mass lesion, intracranial injury, migraine)
  - Renal (uremia, nephrolithiasis)
  - Cardiac (CHF)
  - Endocrine (congenital adrenal hyperplasia, adrenal insufficiency)
  - Metabolic (urea cycle defects, aminoacidopathies)
  - Food intolerance (celiac disease, milk/soy protein allergy)
  - Pregnancy
  - Eating disorder
- Other sources of chest pain:
  - Cardiac
  - Other GI (eosinophilic esophagitis, gastritis/peptic ulcer disease)

- Respiratory (pneumothorax, asthma, pneumonia)
- Costochondritis
- Mass
- If presence of dysphagia, need to consider:
  - Eosinophilic esophagitis
  - Stricture
  - Achalasia

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- For infants who are healthy, feeding well, thriving, and not excessively fussy, treatment is directed toward parental education and reassurance.
- If diagnosed with GERD, consider:
  - Conservative management (lifestyle changes)
  - Medication
  - Surgery

### MEDICATION

Duration of therapy is variable depending on the patient and practitioner.

#### First Line

- H2 blockers to reduce acid reflux, improve symptoms, and aid in healing esophageal mucosa:
  - Ranitidine (Zantac): PO: 4–10 mg/kg/day divided b.i.d., max 300 mg/day; IV/IM: 2–4 mg/kg/day divided q6–8h, max 200 mg/day; adult dose—PO: 150 mg b.i.d. or 300 mg qhs; IM/IV: 50 mg/dose q6–8h, max 400 mg/day
  - Famotidine (Pepcid): 1–12 yrs of age: 1 mg/kg/day PO/IV divided b.i.d., max 80 mg/day; > 12 yr: 20–40 mg PO/IV b.i.d.
  - Cimetidine (Tagamet): 20–40 mg/kg/day PO/IM/IV divided t.i.d.–q.i.d.; adult dose: 800–1,200 mg PO/IM/IV b.i.d.–t.i.d.
- Proton pump inhibitors: The most effective medications for acid suppression; work best when administered 15–30 min before a meal. Not approved for use in infants < 1 yr of age:
  - Omeprazole (Prilosec): 1–2 mg/kg/day PO divided daily b.i.d.; adult dose: 20–40 mg PO daily
  - Lansoprazole (Prevacid): ≤ 10 kg: 7.5 mg PO daily; 11–30 kg: 15 mg PO daily–b.i.d.; > 30 kg: 30 mg PO daily–b.i.d.; adult dose: 15–30 mg PO/IV daily
  - Esomeprazole (Nexium): 1–11 yr of age: 10 mg PO/IV daily; ≥ 12 yr: 20–40 mg PO/IV daily

#### Second Line

- Prokinetic agents: Potential adverse effects outweigh the potential benefits of treatment:
  - Metoclopramide (Reglan): 0.1–0.2 mg/kg/dose PO/IM/IV q.i.d., max single dose 0.8 mg/kg/day; adult dose: 10–15 mg PO/IM/IV qac and qhs
  - Associated with extrapyramidal reactions (dystonia, oculogyric crisis, tardive dyskinesia)
- Antacids PO (magnesium hydroxide, calcium carbonate, aluminum hydroxide); may be used for symptomatic relief but not for chronic therapy

### COMPLEMENTARY THERAPY

- Dietary changes (1–4):
  - Formula changes usually do not improve symptoms in GERD.
  - If milk protein sensitivity/allergy: A 2–4 wk trial of an extensively hydrolyzed protein formula may be beneficial.
  - Thickened feeds with rice cereal (helps with visible emesis but no measurable decrease in frequency of esophageal reflux episodes)

- Avoidance of caffeine, spicy food, high-fat food, acid-containing food (eg, tomato sauce), carbonated beverages, chocolate, and alcohol if they provoke symptoms
- Consume smaller, more frequent meals.
- Avoid eating late at night.
- Positioning therapy:
  - Infants: Prone position (NOT endorsed by the American Academy of Pediatrics [5]); upright position
  - Children and adolescents: Sleeping in left lateral decubitus position with elevation of the head of the bed (2)

### SURGERY/OTHER PROCEDURES

For children with persistent reflux refractory to maximal medical therapy or those with severe complications of GERD (1,2,4):

- Nissen fundoplication (open and laparoscopic)
- Total esophagogastric dissociation (children with neurologic impairment or other conditions causing life-threatening aspiration during oral feedings)
- Endoluminal endoscopic gastroplication

### DISPOSITION

#### Discharge Criteria

- Should be discharged home if the history and physical exam clearly suggests GER or GERD
- For the most part, only parental education, anticipatory guidance, and feeding modifications (composition, frequency, and volume) are necessary for the management of uncomplicated infant GERD (2).

#### Issues for Referral

- Uncomplicated GER can be easily managed by general pediatricians (2).
- Consider referring to gastroenterologist if:
  - Symptoms worsen or do not resolve by 12–18 mo of age
  - Signs/Symptoms of significant GERD develop

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Reassurance, parental education, anticipatory guidance
- Instructions on dietary/lifestyle changes
- Follow up with primary care provider.

### PROGNOSIS

Resolves spontaneously in most by 1 yr of age and almost all by 2 yr of age. In full-term infants, symptoms disappear (6):

- In 55% by 10 mo of age
- In 81% by 18 mo of age
- In 98% by 2 yr of age

### COMPLICATIONS

- Erosive esophagitis
- Esophageal stricture
- Barrett esophagus

ICD9  
530.81 Esophageal reflux

## PEARLS AND PITFALLS

- All that vomits is not reflux.
- A thorough history and physical exam is usually sufficient to make the diagnosis of GER or GERD.
- Parental education, anticipatory guidance, and reassurance are necessary and usually sufficient to manage healthy, thriving infants with uncomplicated GER.

# GASTROINTESTINAL BLEEDING: LOWER

Matthew Lee Hansen  
Garth Meckler

## BASICS

### DESCRIPTION

- Lower GI bleeding is defined as bleeding distal to the ligament of Treitz.
- Lower GI bleeding is usually bright red in color, though it may present with maroon or black tarry stools (melena).

### EPIDEMIOLOGY

#### Incidence

Exact incidence in children is unknown; however, lower GI bleeding is a common problem in children.

#### Prevalence

The prevalence is unknown.

### RISK FACTORS

Constipation is a risk factor for developing anal fissures, which may cause bleeding.

### GENERAL PREVENTION

Prevent constipation.

### PATHOPHYSIOLOGY

- The pathophysiology varies according to etiology.
- Malrotation and intussusception are caused by twisting or sliding of bowel, which results in obstruction of blood flow and resultant ischemia.
- Meckel diverticulum causes bleeding from ectopic gastric or pancreatic tissue, which results in local mucosal erosion and bleeding.
- Infectious colitis is frequently caused by *Escherichia coli* and *Salmonella*, *Campylobacter*, or *Shigella* species and can cause bleeding from local invasion or through the production of toxin.
- Henoch-Schönlein purpura (HSP) causes GI bleeding from diffuse vasculitis.
- Breast-fed infants can swallow maternal blood, which may produce heme-positive stools (see Gastrointestinal Bleeding: Upper topic).
- Formula fed infants can develop milk-protein allergy that may produce heme-positive stools (see Gastrointestinal Bleeding: Upper topic).

### ETIOLOGY

- Neonates: Swallowed maternal blood, necrotizing enterocolitis (NEC), malrotation with volvulus, Hirschprung disease, coagulopathy, vascular malformations, allergic colitis

- Infants: Hirschprung disease, anal fissure, allergic colitis, intussusception, Meckel diverticulum, intestinal duplication, infectious colitis, vascular malformations
- Children: Juvenile polyps, anal fissures, HSP, infectious colitis, Meckel diverticulum, hemolytic uremic syndrome, inflammatory bowel disease

### COMMONLY ASSOCIATED CONDITIONS

- Food allergy
- Eczema

## DIAGNOSIS

### HISTORY

- The typical history is that of passage of bright red blood per rectum (hematochezia), though patients or parents may note maroon or black tarry stools (melena).
- The character of the blood and stool should be included in the history, as it may indicate the anatomic source of bleeding:
  - Stool coated in blood or blood on toilet paper suggests an anorectal source.
  - Bright red liquid blood (hematochezia) suggests a source in the proximal colon.
  - Bloody diarrhea usually results from a colonic source.
  - Maroon or tarry stool (melena) suggests a more proximal source—proximal to the ileocecal valve.
- The history should also include a careful inquiry about associated symptoms (such as tenesmus, abdominal pain, vomiting, constipation, fever, diarrhea, mucus), chronic medical conditions (including constipation and systemic disease), medications (especially NSAIDs and steroids), and familial bleeding or vascular disorders.
- Infectious diarrhea will often have a history of bloody diarrhea with mucus, tenesmus, and sick contacts with similar symptoms or recent travel or ingestion of raw foods.
- In breast-fed neonates, the mother should be asked about cracked or bleeding nipples to identify the potential swallowed maternal blood.
- In formula-fed infants, inquire about past formula intolerance, which could signify protein allergy.
- Ask about ingestion of red substances, as this may give the appearance of blood (eg, beets, red-dyed drinks or foods).

### PHYSICAL EXAM

- Careful documentation of vital signs, especially heart rate and BP will help identify life-threatening hemorrhage.
- Fever, poor skin turgor, delayed capillary refill, dry mucous membranes, and tachycardia may indicate dehydration in infectious diarrhea.
- A careful anorectal exam is essential to identify fissures, which most commonly are found at the posterior aspect of the anus. A digital rectal exam should be performed if stool is not available for inspection and occult blood testing.
- Anoscopy may be useful to identify distal polyps or internal hemorrhoids.
- Abdominal exam may reveal distention or tenderness, which could indicate a more serious etiology such as perforation or volvulus. A sausage-shaped mass may be palpated on the right side in patients with intussusception.
- A careful skin exam may identify characteristic lesions of HSP (palpable purpura of the lower extremities and buttocks), multiple vascular malformations associated with congenital GI malformations, or perioral freckling associated with hereditary polyposis syndromes.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Chemical testing for occult blood (eg, Guaiac smear test) can be useful in confirming the presence of blood from stool.
- Minor bleeding that is self-limited and associated with a normal physical exam and vital signs is likely the result of a benign etiology and rarely requires additional lab testing.
- Patients with significant bleeding should have a CBC evaluated for hematocrit (which may be normal in acute blood loss), RBC indices that might suggest chronic GI bleeding with microcytic anemia, and evaluation of the platelet count.
- Patients with ongoing blood loss should have a blood sample sent for typing and cross-matching if transfusion is necessary.
- Coagulation studies (PT, PTT, d-dimer) are indicated for severe or ongoing bleeding or in the setting of a suspected disorder of coagulation.
- If HSP is suspected, evaluate renal function by measuring creatinine, and evaluate for proteinuria with urinalysis.
- If infectious colitis is suspected, stool should be sent for bacterial cultures including *Shigella*, *Salmonella*, *Yersinia*, *Campylobacter*, and *E. coli* O157:H7. With an appropriate travel or exposure history, ova and parasite exam may be useful.
- An Apt test may be performed on rectal blood to differentiate swallowed maternal blood from fetal blood in breast-fed neonates.
- Inflammatory markers such as ESR and C-reactive protein may be useful in the setting of suspected inflammatory bowel disease.

**Imaging**

- Abdominal x-rays are rarely helpful but may identify free air, a “target sign” in the right upper quadrant suggestive of intussusception; pneumatosis in neonates with NEC; or paucity of bowel gas in malrotation with midgut volvulus (upper GI barium study with small bowel follow-through is diagnostic).
- In the setting of massive painless rectal bleeding, a nuclear medicine “Meckel scan” (technetium-99m) is useful to evaluate for ectopic gastric mucosa in a Meckel diverticulum.
- Abdominal US is sensitive for intussusception but is not therapeutic and should be reserved for cases in which the diagnosis is equivocal.

**Diagnostic Procedures/Other**

- Anoscopy, sigmoidoscopy, or colonoscopy may be useful to evaluate for vascular malformations, inflammatory bowel disease, and polyps.
- Barium/Air contrast enema is diagnostic and frequently therapeutic in intussusception.
- Rectal biopsy provides definitive diagnosis in Hirschsprung disease and may be useful in confirming suspected inflammatory bowel disease.

**Pathological Findings**

Varies depending on cause

**DIFFERENTIAL DIAGNOSIS**

- Neonates: Swallowed maternal blood
- Infants and children: Colored food products

**TREATMENT****PRE HOSPITAL**

- Oxygen via nasal cannula or face mask
- Normal saline 20 cc/kg IV or IO for patients with hemodynamic compromise

**INITIAL STABILIZATION/THERAPY**

- Establish 2 large-bore, short-length IVs if unstable.
- Crystalloid infusion 20 mL/kg; may repeat as necessary
- Blood transfusion 10 mL/kg for life-threatening blood loss; may repeat as necessary
- In intussusception, barium/air contrast enema for reduction
- Malrotation with midgut volvulus is a surgical emergency, and early surgical consultation is critical.

**MEDICATION****First Line**

- In cases of anal fissure, apple juice can be titrated PO to soften stool and warm sitz baths may provide comfort.
- In infectious colitis caused by *Shigella* and *Campylobacter*, antimicrobial therapy is controversial but should be considered: Azithromycin 10 mg/kg/day on day 1, followed by 5 mg/kg/day on days 2–5.
- In NEC, broad-spectrum antibiotic therapy with ampicillin (50 mg/kg/dose) and gentamycin (2.5 mg/kg/dose) should be considered in consultation with neonatology and pediatric surgery.

**Second Line**

- Glycerin suppositories can be used sparingly in cases of anal fissure if other methods do not work.
- Prednisone 1–2 mg/kg/day divided b.i.d. is controversial but may be considered in HSP.

**SURGERY/OTHER PROCEDURES**

- Barium or air contrast enema is often therapeutic for intussusceptions.
- Immediate surgical management is indicated for malrotation with midgut volvulus as well as intussusception with failed hydrostatic reduction.
- Outpatient surgery is definitive care for Meckel diverticulum and Hirschsprung disease.
- Endoscopy is useful in the setting of suspected vascular malformations, polyps, and inflammatory bowel disease.

**DISPOSITION****Admission Criteria**

- Critical care admission criteria:
  - Hemodynamic instability
  - Profuse and ongoing bleeding
- Inpatient admission criteria:
  - History of significant bleeding without hemodynamic instability (eg, self-limited but large-volume blood loss, anemia suggestive of chronic bleeding)

**Discharge Criteria**

- Self-limited, minor bleeding in a hemodynamically stable patient
- Benign etiology of lower GI bleed (eg, anal fissure, polyp, well-appearing child with infectious colitis)

**Issues for Referral**

- Outpatient referrals (routine): Recurrent or chronic but self-limited lower GI bleeding of uncertain etiology without systemic signs should prompt referral to a gastroenterologist for possible endoscopy and further management.
- Immediate referrals (within 1 wk): Congenital malformations of the GI tract (eg, Meckel diverticulum, intestinal duplication) require referral to a pediatric surgeon.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Recurrent bleeding associated with symptoms of dizziness, light-headedness, fainting, or severe abdominal pain should prompt immediate medical care.
- Activity:
  - Normal activity is recommended for most causes of lower GI bleeding.

**Patient Monitoring**

Monitor stool color, and inform the physician if stools are tarry or black or maroon in color.

**DIET**

- Soy-based or elemental formula may be indicated for infants with milk protein allergy.
- Regular diet is otherwise recommended.

**PROGNOSIS**

- The prognosis depends on the underlying etiology; however, lower GI bleeding is rarely life threatening in children.
- Etiologies with guarded prognoses include malrotation with midgut volvulus, inflammatory bowel disease, NEC, or multiple vascular malformations.
- HSP is usually self-limited and benign but may be recurrent and associated with renal involvement in a minority of cases.

**COMPLICATIONS**

Intestinal ischemia and resultant intestinal necrosis may develop in cases of intussusception, malrotation with midgut volvulus, or NEC.

- McCullough M, Shareiff GQ. Abdominal surgical emergencies in infants and young children. *Emerg Med Clin North Am*. 2003;21:909–935.

**ICD9**

578.9 Hemorrhage of gastrointestinal tract, unspecified

**PEARLS AND PITFALLS**

- Consider swallowed maternal blood in breast-feeding neonates, and inquire about maternal nipple irritation.
- Carefully examine the entire skin for cutaneous vascular malformations that may signal occult GI vascular malformations.
- Infants with bilious emesis should be transferred to a center with pediatric surgery available, as malrotations with midgut volvulus are diagnostic considerations that represent true surgical emergency.
- Consider intussusception in children with intermittent severe abdominal pain, though lethargy or intermittent lethargy alone should prompt consideration of this diagnosis.

# GASTROINTESTINAL BLEEDING: UPPER

Matthew Lee Hansen  
Garth Meckler

## BASICS

### DESCRIPTION

Upper GI bleeding is defined as bleeding from a source within the GI tract proximal to the ligament of Treitz.

### EPIDEMIOLOGY

#### Incidence

- The exact incidence in children is unknown; however, upper GI bleeding is uncommon in children.
- The reported incidence among children in the ICU ranges from 6.4–25% (1).

### RISK FACTORS

- Chronic NSAID or steroid use
- Bleeding diatheses (eg, hemophilia)
- Chronic disease leading to portal HTN (eg, cystic fibrosis, congenital hepatic disease) can cause varices with subsequent bleeding.
- Severe retching or repeated vomiting can result in upper GI bleeding.
- Inherited conditions of vascular anomalies (eg, Osler-Weber-Rendu) can predispose children to upper GI bleeding.
- Severe head trauma (Cushing ulcers) or burns (Curling ulcers)

### GENERAL PREVENTION

- Closely monitor NSAID use.
- Prophylaxis (proton pump inhibitors) for ICU patients

### PATHOPHYSIOLOGY

- The pathophysiology varies according to etiology.
- Variceal bleeding results from hepatic venous HTN causing dilation of submucosal veins which may rupture.
- Nonvariceal bleeding can result from:
  - Disorders of the coagulation cascade
  - Loss of mucosal protective factors as a result of medications (eg, NSAIDs)
  - Irritation (eg, foreign body or caustic ingestion)
  - Infection (eg, *Helicobacter pylori*)
  - Congenital vascular malformations may be predisposed to bleeding.

### ETIOLOGY

- Neonates: Hemorrhagic disease of the newborn (vitamin K deficiency), gastritis, esophagitis, vascular malformation, bleeding diatheses
- Infants: Gastritis, esophagitis, stress ulcer, Mallory-Weiss tear, vascular malformations, congenital GI duplications
- Children: Peptic ulcer disease, gastritis, esophagitis, foreign body, Mallory-Weiss tear, caustic or toxic ingestion, esophageal varices, thrombotic thrombocytopenia purpura, Henoch-Schönlein purpura

### COMMONLY ASSOCIATED CONDITIONS

Variceal bleeding is commonly associated with liver disease and portal HTN.

## DIAGNOSIS

### HISTORY

- The typical history is vomiting of blood that is a bright red or coffee-ground color.
- Parents may report dark tarry stools (melena), which may be the result of an upper GI source of bleeding.
- The history should include a careful inquiry about associated symptoms (such as retching or recurrent vomiting), chronic medical conditions, medications, familial bleeding, or vascular disorders.
- In breast-fed neonates, ask about maternal cracked or bleeding nipples to identify potential swallowed maternal blood.
- In formula-fed infants, inquire about formula intolerance, which could signify milk protein allergy (seen with both cow's milk and soy-based formulas).
- Inquire as to non-GI sources of blood such as cough, which could indicate hemoptysis, or epistaxis, which may be swallowed blood.

### PHYSICAL EXAM

- Careful documentation of vital signs, especially heart rate and BP, will help identify life-threatening hemorrhage.
- Inspection of the nose is important to exclude this non-GI source of bleeding.
- Abdominal tenderness and peritoneal signs may suggest life-threatening GI perforation, while hepatomegaly or splenomegaly may suggest portal HTN.
- A thorough exam of the skin is important to identify stigmata of chronic liver disease and vascular malformations.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Minor bleeding with a reassuring exam that is likely the result of a benign etiology (eg, Mallory-Weiss) rarely requires lab testing.
- Chemical testing for occult blood (eg, Gastrocull cards) can be useful in confirming the presence of blood from gastric aspirates or samples of emesis.
- Patients with significant bleeding should have a CBC evaluated for hematocrit (which may be normal in acute blood loss), RBC indices that might suggest chronic GI bleeding with microcytic anemia, and evaluation of the platelet count.
- Patients with ongoing blood loss should have a blood sample sent for typing and cross-matching if transfusion may be necessary.
- Coagulation studies (PT, PTT, d-dimer) are indicated for severe or ongoing bleeding or in the setting of suspected disorder of coagulation.
- ALT and AST may be indicated in the setting of suspected portal HTN.
- The Apt test can distinguish between swallowed maternal and neonatal blood.
- Testing for *H. pylori*: Endoscopic biopsy with rapid urease testing or polymerase chain reaction for bacterial DNA is most sensitive. Serum, saliva, and urine antibodies, stool antigen, or urea breath testing are less invasive but less sensitive.

#### Imaging

Abdominal x-rays (kidney, ureter, bladder, and upright) may be useful in select circumstances to identify foreign bodies or free air indicative of perforation.

#### Diagnostic Procedures/Other

- NG tube aspiration with instillation of normal saline may be useful to identify ongoing upper GI bleeding but is not universally indicated in self-limited or benign cases.
- Endoscopy may be useful in cases of foreign body or variceal bleeding.

#### Pathological Findings

Varies depending on the cause

### DIFFERENTIAL DIAGNOSIS

- Neonates: Swallowed maternal blood
- Infants and children: Epistaxis, colored food products, hemoptysis

## TREATMENT

### PRE HOSPITAL

- Oxygen via nasal cannula or face mask
- Normal saline 20 mL/kg IV or IO for patients with hemodynamic compromise

### INITIAL STABILIZATION/THERAPY

- Establish 2 large-bore, short-length IVs if tachycardia or hypotension is present.
- Crystalloid infusion 20 mL/kg; may repeat as necessary
- Blood transfusion 10 mL/kg for life-threatening blood loss; may repeat as necessary

### MEDICATION

#### First Line

- Medications for gastric acid reduction:
  - H<sub>2</sub> receptor antagonists
    - Ranitidine 1–2 mg/kg IV q6h, max single dose 50 mg
  - Proton pump inhibitors
    - Omeprazole 1 mg/kg/day PO per day–b.i.d., max single dose 20 mg
    - Lansoprazole 15–30 mg/kg/day IV/PO per day–b.i.d.
    - Pantoprazole 1 mg/kg IV/PO per day, max single dose 40 mg
- Antibiotics for suspected or confirmed *H. pylori* infection (see Additional Reading for all recommended regimens) (3):
  - Triple therapy (all 3 in combination):
    - Amoxicillin 50 mg/kg/day PO divided b.i.d.–q.i.d., max single dose 1 g PO b.i.d.
    - Clarithromycin 15 mg/kg/day up to 500 mg PO b.i.d. for 7–14 days
    - Proton pump inhibitor (as noted above)
  - Triple therapy as noted above, substituting clarithromycin with:
    - Metronidazole 20 mg/kg/day up to 500 mg PO b.i.d. for 7–14 days

#### Second Line

- Octreotide (1 μg/kg bolus to 50 μg followed by 1–4 μg/kg/hr continuous infusion) for active bleeding from varices
- Fresh frozen plasma, cryoprecipitate, or specific factor replacement for ongoing bleeding with coagulopathy

### COMPLEMENTARY & ALTERNATIVE THERAPIES

- Licorice and zinc have been recommended as alternative therapies for ulcer disease.
- Chamomile and garlic are thought to have anti-*H. pylori* activity.

### SURGERY/OTHER PROCEDURES

- Endoscopy is often indicated for bleeding requiring transfusion, chronic or recurrent bleeding, and in some instances of variceal or vascular bleeding.
- Banding and sclerotherapy may be performed endoscopically.
- Angiography may be indicated for massive bleeding in patients too unstable for endoscopy.
- Surgical exploration is indicated for patients with persistent bleeding of undetermined cause who remain hemodynamically unstable.

### DISPOSITION

#### Admission Criteria

- Critical care admission criteria:
  - Hemodynamic instability
  - Profuse and ongoing bleeding
- Inpatient admission criteria:
  - History of significant bleeding without hemodynamic instability (eg, self-limited but large-volume blood loss, anemia suggestive of chronic bleeding)

#### Discharge Criteria

- Self-limited, minor bleeding in a hemodynamically stable patient
- Benign etiology of upper GI bleed (eg, Mallory-Weiss tear, mild gastritis, or esophagitis)

#### Issues for Referral

- Outpatient referrals (routine): Chronic or recurrent upper GI bleeding should prompt referral to a gastroenterologist for possible endoscopy and further management.
- Immediate referrals (within 1 wk): Congenital malformations of the GI tract (eg, Meckel diverticulum, intestinal duplication) require referral to a pediatric surgeon.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions:
  - Recurrent bleeding associated with symptoms of dizziness, light-headedness, fainting, or severe abdominal pain should prompt immediate medical care
- Discharge medications:
  - Continue medications as described in medication section (eg, acid suppression therapy, antibiotics for *H. pylori*)
- Activity:
  - Normal activity is recommended for most cases of upper GI bleeding.

#### Patient Monitoring

- Monitor stool color, and inform the physician if stools are tarry, black, or maroon in color.
- Avoid excessive use of NSAIDs in cases of suspected gastritis or ulcer disease.

#### DIET

- Soy-based or elemental formula may be indicated for infants with milk protein allergy.
- Regular diet is otherwise recommended.

#### PROGNOSIS

- The prognosis depends on the underlying etiology; however, upper GI bleeding is rarely life threatening in children.
- Etiologies with guarded prognoses include those associated with cirrhosis, portal HTN, esophageal varices, or multiple vascular malformations.

### COMPLICATIONS

- Gastric or duodenal ulcers may perforate, causing peritonitis and septic shock.
- Varices and arterial bleeding can result in life-threatening blood loss.

### See Also (Topic, Algorithm, Electronic Media Element)

- Gastritis
- Pain, Abdomen

### ICD9

578.9 Hemorrhage of gastrointestinal tract, unspecified

### PEARLS AND PITFALLS

- Consider swallowed maternal blood in breast-feeding neonates, and inquire about maternal nipple irritation.
- Carefully examine the entire skin for cutaneous vascular malformations that may signal occult GI vascular malformations.
- Consider accidental toxic ingestions in toddlers with upper GI bleeding (eg, iron).
- Look for signs of portal HTN such as spider angiomas, palmar erythema, and hepatosplenomegaly as a clue to possible variceal bleeding.
- Gastric lavage with ice or epinephrine is no longer recommended.

# GASTROINTESTINAL POLYPS

Daniel A. Green

Barbara M. Garcia Peña

Laura Umbrello

## BASICS

### DESCRIPTION

- A GI polyp is a tissue growth protruding from the mucosal surface into the lumen of the bowel.
- GI polyps can be solitary or multiple and neoplastic or nonneoplastic.
- Classification by gross appearance:
  - Pedunculated: Attached to the mucosa by a narrow stalk with a mushroomlike head
  - Sessile: Flat lesions broadly attached to the mucosa
- Juvenile polyps:
  - Most common cause of polyps in children
  - Solitary in 75% of cases
  - >3–5 juvenile polyps fulfill the criteria for the diagnosis of juvenile polyposis syndrome
- Juvenile polyposis syndrome (1,2):
  - Mean age of presentation between 5 and 6 yr
  - May be accompanied by:
    - Protein-losing enteropathy
    - Electrolyte abnormalities
    - Failure to thrive
- Peutz-Jeghers syndrome:
  - Average age of presentation is 25 yr.
  - Hamartomatous polyps
  - Increased lifetime risk of malignancy
- Familial adenomatous polyposis:
  - Colorectal and duodenal adenomas
  - Increased lifetime risk of malignancy

### EPIDEMIOLOGY

Juvenile polyposis syndrome (1,2):

- Found in 1 in 100,000–160,000 live births

### RISK FACTORS

Family history of polyposis syndrome

### PATHOPHYSIOLOGY

Mutations in tumor suppressor genes likely lead to dysregulation of cell proliferation and apoptosis in polyposis syndromes.

### ETIOLOGY

Proliferation of colonic epithelium with cystic dilation of normal glandular elements

## DIAGNOSIS

### HISTORY

- Frequently asymptomatic
- Family history of polyps or polyposis syndromes
- Abdominal pain
- Painless, bright red rectal bleeding:
  - Assess amount of blood loss, if present.
- Diarrhea or passage of mucus
- Prolapsing rectal lesion
- History of iron-deficiency anemia
- Weight loss or failure to thrive
- Symptoms of obstruction such as vomiting, abdominal distension, obstipation, etc. (GI polyps may be complicated by intussusception.)

### PHYSICAL EXAM

- Vital signs, especially in a patient with active or significant bleeding
- Complete physical exam looking for signs indicating polyposis syndromes:
  - Juvenile polyposis syndrome (2):
    - Signs of failure to thrive
  - Peutz-Jeghers syndrome:
    - Hamartomatous polyps
    - Black or brown freckles of the lips, buccal mucosa, face, palms, and soles
  - Familial adenomatous polyposis:
    - Colorectal and duodenal adenomas
  - Cronkhite-Canada syndrome:
    - Hamartomatous polyps
    - Alopecia, cutaneous hyperpigmentation, GI polyposis, onychodystrophy
- Signs of obstruction such as abdominal distension and tenderness, etc.
- Digital rectal examination for masses

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- If asymptomatic, diagnostic testing may be deferred to an outpatient appointment with the patient's primary care provider or a gastroenterologist.
- If symptomatic:
  - CBC:
    - Assess for anemia and thrombocytopenia.
    - Low mean corpuscular volume associated with chronic blood loss
  - PT/PTT/INR
  - Type and screen for active bleeding or unstable vital signs.
  - Serum electrolyte testing
  - Stool for occult blood

#### Imaging

Imaging is usually not necessary emergently. The following studies will help aid in the diagnosis:

- Barium enema
- Upper GI with small bowel follow-through
- CT and MR colonography
- Other imaging modalities depending on signs and symptoms

#### Diagnostic Procedures/Other

Imaging is usually not necessary emergently. The following procedures will help aid in the diagnosis:

- Colonoscopy
- Endoscopy
- Capsule endoscopy may be useful to identify small bowel polyps.

### DIFFERENTIAL DIAGNOSIS

- Anal fissure
- Hemolytic uremic syndrome
- Hemorrhoids
- Henoch-Schönlein purpura
- Infectious enterocolitis
- Inflammatory bowel disease
- Intussusception
- Meckel diverticulum
- Rectal trauma
- Vascular malformation

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Address and stabilize ABCs:
  - Place 2 large-bore IV lines if the patient is hemodynamically unstable.
  - Correct volume depletion.
  - Transfuse as necessary for anemia.
- Correct electrolyte disturbances, if present.
- Manage pain with analgesics.

### MEDICATION

- Analgesics are the most commonly indicated medications, though most management is supportive or surgical.
- NSAIDs:
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Ketorolac 0.5 mg/kg IV/IM q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
  - Some clinicians prefer to avoid NSAIDs due to potential for gastritis and theoretical concern over influence on coagulation.
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2  $\mu$ g/kg IV q2h PRN:
    - Initial dose of 1  $\mu$ g/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN

### SURGERY/OTHER PROCEDURES

Once stabilized, the following procedures may be performed during admission or in follow-up with gastroenterology:

- Full colonoscopy with polypectomy is an essential diagnostic and therapeutic tool:
  - Removal of GI polyps can help control symptoms and reduce the risk of malignancy.
  - When adenomatous polyps are identified in familial adenomatous polyposis, prophylactic colectomy should be considered.
- Colectomy in other polyposis syndromes with innumerable polyps or polyps showing premalignant changes

## DISPOSITION

### Admission Criteria

- Significant anemia for age
- Critical care admission criteria:
  - Unstable vital signs despite resuscitation
  - Coagulopathy
  - Continued, significant lower GI bleeding

### Discharge Criteria

- Minor or resolved lower GI bleeding
- Stable vital signs
- Stable hemoglobin
- Normal coagulation function

### Issues for Referral

- Patients suspected of having a polyp or polyposis syndrome should be referred to a gastroenterologist for evaluation.
- Patients with polyposis syndromes should be referred for genetic testing.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Follow up with the primary care provider within 1–2 days.
- Referral to gastroenterology should be made as soon as available.

### DIET

Patients who have had bowel resection may require special nutritional interventions, including vitamin and nutrient supplementation, continuous enteral feedings, or parenteral nutrition.

### PROGNOSIS

- With solitary polyps, usually a benign process that often requires minimal follow-up
- Increased risk of GI malignancy with many of the polyposis syndromes, requiring the need for continued surveillance

### COMPLICATIONS

- Life-threatening GI blood loss is rare.
- Polyps may act as a lead point of an intussusception.
- Increased lifetime risk of malignancy with several of the polyposis syndromes

## CODES

### ICD9

- 211.1 Benign neoplasm of stomach
- 211.2 Benign neoplasm of duodenum, jejunum, and ileum
- 211.3 Benign neoplasm of colon

## PEARLS AND PITFALLS

- Have a high index of suspicion in patients with a family history of polyposis syndromes.
- Consider other organ systems in patients with GI polyps, especially in those with multiple polyps, and provide appropriate referrals.
- Consider intussusception in the diagnosis in any patient with abdominal pain, rectal bleeding, and either a known or unknown diagnosis of GI polyps.
- Depending on the etiology, ongoing follow-up with a gastroenterologist may be critical to detect and manage malignant neoplasms.

# GENITAL WARTS

Shira Yahalom

## BASICS

### DESCRIPTION

- Genital warts (condyloma acuminata) are an epidermal human papillomavirus (HPV) infection.
- Lesions are papillomatous flesh to gray-brown color hyperkeratotic on keratinized epithelia.
- Can be solitary or multiple and sessile or pedunculated. Size varies from 2 mm to 2 cm.
- May occur anywhere below the waist:
  - In men: The most commonly involved area is the penile shaft and the preputial cavity.
  - In women: The posterior introitus is most commonly involved.
- In younger boys and girls, warts are most common in the perianal area but may also involve the penis or labia minora.

### EPIDEMIOLOGY

- The annual incidence of genital warts is 1%.
- ~18–33% of sexually active female adolescents will test positive for HPV.
- Prevalence of HPV infections among men seems to be lower, either due to lower incidence or shorter periods of infection.
- The CDC estimates that 50% of sexually active adults will have HPV at some point in life.

### RISK FACTORS

- Early sexual debut
- Multiple sexual partners
- Lack of condom use
- Cigarette smoking
- Oral contraceptive use
- Immunodeficiency such as from HIV or chemotherapy

### GENERAL PREVENTION

- Delaying age of 1st intercourse
- Condom use
- Limiting the number of sexual partners
- Avoiding tobacco use
- HPV vaccine is now available and offers protection from strains 6, 11, 16, and 18. The vaccine is approved for both males and females.
- Screening using Pap smears should be performed annually 3 yr from the initiation of sexual activity or at age 21 yr, whichever comes first.

### Pregnancy Considerations

- During pregnancy, latent infections may become activated and present lesions may increase. The lesions will often regress postpartum.
- Genital lesions tend to bleed easily during pregnancy and depending on size and location may interfere with vaginal delivery.
- Vertical acquisition of HPV in the birth canal is causative of inoculation of the oropharynx and respiratory tract with HPV.
- Recurrent respiratory laryngeal papillomatosis (RRLP) is a rare complication with tremendous morbidity.
- Recurrence of warts in the larynx and respiratory tree may occur throughout the life of the child

### PATHOPHYSIOLOGY

- HPV invades cells in the anogenital area through microabrasions in the skin and mucosa.
- Following latency of weeks to a year, viral DNA particles are produced, infecting the host cells, which change their morphology to atypical koilocytosis of genital warts.
- Transmission of genital HPV infection in adolescents and adults is almost always through sexual contact.
- Neonates may become infected during passage through the birth canal.
- Other less common forms of transmission, include vertical transmission, autoinoculation, heteroinoculation (transmission from the hands of the caretakers to the anogenital area of the child), and transmission through fomites.

### ETIOLOGY

- HPV is a double-stranded DNA virus that has > 100 different genotypes, with  $\geq 30$  that infect the human genital tract.
- The 2 major groups of HPV genotypes are the low-risk genotypes (types 6, 11, and others) and the high-risk genotypes (types 16, 18, 31, 33, 45, and others).
- HPV types 6 and 11 account for ~90% of all genital warts.
- HPV-16 is responsible for about 50% of cervical cancers.

### COMMONLY ASSOCIATED CONDITIONS

- As with all STIs, coinfection with another STI should be considered.
- The presence of anogenital warts in children should prompt suspicion of sexual abuse.

## DIAGNOSIS

### HISTORY

- Patients will complain of multiple painless (a single wart is less common) raised lesions.
- Associated pruritus and discharge are common.
- Postcoital bleeding may be the presenting complaint.
- Obtain history of prior or concomitant STIs.
- If the patient is an infant or child, obtain the history regarding HPV status of the mother and caregivers.
- History of immunodeficiency and pregnancy status

### PHYSICAL EXAM

- Single or multiple lesions may be seen from a small papule to cauliflower appearance.
- Exam of the entire anogenital area and oropharynx is warranted, as multiple areas may be involved and location may vary with sexual preference.
- Speculum pelvic exam and cervical cultures to inspect for abnormal appearance of the cervix and check for concomitant STIs

**DIAGNOSTIC TESTS & INTERPRETATION**

**Lab**

- No tests are required in the emergency department for diagnosis of genital warts.
- Testing for other STIs such as gonorrhea, chlamydia, syphilis, and HIV should be considered based on the history and physical exam.

**DIFFERENTIAL DIAGNOSIS**

- Neoplasm
- Nevi
- Vulvar neurofibromatosis
- Darier disease
- Hailey-Hailey disease

**TREATMENT**

**MEDICATION**

- Only symptomatic treatment is required in the emergency department setting.
- Imiquimod 5% cream applied to warts 3 times weekly for 1–3 mo:
  - May be prescribed if the emergency department clinician is comfortable with dispensing
  - Side effects include burning, pain, and vesicle formation often mistakenly diagnosed as herpes simplex virus.
- Treat coexistent STIs as warranted.

**DISPOSITION**

**Issues for Referral**

All patients with genital warts should be referred to a dermatologist, OB/GYN, or urology specialist for treatment and follow-up:

- Treatment of genital warts includes topical applications, cryotherapy, or surgical excision.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Follow up with a clinician who can provide long-term treatment as warranted.
- Emphasize infectivity, need for evaluation, and treatment of sexual partners.

**PROGNOSIS**

- Spontaneous regression is more common with children than adults.
- Recurrence after treatment may occur.
- Since HPV cannot be eradicated, the risk of malignant transformation remains despite treatment of warts.

**COMPLICATIONS**

- Cervical, vaginal, penile, and anal cancer
- Bleeding from lesions
- Obstruction of urethral meatus
- Transmission to sexual partners and neonates
- Malignant transformation
- Recurrence after treatment
- RRLP

**See Also (Topic, Algorithm, Electronic Media Element)**

- Herpes Simplex
- Sexually Transmitted Infection

**CODES**

**ICD9**  
078.11 Condyloma acuminatum

**PEARLS AND PITFALLS**

- Suspect abuse in children presenting with genital warts.
- Examine and treat for concomitant STIs.
- Suspect immunodeficiency in a patient presenting with recurrent disease.
- Do not ignore the significant psychological and social implications of diagnosis.
- It is advisable to avoid engaging in patients' attempts to temporally implicate the contact from which the infection may have been contracted.
- In females, cervical HPV clearance typically occurs within 2 yr.
- Classically it was presumed that the infection persists for life, but the accuracy of this is unknown.
- CDC experts believe that persistent infections actually involve re-exposure and reinfection.

# GIARDIASIS

Sujit Iyer

## BASICS

### DESCRIPTION

Giardiasis is caused by infection with the protozoan parasite *Giardia lamblia*, usually with symptoms of flatulence, abdominal bloating, and foul-smelling diarrhea.

### EPIDEMIOLOGY

#### Incidence

- Varies by state reporting. National range of <0.1 cases (Texas) to 23.5 (Vermont) per 100,000 (1)
- The CDC estimates up to 2.1 million cases annually in the U.S. (1).
- 2-fold increase in summer and early fall (likely due to increased outdoor activities and recreational water exposure by humans)

#### Prevalence

- Prevalence is directly related to the degree of sanitation and water treatment.
- Bimodal age distribution: Children (0–5 yr of age) and their caretakers (30–39 yr of age)
- 3 patterns of transmission (1–3):
  - Person to person: Increased prevalence related to poor hygiene and among day care attendees and staff. Also increased in male homosexuals.
  - Waterborne: Reservoirs and surface water can lead to endemic and epidemic spread in hikers and international travelers.
  - Foodborne: Uncommon and killed by cooking. Occurs with uncooked food, and as few as 10 cysts can establish infection.

### RISK FACTORS

- Infants, young children (not toilet trained)
- Day care attendance
- Internationally adopted children
- Hypo- or achlorhydria (previous gastric surgery)
- Cystic fibrosis
- Crohn disease
- Hypogammaglobulinemia/Immunodeficiency (risk for chronic infection)
- Oral–anal sexual contact
- Campers exposed to contaminated surface waters
- Travel to endemic areas

### GENERAL PREVENTION

- Strict hand washing (especially with handling diapers)
- Treatment of symptomatic children
- Boiling or heating water to at least 70°C for 10 min eliminates *Giardia* cysts (5).
- For campers: Iodine-based water treatment for at least 8 hr (5)

### PATHOPHYSIOLOGY

- Incubation period of 1–2 wk after exposure
- Human and zoonotic reservoirs; dogs, cats, sheep, beavers, deer, rodents
- Human infection can occur with ingestion of as few as 10–25 cysts. Cysts survive for a long time in a moist environment (6).
- After ingestion, trophozoites are released in the upper small bowel and attach with an adhesive disc onto the mucosa of the duodenum and jejunum.
- Biopsy of the small bowel shows a range from no changes to subtotal villous atrophy (severe).
- Intestinal changes include damage to the endothelial brush border, enterotoxins, immunologic reactions, and altered gut motility and fluid hypersecretion via increased adenylate cyclase activity.
- Trophozoites can revert to cysts and be excreted from the stool for up to 5 mo after initial diagnosis.
- Pathogenesis of diarrhea and malabsorption is incompletely understood but may be related to villous atrophy, disruption of brush border enzymes (lactase), and parasites as a physical barrier to absorption (2,3).

### ETIOLOGY

*G. lamblia* occurs in 2 forms: Cysts and trophozoites.

## DIAGNOSIS

### HISTORY

- Can be asymptomatic in up to 60% (7)
- 90% of symptomatic patients present with acute diarrhea.
- Acute giardiasis:
  - Watery diarrhea
  - Foul-smelling stools and steatorrhea
  - Bloating
  - Flatulence
  - Anorexia
  - Weight loss
  - Symptoms in young infants may mimic sprue.
  - Classic soft, foul-smelling diarrhea (52%) (2)
  - No tenesmus or bloody diarrhea
  - Symptoms often occur for 2–4 wk.

- Chronic giardiasis:
  - Up to 30% can develop chronic symptoms.
  - Loose stools
- Malabsorption of vitamins, fats, sugars, and protein:
  - Up to 40% can acquire lactose intolerance (8).
  - Should consider in children with failure to thrive

### PHYSICAL EXAM

- Weight loss (10–20% can be seen)
- Abdominal distension
- Malaise, anorexia
- Generalized edema if chronic and there is protein-losing enteropathy
- Hypersensitivity phenomenon (rare): Urticaria, reactive arthritis

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Stool sample:
  - Excretion is intermittent; the sensitivity of 1 stool sample is ~50%, while the sensitivity of 3 samples approaches 90% (9).
- Diagnosis confirmed by:
  - Cysts or trophozoites seen on microscopy of fresh specimen mixed with saline or concentrated in formalin
  - Antigen in stool specimen detected by ELISA

#### Diagnostic Procedures/Other

If high suspicion but negative stool specimens, duodenal biopsy or aspiration may be indicated for those with persistent symptoms.

#### Pathological Findings

- Histologic changes do not always correlate with the presence or absence of symptoms.
- Can be normal; flattening of brush border, damage to epithelial cells, flattening of villi, and increased goblet cells may also be seen.

### DIFFERENTIAL DIAGNOSIS

- Bacterial diarrhea
- Viral gastroenteritis:
  - Rotavirus
  - Hepatitis A
  - Norovirus
- Other protozoa:
  - Cryptosporidia
  - Microsporidia
  - Cyclospora
  - Entamoeba
- Celiac sprue
- Cystic fibrosis
- Inflammatory bowel disease
- Irritable bowel syndrome
- Lactose intolerance

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- All symptomatic children should be treated (1).
- Use of empiric antibiotic therapy in children with symptoms consistent with *Giardia* is warranted even in absence of stool testing or with negative stool assay.
- People receiving treatment should avoid lactose-containing foods for 1 mo after therapy (3).

### MEDICATION

#### First Line

Metronidazole:

- Not FDA approved for this indication but is commonly used as a first-line therapy
- 15 mg/kg/day divided in 3 doses (max single dose 250 mg) for 5 days

#### Second Line

- Tinidazole (children  $\geq 3$  yr of age):
  - FDA approved for children  $>3$  yr
  - 50 mg/kg single dose (max single dose 2 g)
- Nitazoxanide (children  $\geq 1$  yr of age) (10):
  - 2–3 yr of age: 100 mg PO b.i.d. for 3 days
  - 4–11 yr: 200 mg PO b.i.d. for 3 days
  - Albendazole 10–15 mg/kg/24 hr PO per day for 5–7 days
- Combination therapy is indicated if treatment fails with single-agent therapy.

### SURGERY/OTHER PROCEDURES

- Endoscopic duodenal biopsy
- String test (Entero-Test) sampling by swallowing gelatin-coated capsule that later is retrieved.

### DISPOSITION

#### Admission Criteria

Indicated for severe or prolonged symptoms, especially if associated with dehydration, electrolyte abnormalities, or failure to thrive

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Follow up with a primary care provider.
- Infectious disease specialist referral if considering combination therapy
- Immunology referral if having recurrent infection with no identifiable repeat exposure
- Gastroenterology referral if considering other cause of malabsorption or failure to thrive

### DIET

Lactose avoidance for 1 mo following treatment

### PROGNOSIS

After completing appropriate treatment, symptoms resolve within 5–7 days and parasites clear within 3–5 days.

### COMPLICATIONS

- Dehydration
- Malabsorption
- Folate, vitamin B<sub>12</sub>, and vitamin A deficiency
- Lactose intolerance
- Chronic diarrhea:
  - Usually caused by reinfection or drug resistance. Should retake exposure history to identify sources of reinfection and confirm with stool specimens.
  - Reinfection: If reinfection occurs, will respond to original anti-*Giardia* drug.
  - Drug resistance: Increased with combination regimens and with higher doses or longer courses of the original drug (less safe in children and should check stool for cultures for resistance)
    - Switch to a drug of a different class (most successful option and safest in children).
- Hypersensitivity phenomenon: Urticaria, rash, arthralgia, aphthous ulceration, reactive arthritis
- Weight loss, failure to thrive

## CODES

ICD9

007.1 Giardiasis

## PEARLS AND PITFALLS

- Indolent symptomatology often results in lengthy delay in diagnosis, with symptoms often wrongly attributed to lactose intolerance or viral gastroenteritis.
- Always consider in high-risk populations with complaint of diarrhea.
- 3 stool samples are needed to maximize the yield for diagnosis.
- Treatment is not recommended empirically for asymptomatic carriers unless the person is exposed to pregnant women or immunocompromised patients or works as a food handler.

# GLOBE RUPTURE

Mark X. Cicero

## BASICS

### DESCRIPTION

- A globe rupture occurs when there is a full-thickness laceration or puncture to the cornea or sclera.
- Can occur due to blunt trauma, missile, or sharp object
- The sclera is thinnest and weakest where it meets the cornea anteriorly at the limbus, where the extraocular muscles insert, and posteriorly where the optic nerve exits.

### EPIDEMIOLOGY

- In the U.S., the annual incidence of all ocular trauma is 15.2 per 100,000 children.
- Specific incidence for pediatric globe rupture is ~1,600 per year (1).
- Higher incidence in adolescent males
- 1/3 of childhood blindness results from ocular trauma.

### RISK FACTORS

- Male gender
- Work with hand or power tools
- Sports and recreation activities, such as racquet sports, baseball, and paintball
- Collagen disorders may cause a thin sclera or cornea:
  - Marfan syndrome
  - Osteogenesis imperfecta
- Previous eye surgery
- Myopic eyes have a longer AP axis and are more prone to rupture from blunt trauma.

### GENERAL PREVENTION

Safety goggles should be worn during the following activities:

- Working with hand and power tools
- Racquet sports
- Paintball
- Target shooting with firearms

### PATHOPHYSIOLOGY

- Sharp objects and projectiles may directly penetrate the globe:
  - Small foreign bodies (FBs), such as stone chips and metal filings, may penetrate the globe and remain within the eye.
- Blunt trauma causes AP compression, and the subsequent increase in intraocular pressure leads to rupture, usually at one of the scleral thin points:
  - An analogy may be made to a crushed grape, which also ruptures along points of weakness or tension when subjected to blunt trauma.

### ETIOLOGY

4 mechanisms may lead to globe rupture:

- Lacerations:
  - Sharp objects such as knives and scissors
- Penetrating injuries:
  - Objects with a narrow tip such as pencils, pens, nails, and screws
- Retained FBs:
  - Metal debris, flying wood, and stone chips
- Blunt trauma:
  - Assaults, motor vehicle collisions, sports injuries, and paintball injuries

### COMMONLY ASSOCIATED CONDITIONS

- Hyphema
- Vitreous and subconjunctival hemorrhage
- Orbital floor fracture with or without extraocular muscle entrapment
- Retinal detachment
- Retrobulbar hemorrhage

## DIAGNOSIS

### HISTORY

- Clinicians should assess the mechanism of injury, including the type of object involved:
  - Consider the possibility of a retained FB:
    - Organic debris, such as wood and thorns, significantly increases the risk of infection.
  - Assess the patient's tetanus status, especially when soil or metallic etiologies are present or an FB is suspected.
- It is important to ask about the timing of the injury, as delayed presentation increases the risk of endophthalmitis and other infections.
- Previous visual acuity should be considered:
  - Comparison to current acuity
- Patients with collagen disorders, including osteogenesis imperfecta and Marfan syndrome, are prone to globe rupture.
- History of laser keratotomy or other eye surgery may increase risk of globe rupture.
- Presence of pain
- Diplopia indicates specific intercurrent injuries:
  - May be due to extraocular muscle entrapment or cranial nerve injury
  - Monocular diplopia is possible due to lens dislocation.

### PHYSICAL EXAM

- Once a ruptured globe is suspected or confirmed, the exam should cease and precautions to prevent further injury should be initiated.
- Grossly visible globe rupture appears as dark tissue, the iris or choroid, prolapsing through the defect.
- Globe rupture is often not obvious. Several exam techniques aid the diagnosis:
  - Globe rupture may be associated with subconjunctival hemorrhage. Complete or near-complete subconjunctival hemorrhage prompts suspicion for globe rupture and emergent ophthalmologic consultation:
    - 360-degree hemorrhage may obscure globe ruptures that involve the sclera.

- Impaired extraocular movements and decreased visual acuity should increase suspicion for a globe rupture.
- An afferent papillary defect indicates a derangement in the visual axis.
- When the cornea is compromised, the iris flows into the defect. The iris appears oblong and the pupil appears teardrop shaped, with the narrow portion of the teardrop pointing to the injury. When the sclera ruptures, the choroid of the eye fills the defect.
- Examiners should inspect the anterior chamber for hyphema, ideally with a slit lamp. Because instilled drops may enter the globe, corneal abrasion and laceration are assessed with slit lamp exam alone, without fluorescein instillation.
- The orbit is examined for signs of fracture, including bony step-offs and emphysema.
- The position of the globe in the orbit is compared to the contralateral eye:
  - Exophthalmos may indicate retrobulbar hemorrhage, and enophthalmos may indicate loss of intraocular pressure due to globe rupture.
- Eyelid and lacrimal injuries may occur with globe rupture. Their presence should prompt evaluation for rupture. The Birmingham Eye Trauma Terminology Score (2) is calculated using the following variables and may be helpful in determining the prognosis of globe rupture:
  - Initial visual acuity
  - Globe rupture
  - Afferent papillary defect
  - Endophthalmitis
  - Retinal detachment
  - Perforating injury

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Any routine lab assays used for patients with trauma or preoperatively
- CBC, C-reactive protein if considering endophthalmitis

#### Imaging

- CT is the imaging study of choice in the emergency department. Advantages include:
  - Detection of radiopaque FBs
  - Detection of fractures of the bony orbit
  - Visualization of optic nerve injury
  - Detection of retrobulbar hemorrhage
- Plain radiographs have limited utility:
  - Can be used to detect orbital fractures and radiopaque FBs but with less sensitivity than CT
- US is contraindicated since direct pressure should not be placed on the globe.
- MRI may offer superior images when compared to CT:
  - MRI offers excellent visualization of the soft tissue contents of the globe.
  - Best choice for visualizing organic FBs such as soil and small wood chips
  - Contraindicated if a metal FB is suspected

**Diagnostic Procedures/Other**

- Slit lamp
- Fluorescein is to be avoided.

**DIFFERENTIAL DIAGNOSIS**

- Subconjunctival hemorrhage
- Corneal abrasion or laceration
- Orbital fracture
- Lens dislocation or detached retina
- Traumatic iritis

**TREATMENT**

**PRE HOSPITAL**

- Apply a loose-fitting eye shield:
  - An eye patch should not be placed on the eye.
  - A commercially available eye shield may be used, or one may be created using the bottom of a paper or plastic drinking cup.
  - No pressure should be applied to the eyelids.
- Penetrating objects, such as writing instruments, are left in place until the patient is in the operating room.
- The patient and caretakers are encouraged to remain calm:
  - Any straining and activities that increase intraocular pressure should be avoided.

**INITIAL STABILIZATION/THERAPY**

- If not previously done, eye shielding and securing of penetrating objects is done as outlined previously:
  - Timely consultation of ophthalmology
- IV access should be established for medication administration:
  - In some situations, IV access is obtained after the patient has been sedated in the operating room using inhaled anesthetics.
  - Associated trauma may necessitate IV fluid resuscitation.
- No eye drops are administered for ruptured globe.
- Broad-spectrum IV antibiotics with good intraocular penetration are indicated. The need to provide antibiotic coverage is tempered by the risk of increased intraocular pressure due to pain from IV catheter placement.
- Again, efforts should be made to keep the child calm:
  - Provide analgesia (IV or PO) to decrease pain and, ultimately, intraocular pressure.
  - Sedation with a benzodiazepine should be considered:
    - Ketamine may raise intraocular pressure and should be avoided.
  - Antiemetics, such as ondansetron, should be administered to a child with nausea or vomiting.

**MEDICATION**

**First Line**

- Antibiotics with good intraocular penetration include:
  - Gram-negative coverage:
    - Ceftazidime 50 mg/kg dose IV q8h OR
    - Gentamicin 2.5 mg/kg IV q8h
    - Ciprofloxacin 20–30 mg/kg/day IV divided q8–12h
    - Include ceftazidime if concerned about *Pseudomonas* species
  - Gram-positive coverage:
    - Cefazolin 25 mg/kg IV q8h OR
    - Vancomycin 10 mg/kg IV q6h

- Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
  - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.

**Second Line**

Lorazepam 0.1 mg/kg IV up to 2 mg hourly PRN for agitation

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

The interventions of a child life specialist can be invaluable in calming a child with globe rupture.

**SURGERY/OTHER PROCEDURES**

An ophthalmologist performs all surgical interventions.

**DISPOSITION**

**Admission Criteria**

All children with ruptured globe(s) are admitted to the hospital following operative management by the ophthalmology service:

- Transfer to a referral hospital may be necessary.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Patients with a history of globe rupture are instructed to wear eye protection in all sporting events and when working with tools:

- Patients with previous globe rupture may be prone to subsequent rupture.
- Patients are monitored for endophthalmitis and sympathetic ophthalmia.

**PROGNOSIS**

- Blunt trauma has a better prognosis than sharp injuries, as there is less risk of endophthalmitis.
- Serious eye injuries regularly result in permanent visual deficit or blindness. Early, baseless optimism about visual outcome is to be avoided.
- Early poor prognostic signs and symptoms include:

- Vision loss or pupillary defect
- Hyphema or vitreous hemorrhage
- Retinal detachment
- Decreased intraocular pressure

**COMPLICATIONS**

- Blindness and loss of visual acuity are the most serious consequences of globe rupture.
- A blind and painful eye is an indication for enucleation. Often, the globe may be closed and left in place despite blindness.
- Endophthalmitis:
  - An inflammatory condition of the intraocular cavities usually resulting from an infection:
    - Can involve aqueous or vitreous humor
  - Occurs hours to weeks later depending on the organism:
    - Common organisms are coagulase-negative *Staphylococcus epidermidis*, *Staphylococcus aureus*, and *Streptococcus* species.
    - In penetrating injuries, gram-negative organisms like *Pseudomonas* species, *Escherichia coli*, and *Enterococcus* species are more commonly encountered.

- Sympathetic ophthalmia:
  - An autoimmune response in the uninjured eye weeks to months after the injury
  - Presents with pain, photophobia, and decreased visual acuity

**ADDITIONAL READING**

Uysal Y, Mutlu F, Sobac G. Ocular Trauma Score in childhood open-globe injuries. *J Trauma*. 2008;65(6):1284–1286.

**ICD9**

- 871.0 Ocular laceration without prolapse of intraocular tissue
- 871.1 Ocular laceration with prolapse or exposure of intraocular tissue
- 871.2 Rupture of eye with partial loss of intraocular tissue

**PEARLS AND PITFALLS**

- Concurrent injuries may be the only sign of globe rupture, as the globe maintains its integrity. The choroid and/or the iris may close the defect.
- Injuries and findings that should prompt ophthalmologic consultation include:
  - Hyphema
  - Complete or near-complete subconjunctival hemorrhage
  - Vision loss or blindness

# GLOMERULONEPHRITIS

Colette C. Mull

## BASICS

### DESCRIPTION

- Acute glomerulonephritis (AGN) is the presentation for myriad renal inflammatory disorders.
- Hematuria and proteinuria herald glomerular inflammation—the hallmark of glomerulonephritis (GN).
- HTN and edema are usually present.

### EPIDEMIOLOGY

Poststreptococcal acute glomerulonephritis (PSAGN) is one of the most common causes of GN. Incidence in the U.S. is sporadic and declining.

### RISK FACTORS

- Genetic predisposition
- Autoimmune disease
- Streptococcal infection

### PATHOPHYSIOLOGY

- Immune-mediated GN:
  - Trigger: Immune complex deposition in glomerulus
  - Subsequent glomerular cell proliferation and apoptosis and complement activation promote inflammation, sclerosis, and fibrosis.
  - Examples: PSAGN, IgA nephropathy, Henoch-Schönlein purpura (HSP) nephritis, systemic lupus erythematosus (SLE) nephritis
- Non-immune-mediated or pauci-immune GN:
  - Trigger and mechanism less clear
- Antineutrophilic cytoplasmic antibody (ANCA)-positive GN:
  - Trigger: Unclear
  - Autoantibodies to constituents of the neutrophil cytoplasm induce a vasculitis of the renal arterioles and glomerular capillaries.
  - Other organs affected: Skin and lungs
- Hereditary nephritis (aka Alport syndrome):
  - Hereditary defect of type IV collagen in the glomerular basement membrane (GBM)

### ETIOLOGY

- Primary GN, low complement level (C3):
  - Postinfectious GN:
    - Most common etiology of AGN
    - Most common antecedent infecting organism: Group A beta-hemolytic streptococcus (GABHS)
    - Less common antecedent organisms: *Staphylococcus aureus* and *Staphylococcus epidermidis*
  - Membranoproliferative GN (MPGN)
- Secondary GN, low C3:
  - SLE
  - Subacute bacterial endocarditis
  - Ventricular shunt

- Primary GN, normal C3:
  - Alport syndrome
  - Normal serum complement level: Renal disease
  - IgA nephropathy
- Secondary GN, normal C3:
  - HSP: 20% of patients present with nephritis or nephritic syndrome at time of diagnosis.
  - ANCA-positive diseases
  - Wegener granulomatosis
  - Microscopic polyangiitis
  - Goodpasture syndrome/disease

## DIAGNOSIS

### HISTORY

- Hematuria:
  - May be sole symptom
  - “Cola-colored” urine: 30–50% of AGN
  - Gross hematuria: 50% of IgA nephropathy. Pink or red urine and presence of blood clots indicate extraglomerular source of bleeding.
- Pain:
  - Abdominal pain: HSP and IgA nephropathy
  - Headache: Acute malignant HTN
- Hearing loss, ocular defects:
  - Alport syndrome X-linked disorder
- Cough:
  - Wegener granulomatosis
  - Goodpasture syndrome
  - IgA nephropathy
- Edema
- Reduced urine output
- Presentation patterns:
  - PSAGN: History of pharyngitis 1–3 wk or history of pharyngitis, impetigo, or cellulitis up to 6 wk prior to onset of hematuria
  - IgA nephropathy: Gross hematuria, flank pain and low-grade fever 1–3 days after a viral upper respiratory or GI illness (50%), cough and congestion ongoing
  - Rapidly progressive GN: CHF, acute malignant HTN
- Past medical history:
  - High BP
  - Sickle cell disease or trait
  - Other coagulopathy
- Family history:
  - Renal disease
  - Hearing loss

### PHYSICAL EXAM

- Abnormal vital signs:
  - HTN
  - Tachycardia
  - Tachypnea
- Suggestive physical exam findings:
  - Change in mental status
  - Papilledema
  - Gallop, rales, hepatomegaly
  - Edema: Pitting, generalized or localized

- Signs of associated systemic disease:
  - SLE: Fever, rash, arthralgia and/or arthritis
  - Alport syndrome: Corneal, lens, retinal defects
  - HSP, ANCA-positive disease: Purpuric rash
- Genital exam must be conducted to rule out perineal source of bleeding (eg, urethral, meatal, or introital skin trauma)

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- Urinalysis:
  - Presence of RBCs
  - Absence of blood clots
  - Hematuria of GN produces >2+ protein.
  - Presence of RBC cast is pathognomonic for glomerular disease.
  - Pyuria common
- A urine culture helps differentiate urinary tract infection from GN; both entities can have associated proteinuria, hematuria, and pyuria.
- Additional lab testing should be guided by the history and physical exam. Consultation with a pediatric nephrologist is recommended at this time:
  - CBC:
    - Leukocytosis possible
    - Presence of anemia may reflect hemodilution, chronicity, and/or rarely iron-deficiency secondary to pulmonary hemorrhage in Goodpasture syndrome.
  - Serum electrolytes, BUN, and creatinine (Cr) levels:
    - Hyponatremia from water retention
    - Hyperkalemia from decreased urine output
    - Elevated BUN and Cr in renal insufficiency
  - Serum C3 and C4 can be instrumental in identifying GN etiology (see Etiology):
    - A low C4 is seen only in SLE GN.
  - Throat culture or serum antistreptolysin O (ASO), antihyaluronidase (AH), (GABHS pharyngitis):
    - ASO titers peak 10–14 days post-infection
    - AH titers peak 3–4 wk post-infection
  - Anti-DNAse B titers (GABHS cellulitis)
  - IgA levels high in 8–16% of IgA nephropathy
  - Serum ANA and anti-double-stranded DNA serology if suspecting SLE
  - ANCA and anti-GBM serology if suspecting vasculitis and/or Goodpasture syndrome

### Imaging

- Unnecessary in emergency department
- Consider chest radiograph in following clinical scenarios:
  - HTN: Cardiomegaly
  - CHF: Cardiomegaly, pulmonary edema
  - Goodpasture syndrome: Infiltrates

**DIFFERENTIAL DIAGNOSIS**

- Renal interstitial disease: Pyelonephritis, acute interstitial nephritis, tubulointerstitial nephritis with uveitis
- Vascular pathology: Trauma, sickle cell disease and trait, renal artery/vein thrombosis, arteriovenous thrombosis, nutcracker syndrome, malignant HTN, sports- and exercise-related hematuria, hemangioma, hamartoma
- Neoplasms: Wilms tumor, renal cell carcinoma, uroepithelial tumors, rhabdoid tumors, congenital mesoblastic tumor, angiomyolipoma
- Urinary tract pathology—cystitis: Bacterial, viral (adenovirus), parasitic (schistosomiasis), TB
- Medications: Cyclophosphamide cystitis
- Other: Urethritis, urolithiasis, trauma, severe hydronephrosis, foreign body
- Bleeding disorders: Hemophilia A or B, platelet disorders, thrombocytopenia, congenital or acquired coagulopathies
- Miscellaneous: Idiopathic hypercalciuria without urolithiasis, autosomal dominant polycystic kidney disease

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

- Emergently stabilize patients presenting with CHF and/or malignant HTN.
- Restrict sodium intake.
- Restrict fluid intake in ill patients only.
- Consult a pediatric nephrologist.
- Treat the underlying disorder as appropriate.

**MEDICATION**

- There are no specific medications that are used to treat or reverse GN in the emergency department setting.
- Inpatient medication and fluid management should be individualized and determined in consultation with a pediatric nephrologist:
  - Anti-inflammatory agents: IV or oral corticosteroids, cyclophosphamide, azathioprine
  - Proteinuria-reducing agents inhibit tubular injury and fibrosis: Angiotensin-converting enzyme inhibitors, angiotensin 2 receptor blockers, statins, antioxidants.
  - Diuretics for renal failure, CHF
- Plasmapheresis for rapidly progressive GN

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

Fish oil supplements containing omega-3 fatty acids have been used to control inflammation.

**SURGERY/OTHER PROCEDURES**

- Renal transplant is not always curative.
- Recurrence of GN may lead to loss of allograft.

**DISPOSITION**

- Patients with GN and oliguria and/or HTN should be admitted to a monitored bed.
- Critical care is required for patients with rapidly progressive glomerulonephritis, HTN encephalopathy, and/or pulmonary edema.
- Mildly ill patients may be discharged.

**FOLLOW-UP**

- Well children with isolated microhematuria and proteinuria should be referred back to their primary care physician for repeat urinalysis, a diagnostic workup if appropriate, and a referral to a pediatric nephrologist when indicated.
- All other discharged patients require initial and long-term primary care provider follow-up to monitor:
  - Urine output
  - Weight
  - BP
  - Adherence to a low-sodium diet:
    - Young child:  $\leq 2-3$  mEq sodium/kg/day
    - Older child:  $\leq 2,000$  mg/day
- HSP patients require weekly urinalysis for 4 wk, then at 2 mo and at 3 mo following diagnosis.
- Pediatric nephrologist referral:
  - Determines need for fluid restriction

**PROGNOSIS**

- PSAGN:
  - Majority: Spontaneous, complete recovery
  - Clinical signs resolve within weeks.
  - Hematuria resolves within 6–12 mo.
  - Rare progression to nephrotic syndrome and/or renal failure requiring dialysis
  - 2nd cases of PSAGN in the same child have been well documented.
- IgA nephropathy:
  - Variable clinical course
  - Remission in up to half of cases
  - Recurrent gross hematuria during viral respiratory illnesses is common.
  - Chronic renal failure in  $< 50\%$  of cases
- Alport syndrome and MPGN:
  - Rapidly progressive forms of AGN
  - End-stage renal failure is common.
- HSP GN:
  - Excellent prognosis
  - $< 2\%$ : Long-term impairment
  - Presentation with nephritis or nephritic syndrome elevates risk of long-term impairment to close to 20%.
- SLE GN:
  - Markers of poor prognosis: Severity of histology, black race
- Goodpasture syndrome: Poor prognosis
- ANCA-positive GN:
  - High morbidity if patient presents with renal insufficiency

**COMPLICATIONS**

- See Prognosis.
- Most common: CHF, malignant hypertensive encephalopathy

**CODES**

**ICD9**

- 580.0 Acute glomerulonephritis with lesion of proliferative glomerulonephritis
- 580.9 Acute glomerulonephritis with unspecified pathological lesion in kidney
- 583.9 Nephritis and nephropathy, not specified as acute or chronic, with unspecified pathological lesion in kidney

**PEARLS AND PITFALLS**

- All patients with GN require involvement of a pediatric nephrologist.
- Morbidity and mortality may result from uncontrolled HTN as well as secondary infection.

# GONORRHEA

Cynthia J. Mollen

## BASICS

### DESCRIPTION

- *Neisseria gonorrhoeae*, also called gonococcus (GC) is an anaerobic gram-negative bacteria.
- GC is an STI that has multiple manifestations.
- GC is the 2nd most commonly reported notifiable disease in the U.S.
- Common manifestations of GC include cervicitis, urethritis, pelvic inflammatory disease (PID), and neonatal conjunctivitis:
  - Urethritis is the usual presentation in males.
  - Cervicitis or PID is the usual presentation in females.
- GC can also cause pharyngitis, arthritis, epididymitis, proctitis, and disseminated disease. In the neonate, scalp abscesses, arthritis, bacteremia, meningitis, and ophthalmia (infection of the conjunctiva and deep eye structures) can occur.

### EPIDEMIOLOGY

#### Incidence

- According to CDC surveillance, there were 99.1 cases of GC per 100,000 persons in 2009.
- Over 350,000 new cases of GC were reported to the CDC in 2009.
- Rates are highest among women and adolescents.
- Although rates of GC had remained steady for 10 yr, the most recent rates reported in 2009 reflect a 10% decrease from the 2008 rate.

#### Prevalence

- Varies by population screened
- In 2007, the median state-specific gonorrhea test positivity among 15–24-yr-old women screened in selected family planning clinics was 0.9%.
- Also in 2007, the median positivity of women screened in selected prenatal clinics was 0.8%.
- Finally, in 2007, the median positivity for gonorrhea by facility in women entering selected juvenile corrections facilities was 5.3%.

### RISK FACTORS

- Female (due to prolonged contact of mucosal surfaces with infective secretions and larger mucosal surface area of the vagina)
- Adolescence (age 15–19 yr): Biologic and behavioral factors
- Early sexual debut
- Increased number of sexual partners
- Prior history of PID
- Infrequent use of barrier contraception
- Intercourse during menstruation

### GENERAL PREVENTION

- Use of prophylactic ophthalmic antibiotics in newborns
- Limiting number of sexual partners
- Consistent and correct condom use
- Routine screening of sexually active adolescents
- Treatment of sexual partners

### PATHOPHYSIOLOGY

- Incubation period is usually < 1 wk.
- An STI that is spread through contact with the penis, vagina, mouth, or anus
- 4 stages of infection:
  1. Attachment to the mucosal cell surface
  2. Local penetration or invasion
  3. Local proliferation
  4. Local inflammatory response or dissemination
- Can also be transmitted perinatally from mother to infant
- Disseminated disease may occur.

### ETIOLOGY

*N. gonorrhoeae* (GC) is an anaerobic gram-negative bacteria.

### COMMONLY ASSOCIATED CONDITIONS

Coinfection with other STIs, particularly *Chlamydia trachomatis*

## DIAGNOSIS

### HISTORY

- A confidential, private interview with the adolescent may reveal a history of sexual activity and can allow for questioning related to contraception, number of sexual partners, and prior history of an STI, including PID.
- Common complaints include dysuria, penile or vaginal discharge, lower abdominal or suprapubic pain, and irregular menstrual bleeding.
- Many patients are asymptomatic (75–90% in women; 10–40% in men).
- Joint pain, skin rash

### PHYSICAL EXAM

- Symptomatic patients may have a penile or vaginal discharge present on physical exam.
- Females with PID may also have abdominal pain, cervical motion, and/or adnexal tenderness.
- Disseminated GC can present as a tenosynovitis, dermatitis and polyarthralgia syndrome, or as a purulent arthritis without skin manifestations. The rash most commonly presents as a maculopapular rash, with or without petechiae, on the hands and feet.

- Neonates typically present with a purulent conjunctivitis, although scalp abscesses alone can occur.
- Ill-appearing, febrile neonates with presumed GC infection may have bacteremia or meningitis.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Nucleic acid amplification technique (NAAT) testing from urine or pharyngeal specimens (males and females), vaginal or cervical specimens (females) or urethral specimens (males):
  - NAAT tests are highly sensitive and specific on endocervical, vaginal, or urine specimens from females and urethral and urine specimens from males.
  - Not all NAAT tests are FDA approved for use in all sites; in particular, they may not be approved for pharyngeal and conjunctival specimens.
- If NAAT testing is not available, GC culture using Thayer Martin medium can be used for endocervical, pharyngeal, rectal, and conjunctival specimens.
- Gram stain of eye discharge in the neonate to evaluate for intracellular gram-negative diplococci
- Gram stain of a male urethral specimen that demonstrates polymorphonuclear leukocytes with intracellular gram-negative diplococci can be considered diagnostic for infection with GC in symptomatic men; however, because of lower sensitivity, a negative Gram stain cannot rule out infection in this population.
- Gram stain of endocervical, pharyngeal, or rectal specimens are not sufficient to rule out infection.
- Culture of synovial fluid or blood cultures may be appropriate if disseminated disease is suspected.
- Testing for concurrent infection with *C. trachomatis* using NAAT techniques
- Testing for other associated infection:
  - *Trichomonas vaginalis*
  - HIV testing
  - Serum syphilis serology

#### Imaging

For females with significant unilateral adnexal tenderness or fullness, consider obtaining US to screen for tubo-ovarian abscess (see Pelvic Inflammatory Disease topic).

**DIFFERENTIAL DIAGNOSIS**

- Patients with GC who present predominantly with abdominal or pelvic pain have a broad differential including ovarian abscess or torsion, ectopic pregnancy, appendicitis, or renal calculi.
- Other STIs
- Urinary tract infection
- Vaginitis (yeast, bacterial vaginosis, other bacteria, contact)
- For disseminated disease, consider bacterial arthritis, acute rheumatic fever, connective tissue diseases, or infective endocarditis.

**TREATMENT****MEDICATION****First Line**

- Uncomplicated urogenital and anorectal infections: Ceftriaxone 250 mg IM or IV as a single dose, or cefixime 400 mg PO as a single dose
- Pharyngeal infections: Ceftriaxone 125 mg IM or IV as a single dose
- Epididymitis: Ceftriaxone 250 mg IM in a single dose
- Neonatal conjunctivitis: Ceftriaxone 25–50 mg/kg IV or IM in a single dose, not to exceed 125 mg, plus irrigation with normal saline
- Disseminated GC: Ceftriaxone 1 g IV q8h
- Meningitis or bacteremia: Ceftriaxone 1–2 g IV q12h
- Disseminated GC in neonates: Ceftriaxone 25–50 mg/kg/day IV or IM in a single daily dose for 7 days, with a duration of 10–14 days, if meningitis is documented; or cefotaxime 25 mg/kg IV or IM q12h for 7 days, with a duration of 10–14 days, if meningitis is documented.
- In addition, for uncomplicated documented GC infections of the cervix, urethra, epididymis, and pharynx, the most recent CDC guidelines recommend the addition of azithromycin 1 g PO once or doxycycline 100 mg PO b.i.d. for 7 days even if Chlamydia is documented as negative.

**Second Line**

- For penicillin-allergic patients, azithromycin 2 g PO as a single dose can be used as treatment for uncomplicated GC infection. Due to expense, a high rate of side effects, and increasing bacterial resistance, azithromycin is not routinely recommended for the treatment of GC.

- Fluoroquinolones are not routinely recommended for the treatment of gonococcal infections due to increasing bacterial resistance:
  - For patients who have severe penicillin allergies and are unable to tolerate cephalosporins, treatment with a fluoroquinolone can be considered; however, cultures rather than NAAT techniques should be used in order to obtain sensitivity data.

**DISPOSITION****Admission Criteria**

- Patients with disseminated disease or who are ill appearing should be admitted for treatment.
- Neonates with GC ophthalmia need to be hospitalized, and clinicians should have a low threshold for obtaining blood and CSF cultures.

**Discharge Criteria**

Most patients with uncomplicated GC infection can be discharged from the emergency department after receiving antibiotic treatment.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- In most areas, GC is reportable to health authorities.
- Patients treated for uncomplicated GC do not require a test of cure.
- Sexual partners who had contact with the patient within 60 days of the onset of symptoms should be treated empirically for *C. trachomatis* and *N. gonorrhoeae*.
- Patients should refrain from sexual activity until all treatment is complete.

**See Also (Topic, Algorithm, Electronic Media Element)**

- Pelvic Inflammatory Disease
- Urethritis

**CODES****ICD9**

- 098.0 Gonococcal infection (acute) of lower genitourinary tract
- 098.10 Gonococcal infection (acute) of upper genitourinary tract, site unspecified
- 098.11 Gonococcal cystitis (acute)

**PEARLS AND PITFALLS**

- Many cases of GC are asymptomatic.
- GC can present with a wide array of manifestations and has a low threshold for screening.
- Coinfection with other STIs is common.
- NAAT tests are as sensitive as GC cultures.

# GROIN MASS

Marie Waterhouse  
Deborah R. Liu

## BASICS

### DESCRIPTION

- A groin mass is characterized as a bulge or mass noted in the groin or inguinal region, with possible extension into the scrotum or labia.
- Most often due to:
  - Inguinal hernia
  - Hydrocele
  - Undescended testis
  - Inguinal lymphadenopathy or adenitis
- May rarely be caused by a variety of other conditions

### EPIDEMIOLOGY

#### Incidence

- Inguinal hernia:
  - Overall incidence in children 1–5% (1)
  - 9–11% of preterm infants
  - 30% of neonates with birth weight <1,000 g (2)
  - Male to female ratio of 6:1
  - 60% are right-sided (due to later descent of testis on the right)
- Hydrocele: 6% of term males
- Undescended testis: 3–4% of term males

#### Prevalence

5% of all males will develop an inguinal hernia during their lifetime.

### RISK FACTORS

- Hernia, undescended testis, and hydrocele are each more common in premature infants and in those with family histories of genitourinary (GU) anomalies.
- Other risk factors for inguinal hernia:
  - Cystic fibrosis
  - Connective tissue disorders
  - Conditions of increased peritoneal fluid:
    - Ascites
    - Ventriculoperitoneal shunt
    - Peritoneal dialysis

### PATHOPHYSIOLOGY

- Inguinal hernia:
  - “Indirect” hernias are the most common type found in children, resulting from a congenitally patent processus vaginalis.
  - “Direct” hernias are more common in adults and are caused by an acquired weakening of inguinal floor tissues.

- Hydrocele:
  - Congenital hydrocele results from abdominal fluid migrating into the scrotum via a patent processus vaginalis.
  - Hydrocele is most commonly confined to the scrotum, but hydrocele of the cord can be located in the inguinal canal and mistaken for a hernia.
  - Acute hydrocele may be secondary to inflammatory process, viral infection, malignancy, testicular torsion, or torsion of testicular appendage (3).

### ETIOLOGY

- Inguinal hernia
- Hydrocele
- Undescended testis
- Inguinal lymphadenopathy or adenitis (see Lymphadenopathy topic):
  - Lymphogranuloma venereum
  - Granuloma inguinale
  - Herpes simplex
- Abscess/Cellulitis
- Hematoma
- Localized allergic reaction
- Malignancy (rare):
  - Lymphoma
  - Leukemia
  - Germ cell tumors
  - Rhabdomyosarcoma
  - Neuroblastoma may metastasize to testes
  - Benign teratoma
- Hematocele (rare):
  - Adrenal or other retroperitoneal hemorrhage

## DIAGNOSIS

### HISTORY

- Unilateral or bilateral location
- Onset and duration
- Any changes in size with crying or straining
- Family history of hernias or GU anomalies
- Animal or insect bites
- Trauma to lower extremities
- Skin disorders or inflammatory conditions
- Systemic symptoms of malignancy:
  - Fever, weight loss, night sweats
- Symptoms of incarcerated hernia:
  - Colicky abdominal pain
  - Scrotal or labial pain
  - Vomiting
  - Abdominal distension
  - Cessation of stooling

### PHYSICAL EXAM

- May be done with patient laying supine with hip flexed and externally rotated (frog leg) or in standing position
- Should delineate if mass is confined to scrotum/labia or if it extends proximally into the inguinal canal
- Always confirm presence and location of both testes.
- Describe characteristics of the mass:
  - Consistency
  - Fluctuance or induration
  - Erythema
  - Mobility
  - Pain
  - Enlargement with straining or crying
  - Bluish discoloration (concerning for ischemia or necrosis)
- Exam of inguinal canal:
  - Invagination of scrotum with the examining finger toward the inguinal ring may feel a hernia bulge with straining.
  - “Silk glove sign” describes feeling of layers of patent processus vaginalis when the spermatic cord is rolled between the index finger and pubic tubercle.
- Transillumination does not reliably distinguish between hydrocele and incarcerated hernia (both may transilluminate).
- Abdominal exam is important:
  - Rebound, guarding, or other signs of peritonitis could indicate a strangulated hernia.
  - Abdominal pain and nonpalpable testis should prompt consideration of torsion of undescended testis.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Lab testing is generally not necessary for the most common causes of groin mass.
- For generalized lymphadenopathy, the following tests may be helpful for diagnosis:
  - CBC with differential, ESR, C-reactive protein
  - Lactate dehydrogenase, uric acid if suspicion for malignancy
  - PPD placement for suspicion of TB
  - Epstein-Barr virus, cytomegalovirus, toxoplasma, *Bartonella* titers
  - HIV testing
- For testicular tumor suspicious for malignancy, serum alpha-fetoprotein and serum beta-hCG should be ordered.

**Imaging**

- Abdominal radiographs:
  - For most common causes of groin mass with a benign abdominal exam, radiographs are generally not helpful.
  - May reveal loops of intestine within hernia sac
  - Multiple air-fluid levels indicate small bowel obstruction with incarcerated hernia.
  - Free air indicates bowel perforation from strangulation.
- US:
  - May distinguish between hernia and hydrocele
  - Poorly sensitive for locating undescended testis

**DIFFERENTIAL DIAGNOSIS**

See Etiology.

**TREATMENT****PRE HOSPITAL**

Ice or a cold pack may be applied to incarcerated inguinal hernia to decrease edema.

**INITIAL STABILIZATION/THERAPY**

Treatment depends on the etiology of the groin mass. Refer to appropriate topics.

**MEDICATION**

- Analgesic agents IV, IM, or PO:
  - Procedural sedation may be necessary for incarcerated inguinal hernia.
- Antibiotics:
  - Inguinal abscess or cellulitis requires antibiotics to cover skin flora (including MRSA, following regional susceptibility patterns).
  - Broad-spectrum IV antibiotics for strangulated hernia to prevent sepsis from enteric organisms
  - Adenitis from *Bartonella* usually self-resolves in the immunocompetent host:
    - Consider antibiotics only for complicated cases.

**SURGERY/OTHER PROCEDURES**

- Incision and drainage of inguinal abscess:
  - Not routinely recommended due to possibility of formation of a permanent fistula
  - May be attempted if abscess is superficial and the procedure is unlikely to damage nerves, vessels, or other structures
  - Consider US imaging or surgical consult if abscess is deeper or if diagnosis is uncertain (due to risk of associated hernia, bowel perforation, and damage to vascular or other structures).
- Manual reduction of hernia
- Inguinal hernia repair:
  - Emergent for nonreducible or strangulated hernias
  - Elective (within ~1 mo of diagnosis) for reducible hernias in term infants (3)

**DISPOSITION****Admission Criteria**

- Incarcerated hernias, if successfully reduced in the emergency department, will require admission pending surgical repair.
- Strangulated or nonreducible incarcerated hernia will require emergent surgery.
- Inguinal abscess may require IV antibiotics and surgical drainage.

**Discharge Criteria**

- Well appearing with pain adequately controlled
- Patients with hernia may be discharged from the emergency department if the mass is reducible and does not show signs of incarceration or bowel obstruction.

**Issues for Referral**

- Referral to a pediatric surgeon for timely repair of all reducible inguinal hernias.
- Some hydrocele repairs may be postponed until after age 2 yr depending on risk factors.
- Consider referral for biopsy for diagnosis of persistent lymphadenopathy >8 wk (4).

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Instruct parents of children with hernias on signs and symptoms of incarceration.
- Return to emergent medical care for any signs of bowel obstruction or incarceration.

**PROGNOSIS**

- Depends on the etiology of groin mass
- Most congenital hydroceles will resolve by age 2 yr without surgery.
- Inguinal hernia repair generally is safe and effective:
  - 10–20% incidence of developing hernia on contralateral side (1)
  - Presence of connective tissue disorder may predispose the patient to recurrence of hernia after surgical repair.

**COMPLICATIONS**

- Depends on etiology of the groin mass
- Incarceration of the hernia sac can lead to ischemic necrosis of involved structures (bowel, testis, ovary), bowel perforation, and sepsis.
- Undescended testis can be associated with increased future risk of malignancy and infertility.
- Complication rate for hernias requiring emergent surgery is higher than for manually reduced hernias repaired electively.
- Complications of hernia repair include (2):
  - Testicular atrophy (1–2%)
  - Injury to vas deferens (<1%)
  - Iatrogenic cryptorchidism (0.6–2.9%)
  - Case reports of female infertility secondary to fallopian tube injury

**See Also (Topic, Algorithm, Electronic Media Element)**

- Cryptorchidism
- Hernia
- Lymphadenopathy
- Malignancy Topics
- Scrotal Pain

**CODES****ICD9**

- 550.90 Unilateral or unspecified inguinal hernia, without mention of obstruction or gangrene
- 603.9 Hydrocele, unspecified
- 789.30 Abdominal or pelvic swelling, mass, or lump, unspecified site

**PEARLS AND PITFALLS**

- Groin masses in children are most commonly hernia, hydrocele, lymphadenopathy, or undescended testis.
- Do not incise an inguinal abscess until fully certain that the bowel or other structures are not involved.
- Emergency department manual reduction of an incarcerated inguinal hernia is often successful.
- Strangulated or nonreducible incarcerated hernias constitute a surgical emergency.

# GROUP B STREPTOCOCCAL INFECTION

Yamini Durani

## BASICS

### DESCRIPTION

- Group B streptococcus (GBS) is a leading cause of perinatal bacterial infection.
- The most important source of GBS infection in neonates is vertical transmission during delivery.
- Early-onset GBS infection usually occurs within 24 hr of birth but can occur up until 6 days of life.
- Late-onset GBS infection occurs between 7 and 89 days of life
- Late, late-onset GBS infection affects children >3 mo of age and is the least common.
- GBS disease occurring in children >6 mo of age is uncommon and may be an indicator of an underlying immunodeficiency.

### EPIDEMIOLOGY

#### Incidence

- The overall incidence of early-onset GBS disease is 0.3–0.4 cases per 1,000 live births (1,2).
- The overall incidence of late-onset GBS disease is 0.3–0.4 cases per 1,000 live births (1,2).
- Since the introduction of maternal GBS screening and intrapartum chemoprophylaxis, there has been an 80% decrease in the incidence of early-onset GBS in the U.S.:
  - There has been no change in the incidence of late-onset GBS disease in that same time frame (3).

#### Prevalence

Colonization of GBS in the genitourinary or lower GI tract occurs in up to 30% of pregnant women and in the absence of maternal chemoprophylaxis, 50% of infants acquire GBS colonization, and 1–2% develop invasive disease (4).

### RISK FACTORS

- Early-onset GBS disease: Heavy maternal colonization with GBS, prolonged rupture of membranes (ROM), intrapartum fever, chorioamnionitis, prematurity, maternal bacteriuria during pregnancy, and delivery of a previous infant who developed GBS disease (4)
- GBS virulence factors and low levels of maternal GBS type-specific IgG at delivery
- Late-onset GBS disease: Vertical or horizontal transmission (ie, newborn nursery, home, or other community sources)

### GENERAL PREVENTION

- Potential GBS vaccines for pregnant women are being researched and developed.
- As per the CDC (5), all pregnant women should be screened for GBS colonization at 35–37 wk of gestation via culture swabs of the lower vagina and rectum.

- Maternal intrapartum antimicrobial prophylaxis (IAP) is recommended if positive maternal GBS screening (unless planned cesarean delivery and no ROM), prior infant with invasive GBS disease, maternal GBS bacteriuria during pregnancy, or unknown maternal GBS status AND either delivery at <37 wk or ROM > 18 hr or intrapartum fever  $\geq 100.4^{\circ}\text{F}$  (3).
- No antibiotic therapy is indicated at the time of a positive maternal screen; only IAP has been shown to reduce early-onset GBS in the neonate (3).
- IV penicillin G is the drug of choice for maternal IAP:
  - Alternatively, IV ampicillin may be given.
  - Penicillin allergy: IV cefazolin or vancomycin (3)
- Full-term, healthy neonates are not routinely required to received prophylactic antibiotics if maternal IAP is initiated.

### PATHOPHYSIOLOGY

- Early-onset GBS disease most commonly causes sepsis, pneumonia, or meningitis.
- Late-onset GBS disease most commonly causes bacteremia without a focus or meningitis.
- Less common GBS infections: Pneumonia, osteomyelitis, septic arthritis, cellulitis and adenitis, urinary tract infection, endocarditis, otitis media, and necrotizing fasciitis (6)
- With focal GBS infections, young infants may also have GBS bacteremia and/or meningitis (6).

### ETIOLOGY

- GBS is a gram-positive, aerobic diplococci and one of the  $\beta$ -hemolytic streptococci also known as *Streptococcus agalactiae*.
- GBS serotype III is implicated in the majority of cases of early-onset meningitis and most late-onset infections (3).

### COMMONLY ASSOCIATED CONDITIONS

Persistent pulmonary HTN of the newborn is a condition that may be associated with early-onset GBS disease.

## DIAGNOSIS

### HISTORY

- In early-onset GBS disease, the clinical signs and symptoms most commonly occur within the 1st 24 hr of life:
  - History often nonspecific: Irritability, lethargy, difficulty breathing, apnea, poor feeding
  - Fever may or may not be present.
- Neonates with meningitis may or may not have localizing symptoms or signs of infection.
- In late-onset GBS disease, complaints may include fever, irritability, apnea, seizures, or lethargy.

### PHYSICAL EXAM

- Findings may include fever, tachycardia, tachypnea, respiratory distress or apnea, hypotension, hypoxia, altered mental status, irritability, and/or poor perfusion.
- Patients with osteomyelitis or septic arthritis may have decreased range of motion, swelling, tenderness, or pseudoparalysis:
  - The most common site of osteomyelitis is the proximal humerus.
- Cellulitis and adenitis often involves the face and submandibular regions.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- In the newborn nursery, neonates who are <35 wk in gestational age or who are born to mothers who received IAP <4 hr prior to delivery are recommended to have a limited workup including CBC/differential and blood culture and inpatient observation  $\geq 48$  hr (3).
- In the emergency department, neonates who have signs of sepsis (regardless of maternal IAP status) should have a CBC/differential, blood culture, urine culture, and CSF sent for cell count, protein, glucose, Gram stain, and culture (3).
- If the Gram stain shows gram-positive cocci, GBS should be strongly suspected.

#### Imaging

- CXR should be considered in:
  - Neonates with suspected sepsis
  - Patients with GBS infection, especially if there are respiratory signs or symptoms
- If osteomyelitis is suspected, consider MRI or bone scan.
- Prior to discontinuing antibiotics in infants with GBS meningitis, head CT with contrast should be performed to rule out cerebritis, ventriculitis, subdural empyema, and intracranial abscess (6).

### DIFFERENTIAL DIAGNOSIS

- Other causes of neonatal sepsis: *Escherichia coli* and herpes simplex virus
- Hyaline membrane disease
- Congenital heart disease
- Metabolic disorders
- Intracranial hemorrhage (7)

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Critically ill patients with GBS infection may require endotracheal intubation, IV fluid resuscitation, and/or inotropic support.
- Some patients may also need treatment of disseminated intravascular coagulation, seizures, and increased intracranial pressure and electrolyte disturbances.

### MEDICATION

#### First Line

- Broad-spectrum IV antibiotics initially
- Ampicillin and cefotaxime are common choices:
  - Ampicillin 50 mg/kg/dose q6h; if meningitis, 100 mg/kg/dose q6h
  - Cefotaxime 50 mg/kg/dose q8h; if meningitis 100 mg/kg/dose q8h
- Once GBS has been isolated, then IV penicillin G alone is preferred:
  - GBS is universally sensitive to penicillin; no penicillin resistance occurs.
  - Penicillin G 100,000 units/kg/dose IV q6h
  - Duration of therapy for bacteremia, sepsis, and pneumonia is 10 days:
    - For meningitis, consider repeating a lumbar puncture after 24–48 hr to ensure CSF is sterile prior to narrowing therapy to penicillin G alone.
  - GBS meningitis should be treated for 14–21 days.

#### Second Line

For suspected sepsis in neonates <3 wk old, consider empiric acyclovir therapy:

- 20 mg/kg/dose IV q8h

### COMPLEMENTARY & ALTERNATIVE THERAPIES

There is no current evidence to support the routine use of corticosteroids in GBS meningitis.

### DISPOSITION

#### Admission Criteria

- All neonates and infants with suspected GBS infection should be admitted to the hospital.
- Critical care admission criteria:
  - Patients with respiratory or hemodynamic instability
  - Consider for any neonate with suspected GBS meningitis.

#### Discharge Criteria

From newborn nursery: Neonates whose mothers received adequate IAP may be discharged home 24 hr after birth if they are  $\geq 38$  wk of gestation, are healthy appearing, will be observed reliably at home, and there is access to telephone and immediate transport to a health care facility:

- All others should be observed in the hospital for at least 48 hr.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- Neonates may be discharged once the antibiotic course has been completed and they are judged to be stable and accept PO intake without emesis.

### PROGNOSIS

- The case fatality rate of early-onset GBS disease in term infants is 3–5% and up to 20% in preterm neonates (3).
- The case fatality rate of late-onset GBS disease is 1–2% in term infants and 5–6% in preterm infants (2,8).
- Recurrent GBS disease occurs in 1–3% of treated neonates (3). This is thought to occur due to persistent colonization or reinfection.
- Infants may continue to be colonized with GBS for several months after birth and after treatment for systemic infection (3).

### COMPLICATIONS

- Patients with GBS meningitis are at risk for long-term neurologic sequelae such as deafness and motor delays.
- Up to 30% of those with meningitis may have cortical blindness, spasticity, and mental retardation (7).

#### See Also (Topic, Algorithm, Electronic Media Element)

- Arthritis, Septic
- Cellulitis
- Fever topics
- Meningitis
- Osteomyelitis
- Sepsis

#### ICD9

- 041.02 *Streptococcus* infection in conditions classified elsewhere and of unspecified site, streptococcus, group b
- 771.89 Other infections specific to the perinatal period

### PEARLS AND PITFALLS

- GBS infection is a leading cause of neonatal sepsis.
- Incidence of early-onset GBS has declined with universal screening during pregnancy.
- In addition to screening, maternal IAP is a key factor in preventing early-onset GBS infection.
- Early-onset GBS infection typically causes sepsis, pneumonia, or meningitis, while late-onset GBS infection typically causes bacteremia without a focus or meningitis.
- All neonates suspected of having sepsis should have broad-spectrum antibiotic coverage. If GBS has been confirmed by culture, then antibiotic treatment may be narrowed to penicillin G alone to complete the treatment.
- Even in the presence of focal late-onset GBS infection such as cellulitis and adenitis, many infants may have concurrent bacteremia.

# GUILLAIN-BARRÉ SYNDROME

Christopher J. Russo

## BASICS

### DESCRIPTION

- Guillain-Barré syndrome (GBS) is an acquired, inflammatory, peripheral polyradiculoneuropathy.
- Characterized by rapidly progressive, symmetric weakness and areflexia
- GBS is usually preceded by a triggering event such as an infection, which may be minor.
- GBS is the most common peripheral neuropathy affecting children.
- Several clinical subtypes are described:
  - Sporadic GBS—also termed *acute inflammatory demyelinating polyneuropathy* (AIDP)—is the most common subtype (85–90%). AIDP is an immune attack on the myelin or myelin sheaths.
  - Acute motor-sensory axonal neuropathy (AMSAN): Clinical presentation similar to AIDP but has a worse prognosis. Pathophysiology involves axonal degeneration rather than demyelination; there are no inflammatory features, as seen in AIDP.
  - Acute motor axonal neuropathy (AMAN): Similar to AMSAN; however, electrophysiologic studies show normal sensory nerve conduction velocities.
  - Miller-Fisher syndrome (MFS): Symptoms include external ophthalmoplegia, ataxia, and areflexia.
  - Chronic inflammatory demyelinating polyneuropathy (CIDP): Evolution of symptoms is slower.

### EPIDEMIOLOGY

#### Incidence

Overall incidence of 0.5–2 per 100,000 per year in those <18 yr of age

### RISK FACTORS

- Genetics: Most investigations have failed to reveal any association with certain HLA types.
- Male to female ratio of 1.5:1
- Increasing incidence with increased age
- Associated with antecedent infection with *Campylobacter jejuni*, *Mycoplasma pneumoniae*, and certain immunizations such as quadrivalent meningococcal vaccine

### PATHOPHYSIOLOGY

- GBS is an autoimmune disorder that is often preceded by an otherwise trivial infection.
- Weakness is typically most severe several weeks to 1 mo into the process.

- During the infection, complement-fixing IgG antibodies that arise to attack infection also bind to peripheral nerve gangliosides, inducing autoimmune injury:
  - AIDP: Multifocal mononuclear cell infiltration throughout peripheral nervous system. Macrophages invade myelin sheaths; demyelination occurs.
  - AMAN: Macrophages invade nodes of Ranvier, leaving myelin sheath intact. Axonal damage occurs; may cause axonal degeneration.
  - AMSAN: Similar to AMAN, but dorsal and ventral roots are affected.
  - MFS: Pathogenesis is unclear.

### ETIOLOGY

- Preceded by infection in many cases:
  - Viral infections include cytomegalovirus, Epstein-Barr, influenza, and varicella zoster.
  - Bacterial infections include *Campylobacter jejuni* and *Mycoplasma pneumoniae*.
- Surgery, childbirth, and some immunizations such as tetanus toxoid and rabies vaccine have been associated
- Often, no precipitating event can be identified.

### COMMONLY ASSOCIATED CONDITIONS

- Certain systemic illnesses such as systemic lupus erythematosus, sarcoidosis, or HIV infection are associated with GBS.
- Muscle atrophy, joint contractures, and pressure ulcers may be associated with immobility.

## DIAGNOSIS

### HISTORY

- Typical presentation includes a history of progressive, symmetric weakness of muscles and areflexia:
  - A hallmark of the weakness is that it is usually ascending from lower to upper parts of the body.
  - Weakness progresses rapidly (most reach clinical nadir by 2 wk, and almost all reach it by 4 wk).
- Other common initial presentations include difficulty ambulating, facial weakness, and extremity pain.
- Dysarthria and dysphagia may be seen.
- Some patients complain of sensory deficits.
- Many patients will have a history of antecedent illness within the prior 2–3 wk.
- Absence of fever is the rule.
- Weakness can lead to respiratory compromise in ~1 in 3 patients.
- Miller-Fisher variant involves descending weakness that initially involves the facial/bulbar musculature.

### PHYSICAL EXAM

- Autonomic dysfunction may be seen, manifested by tachycardia or HTN.
- Weakness is generally greatest in distal extremities; proximal weakness may occur. Weakness is usually symmetrical.
- Areflexia occurs in most within 1 wk of onset.
- Sensory examination is often normal.
- Cranial nerve involvement is common; facial weakness may occur in up to 50% of patients.
- Respiratory difficulty results in the need for mechanical ventilation in ~1 in 3 patients. Impending respiratory failure can often be unpredictable.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Lab tests may be used to rule out other causes of weakness.
- The hallmark of GBS is the finding of elevated CSF protein levels in the absence of pleocytosis and normal opening pressure.
- Consider other testing as indicated:
  - Botulinum assay
  - Serum electrolyte levels (hypokalemia)
  - Heavy metals and toxins (lead, mercury, arsenic)
  - Organophosphates
  - Porphyrin screen
  - Acetylcholine receptor antibodies (myasthenia gravis)
  - Creatine kinase (myositis)
  - HIV or other assays to assess for infection

#### Imaging

MRI of the brain and spine may be used to rule out a mimic of GBS (myelopathy, cord compression). MRI may also reveal engagement of involved nerve roots or cranial nerves (supporting the diagnosis of GBS).

#### Diagnostic Procedures/Other

- Lumbar puncture:
  - Elevated CSF protein without pleocytosis suggests GBS.
  - CSF may be normal within 7 days of onset of symptoms.
  - CSF glucose level is normal.
  - Opening pressure is normal.
- Electrodiagnostic testing:
  - Nerve conduction studies and electromyography may be employed in the diagnosis of GBS. These may be helpful when clinical findings, imaging, or lumbar puncture fail to clarify the diagnosis. Early electrodiagnostic studies may be abnormal in 85% of patients.

**DIFFERENTIAL DIAGNOSIS**

- Acute myelopathy (transverse myelitis, cord compression)
- Spinal cord tumor/compression
- Epidural abscess
- Vasculitic infarct
- Myasthenia gravis
- West Nile encephalomyelitis, Lyme neuroborreliosis, tick paralysis
- Acute myelitis
- Poliomyelitis
- Heavy metal toxicity (lead, mercury, arsenic)
- Acute intermittent porphyria
- Diphtheria
- HIV
- Hypokalemia, hypophosphatemia
- Myositis, rhabdomyolysis
- Botulism

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

Identify potential for respiratory failure immediately:

- Look for shallow, rapid breathing suggesting impending respiratory failure; may often be unpredictable.
- Monitor vital capacity; may require tracheal intubation and mechanical ventilation.
- Forced vital capacity (FVC) <20 mL/kg is severe, and FVC <15 mL/kg warrants endotracheal intubation.

**MEDICATION**

**First Line**

Intravenous immunoglobulin (IVIG):

- Dosing is institution dependent, with a max of 2 g/kg divided over 2–5 days.
  - 400 mg/kg/day for 5 days or 1 g/kg/day for 2 days, or 2 g/kg as a single dose
  - IVIG and plasmapheresis are equally effective. Complications are less common with IVIG.

**Second Line**

- Corticosteroids have not been shown to be beneficial and are therefore not recommended.
- Pain remains a common symptom and can be controlled with different medications:
  - NSAIDs and acetaminophen are not often helpful.
  - IV morphine 0.1 mg/kg/dose
- Antiepileptic drugs (carbamazepine, gabapentin) are well tolerated and effective:
  - Oral carbamazepine: Initial doses range from 100–200 mg b.i.d. depending on the child’s age.
  - Oral gabapentin: Initial doses are 5 mg/kg/day divided t.i.d.

**SURGERY/OTHER PROCEDURES**

- Plasmapheresis:
  - Removal of antibodies and immunoglobins from the blood
  - Patients with rapid disease progression are most likely to benefit.
- Physical therapy:
  - May help to avoid contractures by splinting lower extremities and proceed with early passive range of motion exercises.
  - Physical and occupational therapy may improve outcomes.

**DISPOSITION**

**Admission Criteria**

- Most children with newly diagnosed GBS require hospitalization, especially those who are nonambulatory, whose symptoms are rapidly progressive, or whose diagnosis remains in doubt.
- Critical care admission criteria:
  - Admission to the critical care unit should be anticipated for those who demonstrate the potential for respiratory compromise.
  - Signs of autonomic dysfunction may be a poor prognostic factor.

**Discharge Criteria**

- Patients can be safely discharged from the hospital upon completion of immunotherapy if their symptoms have stabilized.
- Inpatient rehabilitation may be necessary for optimal outcome.

**Issues for Referral**

Anticipate referral to a specialist (pediatric neurology) to optimize the medication regimen and establish an ongoing relationship with the patient and family.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

**PROGNOSIS**

- Most children (90–95%) demonstrate good recovery within 3–12 mo.
- Overall mortality is <5%.
- The need for mechanical ventilation is a poor prognostic indicator.
- Results of electrodiagnostic studies may help with the prognosis.

**COMPLICATIONS**

- Respiratory failure with the need for tracheostomy for prolonged mechanical ventilation
- Complications related to mechanical ventilation, including aspiration, pneumonia, and other infection
- Autonomic dysregulation (HTN and/or hypotension)
- Urinary retention
- Pain syndromes
- Deep venous thrombosis
- Decubitus ulcers
- Muscle wasting

**Pregnancy Considerations**

- Parturition is associated with GBS.
- Plasmapheresis may be safely carried out during pregnancy.

- Weakness

**ICD-9 CODES**

**ICD9**  
357.0 Acute infective polyneuritis

**PEARLS AND PITFALLS**

- The absence of back pain helps to distinguish GBS from other spinal cord pathology resulting in lower extremity weakness.
- Elevation of CSF protein without pleocytosis suggests GBS.
- Respiratory failure may occur rapidly.
- Reflexes may be preserved early.
- Proximal weakness may predominate early.

# GYNECOMASTIA

Maria Carmen G. Diaz

## BASICS

### DESCRIPTION

- Gynecomastia is enlargement of the male breast due to glandular proliferation.
- May be unilateral or bilateral
- May be asymmetric
- May be physiologic or pathologic (associated with underlying organic disease)
- Physiologic gynecomastia may be seen in newborns due to normal stimulation by maternal hormones.
- Physiologic gynecomastia may also be seen in males from early to mid puberty (Tanner stages 2–4).
- Prepubertal gynecomastia outside of the newborn period requires further investigation.
- Pathologic gynecomastia requires further investigation.

### EPIDEMIOLOGY

#### Incidence

- Peak incidence is in preteen and early teenage prepubertal patients.
- 3% incidence of testicular tumors in all men with gynecomastia

#### Prevalence

- 40% of all pubertal males develop transient gynecomastia during puberty.
- 60–90% of newborns (1)
- 50–70% of pubertal males (2)
- 2/3 of adolescent patients have bilateral gynecomastia.
- ~50% of all adolescents with gynecomastia have a positive family history of gynecomastia.
- >50% of patients with Klinefelter syndrome have gynecomastia (3).

### RISK FACTORS

- Altered estrogen androgen balance
- Increased net effect of estrogen action relative to androgen action

### PATHOPHYSIOLOGY

- Estrogen excess—endogenous estrogen overproduction:
  - Leydig cell tumors
  - Feminizing adrenocortical tumors
  - hCG-secreting tumors
  - Hyperthyroidism
- Drugs:
  - Androgens
  - Ethanol

- Exogenous estrogen administration:
  - Occupational
  - Dietary
  - Percutaneous absorption
- Deficiency in serum androgens:
  - Primary hypogonadism
  - Klinefelter syndrome
  - Medications:
    - Ketoconazole
    - Spironolactone
    - Metronidazole
  - Infection:
    - Mumps
    - Orchitis
  - Secondary hypogonadism:
    - Pituitary/Hypothalamic disease
    - Castration
- Altered serum androgen/estrogen ratio:
  - Chronic liver or kidney disease
- Decreased androgen action:
  - Complete and partial androgen insensitivity syndromes
  - Medications:
    - Spironolactone
    - Cimetidine (2)

### ETIOLOGY

- Physiologic:
  - Newborn:
    - Transient elevation of estrogen levels
  - Tanner stage 2–4 male:
    - Estrogen androgen imbalance
    - Estrogen levels rise sooner than testosterone levels.
    - Later in puberty when estrogen–androgen balance is restored, symptoms resolve.
- Pathologic:
  - Exogenous estrogen
  - Congenital virilizing adrenal hyperplasia
  - Leydig cell tumors of the testis
  - Sertoli cell tumor
  - Feminizing tumors of the adrenal gland
  - Hermaphroditism
  - Klinefelter syndrome
  - Prolactinoma
  - Hyperthyroidism
  - Chronic liver or kidney disease
  - Breast cancer
  - Medications

### COMMONLY ASSOCIATED CONDITIONS

- Milk production (witch's milk) in neonates
- Obesity
- Puberty
- Neoplasm

## DIAGNOSIS

### HISTORY

Detailed history should be obtained to rule out serious underlying systemic or endocrine disease in patients with suspected pathologic gynecomastia. Patients with physiologic gynecomastia should have a benign history. Key questions to ask include:

- Onset, rate of development, and duration of gynecomastia
- Associated breast pain/tenderness
- Nipple discharge
- Weight loss/gain
- Symptoms of liver/kidney disease
- Symptoms of thyroid disease
- Hypogonadism
- Medication use
- Illicit drug use
- Anabolic-androgenic steroid use
- Use of herbal products:
  - Skin and hair care products containing lavender and tea tree oil
- Occupational/Dietary/Accidental estrogen exposure
- Family history:
  - Male relatives with gynecomastia

### PHYSICAL EXAM

- Degree of virilization:
  - Voice, facial/body hair, muscular development
- Breast exam:
  - Place patient in supine position with hand behind head.
  - Examiner should grasp breast between thumb and forefinger and gradually move toward nipple.
  - With gynecomastia, the patient will have a discrete rubbery, mobile subareolar mass or diffusely tender breast (4).
  - Compare subareolar tissue with adjacent subcutaneous fat to distinguish true gynecomastia from pseudogynecomastia.
  - Look for signs of cancer:
    - Firm asymmetric breast mass
    - Nipple discharge
    - Axillary lymphadenopathy
- Genitalia:
  - Testicular size
  - Masses
  - Phallus size and development
  - Pubic hair
  - Palpate thyroid and look for stigmata of thyroid disease.
  - Stigmata of liver or kidney disease

**DIAGNOSTIC TESTS & INTERPRETATION**

**Lab**

**Initial Lab Tests**

- If physiologic gynecomastia (neonatal or pubertal gynecomastia) is strongly suspected after history and physical exam, no lab workup is necessary.
- If pathologic gynecomastia is suspected (eg, prepubertal age, presence of undervirilization, eccentric breast mass, nipple discharge, adenopathy, rapid progression of breast enlargement, testicular mass, persistence of symptoms >2 yr), consider obtaining:
  - BUN/Creatinine
  - Hepatic enzyme tests
  - Thyroid function tests
  - Serum testosterone, luteinizing hormone, follicle-stimulating hormone, prolactin
  - Serum estrogens
  - Adrenal androgens
  - Beta-hcG
  - Alpha-fetoprotein
  - Karyotype to rule out Klinefelter syndrome (2)

**Imaging**

- Testicular US for suspected testicular neoplasm in pathologic gynecomastia
- Breast US is usually not recommended unless a pathologic etiology is suspected.
- Consider CT of abdomen/adrenal glands.
- Consider cranial CT or MRI to rule out pituitary tumor.
- Mammography and fine-needle aspiration are not recommended in the diagnostic evaluation of adolescent breast enlargement (3).

**DIFFERENTIAL DIAGNOSIS**

- Pseudogynecomastia—also known as lipomastia—is fat deposition without glandular proliferation.
- Breast cancer
- Breast abscess
- Lipoma/Hemangioma/Lymphangioma/Dermoid cyst
- Hyperprolactinemia
- Hypogonadism
- Klinefelter syndrome

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

- Pseudogynecomastia:
  - Reassurance
  - Recommend weight loss, as pseudogynecomastia occurs due to deposition of adipose tissue.
- Physiologic—neonatal:
  - Reassurance
  - Symptoms will resolve in a few weeks.
- Physiologic—pubertal:
  - Reassurance
  - Symptoms will resolve within a few months to 2 yr.
  - Rarely persist beyond 2 yr (5).
  - Pathologic
    - Treat underlying disorder
    - Refer to an endocrinologist if needed.
    - Refer to a surgeon and/or oncologist if needed.

**SURGERY/OTHER PROCEDURES**

- Areolar incision or axillary incision to access breast may be used.
- Liposuction is a newer method.
- Consider surgery if:
  - Affected breast measures >4 cm (rarely spontaneously resolves) (4)
  - Breast enlargement persists for >2 yr (rarely spontaneously resolves due to the development of stromal fibrous tissue).
  - Associated with pain/discomfort
  - Severe emotional or psychological reaction (6)

**DISPOSITION**

**Admission Criteria**

- Admission usually is not required for pathologic gynecomastia.
- Consider admission for significant kidney/liver disease.
- Consider admission if malignancy is the likely etiology of gynecomastia.

**Discharge Criteria**

Most children with either physiologic (neonatal or pubertal) or pathologic gynecomastia may be treated as outpatients.

**Issues for Referral**

- Prepubertal males with gynecomastia beyond the neonatal period should be referred to an endocrinologist.
- Refer to an endocrinologist if there is evidence of an underlying pathologic condition in adolescent males with gynecomastia.
- Consult with a surgeon and oncologist if the breast or testicular exam is suspicious for malignancy or other mass.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Physiologic (neonatal and pubertal):
  - Reassurance
  - Follow up with primary care provider.
- Pathologic:
  - Discontinue offending medications.
  - Consider referral to an endocrinologist.
  - Referral for further testing

**PROGNOSIS**

Most gynecomastia resolves spontaneously:

- 75% of pubertal gynecomastia resolves within 2 yr; 90% resolves within 3 yr.
- Neonatal gynecomastia usually resolves in the 1st yr.

**COMPLICATIONS**

- Psychological stress and embarrassment
- Skin erosion of nipple due to rubbing inside clothing
- Breast cancer

**ICD9**

- 611.1 Hypertrophy of breast
- 778.7 Breast engorgement in newborn

**PEARLS AND PITFALLS**

- Patients with gynecomastia require a thorough testicular exam.
- Breast exam in physiologic gynecomastia:
  - Discrete, mobile subareolar mass
  - Diffusely enlarged, painful breast
- Breast exam in pseudogynecomastia:
  - No discrete mass palpable
- Do not overlook a medication-related cause.
- Breast exam concerning for malignancy:
  - Firm asymmetric breast mass
  - Eccentric location
  - Fixation to skin or underlying structures
  - Ulceration
  - Nipple retraction or discharge
  - Axillary lymphadenopathy
- Assess for stress level and depression in pubertal patients.

# HAIR-THREAD TOURNIQUET

Mark R. Zonfrillo

## BASICS

### DESCRIPTION

A hair-thread tourniquet occurs when a hair or an artificial thread fiber wraps around fingers, toes, or genitalia, possibly leading to tissue strangulation, necrosis, or amputation.

### EPIDEMIOLOGY

- In a review of 66 cases of hair or thread tourniquet syndrome in children:
  - 43% involved the toe
  - 24% involved the finger
  - 33% involved the genitalia
- The median age for various body parts is as follows (1):
  - Finger: 3 wk
  - Toe: 4 mo
  - Penis: 2 yr
  - Clitoris or labia: 8 yr

### RISK FACTORS

- Maternal telogen effluvium (hair loss after pregnancy)
- Mitten and glove use

### PATHOPHYSIOLOGY

- Tissue constriction leads to lymphatic obstruction, edema, venous outflow obstruction, and subsequent arterial flow restriction.
- In severe cases, tissue necrosis, bony erosion, or amputation may occur.

### ETIOLOGY

- Hair-thread tourniquets are almost exclusively accidental.
- Thread tourniquets in infants are typically caused by mittens or booties.
- Intentional fiber wrapping should be considered, since abuse by hair tourniquet has been reported (1).

## DIAGNOSIS

### HISTORY

- History of pain, redness, or swelling of a digit or genitalia.
- Irritability or inconsolable crying may be the only symptoms.
- Inquiries regarding fever, trauma, recent insect bite, or a history of sickle cell anemia may reveal an alternative diagnosis.

### PHYSICAL EXAM

- Inflammation of a digit or the penis, labia, or clitoris
- The tissue may be strangulated or necrotic.
- The hair or thread fiber may not always be visible if there is significant edema or skin reepithelialization.

### DIAGNOSTIC TESTS & INTERPRETATION

While hair-thread tourniquet is a clinical diagnosis, other conditions should be considered and individually evaluated when appropriate.

### DIFFERENTIAL DIAGNOSIS

- Infection (eg, cellulitis, paronychia, felon)
- Dactylitis
- Dermatitis
- Insect bite
- Trauma:
  - Inflicted
  - Accidental
- Ainhum (dactyololysis spontanea) involves only the 5th toe.
- Pachyonychia congenita (1,2)

## TREATMENT

- If the hair or thread is visualized, the provider can attempt unwrapping the fiber.
- For a hair tourniquet, a chemical depilatory (such as the hair-removal cream Nair® [Church & Dwight Co., Inc.]) can be used:
  - This should be applied for only 3–5 min. Chemical depilatories are contraindicated for severely inflamed or broken skin (2,3).
- The affected structures are highly sensitive, with increased pain secondary to edema and strangulation:
  - Therefore, instrumented removal of tourniquets requires adequate analgesia with topical preparations or regional nerve blocks.
- For looser fibers that cannot be unwrapped, a blunt probe can be used to expose the tourniquet, which is then cut with a scalpel or fine-tip scissors.

- For tight finger or toe fibers, an incision can be made on the lateral or dorsal aspects of the digit (3).
- For any tightly wrapped fibers refractory to removal attempts, particularly genital tourniquets, prompt surgical consultation is warranted (eg, urology or plastic surgery), and procedural sedation or general anesthesia may be necessary (1,3).

### SURGERY/OTHER PROCEDURES

Manual cutting of the hair thread:

- Usually, significant swelling makes this difficult.
- Local anesthetic administration or procedural sedation may be necessary.
- Incision at the 3 o'clock and/or 9 o'clock position is safest.
- Consider a urology consultation.

### DISPOSITION

- Since constricting bands may not always be visible after fiber removal, observing edema improvement and reperfusion is necessary prior to discharge.
- Even with successful tourniquet release, admission may be necessary for wound care.

### Admission Criteria

- Patients requiring treatment under anesthesia
- Patients with tissue breakdown or necrosis

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Caregivers should closely observe the affected area, and patients should be re-evaluated within 24 hr or sooner if symptoms persist or worsen.

### PROGNOSIS

Usually, prompt relief and full recovery occur:

- Prolonged constriction and strangulation may result in necrosis or loss of digit.

### COMPLICATIONS

- Secondary infection
- Bleeding
- Necrosis
- Amputation

## REFERENCES

### CODES

#### ICD9

- 607.89 Other specified disorders of penis
- 729.81 Swelling of limb

## PEARLS AND PITFALLS

- A high index of suspicion, careful physical exam, and prompt removal of the fiber are critical in preventing tissue necrosis or amputation.
- Unlike inflammation caused by a hair-thread tourniquet, that due to dactylitis typically involves multiple digits.
- Neurovascular status should be documented before and after tourniquet removal.
- Although rare, the provider must consider intentional wrapping from ethnic beliefs, superstitions, or deliberate physical or sexual abuse.
- Caregivers should be given anticipatory guidance about not leaving their infants' hands and feet covered for extended periods of time.

# HALLUCINOGEN POISONING

Robert J. Hoffman

## BASICS

### DESCRIPTION

- Hallucinogens are substances whose primary effects are alteration of sensory perception.
- These are drugs of abuse, though some are legal.
- LSD is the prototypical hallucinogen, others include PCP, mescaline, peyote (cactus button) psilocybin (mushrooms), *Salvia divinorum*, ketamine, dextromethorphan in cough suppressants, and others.
- Though the drug is typically taken volitionally, users may unknowingly be given the drug or may receive it unknowingly in an adulterated drug, such as marijuana laced with PCP or pills purported to contain Ecstasy (MDMA) that also contain dextromethorphan.
- Altered perception and cognition is the effect sought by users, but adverse experiences, called “a bad trip,” often result in the patient being brought to medical care.

### EPIDEMIOLOGY

#### Incidence

- Hallucinogens are widely used, though precise numbers are unknown.
- Marijuana is the most widely used drug of abuse in the U.S.

### PATHOPHYSIOLOGY

- Hallucinogens act by a variety of mechanisms, including agonism at serotonin receptors, sigma opioid receptors, kappa opioid receptors, cannabinoid receptors, and NMDA receptor antagonism.
- Serotonin syndrome may rarely result from serotonergic agonism. This includes severe, hyperthermia, muscle rigidity, and altered mental status.

- Sympathomimetic syndrome may result from adrenergic agonism. This includes HTN, tachycardia, hyperthermia, and possibly end organ injury such as stroke, myocardial dysrhythmia, or MI.
- Synesthesia is a common effect of hallucinogens in which sensory modalities are crossed, mixed, or blended:
  - During synesthesia, patients may sense that they can see sounds, etc.

### ETIOLOGY

- Marijuana
- LSD
- PCP
- Mescaline
- Peyote
- *S. divinorum*
- Dextromethorphan
- Ketamine
- Ecstasy (MDMA)

### COMMONLY ASSOCIATED CONDITIONS

- Vomiting
- Depressed consciousness
- Anxiety, agitation, or fear

## DIAGNOSIS

### HISTORY

A history is typically available from the patient or others who have brought the patient to medical care.

### PHYSICAL EXAM

- Assess vital signs and pulse oximetry:
  - Tachycardia and HTN are common as direct results of drug use as well as secondary to anxiety.
  - Slight elevation of temperature may result from psychomotor agitation.

- HEENT:
  - Miosis or mydriasis may be present depending on the hallucinogen involved.
  - Nystagmus is very common with ketamine and dextromethorphan use.
- CNS: Depressed mental status or coma may be present.
- Choreoathetosis, odd movements, and muscle stiffness or rigidity may be present with dextromethorphan or ketamine.
- Psychiatric:
  - Patients will typically have hallucinations, some of which may be very disturbing or frightening. Other significant cognitive impairment may also be present.
  - Patients may be catatonic.
  - Patients may be a threat to themselves or others.
- Diaphoresis may be present.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Assess serum glucose in any patient with altered consciousness.
- Serum electrolytes
- Drug of abuse screening typically only detects marijuana and no other hallucinogens:
  - Such testing is not recommended because it cannot be used for clinical management. Attempting to use such results for clinical management often results in misinterpretation of the assay and mismanagement.
  - Urinalysis and/or creatine phosphokinase to screen for rhabdomyolysis may be indicated in cases of psychomotor agitation.

**Imaging**

CT of the brain may be indicated if an intracranial lesion is suspected:

- This is not routinely indicated.

**Diagnostic Procedures/Other**  
Obtain ECG.**DIFFERENTIAL DIAGNOSIS**

- Sympathomimetic poisoning
- Ethanol intoxication
- Other drug intoxication
- Psychosis
- Schizophrenia

**TREATMENT****PRE HOSPITAL**

Assess and stabilize airway, breathing, and circulation:

- Protect patients from themselves; restraint may sometimes be necessary.

**INITIAL STABILIZATION/THERAPY**

- The main goals of therapy are ensuring that no other causes of symptoms, such as hypoglycemia, head trauma, etc., are etiologic.
- Once a diagnosis is established, supportive care and maintaining a safe environment are needed.
- Sedation with benzodiazepines is sometimes necessary.

**MEDICATION****First Line**

- Benzodiazepines: First-line therapy and typically the only medication needed to treat hallucinogen poisoning
  - Diazepam:
    - First-line medication for any cocaine-intoxicated patient
    - Administer for agitation, chest pain, or HTN/tachycardia
    - Initial dose 0.1 mg/kg IV, which may be repeated q5min
    - After administering a given dosage 3 times, increase the dose by doubling.

- Lorazepam 0.05 mg/kg IV, max single dose 2 mg, may be repeated q15–20min.
- Antipsychotics are not recommended in treatment of hallucinogen toxicity. The psychotic effects typically resolve very quickly after the responsible drug has been metabolized:
  - Unlike patients with ongoing psychiatric problems, hallucinogen toxicity fully resolves with no need for further treatment.

**Second Line**

Ondansetron:

- 0.15 mg/kg IV, max single dose 8 mg; may repeat q45min to a max total dose 0.6 mg/kg
- For uncommon cases of severe vomiting

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

Placing patient in a darkened, quiet room with minimal sensory stimulation is often practiced and seems to be helpful to minimize agitation, fear, and degree of medication and nursing care required.

**DISPOSITION****Admission Criteria**

- Patients with prolonged symptoms, such as might occur with those who have ingested peyote or another long-acting drug, may need admission for ongoing care until there is return to a safe baseline mental function.
- Admit for concomitant injury or medical issues.

**Discharge Criteria**

After resolution of hallucinations or psychosis, patients may be safely discharged.

**Issues for Referral**

- Refer all patients for drug counseling.
- If patients have persistent psychiatric symptoms, psychiatric consult may be needed:
  - Patients with schizophrenia often are substance abusers, and it is common that the drug use has simply unmasked an underlying psychiatric disease.

**FOLLOW-UP****PROGNOSIS**

Patients usually recover fully without sequelae.

**COMPLICATIONS**

- Injury secondary to psychomotor agitation
- End organ injury secondary to sympathomimetic effect of amphetamine-like hallucinogens
- Serotonin syndrome
- Seizure

**ADDITIONAL READING**

**See Also (Topic, Algorithm, Electronic Media Element)**

Sympathomimetic Poisoning

**CODES****ICD9**

969.6 Poisoning by psychodysleptics (hallucinogens)

**PEARLS AND PITFALLS**

- It is critical to evaluate for alternate etiologies of symptoms, such as hypoglycemia or head trauma.
- Most patients with hallucinogen toxicity require only supportive care.
- If medication is required, benzodiazepines are preferred and usually provide excellent sedation.
- Most patients may be discharged from the emergency department within 4–12 hr.

# HAND-FOOT-AND-MOUTH DISEASE

Esther Maria Sampayo

## BASICS

### DESCRIPTION

- Hand-foot-and-mouth disease (HFMD) is a viral illness characterized by:
  - Fever and malaise
  - Vesiculoulcerative enanthem in the mouth
  - Macular, papular, or vesicular exanthem on the distal extremities
- The most common causative agent is *Enterovirus*.

### EPIDEMIOLOGY

- HFMD is seen in children <10 yr of age, but most commonly is seen in children <5 yr.
- In temperate climates, most commonly summer and fall
- Highly contagious and afflicts up to 50% of those exposed
- Infection results in immunity to the specific virus that caused the illness; however, a 2nd illness may occur to a different strain of *Enterovirus*.
- Infected persons are most contagious during the 1st 2 wk of the illness with respiratory viral shedding but may be carriers for a month after the initial infection with fecal viral shedding.
- It is not transmitted to or from pets or other animals.

### RISK FACTORS

- Contact with oral and respiratory secretions, blister fluid, fecal material or aerosolized droplets in a fecal–oral or oral–oral route
- Risk factors for infection include diaper changing, poor sanitation, crowded living conditions, and low socioeconomic status.
- Children <5 yr of age are the most susceptible to infection due in part to a lack of prior immunity; HFMD is extremely uncommon in adults.

### GENERAL PREVENTION

- Good hand hygiene
- Cleaning dirty surfaces and soiled items such as toys with soap and water initially, then disinfecting them with a dilute solution of chlorine-containing bleach.
- Avoiding close contact with persons with the disease
- Standard and contact precautions in the hospitalized patient
- Breast-feeding reduces risk of infection.

### PATHOPHYSIOLOGY

- *Enterovirus* infection is acquired initially via the oral or respiratory route with viral implantation in the buccal and ileal mucosa.
- The incubation period for most enteroviral infections ranges from 3–10 days.
- Initial replication in the pharynx and intestine is followed by invasion of the lymphatic system within 24 hr.

- A primary or minor viremia results in spread to distant parts of the reticuloendothelial system, including the liver, spleen, bone marrow, and distant lymph nodes.
- The host immune response may curtail replication at this point, resulting in a subclinical infection with only fever, sore throat, and malaise.
- A secondary major viremia usually occurs to target organs such as the pharynx, the skin, the myocardium, and the meninges. It can also involve the adrenal glands, pancreas, liver, pleura, and lungs.
- Tropism to target organs is determined by the infecting *Enterovirus* serotype.
- The minor and major viremia may correlate with the biphasic appearance of fever and symptoms commonly seen with *Enterovirus*.
- Antibody production in response to enteroviral infections occurs within the 1st 7–10 days, and viremia ceases with antibody production.

### ETIOLOGY

- *Enterovirus* is the causative agent, of which coxsackievirus A16 and enterovirus 71 are the most common.
- Sporadic cases of HFMD may also be caused by coxsackieviruses A5, A7, A9, A10, B2, and B5.

## DIAGNOSIS

### HISTORY

- The disease usually begins with a low-grade fever, poor feeding and appetite, malaise, and often a sore throat or mouth.
- Occasionally, patients may have high fever, diarrhea, cough, and arthralgias.
- The enanthem is composed of painful lesions in the mouth, on the tongue, and in gingival and buccal mucosa that develop 1 or 2 days after the onset of symptoms.
- The exanthem is composed of a nonpruritic rash located on the hands and feet that also develops over 1–2 days.
- A person may only have the rash or only the mouth lesions, but both may occur simultaneously.
- Mucosal lesions heal in 5–7 days.
- Cutaneous lesions are usually present for 5–10 days.

### PHYSICAL EXAM

- Most patients with HFMD will be febrile.
- Oral lesions begin as erythematous macules that evolve into 2–3-mm vesicles on an erythematous base, appearing as a halo:
  - Vesicles are rarely observed because they rapidly become ulcerated.
  - Lesions are usually located on the palate, buccal mucosa, gingival, and tongue.
  - The tongue is involved in 44% of cases and is usually tender and edematous.
  - The total number of ulcers averages from 5–10.

- Cutaneous lesions are present in 2/3 of patients:
  - The exanthem may be macular, maculopapular, or papulovesicular and may be petechial.
  - Typically, the dorsal, interdigital aspect of the hands and feet are involved.
  - The lesions are usually elliptical in shape with the long axis of the lesion along the skin lines and start as a 2–10-mm erythematous macule on which a gray, oval vesicle develops.
  - The exanthem may also occur on the proximal extremities, buttocks, and genitalia.
- Some patients may also exhibit a mild lymphadenopathy of the cervical or submandibular glands.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- The diagnosis can be made clinically.
- Routine lab tests are not indicated.
- Although most children will not require culturing to establish the diagnosis, viral cultures from the lesions, throat, CSF, urine, or stool may be sent to classify the virus.
- Polymerase chain reaction assay is more rapid and more sensitive than cell culture and can detect *Enterovirus*.

#### Pathological Findings

- Classic histopathologic findings of HFMD include an intradermal vesicle containing neutrophils and eosinophilic cellular debris.
- The adjacent epidermis is characterized by intracellular and intercellular edema called reticular degeneration.
- The dermis has a mixed infiltrate in which eosinophilic intranuclear inclusions can be visualized with an electron microscope (1).
- Neuropathology in fatal cases of enterovirus 71 have demonstrated features of acute encephalitis involving the brain stem and spinal cord.

### DIFFERENTIAL DIAGNOSIS

- The characteristic findings of HFMD are seldom seen in other diseases. However, early in the disease, when only the exanthem or enanthem occur, the differential diagnosis includes:
  - Herpetic gingivostomatitis
  - Herpangina
  - Aphthous stomatitis
  - Stevens-Johnson syndrome
  - Boston exanthem:
    - The causative organism is echovirus 16.
    - Mild febrile illness with macular rash on the face, trunk, palms, and soles accruing at the time or after defervescence
    - Oral lesions absent
  - Varicella

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Severe cases may require administration of IV fluid to treat dehydration.
- Most cases will resolve spontaneously and require no therapy other than parental reassurance.

### MEDICATION

- Antipyretic/Analgesic
- Acetaminophen 15 mg/kg PO/PR q4h PRN for fever or pain
- Ibuprofen 10 mg/kg PO q6h PRN for fever or pain
- Codeine 0.5–1 mg/kg/dose PO q4–6h PRN for pain

### ALERT

Viscous lidocaine is not recommended for use in young children who are unable to swish and spit due to risk of lidocaine toxicity.

### COMPLEMENTARY & ALTERNATIVE THERAPIES

Symptomatic relief from topical application of “magic mouthwash” composed of a 1:1 mixture of diphenhydramine and magnesium/aluminum hydroxide

### DISPOSITION

#### Admission Criteria

Signs of dehydration or neurologic/respiratory compromise

#### Discharge Criteria

- Most children will not require hospitalization.
- Patient is well hydrated and tolerating oral fluid intake.
- No signs of dehydration, meningitis, respiratory distress, or other serious bacterial infection

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- HFMD generally self resolves within 7–10 days.
- Antipyretics and pain medications such as acetaminophen or ibuprofen may be prescribed.
- Topical solutions such as a 1:1 mixture of diphenhydramine and magnesium/aluminum hydroxide may be prescribed as well.
- Small children must be followed closely for signs of dehydration.

### DIET

- Avoid spicy foods.
- Avoid acidic foods such as orange juice.
- Encourage cool fluids such as popsicles in frequent, small aliquots.

### PROGNOSIS

HFMD is self-limited and generally has a mild course.

### COMPLICATIONS

- The most common complication is dehydration.
- Although not part of HFMD, other rare complications of enteroviral infections include:
  - Aseptic meningitis
  - Myocarditis
  - Pneumonia
  - Enterovirus 71 has the potential to cause severe CNS disease such as meningoencephalitis and acute flaccid paralysis.
- Fatal cases of encephalitis or pulmonary hemorrhage caused by enterovirus 71 have occurred during outbreaks.
- Infection in the 1st trimester of pregnancy may lead to spontaneous abortion or intrauterine growth retardation.

## CODES

### ICD9

074.3 Hand, foot, and mouth disease

### PEARLS AND PITFALLS

- HFMD is characterized by the clinical features of vesiculoulcerative stomatitis, papular or vesicular exanthem on the palms and/or soles, and mild constitutional symptoms of fever, malaise, sore mouth/throat, and poor feeding.
- Unlike herpetic gingivostomatitis, vesicles associated with HFMD are more often located in the posterior pharynx and less often affect the gingiva.
- The illness is usually mild and self-limiting.
- A small proportion of cases, especially those caused by enterovirus 71, develop severe systemic disease with respiratory, encephalitic, or polioli-like features that have a significant mortality.
- HFMD is not to be confused with foot-and-mouth disease (also called hoof-and-mouth disease), which is a disease affecting sheep, cattle, and swine.

# HEADACHE

Denise G. Karasic

## BASICS

### DESCRIPTION

Headache (HA) is a pain in the head involving the intracranial contents, skull, or scalp.

### EPIDEMIOLOGY

#### Incidence

- HA is common in children and adolescents.
- The incidence of migraine HA peaks earlier in boys (7 yr of age) than in girls (11 yr) (1).
- Adolescent females have a higher incidence of migraines compared to their male counterparts (1).

#### Prevalence

- The prevalence of HA of any etiology can range from 37–51% in 7 yr olds to 57–82% in adolescents (2).
- Migraine HA has a prevalence of 3% in preschool children and increases to 11% in those in grade school and 23% for high school (2).

### RISK FACTORS

- Concussion
- Stress
- Sleep deprivation
- Impaired visual acuity
- Family history of migraines
- Caffeine consumption/withdrawal

### GENERAL PREVENTION

- Immunizations to prevent diseases that may cause meningitis or influenza
- Children wearing helmets can prevent injury and may lessen the severity of posttraumatic migraines.
- Avoidance of migraine triggers such as certain foods, sleep deprivation, and stress may decrease the severity and frequency of these HAs.
- Corrective lenses may alleviate HAs caused by visual deficits.
- Avoiding exposure to lead
- Carbon monoxide detectors can alert families to increased levels of carbon monoxide.
- Temporomandibular joint (TMJ) dysfunction may be alleviated with correction of dental malalignment.

### PATHOPHYSIOLOGY

- There are multiple types of HA that likely have different etiologies:
  - Tension, migraine, and cluster HAs are the most commonly recognized types.
- Vascular:
  - Vasodilation has been implicated as the cause of migraine HA. This theory is no longer widely held. A brain-centered sensory processing disturbance of the subcortical aminergic modulating systems is the accepted present theory. Brainstem hypothalamic and thalamic structures are thought to play a primary role in the expression of migraine HA (3).
  - Other vascular causes include systemic HTN.

- Muscle contraction
- Inflammation caused by intracranial, dental, or sinus infections
- Traction/Compression: Secondary to increased intracranial pressure caused by cerebral edema, hydrocephalus, intracranial hemorrhage or hematoma, brain abscess, or pseudotumor cerebri
- Traction/Compression secondary to tumor or following a lumbar puncture
- Posttraumatic/Concussion
- Ocular
- Psychogenic
- Occipital neuralgia
- Caffeine withdrawal

### ETIOLOGY

- Migraine HA is very commonly an inherited disorder (3).
- Patients with migraines commonly have a 1st-degree relative with migraine HA (3).
- The age of onset and characteristics of the migraine may be similar in the child and the 1st-degree relative.

### COMMONLY ASSOCIATED CONDITIONS

- Intracranial infection
- Intracranial bleeding
- Sinusitis
- Dental infections
- Brain tumor
- HTN
- Hydrocephalus
- Increased intracranial pressure

## DIAGNOSIS

### HISTORY

- A concise history is key to determining the etiology of the HA:
  - When did the HA start?
  - Was there an aura prior to the onset of the HA?
  - Was the onset of the HA rapid or gradual?
  - What was the patient doing at the onset of the HA?
  - Was there head trauma?
  - Is this a 1st sudden HA?
- Past medical history:
  - History of similar HA?
  - What is the frequency of HA?
  - Have HAs become more frequent or worse?
  - Is the quality of each HA different or the same?
  - Description and intensity of usual HA?
  - Precise location of pain, if focal?
  - Are there usually associated symptoms such as vomiting, dizziness, numbness, motion sickness, inability to read in a moving car, weakness, eye tearing, or nasal drainage?
  - Does the patient typically experience HA with the menstrual cycle?
  - What usually worsens or improves the HA (including medications)?

- Have school or other activities been missed due to HAs?
- What triggers the HAs?
- Other medical problems?
- Family history (especially in 1st-degree relatives) of HAs?

### PHYSICAL EXAM

- Complete set of vital signs including BP
- Complete physical exam including a neurologic exam
- Careful inspection for sinusitis or dental caries
- Check for meningeal irritation such as nuchal rigidity or Kernig or Brudzinski signs.
- Careful ophthalmologic exam including visual acuity and visualization of the retina. Papilledema is a clue to increased intracranial pressure, as might be seen with pseudotumor cerebri.
- Retinal hemorrhages in infants and small children may indicate nonaccidental trauma (eg, shaken baby syndrome) or the presence of subarachnoid hemorrhage.
- Head circumference in infants

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- The diagnosis of HA is usually evident from the history and exam without a need for further testing.
- Patients suspected to have meningitis or encephalitis require lumbar puncture.
- Patients with suspected pseudotumor cerebri should have an opening and closing pressure measured.
- Patients with papilledema should have a head CT or MRI prior to lumbar puncture.
- Carbon monoxide or lead levels should be obtained in patients with HA and a possible risk of exposure.

#### Imaging

- Generally no imaging is necessary:
  - Families and sometimes referring physicians will strongly prefer imaging such as CT of the brain.
  - Imaging should be performed based on need and appropriate risk:benefit ratio rather than on parental pressure or preference.
- Patients with HA and a focal neurologic exam should have a CT or MRI of the brain performed.
- Also consider neuroimaging in patients with:
  - 1st or worst HA (4)
  - HA worst on 1st awakening or waking child from sleep (4)
  - HA worsens with straining or cough (5)
  - Chronic progressive HA (4)
  - HA awakens patient from sleep (4,5)
  - HA associated with stiff neck and no fever (5)
  - Progressive worsening HA (4)
  - HA not responding to treatment (4)
- Those with suspected migraine HA and a non focal neurologic exam do not need emergent neuroimaging in the emergency department.
- Patients with HA and suspicion of stroke should have MRI, MRA.
- Patients with head injury or suspicion of acute intracranial bleed should have an emergent CT scan of the head. Bleeding is better visualized on a head CT compared to an MRI.
- Consider imaging for suspected extracranial causes such as sinusitis and dental abscesses.

**Diagnostic Procedures/Other**

Administration of oxygen is diagnostic and therapeutic for cluster HA:

- Uncommon in pediatrics, this is HA with intense focal pain perceived behind eye.

**DIFFERENTIAL DIAGNOSIS**

- See Commonly Associated Conditions for a list of diagnoses related to HA.
- HA may be due to an intracranial, skull, or scalp abnormality.
- Consider extracranial causes of HA as listed in the Pathophysiology section.

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Initial management is supportive with maintenance of the airway, breathing, and circulation and cervical spine immobilization if trauma is suspected.
- Careful administration of IV fluids in patients with vomiting

**MEDICATION****First Line**

- Antipyretics may resolve HA caused by fever.
- Migraine sufferers may report specific medications that tend to provide relief for them.
- Generally, therapy for tension or migraine HA involves use of NSAIDs or acetaminophen, with escalation to antiemetics or triptans based on institutional and clinician preference in conjunction with any previous successful treatment regimen for individual patient:
  - Opioids should not be routinely used in the acute treatment of migraine HA (6).
- Initial first-line medications:
  - Often, patients will already have attempted use of these medications prior to the emergency department visit.
- NSAIDs:
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Ketorolac 0.5 mg/kg IV/IM q6h PRN (7)
  - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

**Second Line**

- First-line NSAID/acetaminophen therapy is often inadequate.
- Subsequent choice is based on clinician and consultant preference in conjunction with any past regimen effective for the patient.
- Antiemetics:
  - Commonly provides full relief for migraine HA and also alleviates nausea or vomiting if associated with HA.
  - Metoclopramide 0.01 mg/kg IV (max single dose 10 mg) q8h:
    - Administered over period of time not <30 min to prevent akathisia
    - Diphenhydramine 1.25 mg/kg/dose PO/IV q6h sometimes is used to prevent akathisia.
  - Prochlorperazine 0.15 mg/kg IV single dose
  - Ondansetron 0.15 mg/kg/dose IV:
    - Use for HA is off-label, but vast pediatric experience with administration and excellent safety profile warrant use.

- Sumatriptan:
  - >30 kg: 6 mg SC; may repeat after 1 hr if pain persists. Limit use to 12 mg/24 hr:
    - Use in children <30 kg is not recommended.
    - Triptans are not FDA approved in patients <12 yr of age but are widely used off-label.
    - Do not combine different triptan regimens in same 24-hr period (6).
    - Do not combine with ergot treatment.
- IV valproate (15 mg/kg IV × 1 dose, max single dose 100 mg, infused over 15–20 min) may be used as second-line therapy for treatment of migraines (7).

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Corticosteroids are often used or recommended by pediatric neurologists. Consider use if recommended by the consulting pediatric neurologist.
- Ergotamine occasionally is used, but alternatives such as valproate or triptans are preferred:
  - Poor safety profile and poor efficacy limit circumstances in which use is appropriate

**DISPOSITION****Admission Criteria**

- Persistent, severe HA that cannot be resolved with emergency department treatment
- Critical care admission criteria:
  - Hemodynamically unstable patients with HA (eg, bleed, mass effect, cerebral edema) will require admission to an ICU.

**Discharge Criteria**

Pain eliminated or abated to acceptable level

**Issues for Referral**

- Neurology consult if stroke is suspected
- Neurosurgery should be consulted emergently for an acute intracranial bleed or mass.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- If effective, HA can be treated with acetaminophen or ibuprofen.
- For patients with migraine: Maintain good sleep habits, avoid caffeine, avoid known triggers, and use first-line medication such as ibuprofen at the 1st sensation of HA.
- Medication such as intranasal triptan may be prescribed if effective in the emergency department.
- Initiation of prophylactic medications for migraines should be done only after discussion with a neurologist.
- A “HA diary” documenting the frequency and severity of HA may be helpful at follow-up with the primary care physician or neurologist.

**PROGNOSIS**

Migraine HAs tend to be recurrent; most other etiologies are associated with full recovery once the underlying cause is treated.

**COMPLICATIONS**

Vary depending on underlying etiology

- Meningitis
- Migraine Headaches
- Pseudotumor Cerebri

**ICD9**

- 339.10 Tension type headache, unspecified
- 346.90 Migraine, unspecified, without mention of intractable migraine without mention of status migrainosus
- 784.0 Headache

**PEARLS AND PITFALLS**

- The primary concern of patients, family members, and clinicians evaluating patients with HA is that the HA is caused by a mass or other structural abnormality. Brain lesions are rare causes of acute HAs.
- A complete history is the most important factor in determining the etiology of HA.
- Most children in the emergency department with HA do not need emergent neuroimaging.
- For patients with migraine, offer advice to maintain good sleep habits, avoid caffeine, avoid known triggers, and use first-line medication such as ibuprofen at the 1st sensation of HA.

# HEARING LOSS

Deborah R. Liu  
Benjamin Heilbrunn

## BASICS

### DESCRIPTION

- Hearing loss is an uncommon chief complaint in the pediatric emergency department.
- This topic will focus on acquired causes of hearing loss, especially acute causes.
- However, because patients seek treatment for nonurgent complaints through the emergency department, the emergency physician may need to be familiar with general knowledge related to hearing loss. As congenital and chronic causes may initially present to the emergency department, an overview of the various etiologies will be included.
- Hearing loss can be divided into:
  - Mild: Difficulty keeping up with conversations
  - Moderate: Difficulty keeping up with conversations if not using a hearing aid
  - Severe: Relies on lip reading and sign language
- Noise-induced hearing threshold shifts:
  - Increase in the threshold of audibility for an ear caused by prolonged, excessive noise
  - Previously thought to occur mainly in adults whose occupations exposed them to excessive levels of noise
  - Now recognized as causing hearing loss in people of all ages from exposure to musical concerts, fireworks, snowmobiles, lawn mowers, toys, etc.
- The emergency provider can readily perform a Weber or Rinne test (see Physical Exam section) to determine if the hearing loss is conductive or sensorineural and thus narrow the list of possible diagnoses. Therefore, this categorization will be used in this topic.

### EPIDEMIOLOGY

#### Incidence

The average incidence of neonatal hearing loss in the U.S. is 1.1 per 1,000 infants.

#### Prevalence

Of U.S. children 6–19 yr of age, 12.5% are estimated to have noise-induced hearing threshold shifts (1).

### PATHOPHYSIOLOGY

Types of hearing loss:

- Conductive hearing loss occurs when there is no conduction through the ear canal, ear drum, or middle ear (eg, otitis media, otitis externa, trauma, and tumors).
- Sensorineural hearing loss occurs with damage to the inner ear or auditory nerve (eg, infections, toxins, and noise exposure).
- Mixed hearing loss is a combination of conductive and sensorineural hearing loss.

### ETIOLOGY

- Congenital hearing loss:
  - Conductive: Prenatal use of ototoxic medications
  - Sensorineural:
    - Cytomegalovirus
    - Herpes simplex virus
    - Rubella
    - Syphilis
    - Toxoplasmosis
    - Prenatal exposure to:
      - Alcohol
      - Trimethadione
      - Methylmercury
    - Prenatal iodine deficiency
- Acquired hearing loss:
  - Conductive:
    - Otitis externa
    - Otitis media
    - Impacted cerumen
    - Foreign body
    - Trauma:
      - Direct trauma
      - Temporal bone fractures
      - Blast injury
      - Barotrauma
      - Myringotomy tubes
    - Tumors/Growths:
      - Cholesteatoma
      - Otosclerosis
      - Squamous cell carcinoma
      - Langerhans cell histiocytosis
    - Sensorineural:
      - Neonatal ICU infants
      - Infectious causes:
        - Bacterial meningitis
        - Mumps
        - Measles
        - TB
      - Ototoxic substances:
        - Antibiotics, including aminoglycosides, erythromycin, vancomycin, and tetracycline
        - Chemotherapeutics, including cisplatin and bleomycin
        - Aspirin
        - Antimalarial drugs, such as quinine and chloroquine
        - Lead

- Noise induced (1):
  - May be caused by continuous exposure to noise or by short exposure to extremely loud levels of noise
  - Temporary threshold shifts: Transient hearing loss that may take several hours to recover
  - Permanent threshold shifts: Repeated exposure to damaging sounds
  - Acoustic trauma: Refers specifically to short, high-level noise exposure from explosions, gunfire, or firecrackers
- Tumor/Growths: Acoustic schwannoma
- Perilymph fistula: Characterized by sudden or rapidly progressive unilateral hearing loss
- Other causes:
  - Hypothyroidism
  - Ménière disease (triad of hearing loss, tinnitus, vertigo)

## DIAGNOSIS

### HISTORY

- Determine the onset and progression of hearing loss.
- Unilateral or bilateral
- Associated symptoms such as:
  - Pain
  - Tinnitus
  - Vertigo
  - Bleeding
  - Fever
- Determine if the patient has a history of normal, age-appropriate auditory responses.
- Determine if any family history of hearing loss exists.
- Determine the past medical history, paying particular attention to risk factors mentioned previously.

### PHYSICAL EXAM

- Special attention should be given to the head and neck exam:
  - Abnormal facial features (hypertelorism, microcephaly, hypoplasia of facial structures, heterochromia of irises)
  - Cleft lip or palate
  - Malformations of the ear, including dimpling or skin tags
  - Abnormalities of the tympanic membrane (otitis media, perforation, cholesteatoma, hemotympanum)
- Hearing test: Use 256-Hertz (Hz) and 512-Hz tuning forks:
  - Weber test: Strike the tuning fork and then place on the bridge of the forehead, nose, or teeth. Ask the patient if the sound is louder in 1 ear or the other:
    - Normal hearing: Equal bilaterally
    - Conductive hearing loss: Vibratory sound is louder on the “bad” side.
    - Sensorineural hearing loss: Vibratory sound is louder on the “good” side.

- Rinne test: Compares bone conduction (strike and place the tuning fork on the mastoid bone) to air conduction (strike and hold the tuning fork lateral to the external ear canal):
  - Normal hearing: Air conduction > bone conduction
  - Conductive hearing loss: Bone conduction > air conduction
  - Sensorineural hearing loss: Rinne test not as helpful, as both air and bone conduction may be decreased proportionally

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

- Routine lab evaluation is generally not helpful.
- Specific lab testing should be guided by clinical suspicion of underlying disease and is usually not necessary in the emergency department (eg, TORCH titers in neonates, urinalysis if Alport syndrome is suspected).

### Imaging

- The need for emergent imaging is based on acuity of symptoms. Most subacute causes of hearing loss do not require emergent imaging.
- CT scan may be necessary emergently to detect:
  - Structural abnormalities such as masses or growths
  - Temporal bone fractures
- CXR may be necessary to evaluate associated pulmonary barotrauma in blast injuries.
- MRI: Patients may be referred for outpatient study:
  - Tumor
  - Lipoma
  - Fistula

### Diagnostic Procedures/Other

Referral for audiology evaluation:

- Performed as outpatient by trained specialist
- Evoked otoacoustic emissions
- Automated auditory brainstem response: Gold standard hearing test for infants <6 mo old

### DIFFERENTIAL DIAGNOSIS

See Etiology section for a list of differential diagnoses.

## TREATMENT

Therapy and treatment is determined by the underlying cause of hearing loss. The following is an abbreviated description of treatment:

- Blast injury with temporary threshold shifts:
  - Ruptured tympanic membranes:
    - CXR
    - Observe for 8 hr.
    - Avoid probing or irrigation of the ear canal.
    - Keep the ear canal dry by inserting a petroleum jelly-soaked cotton ball into the ear before bathing; avoid swimming.
    - Small perforations typically heal within a few weeks. Failure to heal with continued hearing loss requires outpatient subspecialty referral.

- Temporal bone fractures require prompt surgical evaluation for possible operative intervention.
- Barotrauma:
  - Auditory canal barotrauma
    - Topical antibiotics (see Medication section)
    - Topical analgesic
  - Middle ear barotrauma:
    - Symptomatic treatment
    - Resume diving/flying after middle ear contusion and tympanic membrane perforation have healed.
  - Inner ear barotrauma:
    - Bed rest for 7–10 days
    - Avoid strenuous activity for 6 wk.
    - Attempt to sneeze through an open mouth.
    - Use laxatives to avoid excessive Valsalva during defecation.
    - Consider corticosteroids.

## MEDICATION

- Topical antibiotic:
  - Neomycin/Polymyxin B/hydrocortisone: 2 drops q3–6h × 7 days. Use suspension for tympanic membrane perforation.
  - Ciprofloxacin/Dexamethasone: 4 drops b.i.d. × 7 days
  - Ofloxacin 3% otic drops: 5–10 drops b.i.d. × 10 days
- Topical analgesic:
  - Benzocaine/Antipyrine: 2 drops q4h PRN
  - Use with caution for tympanic membrane perforation.
- See the Otitis Media or the Otitis Externa topic for oral antibiotic dosing.

## DISPOSITION

### Admission Criteria

Depends on etiology

### Issues for Referral

- Most children with hearing loss require subspecialty evaluation for further workup.
- Because language and cognitive development depend greatly on hearing, patients should be instructed to seek subspecialist evaluation as soon as possible, such as with:
  - Formal audiology evaluation
  - Speech pathologist evaluation
  - Otorhinolaryngology
  - Genetics

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

See the Issues for Referral section.

## REFERENCE

- Meningitis
- Otitis Externa
- Otitis Media

### ICD9

- 388.12 Noise-induced hearing loss
- 389.00 Conductive hearing loss, unspecified
- 389.9 Unspecified hearing loss

## PEARLS AND PITFALLS

- Most causes of hearing loss in children do not require an emergent workup.
- Acute hearing loss due to blast injury or barotrauma does require an emergent evaluation, including an evaluation for associated traumatic injuries.

# HEART BLOCK

Parul B. Patel

## BASICS

### DESCRIPTION

- Heart block is an abnormal transient or permanent conduction of the electrical impulses of the heart between the atria and ventricles through the atrioventricular (AV) node and the bundle branches.
- 1st-degree AV block is a slight delay of the electrical conduction and is manifested by the prolongation of the PR interval.
- 2nd-degree AV block occurs when the conduction is intermittently blocked. It was 1st described by Wenckebach and later divided by Mobitz into 2 types:
  - Mobitz type I (Wenckebach) block is progressive prolongation of the PR interval until a ventricular beat is dropped.
  - Mobitz type II block is when the PR interval is constant with a sudden dropped ventricular beat and often occurs in a pattern (eg, 2:1, 3:2).
- 3rd-degree AV block occurs when the electrical conduction from atria to ventricle is completely blocked. It can be congenital or acquired.
- Bundle branch blocks (BBBs) occur at the bundle branch system that arises between the membranous and muscular system.

### EPIDEMIOLOGY

#### Incidence

Incidence of congenital complete AV block is reported to be between 1/15,000 and 1/25,000 births and may present as familial clusters (1).

#### Prevalence

Prevalence of cardiac conduction disturbances in elementary and high school students without congenital heart disease (CHD) is 0.75% (2):

- Prevalence is 0.48% among elementary school students and 0.97% among junior high school students (2)
- Higher in males than females (0.78% vs. 0.71%)

### RISK FACTORS

- 1st-degree heart block:
  - Normal variant in older children and athletes
  - Infectious conditions: Rheumatic fever, Lyme disease, myocarditis, trichinosis, diphtheria, rubella, mumps, Chagas disease
  - CHD: Endocardial cushion defects, Ebstein anomaly of the tricuspid valve
  - Hypothermia or increased parasympathetic tone
  - Electrolyte abnormalities
  - Duchenne muscular or myotonic dystrophy
  - Kearns-Sayre syndrome
- 2nd-degree heart block:
  - Those with high vagal tones such as athletes
  - Underlying heart disease such as myocarditis, Chagas disease
  - Ischemia
  - Cardiac surgery
  - Drugs that block the AV node
  - Neuromuscular disease (muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy)
  - Idiopathic

- 3rd-degree heart block:
  - Infectious disease such as myocarditis
  - Inflammatory such as Kawasaki disease
  - Maternal and neonatal systemic lupus erythematosus (SLE)
  - Structural cardiac defect
  - Cardiac surgery

### PATHOPHYSIOLOGY

AV block can be due to physiologic or pathophysiologic causes such as congenital conditions, increased vagal tone, fibrosis of the conduction system, structural heart defects, cardiomyopathy and myocarditis, ischemic heart disease, or iatrogenic causes such as drugs and cardiac surgery (3).

### ETIOLOGY

- See Risk Factors.
- Etiology of congenital complete heart block is unclear but may be associated with maternal collagen vascular abnormalities such as in SLE and abnormal embryonic development of the AV node from AV canal musculature (1).
- In children and adolescents, the most common cause of right BBB is cardiac surgery such as ventricular septal defect repair or subpulmonary excision of the tissue such as in tetralogy of Fallot:
  - It may also be due to inflammation such as in myocarditis or endocarditis.
- Left BBB is rare in children and adolescents and is mainly caused by surgery of the aortic valve or subvalve.
- Cardiotoxins such as digoxin, lithium, beta-blockers, calcium channel blockers, and antidysrhythmics may cause heart block.

### COMMONLY ASSOCIATED CONDITIONS

Adams-Stokes syndrome with type II 2nd-degree heart block

## DIAGNOSIS

### HISTORY

- Symptoms of decreased cerebral blood flow (syncope, dizziness, irritability)
- Symptoms of decreased coronary blood flow (chest pain, shortness of breath)
- Older children may have symptoms of rhythm disturbance perceived by the child (palpitations, skipped beats)
- Fatigue
- Exercise intolerance
- Symptoms of CHF including fatigue and respiratory distress
- Family history of arrhythmias or maternal SLE
- Any history of CHD, cardiac surgery, or use of cardiac medications

### PHYSICAL EXAM

- All infants with congenital heart block have bradycardia.
- Signs of CHF and shock such as hepatomegaly, gallop rhythm, rales, pallor, cyanosis, weak pulses, decreased perfusion, peripheral edema, and hypotension
- May be able to auscultate murmurs associated with CHD or heart failure. A flow murmur may be heard due to increased stroke volume.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Basic metabolic panel including calcium and magnesium may be useful to rule out any electrolyte abnormalities.
- Arterial blood gas for patients in CHF may show metabolic acidosis and hypoxemia.
- Consider a toxicology screen if an intentional medication ingestion is suspected.
- Have a low threshold for screening for Lyme disease in a child presenting with unexplained heart block.

#### Imaging

- Prenatal echo is useful in diagnosing congenital heart block in utero and looking for hydrops associated with CHD.
- For patients presenting with signs of shock and CHF, a CXR may reveal cardiomegaly and/or increased pulmonary vascular markings.
- Bedside echo in critical patients may also delineate any underlying heart disease.

#### Diagnostic Procedures/Other

- ECG will demonstrate what degree of heart block is present.
- A 24-hr continuous monitoring of cardiac conduction may be needed to capture transient and infrequent episodes of heart block.
- Exercise testing is an important adjunct in the evaluation of the asymptomatic child with congenital complete AV block.

#### Pathological Findings

In congenital heart block, most patients have fibrous tissue that either replaces the AV node or the surrounding tissue.

### DIFFERENTIAL DIAGNOSIS

Rarely, other ECG abnormalities such as prolonged QT syndrome or blocked premature atrial complexes may be confused with heart block.

## TREATMENT

### PRE HOSPITAL

Assess and stabilize airway, breathing, and circulation.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- IV access should be established in all patients who are symptomatic and in asymptomatic patients with complete heart block.

### MEDICATION

- Epinephrine and chronotropic agents such as isoproterenol and atropine may be used if a patient with complete heart block shows signs of cardiogenic shock.
- While waiting for the isoproterenol infusion:
  - Atropine 0.02 mg/kg IV/IO, min dose 0.1 mg, max single dose child 0.5 mg, max single dose adolescent 1 mg OR
  - Epinephrine 0.01 mg/kg (0.1 mL/kg) 1:10,000 IV/IO, max single dose 1 mg
  - Due to safety and fewer dosing errors, atropine is preferable.
- Isoproterenol can be given as an infusion at 0.05–2 µg/kg/min
- Adequate intravascular volume should be maintained during isoproterenol infusion because its vasodilatory effect may cause a decrease in BP.
- If a toxin-induced etiology, specific therapy may be indicated. Consult a toxicologist or a poison control center:
  - Standard therapies of atropine, epinephrine, or isoproterenol are ineffective in these cases.
  - Digoxin Fab: Digoxin-induced heart block
  - Saline diuresis: Lithium-induced heart block
  - Glucagon: Beta-blocker–induced heart block
  - Calcium, insulin/glucose infusion: Calcium channel blocker–induced heart block

### COMPLEMENTARY & ALTERNATIVE THERAPIES

External transcutaneous cardiac pacing may be appropriate in an emergency situation for patients who are not responding to medical management.

### SURGERY/OTHER PROCEDURES

- Definitive treatment of type II 2nd-degree AV block is an implantable pacemaker.
- Pacemaker is also the treatment for a neonate with complete congenital heart block and older children presenting with complete heart block whose activity is severely restricted.
- Permanent pacing may not be needed in all cases of complete heart block; resolution is most likely in inflammatory conditions such as myocarditis.

## DISPOSITION

### Admission Criteria

Critical care admission criteria:

- All newborns with congenital complete AV block should be admitted to the ICU.
- Any patient who is in CHF should be placed in the ICU.

### Discharge Criteria

- Asymptomatic patients with 1st-degree AV block may be discharged from the emergency department.
- Asymptomatic patients with 2nd- or 3rd-degree AV block should be evaluated in the emergency department by a pediatric cardiologist prior to emergency department discharge.

### Issues for Referral

- All patients with 2nd- and 3rd-degree heart block should be followed by cardiology.
- Consider cardiology evaluation for those with 1st-degree heart block.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

#### Patient Monitoring

Outpatients must be closely monitored by cardiology and told to seek medical attention if they have chest pain, palpitations, shortness of breath, or syncope.

### PROGNOSIS

- Infants with complex CHD and heart block in utero who survive birth have a high prenatal and neonatal mortality rate (3).
- Infants with 1st- or 2nd-degree heart block at birth can progress to complete heart block (3).
- Infants and children with complete heart block who are asymptomatic usually remain so until later in childhood or adulthood but are at risk for sudden death.
- Prognosis following pacemaker placement is excellent, but 5–11% may develop heart failure over the long term (3).

### COMPLICATIONS

Sudden death is a complication of type II 2nd-degree and complete heart block.

- Syncope

### ICD-9 CODES

- 426.9 Conduction disorder, unspecified
- 426.10 Atrioventricular block, unspecified
- 426.11 First degree atrioventricular block

## PEARLS AND PITFALLS

- 1st-degree AV block and type I 2nd-degree heart block are often incidental findings with little clinical significance.
- 1st- or 2nd-degree AV block in neonates can progress to complete heart block (3).
- Type II AV block, although uncommon in children, usually progresses to complete heart block and may be associated with sudden death (1).
- The most common lesion associated with congenital complete AV block is L-transposition of the great arteries with ventricular inversion (1).
- BBBs and fascicular blocks are rare in the pediatric population but may be seen in patients after surgery for CHD (1).
- Up to 40% of infants and young children with complete heart block do not present until later in childhood, with a mean age of 5–6 yr (3).
- Have a low threshold for screening for Lyme disease in a child presenting with unexplained heart block.
- Cardiology should be consulted immediately for all children requiring emergent treatment.

# HEART MURMUR

Calvin G. Lowe

## BASICS

### DESCRIPTION

- Heart murmur (HM) is a result of turbulent blood flow due to pressure differences between adjacent cardiac structures.
- In the absence of anatomic or physiologic cardiac abnormalities, HMs have no clinical significance:
  - These normal HMs can also be called innocent murmurs (IMs) and physiologic, benign, flow, or transitional murmurs.
- An abnormal or pathologic murmur (PM) is indicative of a heart problem:
  - Investigation is warranted to determine the origin of a PM.
- HMs can present at birth or develop later.

### EPIDEMIOLOGY

#### Incidence

- The incidence of HM in the pediatric population is reported to range from 77–95%.
- 1 review reported that IMs were found in 60% of healthy newborn babies (1).

#### Prevalence

- Multiple studies have reported a prevalence of 0.6–1.9 per 1,000 infants (2).
- 1 review noted that 90% of children have an audible HMs at some point in time (1).

### RISK FACTORS

Risks of developing HMs are associated with an underlying cause:

- Anemia
- Arteriosclerosis
- Autoimmune diseases
- Congenital heart disease (CHD)
- Endocarditis (EC)
- HTN
- Hyperthyroidism
- IV drug abuse
- Mitral valve prolapse (MVP)
- Rheumatic fever (RF)
- Pregnancy
- Syphilis

### GENERAL PREVENTION

- The only known preventative measures are detection and treatment of underlying conditions that may lead to HMs (HTN, RF, etc.) before developing a HM.
- Prophylactic antibiotics are recommended to patients with certain HMs prior to dental or surgical procedures to prevent EC.

### PATHOPHYSIOLOGY

- Since a majority of HMs are innocent without physiologic consequences, it is important to determine if a PM is present.
- The characteristics of a murmur depend on the size of the orifice or vessel through which the blood flows, the pressure difference or gradient across the narrowing, and the blood flow or volume across the site.

- Characteristics of a murmur depend on:
  - Timing: Relative position within the cardiac cycle with relationship to the 1st heart sound (S1) and the 2nd heart sound (S2)
  - Intensity: Classified on a scale of I–VI:
    - Grade I: Murmur barely discernible
    - Grade II: Audible and constant
    - Grade III: Loud with no accompanying thrill
    - Grade IV: Loud with accompanying thrill
    - Grade V: Murmur heard with the stethoscope barely touching the chest
    - Grade VI: Murmur audible without the stethoscope making contact with the chest
  - Location on the chest wall with regard to:
    - Point of maximal intensity
    - Extent of radiation
  - Duration: Length of the murmur from beginning to end
  - Configuration: Dynamic shape of the murmur
  - Pitch: Frequency range of the murmur:
    - Described as low, medium or high
  - Quality: Relates to the presence of harmonics and overtones
  - Systolic murmurs can be pansystolic (or holosystolic) or ejection:
    - Pansystolic murmurs begin with S1 during ventricular contraction into either atria or lower pressure right ventricle via a ventricular septal defect (VSD).
    - Ejection murmurs begin after S1 and have a crescendo–decrescendo quality.
    - Due to blood flow into the great vessels
  - Diastolic murmurs are defined as immediate, early, or late:
    - Immediate diastolic murmurs occur after semilunar valve closure.
    - Early or mid-diastolic murmurs: Associated with rapid filling phase of the ventricle
    - Late diastolic murmurs: Atrial systole
  - Thrill: Fine vibration palpable on chest exam indicating a HM of grade IV or greater intensity.
- Many IMs have cardiac origins.
- Still murmur (most common IM):
  - Described as musical or vibratory
  - Heard at the mid to lower sternal border toward the apex
- Supraclavicular bruit: Sound due to turbulence in the carotid arteries, more often on the right
- Peripheral pulmonary stenosis of the newborn (midsystolic murmur of low intensity):
  - Heard over the back, axillae, and base of heart
  - Sound secondary to the acute angle of the pulmonary branch arteries
  - Will disappear within 3–6 mo due to remodeling and ↑ pulmonary blood flow
- Venous hum (VH)—systolic/diastolic murmur in the infraclavicular region best heard with the patient in the sitting forward position:
  - Disappears when the patient is supine or if the head is turned to 1 side
  - Due to blood cascading down the jugular vein

### ETIOLOGY

- CHD is the most common cause of PMs (heart valve and structural cardiac abnormalities, septal defects and cardiac shunts).
- Hyperdynamic blood flow:
  - Severe anemia
  - Arteriovenous malformation
  - Hyperpyrexia
  - Thyrotoxicosis
- MVP
- Myocarditis
- Acute RF
- Subacute bacterial EC
- CHF
- Pulmonary insufficiency

### COMMONLY ASSOCIATED CONDITIONS

- Conditions that lead to ↑ flow of blood:
  - Anemia
  - Fever
  - Hyperthyroidism
  - Physical activity or exercise
  - Pregnancy
- CHD

## DIAGNOSIS

### HISTORY

- Patients can be asymptomatic; a murmur can be coincidentally found on physical exam.
- Common signs and symptoms of PMs include failure to thrive, shortness of breath (SOB), syncope, chest pain, palpitations, hemoptysis, cyanosis, uncontrolled coughing, recurrent respiratory infections, and other signs of infection.

### PHYSICAL EXAM

- Prior to auscultation, palpation of the chest should be performed:
  - Findings of left-sided precordial bulge (suggesting cardiac enlargement), palpable precordial thrill, or substernal heave (indicating right ventricular HTN) may indicate a PM.
- Location of highest intensity can help determine etiology of murmur:
  - Upper right sternal border: Aortic stenosis, VH
  - Upper left sternal border: Pulmonary stenosis, pulmonary flow murmur, atrial septal defect (ASD), patent ductus arteriosus (PDA).
  - Lower left sternal border: Still murmur, VSD, tricuspid valve regurgitation, hypertrophic cardiomyopathy, subaortic stenosis
  - Apex: MVP
- Positional changes of the patient also help in differentiating between IM and PM:
  - Still murmurs will ↓ in intensity with standing.
  - Significant changes in PM do not occur with patient standing.
  - Exception: PM of hypertrophic cardiomyopathy does ↑ in intensity with standing.
- Pathologic ejection murmurs are louder and longer than innocent ejection murmurs.

- Systolic murmurs:
  - Holosystolic murmur: Shunting of blood between 2 structures in which the pressure in 1 structure is higher than the other throughout systole:
    - Harsh: VSD
    - Soft: Atrioventricular valve regurgitation
  - Ejection systolic murmur: ↑ blood flow turbulence as systole progresses due to ↑ blood flow through a restricted orifice (aortic stenosis, pulmonic stenosis, VSD)
  - Midsystolic murmur: ↑ blood volume through normal valves (eg, ASD, anemia)
- Diastolic murmurs:
  - Diastolic murmurs are frequently of low intensity and may be either high or low pitched.
  - Early diastolic murmur: Regurgitant blood flow from the aorta or pulmonary artery into the ventricles (aortic insufficiency, pulmonary insufficiency)
  - Late diastolic murmur: Aortic regurgitation blood flow causes vibration of the left ventricular free wall.
  - Tricuspid diastolic murmurs: Heard best over the xiphoid process or right of the sternum in the 4th intercostal space
  - Tricuspid diastolic murmur related to ASDs
  - Mitral diastolic murmurs: Audible from the left 4th intercostal space to the apex:
    - These murmurs are associated with VSDs.
  - Pulmonary valve regurgitation can occur after tetralogy of Fallot repair.
    - This murmur is a low-pitched, rumbling, and decrescendo sound after S2.
  - Aortic valve regurgitation is a decrescendo, low-intensity, high-pitch murmur.
- Systolic and diastolic murmur: Pressure difference between 2 structures during systole and diastole (PDA, shunts, and collaterals)
- BPs should be measured in the upper extremity (UE) and lower extremity (LE): LE BP > UE BP suggests aortic coarctation.
- Signs of CHF: SOB, ankle/pedal edema, and hepatomegaly

### DIAGNOSTIC TESTS & INTERPRETATION

Since a majority of HM patients have IMs, they do not require lab or imaging studies.

#### Lab

##### Initial Lab Tests

- Lab tests are usually not necessary.
- If an inflammatory or infectious process, consider:
  - CBC
  - ESR
  - C-reactive protein
  - Blood cultures
  - Numerous assays of autoimmune markers exist; consider this in consultation with rheumatology or cardiology.

#### Imaging

Patients with suspected PMs should have the following ordered to determine any cardiac or pulmonary pathology:

- Chest radiograph
- Echo

#### Diagnostic Procedures/Other

If a PM is suspected, a 12-lead ECG should be performed to detect any electrical disturbances.

### DIFFERENTIAL DIAGNOSIS

- See Etiology section.

## TREATMENT

### PRE HOSPITAL

Prehospital personnel should support the patient's ABCs on transport to the emergency department.

### INITIAL STABILIZATION/THERAPY

- Immediate evaluation and treatment of the ABCs and continuous pulse oximetry is crucial.
- Administer oxygen judiciously.
- Complete and thorough cardiac exam to determine if a murmur is an IM or PM.
- Resuscitation as necessary
- If an IM is found, no treatment is necessary.

### MEDICATION

#### First Line

Treatment of a PM depends on the underlying cause and associated symptoms:

- In a neonate with CHD and a ductal-dependent lesion, refer to Cyanotic Heart Disease topic, "Treatment, First Line."

#### Second Line

- Patients with signs and symptoms of CHF can benefit with diuresis. See Congenital Heart Disease topic, "Treatment, Second Line."
- Digoxin can also be used to treat CHF.

### COMPLEMENTARY & ALTERNATIVE THERAPIES

- Angiotensin-converting enzyme (ACE) inhibitors: ↓ BP and treat valve abnormalities
- Beta-blockers: ↓ BP and regulate heart rhythm
- Anticoagulants: Prevent blood clot formation
- Antibiotics: ↓ risk of EC

### SURGERY/OTHER PROCEDURES

See Congenital Heart Disease topic, "Surgery/Other Procedures."

### DISPOSITION

#### Admission Criteria

- Any CHD patient with an ↑ oxygen requirement over baseline, acute respiratory distress, or worsening CHF not responsive to emergency department therapy should be admitted.
- Critical care admission criteria:
  - Any patient who is intubated and/or requiring cardiovascular support should be promptly admitted to a pediatric ICU.

#### Discharge Criteria

- If an IM is diagnosed, discharge.
- A patient with a PM who is deemed to be stable may be discharged with cardiology follow-up.

#### Issues for Referral

- Consider transfer to a tertiary pediatric center if subspecialty support is unavailable.
- A specialized pediatric critical care transport team may be necessary to facilitate the transport.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- Parents should be instructed to look for worsening signs and symptoms of the patient's underlying conditions causing the HM.
- Most HMs are innocent; therefore, there should be no restrictions on activity or diet.
- Discharge medications should be based on the recommendations of the consulting pediatric cardiologist.
- A follow-up appointment with a pediatric cardiologist should be made.

### PROGNOSIS

- Prognosis depends on the etiology.
- Treatment of the underlying cause usually carries a good prognosis.

### COMPLICATIONS

- PMs may indicate ↑ susceptibility to EC.
- EC: Oral bacteria enter the bloodstream from dental procedures causing gingival bleeding.
- Anticoagulant therapy: ↑ risk for bleeding

## CODES

### ICD9

785.2 Undiagnosed cardiac murmurs

## PEARLS AND PITFALLS

- Murmurs radiate in the direction of blood flow.
- Diastolic murmurs (except for VH) should be considered pathologic.
- If a patient with a surgically placed shunt for CHD does not have a shunt murmur, extreme caution must be taken as the shunt may be clotted off:
  - Restriction of blood flow can be fatal.

# HEAT ILLNESS

Rakesh D. Mistry

## BASICS

### DESCRIPTION

- *Heat illness* is a term that describes a spectrum of disorders, ranging from heat cramps to fulminant heat stroke
- Signs and symptoms of heat illness result from a combination of factors, including environmental conditions and inadequate fluid intake.
- Heat stroke is the most severe, life-threatening form of heat illness, defined by severe hyperpyrexia and altered sensorium.
- 2 primary forms of heat stroke:
  - Classic heat stroke typically occurs during heat waves; affects infants, the elderly, and the chronically ill; or occurs in the setting of medications that impair heat tolerance.
  - Exertional heat stroke is commonly seen in athletes performing intense activities in extreme heat and has a higher complication rate than the classic form.
- Heat exhaustion is marked by a hyperpyrexia  $<40^{\circ}\text{C}$ , excessive sweating, and intact sensorium.

### EPIDEMIOLOGY

- Throughout the world, heat illness often occurs as epidemics in association with sustained heat waves.
- Heat illnesses occur less commonly in geographic areas that are typically hot, such as desert countries, probably due to acclimation of inhabitants and their lifestyle and habits.
- Persons unaccustomed to such environments are at higher risk for heat illness.
- Heat illnesses are responsible for ~400–500 deaths per year in the U.S. (1).

### RISK FACTORS

- Infants, the elderly, or incapacitated persons who are unable to self-hydrate or remove themselves from the heat exposure
- Occupation or exercise associated with exposure to extreme heat and/or humidity (eg, laborers, military personnel)
- Predisposing medical conditions: Sweat gland dysfunction, skin disease, cystic fibrosis, diabetes mellitus, hyperthyroidism, cardiovascular disease
- Use of alcohol or drugs that impairs cognition, CNS responses, sweating, or cardiac function
- Ingestion of specific medications that affect thermoregulation
- Mortality from heat stroke is highest in infants, the elderly, males, and blacks (1).

### GENERAL PREVENTION

- Never leave children alone in a locked automobile.
- Avoidance of excessive heat exposure
- If indoors, maintain good ventilation and use of air conditioners when possible.
- Continued monitoring of temperature and humidity (heat index) when outdoors
- Prehydration and ongoing fluid intake with cool, low-osmolality beverages during exercise
- Light-colored, loose-fitting clothing
- On-site preparation for heat illness

- Acclimatization:
  - Refers to the natural physiologic adjustment to repeated heat exposure
  - Typically occurs in ~7–14 days, though exercise alone does not lead to acclimatization
  - Results in improved sweating mechanism and enhanced cardiac performance

### PATHOPHYSIOLOGY

- Physiology of thermoregulation:
  - Heat is produced as a by-product of metabolism, muscle activity, thyroxine, and adrenaline.
  - Heat is dissipated primarily via radiation and evaporative losses (sweating):
    - When ambient temperature is greater than body temperature, no heat loss occurs by radiation; instead, heat is gained from the environment.
  - Maintenance of core temperature occurs in the hypothalamus, which acts as an internal thermostat, integrating ambient and peripheral heat sensory input from the skin.
- In the setting of significant heat stress, several effector responses are produced:
  - Central: Basal metabolic rate, sympathetic tone, and thyroid hormone
  - Behavioral: Seeking shade, increasing thirst and fluid intake, and removing clothing are the most significant responses to heat stress.
  - Local and vascular: Peripheral vasodilation and increased skin blood flow with compensatory renal/GI vasoconstriction enhance conductive and convective heat loss.
  - Sweating: Increased thermal sweat production in combination with increased skin blood flow maximizes evaporative heat loss.
- Heat illness results from disordered thermoregulation within the body:
  - Substantial exogenous heat exposure and/or strenuous exercise can increase heat storage in the body 10- to 20-fold.
  - This often occurs in the setting of dehydration or inadequate fluid intake during exercise (“voluntary dehydration”).
- Increased body heat and inadequate ability to dissipate heat results in disordered thermoregulation and subsequent heat exhaustion.
- In extreme cases, heat illness may advance and impair behavioral responses, leading to further progression of illness.
- Eventually, thermoregulatory mechanisms can become overwhelmed, leading to rapid-onset hyperpyrexia, loss of compensatory vasoconstriction, and heat stroke.
- Fever is not equivalent to hyperpyrexia; in febrile illnesses, biochemical activity intentionally attempts to elevate the core temperature. Hyperpyrexia results from the inability to regulate the core temperature.

### ETIOLOGY

- Heat illnesses usually result from multiple combined host and environmental factors:
  - Extreme ambient heat, humidity, and sun exposure
  - Endogenous heat production from vigorous exercise, intercurrent infection, or medications
  - Dehydration
- Drugs and medications:
  - Anticholinergics
  - Antihistamines
  - Oxidative phosphorylation uncouplers: Dinitrophenol, salicylates
  - Sympathomimetics: Cocaine, amphetamines
  - Stimulants: Caffeine, monoamine oxidase inhibitors, PCP
  - Lithium

## DIAGNOSIS

History and exam findings differ based on the type of heat illness. The primary diagnostic focus is differentiation of heat exhaustion from heat stroke, a life-threatening condition:

- Heat stroke is characterized by the following:
  - Hyperpyrexia with temperature  $\geq 41^{\circ}\text{C}$
  - Altered mental status
  - Anhidrosis (not universally present)

### HISTORY

- Environmental conditions involved (eg, extreme exertion, infant found in car)
- Altered mental status, ranging from irritability to hallucinations to coma
- Syncope
- Dizziness
- Dyspnea
- Nausea and vomiting
- Weakness
- Muscle cramps may herald heat illness (heat cramps) or occur in the setting of heat exhaustion
- Current medication or use of illicit drugs

### PHYSICAL EXAM

- Hyperpyrexia (temperature is best measured with an esophageal or rectal probe)
- Tachycardia and hypotension are often present in an effort to maximize cardiac output to the skin for effective sweating.
- Cyanosis: Impending circulatory failure
- Fixed and dilated pupils may be present, though this phenomena is reversible.
- Bloody emesis due to GI hemorrhage may be present with heat stroke.
- Jaundice is indicative of hepatic injury.
- Diaphoresis is present in heat exhaustion:
  - Anhidrosis with hot, dry skin is highly specific for heat stroke.

**DIAGNOSTIC TESTS & INTERPRETATION****Lab****Initial Lab Tests**

- Diagnosis is clinical and requires no lab assays. Assays may help determine etiology as well as severity and end organ damage.
- Consider:
  - CBC
  - Serum electrolytes, BUN, creatinine, glucose
  - Liver enzymes (AST, ALT)
  - Creatine phosphokinase (CPK), myoglobin
  - Troponin
  - Lactate dehydrogenase (LDH)
  - PT/PTT, INR
  - Urinalysis
- Elevation in AST, CPK, and LDH has a high correlation with mortality (2).

**DIFFERENTIAL DIAGNOSIS**

- Heat cramps
- Heat syncope
- Heat exhaustion
- Heat stroke
- Meningitis
- Encephalitis
- Neuroleptic malignant syndrome
- Thyroid storm
- Drug-induced hyperthermia
- Stimulant/Hallucinogen-induced psychomotor agitation (cocaine, PCP)
- Cerebral malaria

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Heat stroke can lead to vital sign instability.
- Assess and stabilize airway, breathing, and circulation.
- Removal from environmental heat is necessary; affected patients should immediately be moved to a cool, well-ventilated, air-conditioned environment as soon as possible.
- Administration of IV fluid 20 cc/kg of normal saline or lactated Ringer solution:
  - Treats dehydration, improves hypotension, and is useful for rhabdomyolysis
- Heat stroke: Rapid cooling is indicated. Aggressive cooling leads to vasoconstriction, rise in BP, and return of mental status:
  - Evaporative cooling:
    - Use for core temperature  $<41.5^{\circ}\text{C}$  ( $106.7^{\circ}\text{F}$ )
    - Most commonly used cooling method for heat stroke
    - Forced evaporative convection accomplished using warmed air ( $45^{\circ}\text{C}$ ) blown over patient using fans, with cooled water ( $15^{\circ}\text{C}$ ) actively sprayed over body
  - Ice/ice water immersion:
    - Use if temperature  $>41.6\text{--}42^{\circ}\text{C}$  ( $\sim 107^{\circ}\text{F}$ )
    - Placement of patient in an ice water slurry
    - Cooling is accomplished using conduction.
    - Studies have determined that cooled water ( $25^{\circ}\text{C}$ ) is as effective as ice water (3).
    - Many emergency departments lack function-specific equipment.

- If function-specific equipment is not available, placement of the patient in a body bag packed with ice or packing inside sheets on a cholera bed can be used.
- Typically, patients do not initially feel uncomfortable with immersion.
- The time at which the patient feels cold or discomfort often correlates with drop of core temperature to  $38\text{--}39^{\circ}\text{C}$  ( $100.4\text{--}102.4^{\circ}\text{F}$ ).
- Adjunctive cooling measures:
  - Infusion of chilled IV fluid
  - Cooling blankets
  - Ice packs placed at the sites of large vessels (groin and axilla)
  - Ice water NG lavage
  - Wet sheet over patient
- The goal of active cooling is the return of the core temperature to  $38.5\text{--}39^{\circ}\text{C}$ .
- Evaporative cooling is often chosen over ice water immersion since it is more easily performed:
  - As heat stroke is an immediately life-threatening illness, exhaustive attempts to safely conduct ice packing/immersion, if indicated, should be made.
- Heat exhaustion and heat cramps:
  - Rest in a cool, well-ventilated area.
  - Administration of cool liquids orally
  - IV fluids may be administered, especially for orthostasis or electrolyte abnormality.

**MEDICATION**

- Medications are adjunctive to the primary treatment of patients with heat illness.
- Dopamine is the vasopressor of choice if patients with heat stroke remain cyanotic or hypotensive during rewarming procedures.
- Several medications may help to reduce shivering, which results in heat production:
  - Diazepam 0.12–0.8 mg/kg/dose IV/IM q6–8h
  - Chlorpromazine 0.5 mg/kg/dose IV/IM q6–8h
  - Meperidine 0.5–1.0 mg/kg/dose IV q3–4h

**ALERT**

- Due to unfamiliarity with the pathophysiology of heat illnesses, ineffective and erroneous medication choices may be selected during treatment.
- Unless a specific underlying etiology (eg, malignant hyperthermia, infection) is present, there is no role for medications to lower temperature.

**DISPOSITION****Admission Criteria**

- Heat exhaustion with significant dehydration or electrolyte abnormality
- Altered mental status
- Critical care admission criteria:
  - Heat stroke
  - Complications involving end organ injury, such as hepatic injury, disseminated intravascular coagulation (DIC), rhabdomyolysis

**Discharge Criteria**

Resolution of mild heat exhaustion without metabolic derangement if tolerating oral fluids

**FOLLOW-UP****PROGNOSIS**

- Heat exhaustion usually resolves without sequelae.
- Heat stroke has mortality of 30–80% if untreated and up to 10% even with rapid cooling:
  - Mortality is directly related to the severity and duration of hyperthermia (4).
  - There is increased mortality with delayed cooling.
  - Multisystem organ dysfunction is associated with a poor prognosis.
- With treatment, many symptoms are reversible.

**COMPLICATIONS**

- End organ injury:
  - Myocardial
  - CNS
  - Hepatic
  - Renal
- DIC
- Rhabdomyolysis
- Shock
- Death

**REFERENCES**

**CODES****ICD9**

- 992.0 Heat stroke and sunstroke
- 992.1 Heat syncope
- 992.2 Heat cramps

**PEARLS AND PITFALLS**

- Fever reflects a physiological response to processes such as infection while hyperpyrexia is a lack of temperature regulation.
- For patients with suspected heat stroke, active cooling measures should not be delayed irrespective of the degree of hyperthermia, or for diagnostic purposes.
- Regardless of etiology, core temperature  $>42^{\circ}\text{C}$  ( $107^{\circ}\text{F}$ ) warrants ice water immersion.
- The main therapy for heat stroke is rapid cooling, which significantly improves outcomes.
- If patients with hyperpyrexia and altered sensorium are not responding to rapid cooling, consider alternate diagnoses such as meningitis.

# HEMANGIOMA

Sage Myers

## BASICS

### DESCRIPTION

A hemangioma is a benign congenital neoplasm of vascular endothelial cells.

### EPIDEMIOLOGY

- By the end of the 1st yr of life, up to 10–12% of all children will be diagnosed with a hemangioma (1):
  - Present in ~1–2.5% at birth (1,2)
- The most common benign tumor of childhood (2)

### RISK FACTORS

- Female predominance 3:1 to 5:1 (1)
- More common in white infants (2)
- More common in premature infants (3):
  - Occurs in 20% of infants <1,000 g (4)
- Usually sporadic but may be autosomal dominant (2)

### PATHOPHYSIOLOGY

- Vascular tumors composed of hyperplastic vascular endothelial cells
- Endothelial cell hyperplasia with excessive proliferation followed by regression and involution:
  - Separate proliferative stage and involution stage
  - May be superficial (in superficial dermis), deep (in deeper dermis and subcutaneous tissue), or both
  - No longer use terms such as *strawberry*, *capillary*, or *cavernous* to describe hemangiomas; replaced by *superficial*, *deep*, or *mixed* terminology (5)

### ETIOLOGY

Congenital anomaly

### COMMONLY ASSOCIATED CONDITIONS

- PHACES syndrome mnemonic:
  - Posterior fossa malformations (Dandy-Walker, cerebellar atrophy, agenesis of the corpus callosum)
  - Hemangiomas
  - Arterial anomalies (persistent embryonic intracranial and extracranial arteries, aneurismal dilatations and anomalous branches of the internal carotid artery, and absence of the ipsilateral carotid or cerebral vessels)
  - Cardiac defects (coarctation of the aorta, patent ductus arteriosus, ventricular septal defect)

- Eye abnormalities (microphthalmia, congenital cataracts, glaucoma, optic nerve hypoplasia, increased vascularity)
- Sternal malformations (supraumbilical raphae and sternal clefts)
- Patients with PHACES syndrome often have large, plaque-like, segmental, cervicofacial hemangiomas:
  - PHACES syndrome is more common in females.
  - High risk for developmental delay and seizures
  - Should be referred for neurologic and ophthalmologic evaluation
- Thyroid abnormalities: Hypothyroidism has been associated with visceral hemangiomas, thought to be due to large amounts of enzymes inactivating thyroid hormone (6).

## DIAGNOSIS

### HISTORY

- Often not present at birth; may have a precursor lesion that is a pale bluish-gray macule or cluster of telangiectasias
- Typical hemangioma appearance begins in the neonatal to early infantile period:
  - Growth rate highest between ages 3 and 6 mo
  - Reaches maximal size by 12 mo of age
  - Involution begins by age 18 mo.

### PHYSICAL EXAM

- Deep hemangiomas appear as bluish or purplish nodules with a rubbery, compressible feel.
- May have obvious overlying superficial veins
- Superficial hemangiomas appear red, raised, and nonblanchable.
- May have a surrounding zone of pallor
- Mixed hemangiomas have characteristics of both.
- Hemangiomas are most common on the head and neck (60%) and less common on the trunk (25%) and extremities (15%) (4,5).

## DIAGNOSTIC TESTS & INTERPRETATION

### Imaging

- US with Doppler. CT and MRI may be used if appearance or progression is atypical or there is concern for other vascular malformations or soft tissue tumors.
- Children with midline lumbosacral hemangiomas should undergo MRI or US evaluation to evaluate for anomalies of the underlying spinal structures.
- Children with numerous cutaneous hemangiomas may require imaging of the brain and/or chest and abdomen to assess for visceral hemangiomas.

### Diagnostic Procedures/Other

Usually diagnosed clinically but may require biopsy (discussed below)

### Pathological Findings

- Pathology is usually not needed for diagnosis.
- Proliferative stage:
  - Microscopic evaluation reveals masses of “plump” endothelial cells.
  - Rapidly dividing endothelial cells with or without lumens
  - Many mast cells present (5)
- Involution stage:
  - Microscopic evaluation reveals more flattened endothelial cells and more dilated lumens within fibrous tissue.
- GLUT1 glucose transporter normally found in endothelium of blood-brain barrier vasculature is expressed in hemangiomas but not in other types of vascular lesions (2).

### DIFFERENTIAL DIAGNOSIS

- Kaposiform hemangioendothelioma
- Capillary malformations
- Tufted angioma
- Infantile myofibromatosis
- Rhabdomyosarcoma
- Fibrosarcoma
- Arteriovenous malformations
- Venous malformations
- Lymphatic malformations
- Pyogenic granuloma

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Rarely, laryngeal or subglottic hemangiomas may create significant airway compromise requiring emergent stabilization.
- Kasabach-Merritt syndrome is relative thrombocytopenia due to sequestration of platelets within hemangioma. Can cause a dangerously low platelet count and hemorrhage.
- For bleeding hemangiomas, apply direct pressure.
- For ulcerated hemangioma, apply a wet dressing with pressure.

### MEDICATION

#### First Line

Corticosteroids:

- Lead to decrease in growth rate and promote regression
- Required to treat hemangiomas that threaten visual development or compress vital structures
- Can be given orally or intralesionally, usually under the guidance of a pediatric dermatologist
- Prednisone is the most commonly used oral steroid for treatment of hemangiomas, usually in doses ranging from 1–5 mg/kg/day in once-daily dosing:
  - Higher doses in this range have been associated with improved time to response (7)

#### Second Line

Hemangiomas that threaten to cause significant morbidity, and even mortality, and have not responded to systemic corticosteroids may be treated with interferon-alpha.

### SURGERY/OTHER PROCEDURES

- Pulsed-dye laser may be used to treat superficial hemangiomas:
  - Pulsed-dye laser causes vascular coagulative necrosis in treated areas.
  - Not effective in treating deep hemangiomas
- Surgical excision may be necessary for hemangiomas unresponsive to medical treatment that are causing compression or obstruction of vital structures.
- Rarely, sclerotherapy or liquid nitrogen is used to treat residual hemangiomas that have not completely involuted or are in cosmetically sensitive areas.

### DISPOSITION

#### Admission Criteria

- Ulceration or cellulitis may require inpatient treatment.
- Patients with large visceral hemangiomas may require admission if they exhibit signs of new or worsening CHF.
- Critical care admission criteria:
  - Airway compromise or vital sign instability warrants management in a critical care unit.

### Issues for Referral

- Children with hemangiomas that are large, bleeding, in cosmetically sensitive areas, or in the following locations should be referred to pediatric dermatology for evaluation:
  - Beard distribution
  - Periorbital
  - Lip
  - Ear
  - Tip of nose
  - Diaper area
- Consider psychological counseling for patients with severely disfiguring lesions or a disturbed self-image.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- Expected progression of the lesion and signs of complication that warrant re-evaluation should be explained to families.

### Patient Monitoring

Patients with complicated hemangiomas or hemangiomas in sensitive areas should be followed closely by a dermatologist to assess for impending complications or the need for treatment initiation or alteration.

### PROGNOSIS

Hemangiomas usually increase in size until about age 12 mo, begin to involute by 12–18 mo of age, and involute in early childhood:

- Involution is often complete, but there may be some residual scarring or skin changes.
- Maximal involution occurs by 10 yr of age.
- 50% reach complete involution by age 5 yr.
- 90% reach complete involution by age 9 yr (5).

### COMPLICATIONS

- Ulceration
- Hemorrhage
- Kasabach-Merritt syndrome
- Visual compromise
- Airway compromise
- Lumbosacral skeletal disturbance
- Difficult locations:
  - Hemangiomas of the nasal tip, lips, and ears may be associated with incomplete resolution and residual deformity or scarring.
- Hemangiomatosis:
  - Children with many cutaneous hemangiomas may also have visceral hemangiomas (often in the liver, lung, GI tract, brain, and meninges).

## CODES

### ICD9

- 228.00 Hemangioma of unspecified site
- 228.01 Hemangioma of skin and subcutaneous tissue

## PEARLS AND PITFALLS

- Hemangiomas proliferate for the 1st yr and then begin a slow regression, with maximal involution occurring by 10 yr of age.
- Less benign tumors of childhood may mimic hemangiomas; lesions thought to be hemangiomas that do not follow the usual progression through proliferative and involution phases should be further evaluated to verify the diagnosis
- Hemangiomas in specific areas of the body must be followed more closely or be further evaluated by specialists due to their risks for complication or associated disorders:
  - Beard distribution
  - Periorbital
  - Perineal
  - Lip, nose, ear
  - Lumbosacral
  - Multiple hemangiomas

# HEMATURIA

Corrie E. Chumpitazi  
Manish I. Shah

## BASICS

### DESCRIPTION

- Hematuria is an abnormal number of RBCs in the urine: 2–5 RBCs per high-power field (HPF) using a standard urinalysis on a centrifuged sample or  $\geq 1$  positive RBCs on a peroxidase dipstick.
- Macroscopic hematuria is visible to the naked eye, while microscopic hematuria is typically detected by a dipstick during routine exam.
- The 1st voided urine is best for exam, as it is the most concentrated.
- The urine should be examined within 2 hr of voiding, after which lysis of casts occurs and the analysis is inaccurate.
- Red or brown urine may not be hematuria since factitious causes may color the urine, such as beets, blackberries, urates, aniline dyes, bile pigments, porphyrin, diphenylhydantoin, phenazopyridine (Pyridium), rifampin, deferoxamine, benzene, phenolphthalein, ibuprofen, methyl dopa, chloroquine, cyclophosphamide, methemoglobinemia, and homogentisic acid.
- The majority of children with asymptomatic hematuria are healthy, and no serious underlying cause will be found.

### EPIDEMIOLOGY

#### Incidence

- Incidence of gross hematuria is 1.3/1000 (1).
- Microscopic hematuria incidence is greater,  $\sim 41/1,000$  (2).

#### Prevalence

- The complaint of gross hematuria may account for 0.1–0.15% of pediatric acute care walk-in visits (1).
- 3–4% of unselected school-age children between 6 and 15 yr of age have a positive dipstick for blood in a single urine sample (2).

### RISK FACTORS

- Family history raises concern for renal cystic disease, Alport syndrome, and renal stones.
- Prior history of urinary tract infection (UTI), immunosuppressed state, or genitourinary (GU) anomalies raises the risk of infection.

### PATHOPHYSIOLOGY

- RBCs can originate from any point along the urinary tract and appear in the urine.
- Glomerular bleeding is typically brown, smoky, cola-colored, or tea-colored as a result of the hematin formation from hemoglobin in the acidic environment. RBCs form casts when they are entangled in the protein matrix, indicating glomerular etiology.
- Grossly bloody urine that is bright red or pink or without clots most likely originates from the lower urinary tract.
- Trauma may cause contusions, hematomas, or lacerations at any point along the urinary tract.
- Microthrombosis of the renal papillae, as occurs in sickle cell disease, may cause hematuria.

### ETIOLOGY

- Glomerular causes: Strenuous exercise, acute poststreptococcal glomerulonephritis (PSGN), IgA nephropathy, thin basement membrane disease (benign familial hematuria), Alport syndrome, nephritis of systemic disease (Henoch-Schönlein purpura [HSP]), systemic lupus erythematosus (SLE), diabetic nephropathy
- Nonglomerular renal causes: UTI or pyelonephritis (most common bacterium is *Escherichia coli*), hemorrhagic cystitis (bacterial, viral, drug induced), hypercalciuria, interstitial nephritis, renal contusion, nephrolithiasis, hemoglobinopathies, renal vein thrombosis, anatomic (ureteropelvic junction obstruction, posterior urethral valves, Wilms tumor, urethral prolapse, urethral diverticula, polycystic kidney disease, multicystic dysplastic kidney)
- Extrarenal causes: Coagulation disorders, sickle cell disease or trait, anticoagulant therapy, drugs (aspirin, NSAIDs, phenacetin, penicillins, cephalosporins, cyclophosphamide, topiramate), perineal trauma or irritation, nutcracker syndrome (compression of the renal vein), foreign body in the bladder or urethra
- Systemic diseases: Serum sickness, hemolytic uremic syndrome (HUS), polyarteritis nodosa, shunt nephritis, subacute bacterial endocarditis, TB, hepatitis

## DIAGNOSIS

### HISTORY

- Dysuria
- Heavy exercise, menstruation, or trauma
- Use of drugs or foods that discolor the urine or have a nephrotoxic effect, especially NSAIDs, penicillins, and cephalosporins.
- Timing of hematuria with micturition revealing terminal hematuria is suspicious for urethral injury.
- History of recent upper respiratory infection or pharyngitis within 1–2 days may be associated with IgA nephropathy.
- Pharyngitis or impetigo occurring 2–4 wk prior is suggestive of PSGN.
- Fever, polyuria, and dysuria may be associated with infection.
- Fever, rash, arthritis, or arthralgias point to systemic illness such as HSP or SLE.
- Family history of hematuria suggests benign familial hematuria, Alport syndrome, hereditary nephritis, cystic disease, or stones.
- Family history of sickle cell disease
- Nephrolithiasis is hereditary and is also common in patients with recurrent UTIs, bladder dysfunction, hypercalciuria, metabolic disease, or chronic diuretic therapy.
- In the neonate, the history should include asking about previous umbilical vessel catheters (renal venous or arterial thrombosis) or significant birth asphyxia (corticomedullary necrosis).

### PHYSICAL EXAM

- HTN may indicate glomerulonephritis, obstructive uropathy, Wilms tumor, polycystic kidney disease, or a vascular process.
- Abdominal: Peritoneal signs are concerning for trauma. Masses suggest tumor, hydronephrosis, multicystic dysplastic kidney, or polycystic kidney disease.
- GU: Dependent edema, penile urethra meatal erosion, or introitus pathology such as urethral prolapse
- Extremity: Edema and joint swelling
- Back: Flank or back pain may be caused by pyelonephritis, renal obstruction, stones, or trauma.
- Skin: Evaluate for petechiae, vasculitic rash, or ulcerations as seen in HSP, HUS, and SLE. Bruising is suggestive of trauma (including child abuse). Pallor may indicate anemia from chronic renal insufficiency, hemoglobinopathy, HUS, leukemia, or tumors.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Complete urinalysis with microscopic exam is the gold standard, and the only required uniform lab test for patients with hematuria (3):
  - Urine dipstick positive for blood requires a microscopic analysis to confirm RBCs are present.
  - Positive dipstick in the absence of RBCs warrants evaluation for myoglobinuria.
  - RBC casts, cellular casts, tubular cells, tea- or smoky-colored urine and proteinuria  $\geq 2$  positive by dipstick, dysmorphic RBCs, or acanthocytes can be seen in the setting of glomerular bleeding.
  - Nonglomerular hematuria can have blood clots, no proteinuria, and normal RBC morphology.
- In a patient with gross hematuria or an acutely ill patient with microscopic hematuria, serum electrolytes, BUN, creatinine, CBC, and albumin should be obtained.
- Urine culture should be obtained if there is a history of polyuria, fever, dysuria, or related concerns and in all cases of gross hematuria.
- Obtain hemoglobin electrophoresis if clinical suspicion arises for sickle cell disease/trait.
- Complement studies (C3 and C4) should be sent for immune complex disease or to delineate acute glomerulonephritis from SLE.
- Antistreptolysin O titers, antihyaluronidase titers, anti-DNaseB, and throat culture should be sent for suspected streptococcal sequelae.

#### Imaging

- Imaging is unnecessary for asymptomatic isolated microscopic hematuria.
- In the setting of trauma,  $\geq 20$ –50 RBC/HPF or history of significant mechanism of injury to the flank or abdomen, obtain a CT scan of the abdomen and pelvis.
- Stones may be seen on plain kidney-ureter-bladder radiograph, but radiolucent stones such as uric acid stones will be missed.

- Presence of RBC casts indicates a need for renal and bladder US to exclude malignancy or cystic renal disease.
- Renal US is necessary in gross hematuria.
- US of the left renal vein for diameter and peak flow velocity diagnoses nutcracker syndrome.

#### Diagnostic Procedures/Other

Cystoscopy is rarely indicated but is useful to delineate a bladder mass found on US or for urethral abnormalities following trauma (4).

#### Pathological Findings

- IgA deposits on immunofluorescence of the renal biopsy reveal IgA nephropathy.
- Benign familial hematuria is diagnosed by biopsy with thin basement membrane on electron microscopy.
- Characteristic fraying and laminations may be seen along the glomerular basement membrane in Alport syndrome.

#### DIFFERENTIAL DIAGNOSIS

See the Etiology section for the complete differential diagnosis.

## TREATMENT

#### INITIAL STABILIZATION/THERAPY

BP and urine output should be monitored frequently.

#### MEDICATION

- Children requiring outpatient treatment for UTI may be discharged on:
  - Cefixime 8 mg/kg/day divided q12–24h, max single dose 400 mg/day
  - Cefpodoxime proxetil (children 2 mo to 12 yrs of age) 10 mg/kg/day divided q12h, max single dose 800 mg/day
  - Cephalexin 30–50 mg/kg/day t.i.d. for 7–10 days, max single dose 500 mg
  - Amoxicillin and trimethoprim/sulfamethoxazole should be reserved for infections with known susceptibility.
- Pain control in nephrolithiasis may be achieved with any of the following PRN:
  - Ibuprofen 10 mg/kg q6h
  - Ketorolac 0.5 mg/kg IV/IM q6h, max single dose 30 mg
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
- Treat symptomatic HTN with labetalol 0.2–1 mg/kg IV q2–6h or infusion 0.5–3 mg/kg/hr titrating by 0.5 mg/kg, as it is safe in acute renal failure and CHF.
- For management of severe HTN, hypertensive urgency, or hypertensive emergency, refer to the Hypertension topic.

#### SURGERY/OTHER PROCEDURES

- Urologic surgery may be necessary in the setting of acute trauma.
- Renal biopsy is not emergent and is reserved for cases requiring nephrology consultation (3).

#### DISPOSITION

##### Admission Criteria

- Critical care admission criteria:
  - May be necessary in the setting of trauma, uncontrollable HTN requiring continuous antihypertensive therapy, or renal failure

- Inpatient ward criteria:
  - Children with HTN, edema, oliguria, significant proteinuria (>500 mg/24 hr), elevated creatinine, or RBC casts
  - Inability to orally hydrate or need for IV fluids
  - HSP patients with significant GI bleeding, severe abdominal pain, or change in mental status

#### Discharge Criteria

Children with asymptomatic microscopic hematuria and a normal physical exam may follow up with the primary care physician for urinalysis and BP measurement (3).

#### Issues for Referral

- Immediate consultation:
  - Urologic surgery consultation for anuria, uncontrollable bleeding, nephrolithiasis with urosepsis, or severe pain
  - Immediate hematologic consultation is necessary for coagulopathy.
  - Patients with elevated creatinine or significant proteinuria should receive consultation with a pediatric nephrologist.
- Outpatient referral:
  - A urologist should evaluate children with recurrent nonglomerular macroscopic hematuria of undetermined origin and those with a stone >10 mm in diameter or who fail to pass the stone after a trial of conservative management.
  - Pediatric nephrology referral is necessary for patients with signs of glomerular disease.

## FOLLOW-UP

#### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Based on the underlying cause
- Activity:
  - Based on the underlying cause

#### Patient Monitoring

- Isolated asymptomatic hematuria should have a repeat urinalysis weekly for 2 wk. The patient should not exercise prior to the test.
- Patients with suspected HSP should have weekly follow-up with their primary care physician for 1 mo to check for HTN and ongoing hematuria.

#### DIET

Food and medications that discolor the urine may be continued if true hematuria is not present.

#### PROGNOSIS

Most hematuria in children is benign.

#### COMPLICATIONS

Glomerular processes can proceed to renal failure, hypertensive encephalopathy, or fluid overload. Thus, patients with glomerular disease require pediatric nephrology referral for follow-up.

## CODES

#### ICD9

- 599.69 Hematuria
- 599.70 Hematuria, unspecified
- 599.71 Gross hematuria

## PEARLS AND PITFALLS

- ~50% of children without a history of trauma evaluated for gross and/or microscopic hematuria in the emergency department have a UTI.
- No etiology will be found for the majority of children with asymptomatic hematuria, and in most cases no specific emergency department treatment is required as long as follow-up is arranged (3,4).
- Urine dipstick positive for RBCs can indicate hemoglobinuria or myoglobinuria, so a microscopic exam must be performed to verify the presence of RBCs.
- The presence of RBC casts, proteinuria, and/or dysmorphic RBCs indicates a glomerular source of bleeding.

# HEMOLYTIC DISEASE OF THE NEWBORN

Angela M. Ellison

## BASICS

### DESCRIPTION

- Hemolytic disease of the newborn (HDN) describes the condition in which RBCs of the newborn are destroyed by maternally derived IgG antibodies.
- Alloimmune HDN primarily involves the major blood groups of Rhesus (Rh), A, AB, and O.
- Rh antibody (anti-D) is the most common form of HDN involving the Rh system, but other alloantibodies of the system, including anti-K, anti-c, and anti-E, can cause severe disease.
- Minor blood group incompatibilities (eg, Kell, Duffy, and MNS system) can also result in severe disease.

### EPIDEMIOLOGY

#### Incidence

- In 1991, the estimated incidence of Rh alloimmune HDN was 10.6 per 10,000 total births in the U.S.
- Incidence of disease has declined after the widespread use of anti-D immunoglobulin (Ig) prophylaxis; however, true incidence data for recent years are unavailable.
- HDN secondary to ABO incompatibility occurs in ~2% of all births.
- 50% of ABO HDN occurs in the 1st pregnancy.
- 15% of fetuses of Rh-negative women are Rh-positive.
- For Rh-sensitized pregnancies:
  - 50% require no treatment.
  - 31% require treatment after full-term delivery.

### RISK FACTORS

- Fetomaternal hemorrhage during any pregnancy including abortions, miscarriages, and ectopic pregnancies
- Exposure to fetal RBCs during procedures such as chorionic villus sampling and amniocentesis
- Inadvertent transfusion of Rh-positive blood to Rh-negative women

### GENERAL PREVENTION

- Anti-D immunoglobulin (Rhlg) prophylaxis prevents sensitization in pregnant Rh(D)-negative women.
- Unsensitized women receive injection of 300  $\mu$ g of Rhlg at 28 wk of gestation, with an additional dose given just after delivery if the baby is Rh-positive.
- Rhlg should be administered to unsensitized Rh(D)-negative women after any event known to be associated with transplacental hemorrhage.
- There is no routine prophylaxis for HDN caused by incompatibility of other blood groups.

### PATHOPHYSIOLOGY

- The maternal antibody that is formed at the initial time of sensitization is of the IgM isotype, which cannot cross the placenta. Antibodies of the IgG isotype are produced later. The maternal IgG antibodies cross the placenta into fetal circulation and attach to the antigen on fetal RBCs. These cells are then destroyed by macrophages in the spleen.
- Isoimmunization does not occur in maternal blood types A and B because the naturally occurring antibodies (anti-A and B) are IgM, not IgG. In type O mothers, antibodies are predominantly IgG and therefore can cross the placenta.
- Individuals naturally make A and/or B antibodies to antigens they do not possess at ~3–6 mo of age. Therefore, ABO alloimmune HDN can occur with the 1st pregnancy.
- Rh alloimmune HDN generally does not occur with the 1st pregnancy.
- HDN secondary ABO incompatibility is usually less severe than what is seen with Rh incompatibility. A and B antigens are generally present on cells of other tissue and body fluids. Therefore, the fetal RBCs are somewhat protected because the presence of antigen in other places aids in neutralizing transferred maternal antibody. Infants are usually asymptomatic at birth, with the onset of hyperbilirubinemia within the 1st 24 hr. Anemia is either absent or mild.

### ETIOLOGY

See Pathophysiology.

### COMMONLY ASSOCIATED CONDITIONS

- Hyperbilirubinemia
- Anemia

## DIAGNOSIS

### HISTORY

- The presence of any of the above risk factors for maternal sensitization should be obtained in the history or by review of the medical record.
- Ask mother and father about ABO and Rh type.
- History of previous stillbirths or miscarriages may be elicited.
- Previous abortion or stillbirth without administration of Rhlg
- Exposure of mother to blood products or previous pregnancy
- A history of unexpected jaundice within the 1st 24 hr of life may be elicited.
- Parents may also report poor feeding, lethargy, or decreased urinary/stool output in affected infants.
- Reported blood type of the mother and neonate should be verified.

### PHYSICAL EXAM

- Jaundice may be the only physical exam finding, typically absent at birth and occurring within 24 hr of birth.
- Severely affected neonates may present at delivery with shock or near shock and often have evidence of hydrops fetalis (skin edema, pleural or pericardial effusion, or ascites) or massive hepatosplenomegaly from extramedullary hematopoiesis.
- Lethargy secondary to severe anemia, hypoglycemia, dehydration, or hyperbilirubinemia may be present.
- Although uncommon, infants should be carefully assessed for signs of bilirubin encephalopathy or kernicterus; these may include seizures, hypotonia, or abnormal posturing.
- Some newborns may present clinical evidence of anemia (tachypnea, tachycardia, and pallor). Late-onset anemia may occur in affected infants at 4–6 wk of age.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Blood type and Coombs tests (direct and indirect) to confirm the diagnosis
- CBC with smear. Peripheral blood smear findings consistent with HDN include anemia, macrocytosis (Rh HDN), microcytosis (ABO HDN), and polychromasia. Schistocytes and burr cells may be seen in severe disease.
- Reticulocyte count: Usually elevated in HDN
- Indirect, direct, and total serum bilirubin (TSB) concentration
- Electrolytes, BUN, creatinine, calcium, and serum glucose
- All of the above will help guide decisions on therapeutic interventions.

### DIFFERENTIAL DIAGNOSIS

- Neonatal hyperbilirubinemia differential:
  - Physiologic jaundice
  - Hereditary spherocytosis or elliptocytosis
  - G6PD
  - Pyruvate kinase (PK) deficiencies
  - Gilbert syndrome
  - Crigler-Najjar syndrome
  - Alpha-thalassemia
  - Breast milk jaundice
  - Breast-feeding jaundice
  - Galactosemia
  - Tyrosinemia
  - Enclosed hemorrhages
  - Hypothyroidism
  - GI obstruction
  - Other metabolic diseases

- Hydrops fetalis:
  - Alpha-thalassemia
  - Severe G6PD deficiency
  - Twin-to-twin transfusion
  - TORCH infections
  - Cardiac disease: Hypoplastic left heart, heart block
  - Renal: Renal vein thrombosis, urinary tract obstruction

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Initial assessment includes evaluation of the infant's airway, breathing, and circulation.
- Bedside glucose should be obtained, particularly in neonates with history of poor feeding or decreased urinary or stool output. Hypoglycemia should be immediately corrected.

### MEDICATION

- The American Academy of Pediatrics (AAP) has developed guidelines for phototherapy, immunoglobulin therapy (IVIG), and exchange transfusion based upon TSB values at specific hourly ages of the patient, gestational age, and the presence or absence of risk factors for hyperbilirubinemia including alloimmune HDN.
- IVIG (100 mg/kg/dose IV) is recommended if the newborn is suspected to have HDN and the TSB is rising despite intensive phototherapy or is within 2 or 3 mg/dL of threshold for exchange transfusion. The dose may be repeated q12h if necessary.
- If an infant has severe anemia and severe hyperbilirubinemia despite treatment, an exchange transfusion should be performed based upon the AAP guidelines.
- Infants with impending risk of evidence of acute bilirubin encephalopathy should be treated with immediate exchange transfusion.
- For infants with symptomatic anemia (eg, lethargy or tachycardia) but no evidence of severe anemia such as circulatory compromise or severe hyperbilirubinemia, simple transfusion with cross-matched RBCs is indicated.
- For infants with severe anemia, exchange transfusion is preferred over simple transfusion. However, in infants with shock or pending shock due to severe anemia or cases in which there is a delay or inability to perform an exchange transfusion, emergent simple transfusion using type O, Rh(D)-negative RBCs should be performed.
- Asymptomatic newborns with late-onset anemia are usually managed with recombinant erythropoietin and iron supplementation.

## DISPOSITION

### Admission Criteria

- All infants with suspected alloimmune HDN require hospital admission.
- Critical care admission criteria:
  - Severe anemia, severe hyperbilirubinemia, unstable vital signs, or evidence of kernicterus

### Discharge Criteria

Patients not requiring treatment according to AAP clinical practice guidelines may be discharged.

### Issues for Referral

Patients should be referred based on etiology.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- Need for repeat bilirubin testing will be based on etiology, risk based on gestational age, postnatal age, and bilirubin level:
  - Repeat bilirubin testing is often needed within 12–24 hr. Follow-up in the emergency department is preferable for such cases in the event the bilirubin level requires admission for phototherapy or transfusion.

### DIET

- Infants who are hemodynamically stable and not likely to need an exchange transfusion should be allowed to feed. Mothers should be encouraged to breast-feed, if desired.
- Phototherapy increases insensible skin losses. If oral hydration is inadequate (or not possible), IV hydration may be necessary.

### PROGNOSIS

50% of affected newborns have mild hemolytic disease and usually only require early phototherapy:

- 25% have moderate hemolytic disease and are at risk of developing bilirubin encephalopathy if not adequately treated. These newborns are at risk of developing late anemia of infancy at 4–6 wk of life.
- The remaining 25% of affected newborns are severely affected in utero and either die or become hydropic.

### COMPLICATIONS

- Kernicterus
- Anemia
- Shock
- Hydrops fetalis

## CODES

### ICD9

- 773.0 Hemolytic disease of fetus or newborn due to rh isoimmunization
- 773.1 Hemolytic disease of fetus or newborn due to abo isoimmunization
- 773.2 Hemolytic disease of fetus or newborn due to other and unspecified isoimmunization

## PEARLS AND PITFALLS

- Direct antibody tests may be negative in some cases of HDN (particularly in cases of ABO incompatibility). Therefore, the diagnosis may not be established until after indirect Coombs testing.
- The presence of a positive direct or indirect Coombs test confirms the diagnosis of HDN. However, other disorders (listed in the Differential Diagnosis section) may occur concomitantly and should be considered in infants with severe or refractory hyperbilirubinemia.
- Other conditions such as autoimmune hemolytic anemia or drug-induced hemolytic anemia may also yield a positive Coombs. However, these conditions are rare in infants.

# HEMOLYTIC UREMIC SYNDROME

Manoj K. Mittal

## BASICS

### DESCRIPTION

- Hemolytic uremic syndrome (HUS) is a serious multisystem disorder characterized by the triad of:
  - Acute microangiopathic hemolytic anemia
  - Thrombocytopenia
  - Oliguric renal failure
- Most common cause of acute renal failure and renal transplantation in children (1)
- HUS occurs in 2 subtypes:
  - Typical:
    - Diarrhea, caused by shiga toxin-producing *Escherichia coli* (STEC) or enterohemorrhagic *Escherichia coli* (EHEC), or *Shigella dysenteriae* type 1; this form accounts for >90% of cases of HUS in children and usually occurs in epidemics (2).
    - Not associated with diarrhea but with invasive *Streptococcus pneumoniae* infection; sporadic distribution
  - Atypical: Not associated with above infectious causes. More common in infants <6 mo of age, those with insidious onset or relapse of HUS, or those with asynchronous family history of HUS (3)
- Both subtypes most commonly occur as a serious sequela of enteric infection with shiga-toxin producing, enterohemorrhagic *E. coli* (STEC or EHEC), the prototype of which is *E. coli* O157:H7.
- This strain is responsible for up to 3/4 of all cases of HUS.

### EPIDEMIOLOGY

- 1–10 cases per 100,000 children (2)
- Affects infants and younger children disproportionately; 2/3 of affected patients <5 yr of age
- HUS occurs in 5–20% of children with *E. coli* O157:H7 diarrhea (1).

### RISK FACTORS

- More common in white children
- Petting zoos or close contact with animals
- Eating undercooked ground beef, roast beef, or salami; salad dressings; contaminated water; or produce like lettuce, alfalfa, and radish sprouts
- Drinking unpasteurized milk
- Atypical HUS may be associated with a risk factor in up to 60% of cases, the most common being a disorder of complement regulation (3).

### GENERAL PREVENTION

- Cook ground beef thoroughly.
- Do not ingest raw milk or unpasteurized apple juice products.
- People with *E. coli* O157:H7 infection should not use recreational water bodies like swimming pools and water slides for 2 wk after the resolution of symptoms.
- Report to public health authorities any case of infection with *E. coli* O157:H7.

### PATHOPHYSIOLOGY

- E. coli* O157:H7 produces a large amount of toxin (verotoxin or shiga-like toxin).
- The toxin binds to and destroys colonic epithelial cells, causing bloody diarrhea.
- On entering the circulation, it binds to renal endothelial cells, leading to vascular occlusion and sclerosis of the glomeruli.
- The small blood vessel narrowing leads to mechanical damage of RBCs, resulting in microangiopathic hemolytic anemia.
- Thrombocytopenia results from shortened platelet survival, which is caused by fibrin deposition and platelet adhesion and consumption in the clots.
- Reduced blood flow through the stenotic blood vessels in the glomeruli leads to reduction in glomerular filtration rate and renal insufficiency.

### ETIOLOGY

- HUS most commonly follows infection with STEC.
- The most common STEC strain in the U.S. is O157:H7. The other STEC strains linked to HUS include O26, O45, O103, O111, O121, and O145.
- Rarely, HUS may follow infection with:
  - S. dysenteriae* type 1 (produces the shiga toxin, which is similar structurally to the toxin produced by STEC).
  - S. pneumoniae*: Usually in the course of complicated invasive disease (eg, pneumonia with empyema or meningitis) (4)
- Pneumococcal HUS:
  - 5% of all cases of HUS in children and 40% of HUS cases not caused by STEC (4)
  - Usually develops 3–13 days after onset of pneumococcal infection-related symptoms (4)
  - Affects younger children with a more severe initial course and greater morbidity than STEC HUS (1,4)

### COMMONLY ASSOCIATED CONDITIONS

- Diarrhea
- Gastroenteritis
- Thrombotic thrombocytopenic purpura (TTP)
- Atypical cases may be associated with disorders of complement regulation, ADAMTS 13 deficiency, defective cobalamin metabolism, HIV infection, malignancy, organ transplantation, use of calcineurin inhibitors, pregnancy, oral contraceptives, and SLE (3).

## DIAGNOSIS

### HISTORY

- Diarrhea:
  - Watery initially, then grossly bloody or heme-occult positive
- Severe abdominal pain
- Vomiting
- Fever in ~1/3 of cases
- HUS usually develops within 1–2 wk of the onset of diarrhea with a history of an abrupt onset of:
  - Pallor
  - Fatigue
  - Irritability
- Oliguria: Renal involvement can range from mild azotemia and normal urine output to anuria and the need for dialysis.

### PHYSICAL EXAM

- Sallow complexion (pallor and mild icterus)
- Features of dehydration
- Petechiae
- Features of renal insufficiency vary; ~50% may have edema and/or HTN.
- Hepatosplenomegaly may sometimes be present.
- Neurologic: Some degree of encephalopathy may often be present manifesting as listlessness, agitation, confusion, or irritability.
- CNS findings: Drowsiness, hemiparesis, seizures, and cranial nerve palsies:
  - May be related to development of cerebral edema or stroke

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC—moderate to severe anemia:
  - Hemoglobin usually between 5 and 9 g/dL
  - Reticulocyte count is mildly elevated.
  - Platelet count as low as 20,000/mm<sup>3</sup>
  - The peripheral blood smear shows schistocytes, helmet cells, burr cells—evidence of microangiopathic hemolytic anemia.
- Urinalysis: Hematuria and variable degree of proteinuria. WBCs may also be present. Granular and hyaline casts are often seen on microscopy of the sediment.
- BUN and creatinine, electrolytes:
  - Renal insufficiency with elevation of BUN and creatinine
  - Hyponatremia, hyperkalemia, and metabolic acidosis may be present.
  - LFTs and lactate dehydrogenase (LDH): Bilirubin and LDH levels may be raised due to hemolytic anemia.
- PT and PTT are usually normal or only slightly prolonged.
- Stool culture may grow *Shigella*:
  - Routine stool cultures will not reveal *E. coli* O157:H7.
  - Stool has to be cultured in a special sorbitol-containing medium—Sorbitol MacConkey agar culture. The *E. coli* O157:H7 are sorbitol negative, as are 90% of other *E. coli*. Sorbitol-negative *E. coli* are then serotyped using commercially available antisera to determine whether they are O157:H7.
- Negative stool culture does not rule out infection with STEC; culture may be negative by the time HUS is diagnosed.
- Coombs test: Positive direct Coombs test in the setting of an invasive pneumococcal infection and other features of HUS supports the diagnosis of pneumococcal HUS (4).
- DNA probes, polymerase chain reaction assay, enzyme immune assay (ELISA), phenotypic testing, and stool analysis for shiga toxin may be used by the reference or research labs for more definitive testing of the STEC isolate.
- Serologic diagnosis using ELISA to detect antibodies against *E. coli* O157:H7

**DIFFERENTIAL DIAGNOSIS**

- Bloody diarrhea:
  - Intussusception
  - Colitis
  - Inflammatory bowel disease
  - GI obstruction
- Pallor:
  - Iron-deficiency anemia
  - Lead poisoning
  - Protein-losing enteropathy
  - Hemolysis
  - Leukemia
- Also: Disseminated intravascular coagulation, collagen vascular disease, and malignant HTN

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Maintain vital signs within acceptable limits:
  - Correct dehydration with isotonic fluids:
    - Fluid therapy must account for deficit as well as renal function.
  - Administer antihypertensives if hypertensive crisis or hypertensive with evidence of end organ injury.

**MEDICATION****First Line**

- Furosemide 2 mg/kg/dose IV q8h:
  - Used to treat oliguria, efficacy unproven
- Antibiotics:
  - No evidence that treatment with antibiotics prevents or ameliorates typical HUS
- Pneumococcal HUS should be treated with vancomycin and 3rd-generation cephalosporin:
  - Cephalosporins:
    - Ceftriaxone 50 mg/kg/dose IV per day
    - Cefotaxime 25–50 mg/kg/dose IV q6h
  - Vancomycin 10 mg/kg/dose IV q6h:
    - In severe renal failure, dose adjustment is necessary.

**Second Line**

- Nifedipine 0.25–0.5 mg/kg/dose PO/SL q4–6h until HTN controlled, max single dose 10 mg/dose or 2 mg/kg/day
- Nicardipine (immediate release) 0.5–5 µg/kg/min:
  - For hypertensive emergency
  - Begin at a low dose and titrate upward.
- Anemia and thrombocytopenia may be corrected with transfusions of RBCs and platelets as needed.
- Platelet transfusions are indicated for clinically significant hemorrhage or prior to invasive procedures.
- No evidence of benefit of fresh frozen plasma or plasmapheresis in the diarrhea-associated form of HUS. May be beneficial in nondiarrheal forms of HUS and in TTP.

**SURGERY/OTHER PROCEDURES**

Oliguric acute renal failure may require treatment with dialysis. Peritoneal dialysis may work as well as hemodialysis. The indications for dialysis are:

- BUN > 100 mg/dL
- Hyperkalemia, especially if associated with significant ECG changes or dysrhythmia
- CHF
- Encephalopathy

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

Novel strategies being devised for disease prevention or amelioration include STEC-component vaccines, toxin neutralizers (shiga toxin neutralizing monoclonal antibodies), and small molecules that block shiga toxin-induced cell activation/apoptosis (5).

**DISPOSITION****Admission Criteria**

- All patients diagnosed with HUS should be admitted to a hospital with facilities for dialysis.
- Critical care admission criteria:
  - Renal failure
  - CHF
  - Hyperkalemia
  - Dysrhythmias
  - Severe anemia, thrombocytopenia
  - Encephalopathy

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS****Patient Monitoring**

Patients should be screened long term for abnormal renal function, HTN, neurologic defects, pancreatic insufficiency, diabetes mellitus, and GI complications such as colonic stricture and gallstones (1).

**PROGNOSIS**

- 3–5% mortality rate (1)
- Up to 50% of patients require dialysis during the acute phase (1).
- Aggressive supportive management including dialysis leads to >90% survival rate, with return of normal renal function in 65–85% of cases.
- Death or end-stage renal disease occurs in ~12% of patients with diarrhea-associated HUS (2).
- Patients with nondiarrheal atypical or sporadic illness have a worse prognosis.
- Patients with severe HTN and arteriolar changes on renal biopsy and those with recurrent disease are more likely to develop a persistent renal insufficiency and need closer monitoring.

**COMPLICATIONS**

- Renal insufficiency or end-stage renal failure
- Electrolyte imbalance, particularly hyperkalemia
- Insulin-dependent diabetes mellitus
- Pancreatitis
- Cardiomyopathy
- Neurologic sequela such as cerebral bleed or thrombosis
- HTN
- Pulmonary hemorrhage (1,5)

**CODES**
**ICD9**

283.11 Hemolytic-uremic syndrome

**PEARLS AND PITFALLS**

- Consider HUS in any ill child with current or recent history of bloody diarrhea or with anemia, thrombocytopenia, or azotemia.
- Assess for cardiovascular complications including hypertensive crisis, end organ injury secondary to HTN, and thrombocytopenia-associated hemorrhage.
- EHEC is the most common cause of HUS. There is no evidence that antibiotic therapy improves outcome.
- HUS is a multisystem disease that in addition to renal and hematologic effects may affect GI, endocrine, cardiac, and neurologic systems.

# HEMOPHILIA

Angela M. Ellison

## BASICS

### DESCRIPTION

- Hemophilia refers to a group of inherited disorders characterized by a deficiency of particular clotting factors.
- Factor VIII deficiency (hemophilia A) and factor IX deficiency (hemophilia B) will be discussed in this topic.

### EPIDEMIOLOGY

#### Incidence

The combined incidence of hemophilia A and hemophilia B is 1 in 5,000 live male births (1).

#### Prevalence

- Hemophilia A: 1 in 10,000 persons (2)
- Hemophilia B: 1 in 60,000 persons (2)

### RISK FACTORS

- Hemophilia A and B are X-linked recessive diseases:
  - Daughters of fathers with hemophilia are obligate carriers for the hemophilia gene mutation.
- Spontaneous mutation occurs in 25–33% of cases (3).

### GENERAL PREVENTION

- Male infants born to known or suspected carrier mothers should not be circumcised until hemophilia has been excluded.
- Immunizations should be given SC instead of IM.
- Aggressive contact sports should be avoided.
- Prophylactic therapy with infusion of factor VIII or factor IX concentrates may be initiated prior to any joint destruction (primary) or after joint disease has occurred (secondary prophylaxis).
- Primary prophylactic treatment of clotting has been shown to markedly reduce the risk of subsequent arthropathy in patients with severe disease (4):
  - This is typically initiated prior to a 2nd joint bleed.
- The decision to start prophylactic therapy should be made by a provider with expertise in hemophilia.

### PATHOPHYSIOLOGY

- Factors VIII and IX are necessary for the adequate formation of thrombin via the intrinsic clotting pathway:
  - In the absence of either factor, thrombin and fibrin are not adequately formed.
  - Patients are therefore susceptible to episodes of abnormal and prolonged bleeding.

- Joint spaces and other closed spaces usually have limited blood loss because of tamponade:
  - Open spaces (eg, iliopsoas muscle, open wounds, GI tract) may accumulate large amounts of blood, resulting in extensive hemorrhage or death if left untreated.
  - Recurrent joint bleeding leads to synovial thickening and joint cartilage erosion, resulting in narrowing of the joint spaces and eventually fusion.

### COMMONLY ASSOCIATED CONDITIONS

Coinheritance of factor V Leiden mutation and other prothrombotic markers occurs in a small proportion of patients with severe hemophilia A:

- The presence of these prothrombotic markers can result in fewer bleeding episodes and a later onset of 1st bleeding.

## DIAGNOSIS

### HISTORY

- Easy bruising or bleeding with minimally traumatic activity like brushing teeth
- Hematuria or abnormally prolonged bleeding in association with procedures or injury, excessive bruising, hematomas, or joint bleeding (hemarthrosis) with typical activities.
- 50% of undiagnosed hemophiliacs bleed in association with circumcision:
  - Hemophilia should be considered in the differential diagnosis of any infant who presents with bleeding post circumcision.
- 1/3 of patients with hemophilia have no family history. Lack of family history is of little value in excluding the possibility of hemophilia.
- The mother of a male patient may be identified as a carrier because of the presence of abnormal bleeding in other members of her family.

### PHYSICAL EXAM

- The most common sites of bleeding are into the joints, muscles, and GI tract.
- Clinical manifestations of hemarthrosis may vary by age:
  - Infants may present with irritability and decreased use of the affected limb.
  - In older children, hemarthrosis may be manifested by prodromal stiffness that is followed by acute pain and swelling.
  - Large weight-bearing joints such as the knees, hips, and ankles are most commonly affected.

- The quadriceps, iliopsoas muscle, and forearm are the major sites of bleeding involving the skeletal muscle:
  - A hematoma is usually present, and in severe cases, compartment syndrome may occur.
- GI bleeding may present with abdominal pain mimicking an acute abdomen or bloody stool. Bleeding may occur in the absence of trauma.
- Hematuria is a common manifestation of severe hemophilia; usually it is benign, although it may last for a few weeks.
- Intracranial bleeding can occur spontaneously or after trauma:
  - Patients usually present with headache, vomiting, lethargy, or altered mental status; however, some patients may be asymptomatic.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC
- PTT
- Activated partial thromboplastin time (aPTT):
  - A normal platelet count, normal PT, and prolonged aPTT are characteristic of hemophilia A, hemophilia B, and heparin therapy.
  - Some patients with mild hemophilia B may have a normal aPTT. For this reason, factor VIII and IX assays should be performed in patients with suspected undiagnosed bleeding disorders, even if the aPTT is normal.
- Severe hemophilia is defined as <1% factor activity, whereas 1–5% and >5% of normal activity are defined as moderate and mild disease, respectively (5).

#### Imaging

- Head CT should be performed in any patient with suspected intracranial hemorrhage:
  - Do not wait for result of head CT to administer clotting factors if hemorrhage is suspected.
- US or CT scan may be needed to confirm the presence of an iliopsoas bleed.
- Abdominal CT should be performed in any patient with suspected intra-abdominal bleeding.

### DIFFERENTIAL DIAGNOSIS

- The following differential diagnoses should be considered in patients with abnormal bleeding and a normal PT and prolonged aPTT:
  - Deficiency of factors VIII, IX, or XI
  - Deficiency of factor XII, prekallikrein
  - Von Willebrand disease
  - Heparin administration
  - Inhibitors of factors VIII, IX, XI, or XII
  - Lupus anticoagulant
- The differential for those with excessive bruising or petechia includes:
  - Idiopathic thrombocytopenic purpura
  - Leukemia
  - Henoch-Schönlein purpura
  - Sepsis/Meningococemia

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation.
- Direct pressure should be applied to sites of active bleeding.

### INITIAL STABILIZATION/THERAPY

- Bleeding into and around the airway should be considered in the setting of blunt or penetrating trauma to the face, neck, or chest. Emergent intubation may be required in these cases.
- Maintain adequate ventilation.
- The possibility of exsanguinating hemorrhage into large spaces should be considered. Direct pressure should be applied to sites of active bleeding; if necessary, fluid resuscitation should be initiated.
- Prompt therapy with clotting factor concentrate should start immediately and prior to any diagnostic procedures.

### MEDICATION

#### First Line

- Dose calculations of clotting factor concentrates:
  - Dose of factor VIII (international units) = weight (kg) × (desired % increase) × 0.5
  - Dose of factor IX (international units) = weight (kg) × (desired % increase) × F:
    - F = 1.0 for AlphaNine and Mononine products
    - F = 1.4 for BeneFIX
- Early joint or muscle bleeding (except iliopsoas) episodes are treated to achieve factor levels of 40–80% of normal (5).
- Patients with iliopsoas bleeding should be treated to achieve levels of 80–100% of normal (5).
- Severe bleeding or serious episodes such as intracranial and intra-abdominal hemorrhage or bleeding in the areas of the throat and neck require correction to achieve levels of 80–100% of normal (5).
- Plans for initiating therapy and duration of therapy should be discussed with a hematology consultant with expertise in hemophilia.

#### Second Line

- Desmopressin (DDAVP) is a synthetic vasopressin analog that stimulates release of endogenous factor VIII and von Willebrand factor:
  - It is recommended for mild to moderate bleeding in most individuals with hemophilia A who have shown a response to DDAVP in a previous trial.
  - Recommended dosing is 150  $\mu$ g (1 intranasal spray) for patients <50 kg and 300  $\mu$ g (1 spray in each nostril) for those >50 kg.
  - IV dosing is 0.3  $\mu$ g/kg mixed in 25–50 mL of normal saline infused over 15–30 min.

- Antifibrinolytic therapy may be used for treatment of oral hemorrhages or to minimize bleeding from dental procedures:
  - Choices include aminocaproic acid (Amicar), 100 mg/kg/dose PO q6h (max single dose 6 g/dose) or tranexamic acid (Cyklokapron), 25 mg/kg/dose PO q6h (max single dose 1.5 g).
- Thrombin may also be applied directly to the site of oral bleeding or epistaxis.

### DISPOSITION

#### Admission Criteria

Critical care admission criteria:

- Patients with intracranial bleeding or altered mental status should be admitted to the ICU.
- Patients at risk of airway compromise secondary to hemorrhage should be managed in an ICU setting.
- Moderate to severe bleeding into a large cavity (iliopsoas, intra-abdominal bleeding, etc.) may also require monitoring in an ICU setting.

#### Discharge Criteria

- Disposition should be discussed with the patient's primary hematologist.
- In general, patients with minor to moderate joint bleeding or other injury without obvious bleeding are eligible for discharge after appropriate factor replacement.

#### Issues for Referral

- Patients with hemophilia should receive integrated care as soon as the diagnosis is made.
- Designated treatment centers have been established in the U.S. to provide multidisciplinary care.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - The plan for further factor replacement and prophylactic therapy should be established in conjunction with the hematologist prior to discharge.
- Activity:
  - Activity may be restricted depending on the degree of injury and bleeding. All patients are encouraged to avoid activities that could aggravate their current injury or result in repeat injury.

#### Patient Monitoring

Plan for therapeutic monitoring of factor levels should be made in conjunction with the hematologist responsible for patient follow-up.

### PROGNOSIS

- Prognosis in hemophilia disorders depends on the type of hemophilia and the severity.
- The development of clotting factor products has made it possible for most people with hemophilia to look forward to a near-normal life span.

### COMPLICATIONS

- Chronic hemarthrosis with joint destruction
- Transmission of bloodborne infections from clotting factor concentrates and development of inhibitor antibodies
- Intracranial hemorrhage
- Exsanguination secondary to trauma

### CODES

- ICD9
- 286.0 Congenital factor viii disorder
  - 286.1 Congenital factor ix disorder

### PEARLS AND PITFALLS

- Although characterized as X-linked recessive disorders, females may also have hemophilia. This may occur secondary to X-chromosome inactivation during embryogenesis, via mating between an affected male and a carrier female (this produces homozygous disease in 50% of female offspring) or as an abnormal karyotype.
- Neonates have physiologic reduction in vitamin K–dependent factors, including factor IX. Therefore, reported low factor IX levels must be confirmed after 6 mo of age.

# HEMOPTYSIS

Masafumi Sato

Christopher J. Haines

## BASICS

### DESCRIPTION

Hemoptysis is bleeding that originates below the vocal cords into the respiratory tract with subsequent expectoration:

- Ranges from blood-tinged sputum to massive bleeding (frothy with a bright red/rusty color) with an alkaline pH
- Life-threatening hemoptysis is defined as >8 mL/kg in 24 hr (1–3).
- Small amounts of hemoptysis may go unnoticed in children <6 yr old secondary to a tendency to swallow their sputum (3,4).

### EPIDEMIOLOGY

- Hemoptysis is an uncommon event in children.
- A large 10-yr study examining the development of hemoptysis in children with cystic fibrosis (CF) described (5):
  - 4% developed massive hemoptysis.
  - >25% had recurrent episodes.
  - <25% had a 1st episode before 18 yr of age.

### PATHOPHYSIOLOGY

- The lungs and their supporting structures receive blood supply from 2 different systems:
  - The pulmonary system supplies the alveoli and produces small amounts of bleeding due to low venous pressure.
  - The bronchial system supplies the bronchi and connective tissue of lungs and produces massive bleeding due to high systemic pressure (originates from the thoracic aorta).
- Bronchiectasis results in tortuosity and dilation of the bronchial arteries. Secondary to these changes, collateral vessels form with an associated increased risk of bleeding.
- Diffuse alveolar hemorrhage (DAH) is a consequence of inflammatory/immune-mediated insults to the alveolar-capillary basement membrane with resultant bleeding. There are many pathophysiologic mechanisms responsible for the development of DAH.

### ETIOLOGY

- As many as 20% of the cases are idiopathic in origin (1,3).
- Infection:
  - The most common cause in children
  - Pneumonia: Bacterial/Pulmonary abscess, viral, TB, fungal (aspergillosis), parasitic (echinococcus)
- Foreign body aspiration
- Tracheostomy related
- Pulmonary disease:
  - CF
  - Tracheoesophageal fistula
  - Idiopathic pulmonary hemosiderosis (most commonly seen in children <6 yr old)
  - Pulmonary emboli (rare in children/adolescents)
  - Pulmonary endometriosis
  - Bronchiectasis
  - Arteriovenous malformations
  - Familial telangiectasia
  - Congenital bronchogenic cyst

- Congenital heart disease/cardiovascular disease
- Trauma:
  - Pulmonary contusion
  - Iatrogenic: Bronchoscopy, airway manipulation
  - Nonaccidental trauma (suffocation) (6)
- Coagulation disorders
- Immune-mediated/Collagen vascular diseases:
  - Systemic lupus erythematosus (SLE), Goodpasture syndrome, Henoch-Schönlein purpura (HSP), Wegener granulomatosis
- Tumors

## DIAGNOSIS

### DIFFERENTIAL DIAGNOSIS

- Hematemesis:
  - Vomiting of GI blood originating proximally to the ligament of Treitz
  - This blood is commonly darker red or brown with an acidic pH. Food particles may be present.
- Pseudo-hemoptysis:
  - Bleeding originating from the oropharynx or nasopharynx

### HISTORY

- Quantify the amount and frequency of hemoptysis.
- Assess for:
  - Trauma
  - The presence of pleuritic chest pain with shortness of breath, which may be associated with pulmonary emboli
  - Signs and symptoms of CF including chronic diarrhea, poor weight gain/failure to thrive, recurrent lung infections, recurrent wheezing unresponsive to standard therapy, and pancreatitis. Although the diagnosis may be made with newborn screening (varies by state), a small percentage of infants and young children may be missed.
  - A family history of pulmonary disease or bleeding disorders
  - Risk factors for TB, travel history, and sick contacts
  - Recent tonsillectomy causing pseudo-hemoptysis
  - Elicit aspiration risk factors such as a young age as well as a history of choking or running with objects in the mouth

### PHYSICAL EXAM

- Close attention to vital signs
- Blood loss may be evidenced by pallor, hypotension, and/or tachycardia.
- Attempt to localize the source of bleeding (true hemoptysis vs. pseudo-hemoptysis vs. hematemesis):
  - Inspect the oropharynx and nasopharynx for signs of bleeding to rule out pseudo-hemoptysis.
- Inspect for digital clubbing.
- Inspect for cutaneous or mucosal telangiectasia, as this may be associated with pulmonary arteriovenous malformations.
- Perform a full physical exam to elicit signs that are etiology specific.
- Infection/Pneumonia:
  - Tachypnea, crackles, wheezing, decreased air sounds, dullness to percussion

- Foreign body aspiration:
  - Unilateral absence or decreased breath sounds
- DAH syndrome:
  - Persistent cough with unexplained pallor
  - Lung exam may reveal diffuse wheezing unresponsive to treatment
- CF:
  - Appearance of failure to thrive, tachypnea, wheezing/coarse breath sound as well as clubbing may be present.
- Arteriovenous malformation:
  - Bruits over the lung fields
- Cardiac disease:
  - Tachycardia, tachypnea, characteristic murmurs, gallops, hepatomegaly, jugular venous distension, and edema may be seen.
- HSP:
  - Purpura on buttocks and extensor surfaces, hematuria, abdominal pain, arthritis
- SLE:
  - Malar rash, arthritis, photosensitivity, discoid rash, oral ulcers
- Infants presenting with hemoptysis warrant further investigation for signs of nonaccidental injury.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC with differential and coagulation panel (PT/PTT) should be obtained in all patients with suspected hemoptysis.
- In addition, the following tests should be obtained in patients with hemodynamic instability:
  - Type and cross, arterial blood gas, complete metabolic panel including LFTs
- Additional studies may be warranted but should be tailored to the specific clinical scenario:
  - Infectious: Blood cultures, PPD, sputum Gram and AFB stains, sputum cultures, serum IgE (aspergillosis)
  - CF: Electrolytes and referral for a sweat chloride test
  - Immune-mediated/Collagen vascular diseases: ESR, C-reactive protein, antinuclear antibody (ANA), urinalysis, complement
  - Additional coagulation studies should be obtained if a bleeding disorder is suspected.

#### Imaging

Choice of imaging should be based on history and physical exam findings. Options include:

- CXR (AP and lateral):
  - Useful as an initial screening study to identify bronchiectasis, cardiomegaly, consolidation, foreign bodies/air trapping, and effusions
  - Up to 1/3 of patients with hemoptysis may have a normal CXR.
- Chest CT scan:
  - This study may assist with the localization of bleeding, including the delineation of abscesses, arteriovenous and congenital malformations, bronchiectasis, or tumors.
- Technetium-99 scan
- CT angiography

**Diagnostic Procedures/Other**

- Flexible bronchoscopy can be performed at the bedside:
  - Allows inspection of the distal airways, but securing the airway can be difficult
  - Bronchoalveolar lavage (BAL) may be performed in conjunction with this procedure.
  - Flexible bronchoscopy may be performed in the settings of the emergency department, ICU, or operating room.
- Rigid bronchoscopy must be performed in the operating room:
  - Advantages include the ability to secure the airway and remove foreign bodies.
  - This is the preferred method of visualization for massive hemoptysis.

**Pathological Findings**

- Blood-tinged BAL definitively represents the presence of blood in the respiratory tract.
- Hemosiderin-laden macrophages may be obtained from BAL or gastric aspirates. This finding implies that bleeding has been present for at least 2 days but does not delineate an etiology.

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Attention to and stabilization of airway, breathing, and circulation
- Airway suctioning, endotracheal intubation if necessary:
  - Selective intubation of the nonhemorrhaging lung may be necessary.
- Supportive care may be all that is required in many cases.
- Supplemental oxygen and airway management should be provided as needed.
- Establish IV access for fluid resuscitation as needed for signs of hypovolemia.
- Correct coagulopathy with platelet and fresh frozen plasma infusions.
- Early consultation with a pulmonologist is recommended.
- Although most bleeding is mild and self-limited, massive bleeding from a tracheostomy may represent innominate artery bleeding requiring direct pressure and urgent ENT consultation.
- Additional management should be based on the underlying etiology:
  - Infectious: Antibiotics
  - CF: Antibiotics and corticosteroids
  - Foreign body: Removal with rigid bronchoscopy
  - Pulmonary hemosiderosis: Corticosteroids

**MEDICATION**

- Not all cases of hemoptysis require pharmacologic intervention. Many cases may be managed with airway support alone.
- The following medication may be utilized in conjunction with airway support:
  - Topical epinephrine (1:10,000–1:20,000 dilution) lavage via bronchoscopy

- Recombinant factor VIIa (rFVIIa) has been successfully used (off-label) in treatment of severe hemoptysis due to various causes (7):
  - Commonly used dosage is 90  $\mu\text{g}/\text{kg}$  q2–3h for 2–3 doses
- IV methylprednisolone is the initial drug of choice for DAH syndrome.

**SURGERY/OTHER PROCEDURES**

- Bronchial artery embolization may be used for life-threatening or chronic recurrent hemoptysis.
- Surgical lung resection/vessel lateralization is generally a last option with massive pulmonary bleeding:
  - This should be avoided in patients with CF, as this procedure has been associated with poor outcomes.

**DISPOSITION****Admission Criteria**

Critical care admission criteria:

- Massive hemoptysis, signs of respiratory insufficiency, hemodynamic instability, severe anemia, and/or coagulopathy
- All other patients with documented significant hemoptysis should be admitted for serial lab studies and additional testing as needed.

**Discharge Criteria**

- A select group of patients may be considered for discharge after pulmonary consultation, after observation in the emergency department, and after definitive outpatient follow-up has been arranged.
- These patients include those in which the diagnosis of hemoptysis is questionable or those who have had a single episode of low-volume hemoptysis without signs or symptoms of anemia or hemodynamic or respiratory compromise.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Patients should be instructed to return promptly with the development of recurrent hemoptysis, dyspnea, lethargy, or pallor.
- Caregivers should be informed that hemoptysis due to idiopathic pulmonary hemosiderosis may recur.
- Most patients who have had a single episode of low-volume hemoptysis should be instructed to follow up with their primary care physician and do not need to routinely follow up with a specialist such as a pulmonologist.

**Patient Monitoring**

Specific monitoring is not required for patients who have experienced low-volume hemoptysis.

**PROGNOSIS**

- Most pediatric hemoptysis is self-limited and non-life threatening.
- 1 published report examined predictors for increased mortality encompassing all etiologies of hemoptysis (8):
  - Young age at 1st hemoptysis, large amount of hemoptysis, need for blood products, presence of fever

**COMPLICATIONS**

- Respiratory insufficiency
- Respiratory failure
- Hypovolemic shock
- Pneumonia/Pneumonitis

**CODES****ICD9**

786.30 Hemoptysis, unspecified

**PEARLS AND PITFALLS**

- Most hemoptysis is idiopathic, self-limiting, and non-life threatening, requiring supportive care only.
- Unlike hemoptysis, pseudo-hemoptysis is bleeding that originates from the oropharynx or nasopharynx.
- Mortality from hemoptysis most commonly results from respiratory compromise. Immediate airway management decreases morbidity and mortality.
- Have a high index for nonaccidental injury in infants presenting with hemoptysis.

# HEMOTHORAX

Kevin Ching

## BASICS

### DESCRIPTION

A hemothorax is a collection of blood in the intrapleural space, usually as a complication of blunt or penetrating chest trauma:

- Can cause lung compression and increased intrathoracic pressure with resulting hypoxia and decreased cardiac output

### EPIDEMIOLOGY

- In a study that reviewed 2,086 children <15 yr of age admitted from a single level-1 trauma center for blunt or penetrating trauma, 15 had hemopneumothorax (with a 26.7% mortality rate) and 14 had hemothorax (with a 57.1% mortality rate) (1).
- No clear estimate as to overall prevalence and overall incidence

### RISK FACTORS

- Improper use or lack of use of car restraints
- Genetic predisposition to bleeding diathesis
- Presence of nontraumatic etiologies:
  - See Etiology section.

### PATHOPHYSIOLOGY

A hemothorax develops when blood enters the intrapleural space:

- Respiratory impairment may develop if significant volumes of blood interfere with oxygenation and ventilation.
- May coexist with a pneumothorax
- Rate of hemorrhage may lead to hypovolemia, hypotension, and shock with a volume >30%.

### ETIOLOGY

- Traumatic:
  - Blunt injury:
    - Rib fractures accompanied by laceration of the intercostal or internal mammary arteries
    - Because of pediatric thoracic wall compliance, rib fractures may be absent.
  - Penetrating injury:
    - Violent (deliberate), accidental, or iatrogenic (eg, subclavian venous catheterization)
    - Direct laceration of arteries (intercostals, internal mammary, great vessels, or heart itself)
- Nontraumatic:
  - Infections
  - Neoplasm
  - Pulmonary arteriovenous malformation
  - Pulmonary embolism
  - Congenital cystic adenomatoid malformation
  - Pulmonary sequestration
  - Bleeding diathesis
  - Von Recklinghausen disease
  - Connective tissue disorders

## DIAGNOSIS

### HISTORY

- Chest pain
- Dyspnea
- Hemoptysis

### PHYSICAL EXAM

- Tachypnea
- Hypoxia
- Tachycardia
- Hypotension
- Unilateral diminished (or absent) breath sounds
- Dullness to percussion (difficult to appreciate when supine)
- Diminished chest wall excursion
- External chest wall bruising or lacerations
- Flail chest (multiple adjacent fractured ribs lead to paradoxical motion of a flail segment)

- Predictors of thoracic injury in children:
  - Low systolic BP
  - Elevated respiratory rate
  - Abnormal results on thoracic exam
  - Abnormal chest auscultation
  - Femur fracture
  - Glasgow Coma Scale (GCS) <15 (2)

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC
- PT/PTT, INR
- Type and cross-match

#### Imaging

- CXR (3):
  - Min of 200 mL of intrapleural blood is required for visualization in an adult.
  - Supine film:
    - Diffuse opacification as blood layers posteriorly without a visible fluid level:
      - May miss up to 1 L in an adult
  - Erect film:
    - Air-fluid level or blunting of costophrenic angles:
      - May require as much as 400–500 mL blood in an adult
- Chest CT scan:
  - More sensitive than CXR in detecting a small hemothorax or retained clots

#### Diagnostic Procedures/Other

US (focused abdominal sonograph for trauma [FAST] exam) (4):

- More rapid and sensitive than CXR:
  - Can detect as little as 20 mL of intrapleural blood
- Consider the reverse Trendelenberg position.
- During right and left intercostal oblique views, slide the probe cephalad to obtain views of the diaphragm:
  - Intrapleural fluid will appear as a black triangle above the diaphragm.
  - Clotted blood may be mistaken for normal soft tissue.

### DIFFERENTIAL DIAGNOSIS

- Pneumothorax
- Pulmonary contusion
- Pleural effusion
- Empyema

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation (ABCs).
- Needle decompression only if tension pneumothorax suspected and patient is unstable:
  - See Pneumothorax topic for further details.
- Establish large-bore IV access:
  - Initiate fluid resuscitation with isotonic crystalloid.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation (ABCs):
  - Administer supplemental oxygen via a nonrebreather mask.
  - Consider intubation.
  - Establish large-bore IV access if not already in place.
  - Aggressive fluid resuscitation with 20 mL/kg of normal saline or lactated Ringer boluses
  - Consider blood transfusion.
  - Cervical spine immobilization as appropriate
- Position upright if possible.
- Tube thoracostomy (5):
  - Definitive therapy for evacuation of hemothorax:
    - Locate the 6th intercostal space, posterior axillary line.
    - Insert appropriately sized chest tube posteriorly and inferiorly.
    - Connect tube to an underwater seal and vacuum device (inspect for air bubbles and/or blood).
    - Obtain CXR for confirmation of position.
    - If evacuation is unsuccessful or if concomitant pneumothorax, consider inserting a 2nd chest tube (positioned superior and anteriorly).
  - If hemodynamically stable, consider procedural sedation.

### SURGERY/OTHER PROCEDURES

- Thoracotomy:
  - Surgical consultation is highly recommended.
  - Surgical exploration if traumatic hemothorax produces:
    - Massive hemothorax: > 1 L of blood return immediately
    - Persistent bleeding > 150–200 mL/hr for 2 hr
    - Hemodynamic instability despite aggressive blood transfusions
- Video-assisted thoracoscopy:
  - Permits direct removal of a retained clot
  - Reduces incidence of empyema and fibrothorax

## DISPOSITION

### Admission Criteria

- All hemothoraces require inpatient clinical and radiographic monitoring.
- Critical care admission criteria:
  - Tension pneumothorax
  - Open pneumothorax
  - Unstable vital signs
  - Mechanical ventilation
  - Presence of other systemic injuries requiring critical care

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

#### Patient Monitoring

- Transition chest tube to water seal:
  - When lung is fully expanded
  - <50 mL blood drained in 24 hr
- Chest tube removal:
  - No air leak and <50 mL blood collected in 24 hr

### COMPLICATIONS

- Retained hemothorax:
  - Usually due to a residual clot
- Empyema
- Fibrothorax
- Trapped lung:
  - Refers to an unexpandable lung due to visceral pleural restriction

## CODES

### ICD9

- 511.1 Pleurisy with effusion, with mention of a bacterial cause other than tuberculosis
- 511.89 Other specified forms of effusion, except tuberculous

## PEARLS AND PITFALLS

- Pearl:
  - A coagulopathy is not a contraindication to drainage but necessitates discontinuation of anticoagulants and correction of factor deficiencies prior to thoracostomy whenever possible.
- Pitfall:
  - Patients with a diminished level of consciousness (GCS <15) or distracting injuries (such as a femur fracture) may not complain of chest pain or thoracic tenderness despite a rib fracture and hemothorax.

# HENOCH-SCHÖNLEIN PURPURA

Kari R. Posner

## BASICS

### DESCRIPTION

- Henoch-Schönlein purpura (HSP) is the most common form of systemic vasculitis in children.
- It is an immune complex-mediated disease of widespread nature and multisystem involvement.
- Characterized by palpable purpura in patients with neither thrombocytopenia or coagulopathy; associated with arthritis/arthralgia, abdominal pain, and renal disease
- 90% of cases occur in the pediatric age group.

### EPIDEMIOLOGY

#### Incidence

HSP occurs in 10–20 per 100,000 children annually (1):

- Peak incidence between 4 and 6 yr of age (2)
- Slight male predominance of 1.2:1 (1)
- Lower incidence in black children compared with white or Asian children (1)
- More common in autumn and winter months

### RISK FACTORS

Possible genetic predisposition:

- Immune complex reaction to antigenic stimuli

### PATHOPHYSIOLOGY

Immune-mediated vasculitis associated with IgA deposition:

- IgA complexes are deposited in the skin, gut, and glomeruli, triggering a localized inflammatory response and necrosis of small blood vessels.

### ETIOLOGY

Pathogenesis is not clearly understood:

- Often preceded by an upper respiratory tract infection 1–3 wks prior to onset of symptoms
- Many cases follow streptococcal infection.
- Other pathogens implicated include parvovirus, adenovirus, hepatitis A virus, mycoplasma, and bartonella (3).

## DIAGNOSIS

### HISTORY

- Preceding upper respiratory tract or streptococcal infection
- Abdominal pain
- Arthritis of knees, ankles, wrists, elbows, or digits
- Rash and/or edema predominantly or exclusively involving areas below the waist:
  - Rash is petechial or purpuric.
- Hematuria
- Blood in stool
- Scrotal swelling
- Usually no history of fever

### PHYSICAL EXAM

- Skin:
  - Painless palpable purpura is the presenting sign in 25% of affected children (3).
  - Crops of erythematous, raised patches are most commonly localized to the lower extremities and buttocks in a symmetric distribution.
  - Localized subcutaneous edema of the scalp and extremities
- Joints:
  - Arthritis/Arthralgia that is transient or migratory, typically oligoarticular and nondeforming
  - Large joints of lower extremities
  - Periarticular swelling and tenderness without joint effusion, erythema, or warmth
  - May precede purpura by 1–14 days
- Abdomen:
  - Tenderness in periumbilical or epigastric region
  - Abdominal pain is colicky in 50–75% of patients and may precede purpura in 15–35% of cases (2).
  - Intussusception is a recognized complication
- BP may be elevated secondary to glomerulonephritis.
- Scrotal tenderness or swelling in a small percentage of males

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Urinalysis: Hematuria/Proteinuria present
- Stool: 30% of patients have blood in stool.
- CBC: Normal platelets and hemoglobin; possible leukocytosis
- PT/PTT: Normal
- ESR may be normal or elevated.
- Screen for group A streptococcal pharyngitis: Positive in 70% of cases (4)

#### Imaging

- Abdominal US: Can detect increased bowel wall thickness and screen for intussusception
- Testicular US and Doppler flow if scrotal complaints

#### Diagnostic Procedures/Other

- Skin biopsy: Not necessary for diagnosis, but if performed due to diagnostic uncertainty, lesions demonstrate IgA and complement deposition.
- Renal biopsy if progressive renal involvement

#### Pathological Findings

- Skin: IgA deposition; shown on immunofluorescent microscopy
- Renal: Glomerulonephritis involving endothelial and mesangial cells, similar to that of IgA nephropathy. Epithelial crescent formation represents more significant inflammatory damage.

### DIFFERENTIAL DIAGNOSIS

- Acute abdomen:
  - Appendicitis
  - Intussusception
  - Testicular torsion
- Purpuric rash:
  - Septicemia/Meningococemia
  - Idiopathic thrombocytopenic purpura
  - Hemolytic uremic syndrome
  - Leukemia
  - Coagulopathies
  - Rickettsial infections
  - Child abuse
  - Bacterial endocarditis
  - Acute hemorrhagic edema of childhood: Affects children <2 yr of age
- Vasculitis:
  - Systemic lupus erythematosus
  - Wegener granulomatosis
  - Polyarteritis nodosa
  - Hypersensitivity vasculitis
- Rheumatic fever
- Rheumatoid arthritis

## TREATMENT

### INITIAL STABILIZATION/THERAPY

IV fluid and pain control for severe abdominal pain, emesis, or GI bleed

### MEDICATION

#### First Line

- Usually resolves spontaneously without specific therapy
- Analgesia: NSAIDs or acetaminophen are typically used; rarely, opioids may be needed for severe pain.
  - NSAIDs:
    - Avoid with GI bleeding.
    - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
    - Ketorolac 0.5 mg/kg IV/IM q6h PRN
    - Naproxen 5 mg/kg PO q8h PRN
  - Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
  - Opioids:
    - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
      - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
    - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
- Abdominal pain: Consider prednisone 2 mg/kg/day PO (max single dose 60 mg) for 1 wk with weaning over the next 2 wk (5):
  - Corticosteroid use in HSP is not well-established, although some studies have shown a statistically significant decrease in duration of abdominal symptoms.

- HTN: Angiotensin-converting enzyme inhibitors may be indicated:
  - Captopril 0.3–0.5 mg/kg/dose PO; titrate up to 6 mg/kg/day in 2–4 divided doses
  - Renal manifestations: No evidence of benefit of prednisone in preventing serious long-term kidney disease (6)

**Second Line**

Severe renal involvement: High-dose corticosteroid (2 mg/kg/day PO with a max of 80 mg/day with a slow taper) plus oral cyclophosphamide (2 mg/kg/day PO for 12 wk) appears to reduce proteinuria significantly (7).

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

Other immunosuppressive therapies such as cyclosporine or azathioprine are less well established and should be considered carefully since the risks may outweigh the benefits.

**DISPOSITION**

**Admission Criteria**

- Severe abdominal pain
- Significant GI bleeding
- Intractable vomiting
- Marked renal insufficiency
- Intractable joint pain
- Hypertensive emergency
- Diagnosis in doubt

**Discharge Criteria**

- Well appearing and normotensive
- Adequate analgesia
- No evidence of intussusception or bowel ischemia
- No evidence of renal insufficiency

**Issues for Referral**

Abnormal renal function, HTN, nephritis, or nephrotic syndrome should prompt immediate discussion with a pediatric nephrologist.

 **FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - See the primary care physician weekly during the acute illness for urinalysis and BP measurement.
  - Check urine monthly after acute illness for at least 6 mo.
- Activity:
  - As tolerated

**Patient Monitoring**

- 6–12 mo after diagnosis to screen for development of renal involvement
- Women with HSP will need to be closely monitored during pregnancy due to increased risk for preeclampsia.

**DIET**

- Low salt for hypertensive patients
- Simple diet if severe abdominal pain
- Parenteral nutrition may be necessary, as feeding can worsen pain.

**PROGNOSIS**

- Usually self-limiting with resolution of disease within 8 wks
- Better prognosis in the younger age groups
- Recurrence within the 1st year in 30–40% of patients (2)
- GI disease accounts for the most significant morbidity in the short term.
- Renal involvement is the cause of the most serious long-term morbidity: 20–54% have some sort of renal manifestation, with 2–12% progressing to renal failure (8).

**COMPLICATIONS**

- HTN
- Renal disease
- Intussusception: Most commonly ileoileal
- Protein-losing enteropathy
- Hydrops of the gall bladder
- Bowel perforation, ischemia, and infarctions
- Skin necrosis
- Scrotal swelling and pain
- Torsion of the testis and appendix testis
- Pulmonary hemorrhage, mild interstitial lung disease
- Headaches, seizures, focal neurologic deficits, ataxia, central and peripheral neuropathy

**See Also (Topic, Algorithm, Electronic Media Element)**

- Hypertension
- Idiopathic Thrombocytopenic Purpura
- Intussusception
- Meningococemia
- Pain, Abdomen
- Rash, Purpura

ICD9  
287.0 Allergic purpura

**PEARLS AND PITFALLS**

- Joint and GI symptoms precede the onset of purpura in 20–25% of cases of HSP.
- Nephritis rarely precedes the onset of purpura in HSP.
- Abdominal US is indicated in patients with severe abdominal pain. Contrast enema may miss intussusception in HSP since it is usually confined to the small bowel.
- The diagnosis of HSP is more difficult if there is only incomplete presentation of constellation of typical symptoms. In these circumstances, other causes for purpura, abdominal pain, arthritis, and renal disease must be considered.
- HSP is usually self-limited, and therapy has remained controversial. Consultation with a nephrologist is warranted in any patient with renal involvement.

# HEPATIC ENCEPHALOPATHY

Angela M. Ellison

## BASICS

### DESCRIPTION

Hepatic encephalopathy (HE) describes a spectrum of potentially reversible neuropsychiatric abnormalities in patients with liver dysfunction, after exclusion of other known brain disease (1):

- HE is clinically classified into 3 major categories (1):
  - Type A occurs in patients with acute liver failure.
  - Type B occurs in patients without intrinsic liver disease but with large, noncirrhotic portosystemic shunting (eg, portal vein thrombosis).
  - Type C (most common form) is related to underlying cirrhosis with portosystemic shunting.

### RISK FACTORS

- Liver disease (acute, chronic, or severe)
- Placement of a transjugular intrahepatic portosystemic shunt (TIPS)
- Vaso-occlusion including portal vein thrombosis or hepatic vein thrombosis
- Factors that increase ammonia production, absorption, or entry into the brain, including excessive protein intake, GI bleeding, constipation, diuretic therapy, infection, metabolic alkalosis, and electrolyte abnormalities (hypokalemia and hyponatremia)
- Renal failure or renal obstruction
- Hypovolemia
- Administration of sedatives, tranquilizers, or analgesics

### GENERAL PREVENTION

- Aggressive treatment of underlying liver disease
- Avoidance of precipitating factors

### PATHOPHYSIOLOGY

- HE ultimately results from portosystemic shunting, alterations in the blood-brain barrier, and the interactions of accumulated toxic metabolites in the brain.
- Putative explanations:
  - Portosystemic shunting allows toxic metabolites, which are usually removed by a healthy liver, directly into the systemic circulation.
  - The blood-brain barrier, which usually protects the brain from neurotoxins, has increased permeability in liver failure. Therefore, the brain is left susceptible to the effects of neurotoxins.
  - Ammonia is the most commonly implicated neurotoxin in the pathogenesis of HE. In severe liver disease, conversion of ammonia to urea is markedly reduced.
  - Ammonia can have multiple neurotoxic effects on the brain, including impairment of amino acid metabolism, alteration of the transit of water and electrolytes across cells, and inhibition of excitatory and inhibitory postsynaptic potentials.
  - Treatments that decrease blood ammonia levels can improve HE symptoms, suggesting ammonia's role in HE (3).

- Arguments against ammonia's role in the pathogenesis of HE include the observation that ~10% of patients with significant encephalopathy have normal serum ammonia levels. In addition, many patients with cirrhosis have elevated ammonia levels but no evidence of encephalopathy.
- GABA is a neuroinhibitory substance produced in the GI tract. Over the past 2 decades, it has been postulated that HE may result from increased GABA tone in the brain. Recent studies have shown there are no changes in brain GABA levels and that brain GABA receptors are normal in number and activity in individuals with HE (4). It is possible that false GABA-like neurotransmitters may play a role.
- Mercaptans and short- and medium-chain fatty acids may contribute to HE by interfering with ammonia metabolism.
- Glutamine contributes to impairment of cerebral energy metabolism and increases the blood to brain transport of certain amino acids. The metabolites of these amino acids may be implicated in HE.
- New theories suggest it may be that multiple toxins, each unable to produce encephalopathy on their own, are necessary for HE to develop (5).

### ETIOLOGY

- Liver failure as in fulminant hepatitis
- Noncirrhotic portosystemic shunting
- Portosystemic shunting with cirrhosis

## DIAGNOSIS

### HISTORY

- A history of liver dysfunction or history of previous TIPS placement with onset of behavior changes or altered mental status may be elicited.
- History of abdominal pain, distension, vomiting, diarrhea, edema, or jaundice
- Weight loss or changes in appetite may help to establish a time line of current illness.
- Cardiac history, including history of pulmonary HTN, should be determined.
- Obtain a list of current medications including herbal remedies.
- Determine risk for medication-induced hepatotoxicity, such as that from acetaminophen.
- Current or previous IV drug use by the patient or close contacts should be determined.
- Transfusion history
- Verify hepatitis B immunization status.
- Travel history should be obtained especially if there has been recent travel to areas with high rates of hepatitis B infection.
- Individuals with fulminant hepatic liver failure may present with signs of HE.

### PHYSICAL EXAM

- Findings associated with hepatic disease: Jaundice, muscle wasting, ascites, asterixis, palmar erythema, edema, spider telangiectasias, and fetor hepaticus
- The clinical stages of HE range from disorientation to coma (5):
  - Stage 0: Normal level of consciousness, normal personality and intellect, and no neurologic signs. Subclinical disease: Normal level of consciousness, normal personality, but abnormalities on psychometric testing.
  - Stage 1: Inverted sleep patterns, restlessness; demonstrates forgetfulness, mild agitation, confusion, or irritability. Neurologic signs include tremor, apraxia, incoordination, impaired handwriting, and performance of simple cognitive tasks such as addition/subtraction.
  - Stage 2: Lethargic or slow to respond, disoriented, decreased inhibitions and inappropriate behavior. Neurologic signs include asterixis, dysarthria, ataxia, and hypoactive reflexes.
  - Stage 3: Somnolent but able to be aroused, gross disorientation, and aggressive behavior. Neurologic signs include asterixis, hyperactive reflexes, Babinski sign, and muscle rigidity.
  - Stage 4: Coma; may have decerebrate posturing

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Serum ammonia level should be drawn in a nonheparinized container, placed on ice immediately, and assayed within 30 min.
- Hepatic enzyme tests including ALT, AST, alkaline phosphatase, GGT, PTT, PTT, and INR should be obtained to further assess underlying liver disease.
- Serum electrolytes, BUN, creatine, glucose
- Additional testing to rule out other potential diagnoses should be guided by the history and physical exam.

#### Imaging

Head CT should be performed to rule out other potential etiologies (hemorrhage, tumor, or traumatic injury) as well as to determine the presence of generalized or localized brain edema.

#### Diagnostic Procedures/Other

- EEG if it is unclear whether seizure is the cause of symptoms:
  - EEG is typically abnormal in HE, with generalized slowing and nonspecific changes.

**DIFFERENTIAL DIAGNOSIS**

- Metabolic abnormalities including hypoglycemia, ketoacidosis, and hypercarbia
- Head trauma: Inflicted or accidental
- Electrolyte imbalance
- Alcohol or other toxic ingestions
- Reye syndrome
- Uremia secondary to other causes such as renal failure and inherited urea cycle disorders
- CNS disease
- Hemorrhage
- Meningitis
- Encephalitis
- Abscess
- Ischemia, stroke
- Neoplasm
- Sepsis
- Seizure disorder (postictal state)

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Any patient with suspected HE should have immediate evaluation of the airway, breathing, and circulation.
- Patients with grade 3 or 4 encephalopathy will likely require endotracheal intubation.
- Check serum glucose.
- Prompt identification and correction of precipitating factors should occur. Most patients will improve after correction of precipitating factors.
- Sedatives should be avoided.
- Once the patient is stabilized, prompt consultation with a pediatric gastroenterologist is recommended.

**MEDICATION****First Line**

Oral lactulose is the mainstay of therapy for treatment of HE. Its method of action is thought to be ammonia trapping by acidification of feces:

- Usual infant dose is 2.5–10 mL/day divided q6–8h (6). Pediatric dose is 40–90 mL/day divided q6–8h (6). All doses should be titrated to produce 2–3 soft stools per day.
- Comatose patients should receive lactulose via an NG tube.
- Oral lactulose should not be given to patients with an ileus or with tense ascites.

**Second Line**

- Neomycin may be administered in an effort to decrease colonic concentration of ammoniagenic bacteria. Initial oral dose in infants and children is 50–100 mg/kg per day divided q6–8h, max single dose 12 g/24 hr (6).
- Neomycin should not be given to patients with evidence of intestinal obstruction.
- Usually, therapy with either lactulose or neomycin is sufficient to treat most patients. If combined therapy is used, it is important that stools remain acidic.

**DISPOSITION****Admission Criteria**

- Pediatric patients with suspected HE stage II, III, or IV require hospital admission.
- Critical care admission criteria:
  - Those with HE stage 2, 3, or 4 should be admitted to an ICU.

**Discharge Criteria**

Patients with HE grade 0 or 1, known underlying cause, and adequate home care

**Issues for Referral**

Refer to primary care physician, gastroenterologist, or hepatologist.

**FOLLOW-UP****DIET**

- In acute HE, all dietary and IV protein should be avoided.
- As encephalopathy regresses, patients should resume normal protein content (0.8–1.5 g/kg/day) (7).
- Vegetable protein or supplementation with branched-chain amino acids may be considered in situations where patients are not able to tolerate normal amounts of dietary protein.

**PROGNOSIS**

- Most cases of HE resolve without neurologic sequelae if appropriately treated.
- HE in the setting of acute liver failure in children is associated with a very poor outcome.

**CODES****ICD9**

572.2 Hepatic encephalopathy

**PEARLS AND PITFALLS**

- In cases of suspected HE, investigate for precipitating factors.
- Only arterial or free-flowing venous blood samples should be used to check ammonia levels (the use of tourniquets will provide falsely elevated levels).
- Blood ammonia levels and hepatic enzyme tests correlate poorly with clinical status. Progression or improvement should be determined by bedside exam.

# HEPATITIS, ACUTE

Angela M. Ellison

## BASICS

### DESCRIPTION

- *Hepatitis* is a term used to describe inflammation in the liver.
- Hepatitis may result from both infectious (viral, bacterial, fungal, and parasitic organisms) and noninfectious (medications, toxins, and autoimmune) causes.
- This topic will focus primarily on viral causes of hepatitis, including hepatitis A, B, and C.

### EPIDEMIOLOGY

#### Incidence

Each year in the U.S., an estimated 25,000 persons become infected with hepatitis A virus (HAV), 32,000 with hepatitis B virus (HBV), and 17,000 with hepatitis C virus (HCV) (1).

#### Prevalence

1.2 million Americans are living with chronic HBV, and 3.2 million are living with chronic HCV (1).

### RISK FACTORS

- HAV is predominantly transmitted via the fecal–oral route. Risk of HAV infection is greatest in developing countries, areas with poor sanitation, and day care settings (2).
- Those at greatest risks for HBV infection include (3):
  - IV drug users
  - Those who have sexual contact with a person who has HBV
  - Infants born to infected mothers
- Additional HBV risk factors include (3):
  - Recipients of contaminated blood and blood products
  - Hemodialysis patients
  - Prisoners
  - Health care workers
  - Household contacts of HBV carriers
- The major risk factors for HCV infection include (4):
  - IV and intranasal drug use
  - Needlestick injuries (health care workers)
  - Transfusion of infected blood and blood products
- Sexual and household transmission of HCV occurs infrequently (4).
- Perinatal transmission of HCV occurs but is relatively uncommon (4).

### GENERAL PREVENTION

- Immunization for hepatitis A and B are the most effective methods of prevention.
- Patients should not share any items with potential for contamination with blood and other infectious body fluids.
- HAV:
  - Travelers to HAV-endemic areas should not drink untreated water or ingest raw seafood or shellfish. Use caution when eating fruits and vegetables from these regions.
  - Strict hand washing and improved sanitation help to prevent the spread of HAV.
  - HAV vaccine is recommended for patients with chronic liver disease and travelers to endemic areas (2).
  - Travelers should receive the 1st dose of HAV vaccine at least 4 wk prior to travel.
  - Administration of HAV immune globulin may also serve as an alternative to vaccination against HAV.
  - It should be given q4–6mo if one plans to spend more than 3 mo in regions where HAV is endemic.
  - Postexposure prophylaxis with HAV immune globulin can protect household, day care, and intimate contacts of patients with HAV.
  - Coworkers of food handlers should also receive HAV immune globulin.
  - Prophylaxis should be administered within 2 wk of exposure (2).
  - Infants born to women infected with HAV during the 3rd trimester should receive postexposure prophylaxis with immune globulin.
- HBV:
  - Adults, infants, and children should receive active immunization with the 3-dose recombinant DNA HBV vaccine.
  - Nonimmunized persons (including pregnant patients) who suffer percutaneous exposure to HBV and neonates born to potentially infected mothers should receive passive immunization with HBV immune globulin in addition to active immunization.
- HCV:
  - There are no vaccines available to prevent HCV infection, and immune globulin has not been proven to prevent transmission of HCV.

### PATHOPHYSIOLOGY

- Degree of hepatic damage from acute viral hepatitis can vary from a mild injury to massive hepatic necrosis.
- Regeneration generally begins within 48 hr of hepatic necrosis.
- When infection is severe, fulminant hepatitis (liver failure from severe acute infection) may occur.
- Obstruction can occur in the blood vessels that perfuse the liver, resulting in tissue hypoxia.
- Bile flow can also become obstructed.

## DIAGNOSIS

### HISTORY

- The most common symptoms of acute hepatitis include abdominal pain, nausea, vomiting, fatigue, and anorexia.
- Fever is variably present.
- Jaundice and dark urine occur after disease severity increases.
- Some patients may be asymptomatic or mildly symptomatic, while others may present with rapid onset of fulminant hepatic failure.
- Weight loss and changes in appetite may help to establish a time line.
- A list of current medications should be obtained.
- Possible exposures including blood transfusions, IV and intranasal drug use, alcohol consumption, tattoos, and sexual history should be elicited.
- Travel history should be documented.
- Important considerations should also include the use of or exposure to any chemicals or medications that may cause similar symptoms.
- Immunization status should be verified.

### PHYSICAL EXAM

- Scleral icterus and jaundice may be present.
- Right upper quadrant abdominal tenderness and hepatomegaly may be elicited.
- Evidence of dehydration (tachycardia, dry mucous membranes, and delayed capillary refill) may be present in those experiencing significant vomiting and anorexia.

**DIAGNOSTIC TESTS & INTERPRETATION****Lab****Initial Lab Tests**

- Hepatic enzyme tests including ALT, AST, alkaline phosphatase, GTT, PTT, PT, and INR should be obtained to assess underlying liver disease.
- Serum bilirubin level (total and fractionated) should be obtained.
- Serum electrolytes, BUN, creatinine, and glucose should be measured.
- Screening for specific viral etiology includes:
  - Hepatitis A antibody (IgM anti-HAV)
  - Hepatitis B core antibody (IgM anti-HBc) and hepatitis B surface antigen (HbsAg):
    - HbsAg may be present in acute infection or in patients who are chronic carriers. The presence of HbsAg in serum for 6 mo or longer is indicative of chronic infection.
    - Determining the presence of IgM anti-HBc in the serum is required to make the diagnosis of acute HBV infection (5).
  - Anti-HCV antibody testing and qualitative polymerase chain reaction (PCR) assay for the presence of HCV particles should be performed.
- Additional testing for noninfectious etiologies should be performed based on history and physical exam findings.

**Imaging**

Abdominal US or CT may be necessary to rule out other abdominal pathology such as abdominal masses, gallbladder disease, and biliary tract obstruction.

**DIFFERENTIAL DIAGNOSIS**

- Gastroenteritis
- Pancreatitis
- Drug-induced hepatitis
- Autoimmune hepatitis
- Infectious mononucleosis
- Hepatic tumor or abscess
- Abdominal trauma
- Cholecystitis
- Cholangitis

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Assure the airway is patent and ventilation is adequate.
- IV fluids may be required for treatment of moderate to severe dehydration.

**MEDICATION**

Medications are not routinely given for the treatment of uncomplicated acute viral hepatitis.

**SURGERY/OTHER PROCEDURES**

Liver biopsy may be recommended at follow-up to assess disease severity and develop treatment plans for those patients who are found to have chronic HBV or HCV infections.

**DISPOSITION****Admission Criteria**

- Patients with evidence of fulminant hepatitis or hepatic encephalopathy require hospital admission.
- Patients with significant vomiting, dehydration, and electrolyte abnormalities require admission.

**Discharge Criteria**

Most patients with uncomplicated hepatitis are eligible for discharge.

**Issues for Referral**

All patients with suspected or confirmed HBV or HCV infection should be referred to a gastroenterologist or hepatologist for further evaluation and treatment.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Patients should avoid any potential hepatotoxins such as alcohol and acetaminophen.
  - Patients should be informed of the infectious nature of the disease and cautioned to practice appropriate hygiene and avoid activity that may spread infection to other contacts.
- Activity:
  - Patients may resume normal physical activity once their symptoms improve.
  - Strenuous exercise and contact sports should be avoided in the presence of hepatomegaly and/or splenomegaly.

**PROGNOSIS**

- HAV infection is usually mild and self-limited and never progresses to chronic infection (4):
  - HAV rarely results in fulminant hepatic failure.
  - HAV-associated mortality is estimated to be 0.01% (1).
- ~5,000 deaths per year occur as a result of chronic infection with HBV (1).
- An estimated 8,000–10,000 deaths occur as a result of chronic HCV infection (1):
  - Chronic HCV infection is the leading indication for liver transplantation in the U.S. (4).

**COMPLICATIONS**

- Rare complications of HAV infection include:
  - Fulminant hepatitis
  - Cholestatic hepatitis
  - Relapsing hepatitis
- The major complications of HBV and HCV infections include:
  - Chronic hepatitis
  - Cirrhosis
  - Hepatic failure
  - Hepatocellular carcinoma (2,3)

**ADDITIONAL READING****See Also (Topic, Algorithm, Electronic Media Element)**

- Gastroenteritis
- Pain, Abdomen

**ICD9**

- 070.1 Viral hepatitis A without mention of hepatic coma
- 070.30 Viral hepatitis B without mention of hepatic coma, acute or unspecified, without mention of hepatitis delta
- 070.9 Unspecified viral hepatitis without mention of hepatic coma

**PEARLS AND PITFALLS**

- Antibodies to HCV may be absent early in the disease process; qualitative PCR assay for the presence of viral particles is more specific and will detect infection before antibodies have developed.
- 5–32% of those vaccinated against HBV are nonresponders. Therefore, health care workers should undergo postvaccination testing to confirm response.

# HEPATOMEGALY

Amy D. Thompson

## BASICS

### DESCRIPTION

- Hepatomegaly is liver enlargement beyond the normal values for age.
- Mean normal values for liver span are 5.6–5.9 cm in a newborn, 6.5 cm at 2 yr of age, 7.5 cm at 4 yr of age, and 9 cm at 12 yr of age (1).
- In general, a liver edge >3.5 cm below the right costal margin in neonates and 2 cm in children is concerning for hepatomegaly.

### PATHOPHYSIOLOGY

Hepatomegaly occurs via 5 mechanisms: Inflammation, infiltration, storage accumulation, congestion, and obstruction (2):

- Inflammation: Occurs in response to hepatocellular destruction from infections, toxins, and autoimmune processes
- Infiltration: Secondary to cells from primary hepatic tumors, metastatic disease, parasitic cysts, and extramedullary hematopoiesis
- Accumulation: Occurs within the hepatic parenchyma or Kupffer cells; can be a collection of metabolic pathway by-products, metals, abnormal proteins, or fat
- Congestion: Result of expansion of the sinusoidal and vascular spaces from venous obstruction caused by portal HTN, venous thrombosis, and veno-occlusive disease
- Obstruction: Secondary to either anatomic abnormalities within the biliary tree or blockages within or compressing the biliary canal

### ETIOLOGY

- Anatomic: Alagille syndrome, Caroli syndrome, biliary atresia, choledochal cyst, hepatic cysts, congenital hepatic fibrosis, biliary stones, biliary strictures
- Infection:
  - Prenatal: Toxoplasmosis, rubella, cytomegalovirus, HIV, herpes simplex virus, syphilis, parvovirus, varicella zoster
  - Viral: Hepatitis A–E, cytomegalovirus, Epstein-Barr (EBV), varicella zoster, herpes simplex, HIV
  - Bacterial: Fitz-Hugh-Curtis syndrome, liver abscess, infectious endocarditis, septicemia, cholangitis, cholecystitis, typhoid fever, Bartonella, pasteurella, TB, brucellosis, syphilis
  - Other: Rocky Mountain spotted fever, Q fever, leptospirosis, brucellosis, amebiasis, malaria, candidiasis, histoplasmosis, cryptococcus, aspergillosis, helminth infections, liver flukes
- Autoimmune: Sclerosing cholangitis, autoimmune hepatitis, sarcoidosis, inflammatory bowel disease, juvenile rheumatoid arthritis, systemic lupus erythematosus, Behçet syndrome
- Toxin: Acetaminophen, aspirin, isoniazid, erythromycin, sulfonamides, oral contraceptives, anabolic steroids, nitrofurantoin, carbamazepine, phenobarbital, valproic acid, phenytoin, methotrexate, antineoplastic drugs, vitamin A, iron, parenteral hyperalimentation, herbal remedies, alcohol

- Tumor: Hemangioma, mesenchymal hamartoma, hepatoblastoma, hepatic adenoma, hepatocellular carcinoma, focal nodular hyperplasia, teratoma, histiocytosis; metastases including infiltration from leukemia and lymphoma
- Genetic or metabolic: Inborn errors of carbohydrate metabolism, amino acid metabolism, fatty acid oxidation, peroxisomal function, bile acid synthesis; Wilson disease, Reye syndrome, Crigler-Najjar syndrome, Beckwith-Wiedemann syndrome, Woman disease, cystic fibrosis hemochromatosis, alpha-1 antitrypsin deficiency, diabetes mellitus
- Miscellaneous: Traumatic hemorrhage, hemolytic anemia, iron-deficiency anemia, thalassemia, sickle cell disease, isoimmunization disorder, amyloidosis, CHF, restrictive pericarditis, veno-occlusive disease, Budd-Chiari syndrome, portal HTN, fatty liver of pregnancy, obesity, malnutrition

## DIAGNOSIS

### HISTORY

- Acholic stools and jaundice in a newborn are concerning for neonatal cholestasis, including biliary atresia.
- Pruritus may be a manifestation of cholestasis in older children.
- Fever, malaise, anorexia, sore throat, and rash are common findings in infectious mononucleosis.
- Jaundice, fever, abdominal pain, anorexia, malaise, and vomiting can be features of both acute or chronic hepatitis.
- Fever, weight loss, chronic abdominal pain, arthritis, rash, and oral ulcers can be present in autoimmune disorders.
- Poor weight gain, loss of neurodevelopmental milestones, ataxia, tremors, and seizure disorder suggest metabolic disease.
- Past medical history should include exposure to blood products, use of total parenteral nutrition, immunization history, and recent respiratory and GI illnesses.
- Prenatal history should focus on maternal infections, placement of an umbilical catheter, and Rh or ABO incompatibility.
- Family history should focus on early infant death, autoimmune disorders, and hepatic and neurodegenerative disease.
- Social history should include foreign travel, sexual activity, illicit use of IV drugs, and presence of tattoos.
- Medication history should include all prescribed and over-the-counter medications, including vitamin and herbal supplements.
- In the case of an ingestion, a list of all medications kept in the home should be obtained.
  - Other inquiries include recent insect bites, animal exposures, or ingestion of shellfish.

### PHYSICAL EXAM

- Liver size is most accurately measured in the midclavicular line.
- The upper border of the liver is best percussed, while the lower edge may be palpated or percussed.

- The liver should also be assessed for shape, consistency, and tenderness.
- The classic stigmata of chronic liver disease including asterixis, spider angiomas, and xanthomas are rarely seen in children.
- Concomitant splenomegaly occurs with portal HTN, infection, extramedullary hematopoiesis, storage disorders, and malignancy.
- Jaundice is clinically evident in infants when total bilirubin levels are >5 mg/dL and in older children when levels are >2 mg/dL (3).
- Pertinent ocular findings include cataracts, iritis, papilledema, and Kayser-Fleisher rings.
- Pertinent dermatologic findings include cutaneous hemangiomas, purpura, and papular acrodermatosis.
- Pertinent neurologic findings include altered sensorium, microcephaly, hypotonia, ataxia, and tremors.

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- Hepatic enzyme tests evaluate the liver's function, detect injury to hepatocytes, and assess for biliary obstruction.
- Hepatic enzyme tests may be abnormal in the setting of diseases unrelated to the liver (CHF, metastatic disease) and may be normal in patients with fulminant hepatic disease:
  - Tests evaluating the liver's functional capacity include PT, PTT, albumin, and ammonia.
  - Tests of biliary obstruction include alkaline phosphatase, GGTP, and total/direct bilirubin.
  - Tests evaluating hepatic cellular injury include ALT, AST, and lactate dehydrogenase.
- Other useful studies include CBC, electrolytes, glucose, monospot, EBV titers, and cytomegalovirus titers:
  - Monospot results should be interpreted in the context of a patient's age and course of disease.
  - False-negative rates with heterophile antibody testing occurs in up to 50% of children <12 yr of age and in 25% of patients tested during the 1st wk of illness (4).
- Based on the history and physical exam, additional studies may be considered, including urinalysis, blood culture, reticulocyte count, total protein, lactic acid, pyruvic acid, triglycerides, carnitine, acylcarnitine, plasma amino acids, urine organic acids, hepatitis serologies, alpha-fetoprotein, carcinoembryonic antigen, serum ceruloplasmin, purified protein derivative of tuberculin, stool for ova and parasites, urinary excretion of copper, ferritin, total iron-binding capacity, and serum alpha-1 antitrypsin.

### Imaging

- In general, US is the screening modality of choice for the evaluation of liver and biliary disease (5).
- CT and MRI may be superior to US in detecting small focal hepatic lesions and in determining tumor extent (5).
- Cholangiography may be useful in defining biliary tree anatomy in the case of suspected biliary atresia.

**DIFFERENTIAL DIAGNOSIS**

- See Etiology for a complete listing of diagnoses associated with hepatomegaly.
- Pulmonary hyperinflation, subdiaphragmatic abscesses, retroperitoneal mass lesions, and rib cage anomalies can downwardly displace a normal-sized liver.
- Patients with peritoneal cysts, renal masses, and adrenal lesions can also be mistakenly diagnosed with hepatomegaly.

**TREATMENT****MEDICATION**

- Rapid administration of 10% IV dextrose 2–4 cc/kg or 1–2 cc/kg of 25% dextrose should be administered for treatment of symptomatic hypoglycemia of serum glucose <50 mg/dL (7):
  - Plasma glucose can then be maintained on IV fluids with 10% dextrose at 1–1.5 times maintenance (7).
- Rapid correction of acidosis in a patient with hyperammonemia can lead to cerebral edema and hemorrhage.
- Sodium bicarbonate 0.35–0.5 mEq/kg/h may be considered for patients with underlying metabolic disorders presenting with a severe metabolic acidosis (pH <7.0) (8).
- IV sodium phenylacetate, IV sodium benzoate, and IV arginine-HCL may be warranted in patients with underlying metabolic disorders presenting with hyperammonemia (8).
- Although limited evidence exists to demonstrate its efficiency, oral lactulose is the first-line medication for hepatic encephalopathy (9):
  - The dosing of lactulose is 30–60 mL/day divided 3–4 times/day in children (10).
- Patients with hepatomegaly and coagulopathy should be given IV vitamin K; 2.5-mg dosing in infants and 5 mg in children (11):
  - Patients in fulminant hepatic failure may be unresponsive to vitamin K.
- In the setting of renal failure or respiratory distress, ascites can be treated with IV 25% albumin 1 g/kg followed by IV furosemide 0.5–1 mg/kg (11).
- Patients with cholecystitis, cholangitis, or hepatic abscesses should receive antibiotic coverage for gram-negative and anaerobic organisms.
- Infectious mononucleosis–induced hepatitis requires supportive therapy only
- Acyclovir and corticosteroids are not recommended for routine treatment (4).
- Fitz-Hugh-Curtis syndrome is treated with antibiotics appropriate for gonococcal and chlamydial infections.
- Acute hepatitis A, B, and C are routinely managed with supportive therapy alone.

**SURGERY/OTHER PROCEDURES**

- Percutaneous liver biopsy is rarely indicated in an emergent setting but may ultimately be required for a definitive diagnosis.
- Cholecystitis and cholangitis associated with gallstones are general indications for surgery.
- Surgical intervention is rarely required for blunt traumatic injury to the liver. Exceptions include hemodynamic instability or a transfusion requirement of >40 cc/kg of packed RBCs (12).

**DISPOSITION****Admission Criteria**

- Ill appearing
- Persistent anorexia, emesis, abdominal pain
- Failure to thrive
- Mental status changes
- Known toxin-induced hepatic injury
- Worsening ascites
- Abnormal PT/PTT or INR
- Elevated ammonia level
- Bilirubin levels >20 mg/dL
- Transaminase levels >2,000 units/L
- Hypoglycemia
- Metabolic acidosis
- Radiographic evidence of cholecystitis, cholangitis, hepatic abscess, trauma, neoplasm, or anatomic disease including biliary atresia and hepatic fibrosis

**Discharge Criteria**

Patients with mild hepatomegaly, otherwise normal physical exams, and normal lab studies may be discharged home with follow-up with a primary care provider.

**Issues for Referral**

A pediatric gastroenterologist should be consulted on all patients with hepatic failure or suspected anatomic disease such as biliary atresia and hepatic fibrosis.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Follow-up depends on the causative agent.
- Repeat lab studies should be performed in all patients with acute hepatitis to document resolution.

**CODES**

ICD9

789.1 Hepatomegaly

**PEARLS AND PITFALLS**

- Transient hepatomegaly can occur with systemic viral infections but can also be indicative of intrinsic liver disease or a more serious generalized disorder.
- A liver edge >3.5 cm below the right costal margin in neonates and 2 cm in children is concerning for hepatomegaly.
- The presence of a palpable liver does not always indicate hepatomegaly.
- US is the screening modality of choice for the evaluation of liver and biliary disease.

# HERNIA

Eileen C. Quintana

## BASICS

### DESCRIPTION

- Hernia is a protrusion of peritoneal contents through a defect in the abdominal wall.
- Incarcerated inguinal hernias result from bowel becoming edematous and engorged while trapped outside the abdominal cavity.
- A strangulated inguinal hernia is an incarcerated hernia in which the vascular supply is severely compromised, possibly leading to ischemic necrosis and perforation. This is a true surgical emergency.
- Congenital diaphragmatic hernia (CDH) is due to large diaphragmatic defects including agenesis of the hemidiaphragm, leading to viscera herniation into the chest/mediastinum.

### EPIDEMIOLOGY

#### Incidence

- Umbilical hernias have an incidence of up to 15% in the 1st yr of life.
- Inguinal hernias have an incidence of 1–5%, although the exact incidence is unknown. Right-sided hernias are found in 60% of all cases.
- Inguinal incarcerated hernia is the most common cause of intestinal obstruction in infants and children.
- It will present in 60% of premature and low-birth-weight infants with inguinal hernias.
- >50% of incarcerated inguinal hernias will present in the 1st 6 mo of life. There is a female predilection.
- CDH occurs in ~1 in 3,000 live births. These may be associated with other anomalies such as cardiac, renal, genital, or neural tube anomalies or trisomies 13, 18, or 21.

### RISK FACTORS

- Hernias are found at a higher incidence in premature and low-birth-weight infants.
- Umbilical hernias are more common in infants with low birth weight; black race; trisomy 13, 18, or 21; and Beckwith-Wiedemann syndrome.
- Inguinal hernias are found in up to 30% of premature or low-birth-weight infants and are more frequent among those with other abdominal wall or urologic abnormalities. There is a male predilection of 4:1.
- CDHs are found at a higher prevalence among those with chromosomal abnormalities.

### PATHOPHYSIOLOGY

- Umbilical hernias: The umbilical opening is reinforced by the following ligaments: Median umbilical and the paired medial umbilical and round ligaments. Ricket fascia and the aforementioned ligaments are variably attached, thus predisposing to umbilical hernias. The underlying bowel exerts pressure on the overlying skin, leading to a protrusion through the umbilicus.

- Inguinal hernias: These are formed when the layers of the processus vaginalis remain patent, thus failing to close off the entrance to inguinal canal from the abdominal cavity.
  - A widely patent processus vaginalis may allow herniation of bowel. A smaller opening may allow fluid to enter resulting in a hydrocele.
  - In the female embryo, the canal of Nuck is a patent processus vaginalis extending to the labium majoris.
  - In the male embryo, the processus vaginalis covers each testis and becomes the tunica vaginalis.
- CDH: Due to failure of closure of pleuroperitoneal canals leading to pulmonary hypoplasia, HTN, immaturity, and left ventricular hypoplasia.

### ETIOLOGY

- Umbilical hernias are due to a patent umbilical ring at birth.
- Inguinal hernias are caused by a patent processus vaginalis in both males and females.
- CDHs are theorized to be due to either failure of pleuroperitoneal canal closure or diaphragm agenesis.

### COMMONLY ASSOCIATED CONDITIONS

See Risk Factors.

## DIAGNOSIS

### HISTORY

- Umbilical hernias present at birth or early in life when the infant is increasing his or her intra-abdominal pressure by crying or straining. The umbilical skin stretches, leading to a protrusion that could be alarming to parents.
  - Umbilical hernias are painless.
- Inguinal hernias may present with a bulge or swelling at the inguinoscrotal or inguinolabial region. The swelling may be intermittent, seen only with crying or straining.
- History may reveal resolution of the swelling when the infant is sleeping. It may be associated with pain, fussiness, anorexia, or crying.
- A history of hematochezia or melena, intractable vomiting or intractable crying, or abdominal distention should raise the concern for an incarcerated or strangulated hernia.
- CDHs are prenatally diagnosed during a level II US. Postnatally, the neonate may present with feeding intolerance, tachycardia, or some degree of respiratory distress.

### PHYSICAL EXAM

- Umbilical hernias are usually asymptomatic and painless. The physical exam reveals an obvious protuberance from the umbilicus that varies in size, is intermittently present, is easily reduced, and is not associated with inflammation.
- Inguinal hernias present as a smooth mass protruding from the external ring lateral to the pubic tubercle.

- Hernias that are not incarcerated are easily reduced and may only be present when intra-abdominal pressure is increased, as with the Valsalva maneuver.
- A hydrocele is a collection of fluid within the processus vaginalis that produces a swelling in the inguinal region or scrotum.
- To help distinguish a hydrocele from a hernia, the examiner should palpate just superior to the swelling. Palpation of a sausage-shaped mass (intestine) suggests hernia, while palpation of the spermatic cord suggests hydrocele.
- An incarcerated inguinal hernia is trapped, engorged bowel. Erythema or discoloration may be noted with pain on palpation. This is a true surgical emergency.
- Newborns with CDH may have a scaphoid abdomen with unilaterally diminished breath sounds or bowel sounds heard in the chest. Heart sounds may be laterally displaced and somewhat distant. A neonate with CDH may have signs of intestinal obstruction or shock.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Hernias are diagnosed based on physical exam; lab studies are not routinely indicated.
- Newborns with CDH and severe respiratory distress may require blood gas analysis to assess for hypercapnia, hypoxemia, and metabolic acidosis.

#### Imaging

- Umbilical hernias do not require routine imaging unless there is a suspected sinus (fistulography) or a cyst (US) is present within the hernia.
- Inguinal hernias do not require routine imaging, though US may be helpful if ruling out other diagnoses such as hydrocele or testicular torsion.
- Newborns with CDH may have had US prenatally. Postnatally, a CXR will reveal a unilateral lucency that may appear to be a pneumothorax. Insertion of an NG tube will reveal the tip of the tube residing in the thorax rather than in the abdomen.

### DIFFERENTIAL DIAGNOSIS

- Umbilical granuloma, umbilical/urachal cysts, umbilical/urachal sinuses/tracts, or umbilical polyps
- Hydroceles or varicoceles
- Scrotal abscess
- Scrotal hematoma
- Testicular torsion
- Epididymitis
- Inguinal adenitis or abscess
- Psoas abscess
- Malignancy

## TREATMENT

### PRE HOSPITAL

Assess and stabilize airway, breathing, and circulation.

### INITIAL STABILIZATION/THERAPY

- Patients with incarcerated or strangulated hernias may be in hypovolemic or septic shock. Fluid resuscitation must be initiated:
  - Normal saline boluses of 20 cc/kg should be given, up to 60 cc/kg.
  - After 60 cc/kg have been given, persistent hypotension or poor perfusion is an indication for use of vasopressors.
  - Broad-spectrum antibiotics should be administered.
- Patients with CDH may need support of airway and breathing. Consider early intubation and ventilating with the lowest airway pressures possible:
  - An NG tube may be used to decompress the stomach and to avoid intestinal distention.
  - Other alternative methods of support such as extracorporeal membrane oxygenation, high-frequency oscillatory ventilation, or nitric oxide should be considered early if ventilation is difficult to maintain via a conventional ventilator.

### MEDICATION

Morphine 0.1 mg/kg IV/IM/SC q2h PRN:

- Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.

### COMPLEMENTARY & ALTERNATIVE THERAPIES

Taping a coin over an umbilical hernia is widely practiced among many cultures; this practice has no impact on hernia resolution.

### SURGERY/OTHER PROCEDURES

- Incarcerated inguinal hernias should be manually reduced if there are no systemic signs of toxicity. If the patient appears septic with a strangulated hernia, emergent surgical exploration after appropriate fluid resuscitation is warranted.
- Inguinal hernia reduction: Adequate analgesia and sedation must be provided.
- Place in the Trendelenburg position with the ipsilateral leg externally rotated and flexed.
- Gently place fingers at the edge of the inguinal hernia ring while simultaneously applying firm, steady pressure to guide the hernia contents through the opening.
- Surgical consultation is recommended after several unsuccessful attempts at reduction.
- CDH can generally be surgically repaired in a semielective basis after medical stabilization has been achieved.

## DISPOSITION

### Admission Criteria

- Patients with umbilical hernias typically do not require hospitalization.
- Patients with inguinal hernias should be admitted for emergent surgical repair if signs of incarceration or strangulation are present and manual reduction attempts are unsuccessful.
- Newborns with CDH should always be admitted to an ICU setting.

### Discharge Criteria

Patients with umbilical hernias or those with inguinal hernias that are easily reduced could be discharged with surgical follow-up.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Umbilical hernias can be followed by primary care providers. If the umbilical ring is small, spontaneous closure is expected. If a large umbilical ring is noted, umbilical hernias could be repaired electively for cosmetic purposes.
- Instruct parents and caregivers on signs and symptoms of incarcerated hernias. Advise them to seek immediate medical attention if there are any concerns for incarceration.

### PROGNOSIS

- An umbilical hernia's prognosis is directly related to the umbilical ring diameter. Spontaneous closure is more likely in umbilical rings <1 cm, whereas umbilical rings >1.5 cm will more likely require repair if there are cosmetic concerns.
- Inguinal hernia has a good prognosis; serious adverse outcomes due to delay in recognition of strangulation is rare.
- CDH is associated with long-term pulmonary disease, such as bronchopulmonary dysplasias and restrictive or obstructive lung disease. Failure to thrive and gastroesophageal reflux is often present.

### COMPLICATIONS

- Incarceration
- Strangulation
- Bowel obstruction
- Bowel perforation
- Erosion of overlying skin
- Umbilical hernias are usually asymptomatic and rarely have complications.
- Inguinal hernia can lead to decreased testicular size, atrophy, and wound infection in 1–2% of cases, post-surgically.

## CODES

### ICD9

- 550.10 Unilateral or unspecified inguinal hernia, with obstruction, without mention of gangrene
- 550.90 Unilateral or unspecified inguinal hernia, without mention of obstruction or gangrene
- 553.9 Hernia of unspecified site without mention of obstruction or gangrene

## PEARLS AND PITFALLS

- In young children, analgesia is often required to allow rapid diagnosis of incarceration and strangulation is critical to preventing morbidity and bowel necrosis.
- In young children, adequate analgesia is often adequate to allow incarcerated hernias to be reduced or to allow spontaneous reduction when crying ceases.
- Inguinal hernias can often coexist with hydroceles.
- Appropriate discharge instructions for caregivers are important in identifying early signs of incarceration or strangulation. Delay in medical care can lead to increased morbidity and mortality.

# HERPES SIMPLEX

Natasha A. Tejwani  
Jacobo Abadi

## BASICS

### DESCRIPTION

- Herpes simplex virus (HSV) is a double-stranded DNA neurotropic virus that establishes latency in sensory ganglia to later reactivate, causing recurrent outbreaks.
- HSV types 1 and 2 are identified by unique glycoproteins. They have different virulence and traditionally different epidemiology.
- HSV has varying presentations, from minor skin lesions (recurrent “cold sores” or genital lesions) to severe, often fatal disseminated disease (neonates) or meningoencephalitis.
- Though orolabial and genital herpes infections are predominant, other forms such as HSV conjunctivitis, whitlow, and herpes gladiatorum occur in other dermatomes.

### EPIDEMIOLOGY

- Neonatal HSV: 1 in 3,000–5,000 births
- HSV types 1 and 2 are ubiquitous. Infections have no seasonal pattern.
- In the U.S., HSV-1 seropositivity is present in >50% of adults.
- In the U.S., HSV-2 genital infections have dramatically increased and now occur in ~25% by college age.
- Often, carriers are unaware of their carrier status and have asymptomatic shedding or are unaware of outbreak symptoms.
- HSV-1 is usually implicated in cases of encephalitis beyond the neonatal period and nongenital lesions.
- HSV-2: Majority of neonatal cases
- Gingivostomatitis: Common at 6 mo to 5 yr of age
- Pharyngitis: Childhood through adolescence
- Though previously HSV-1 was considered to be causative of orolabial herpes and HSV-2 was considered to be causative of genital herpes, there is an increasing number of orolabial infections with HSV-2 and an increasing number of genital infections with HSV-1:
  - It is presumed that oral sex is responsible for this transference between traditionally orolabial and genital herpes strains.
- Sexual orientation is related to incidence of genital herpes: Homosexual male > heterosexual male/female > homosexual female.

### RISK FACTORS

- Day care attendance increases the risk of orolabial herpes.
- Sexual behavior:
  - Contact with seropositive sex partner
  - Earlier sexual debut (onset of sexual activity)
  - Multiple sexual partners
- Lower socioeconomic groups (though seen in higher socioeconomic groups as well)
- Nonoral, nongenital herpes:
  - Herpetic whitlow: Thumb sucking or persons employed in nursing and patient care
  - Herpes gladiatorum: Competitive wrestling

### GENERAL PREVENTION

Preventing contact from infected individual or diminishing virus shedding are main methods:

- Individual with HSV infection, if known, may take suppressive antiviral medication when asymptomatic or during an outbreak.

### Pregnancy Considerations

- C-section is indicated in women with active lesions or prodromal symptoms.
  - This reduces the risk of neonatal infection, independent of rupture of membranes duration.
- Mothers with history of genital HSV should take oral suppressive therapy from 36 wk until delivery.

### PATHOPHYSIOLOGY

- Most transmissions are from asymptomatic carriers and occur by intimate contact. Viral replication begins at entry points including oral or anogenital mucosa, breaks in the skin, and even ocular conjunctiva (primary infection).
- HSV travels up nerve tissue to the sensory ganglia and is latent until reactivation.
- Recurrent infections and viral shedding may or may not be associated with symptoms.
- The hallmark of HSV encephalitis is the necrotizing nature of the process.
- It is possible to contract both serotypes of HSV, though infection with 1 serotype offers some immunity from contracting the other.

### ETIOLOGY

- HSV-1 and/or HSV-2 viruses
- Orolabial HSV was once usually HSV-1 and genital HSV was previously usually HSV-2, but this is changing. Either HSV-1 or HSV-2 may cause orolabial or genital herpes.
- It is possible for patients to have both serotypes.
- Neonatal Infections:
  - Occur most commonly from an HSV-2–infected mother. Usual mode of transmission is from spread in vaginal canal.
  - Also may be contracted by oral contact, such as kissing child

### COMMONLY ASSOCIATED CONDITIONS

Other STIs

## DIAGNOSIS

### HISTORY

- Maternal history of herpetic infection
- Birth history: Vaginal delivery vs. C-section; use of scalp electrodes
- Pain, burning, itching, or tingling sensations prior to manifestation of lesions
- Genital herpes: Sexual activity with an infected partner, history of multiple partners, activity without barrier protection
- HSV meningoencephalopathy: Poor feeding, seizures, lethargy
- History of eczema: Eczema herpeticum
- Thumb sucking or nursing: Herpetic whitlow
- Wrestling: Herpes gladiatorum

### PHYSICAL EXAM

- The hallmark of HSV is the characteristic vesicular lesion, commonly in clusters.
- Neonatal HSV:
  - Skin, eye, mucous membranes disease +/- CNS symptoms
  - Clustered vesicular lesions with an erythematous base or ulcerative lesions, erythematous conjunctiva
  - Hypo-/Hyperthermia, lethargy, full anterior fontanel, irritability
- Gingivostomatitis:
  - Vesicles and ulcers in the anterior oral cavity or lips; often so numerous that they crust over
  - Cervical lymphadenopathy and fever
- Herpes labialis:
  - Lesions on vermilion border of lip or inside oral cavity; may involve the nose, chin, cheeks
- Genital herpes:
  - Vesicles on an erythematous base, when ruptured, leave ulcers.
- HSV encephalopathy:
  - Nonspecific: Headache, fever, vomiting, altered mental status, seizures
  - Focal neurologic findings: Anosmia, hallucinations, changes in speech
- Keratoconjunctivitis:
  - Usually unilateral with tender preauricular lymphadenopathy, blepharitis, chemosis
  - Fluorescein staining reveals dendritic lesions.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Main types of tests include those for direct detection of virus and serology:
  - Viral detection:
    - DNA polymerase chain reaction (PCR)
    - Immunofluorescence
    - Viral culture typically is sent in Hank media.
  - Serology (IgM, IgG)
- Neonatal HSV:
  - CBC with differential, metabolic panel, LFTs, CSF studies: Cell count, glucose, protein, viral culture, HSV DNA PCR
  - Mucocutaneous lesions: Direct immunofluorescence (DFA), immunoperoxidase staining
  - Viral culture: Surface cultures of skin/mucous membranes (eye, mouth, and anogenital region)
- Genital herpes:
  - Typically diagnosed clinically
  - Viral cultures may be sent, but negative cultures do not rule out infection.
  - Serology may be sent to confirm seroconversion. These tests are costly, difficult to interpret, and not routinely recommended, though patients may request them.
- Herpes encephalopathy:
  - CSF HSV PCR
  - Second-line testing: Brain biopsy if deterioration after treatment has begun and PCR is negative
- Herpetic whitlow, herpes gladiatorum:
  - Typically diagnosed clinically
  - Viral cultures may be sent, but negative cultures do not rule out infection.

**Imaging**

Despite their widespread use, these tests have limited diagnostic value:

- MRI is more sensitive early in disease.
- CT brain: Typical findings are prominent late in the illness, with mostly localized involvement to the temporal lobes.

**DIFFERENTIAL DIAGNOSIS**

- Neonatal herpes: Sepsis, TORCH infections
- Genital herpes: Granuloma inguinale, herpes zoster, syphilis. Use of topical therapy for genital warts may result in crops of vesicles identical in appearance to HSV.
- Gingivostomatitis/Orolabial: Impetigo, Stevens-Johnson syndrome, herpangina, aphthous ulcers
- Meningoencephalitis: Meningitis, abscess

**TREATMENT****INITIAL STABILIZATION/THERAPY**

Pharmacologic treatment

**MEDICATION****First Line**

- Neonatal HSV:
  - Acyclovir 60 mg/kg IV q8h for 14–21 days depending on localized vs. disseminated and/or CNS disease
- Gingivostomatitis:
  - Acyclovir may decrease duration/severity of disease if given in 1st 1–2 days of infection. This is not widely practiced:
    - Acyclovir IV: 15 mg/kg/24 hr divided q8h for 5–7 days
    - Acyclovir PO: 1,200 mg/kg/24 hr divided q8h for 7–10 days (max dose 80 mg/kg/24 hr divided q6–8h)
  - Pain control and supportive care
  - School-age children with capability to spit may swish and spit Magic Mouthwash (1:1:1 Maalox: diphenhydramine:viscous lidocaine):
    - This is contraindicated in younger children due to risk of seizure from swallowing lidocaine (may give without lidocaine).
- Herpes labialis > 12 yr of age, recurrence:
  - Valacyclovir: > 12 yr of age, 2 g/dose PO q12h for 1 day
  - Acyclovir 200–400 mg PO 5 times a day for 5 days
  - Famcyclovir 500 mg PO t.i.d. for 5 days
- Genital herpes ≥ 12 yr of age:
  - Acyclovir PO:
    - Initial: 1,000–1,200 mg/24 hr divided q8h for 7–10 days
    - Recurrence: 1,000–1,200 mg q8h for 5–7 days
    - Suppressive treatment: 800–1,200 mg/day b.i.d. for 1 yr
  - Valacyclovir PO:
    - Initial: 1 g b.i.d. for 10 days
    - Recurrence: 500 mg b.i.d. for 3 days
    - Suppressive treatment: 500–1,000 mg per day for 1 yr
  - Famcyclovir PO (safety and efficacy not established ≤ 18 yr of age; however, this is still used for those ≥ 12 yr of age):
    - Initial: 750 mg/24 hr divided q8h for 7–10 days
    - Recurrence: 250 mg/day b.i.d. for 3–5 days
    - Suppressive treatment: 500 mg/day b.i.d. for 1 yr

- Herpes encephalopathy:
  - Acyclovir IV: > 12 yr of age, 10 mg/kg divided q8h; 3 mo to 12 yr, 60 mg/kg/24 hr divided q8h; treat from 14–21 days
- Keratoconjunctivitis:
  - Trifluridine, iododeoxyuridine, or vidarabine
  - Consult an ophthalmologist for dosing.

**Second Line**

Foscarnet:

- For acyclovir resistance, dose according to the consulting infectious disease specialist.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

Several HSV vaccines are in development.

**DISPOSITION****Admission Criteria**

- Neonatal HSV infection
- Immunocompromised host
- Dehydration secondary to decreased oral intake in gingivostomatitis
- Critical care admission criteria:
  - Unstable vital signs or severe illness, usually a neonate or an immunocompromised patient

**Discharge Criteria**

- For neonates, resolution of symptoms after full course of treatment for meningoencephalitis
- Gingivostomatitis: Ability to take and tolerate PO to maintain hydration
- For immunocompromised patients: Resolution of disease spread to limited focus capable of being managed as outpatient

**Issues for Referral**

- Refer for HIV testing.
- If meningoencephalitis, close follow-up with neurology
- If keratoconjunctivitis, close follow-up with ophthalmology

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - For acute outbreak, use antiviral medication and advise the patient of the contagious nature of the disease as well as the particular risk for young infants.
  - Prescriptions for suppressive therapy are typically given from the primary care provider and not the emergency department physician.
- Activity:
  - Patients with recurrent herpes may learn to recognize a pattern of behavior, such as missing sleep, that triggers outbreaks.

**Patient Monitoring**

Monitor neurodevelopment of neonatal HSV survivors with CNS involvement.

**PROGNOSIS**

- HSV in any dermatome typically recurs.
- Over time, outbreaks, particularly HSV-1, tend to become less frequent and less severe:
  - HSV-1 is more self-limited.
  - HSV-2 is typically more aggressive; more recurrent outbreaks of greater intensity.

- Neonates with HSV, particularly meningoencephalitis, typically have a poor prognosis. Permanent neurologic injury, developmental delay, or death may result.
- Patients with immunocompromise, burns, or CNS involvement also have complications.

**COMPLICATIONS**

- Neonatal HSV and meningoencephalitis may result in neurologic injury or death.
- Blindness from HSV keratoconjunctivitis
- Recurrence with HSV in any dermatome

**ADDITIONAL READING**

- CDC. Seroprevalence of herpes simplex virus type 2 among persons aged 14–49 years—United States, 2005–2008. *MMWR Morb Mortal Wkly Rep.* 2010;59(15):456–459.
- Kimberlin DW. HSV infections in neonates and early childhood. *Semin Pediatr Infect Dis.* 2005;16:271–281.

**See Also (Topic, Algorithm, Electronic Media Element)**

- Genital Warts
- Sexually Transmitted Infection

**ICD9**

- 054.2 Herpetic gingivostomatitis
- 054.9 Herpes simplex without mention of complication
- 054.10 Genital herpes, unspecified

**PEARLS AND PITFALLS**

- Consider possible abuse in young children.
- Conduct or refer for HIV testing.
- Consult an ophthalmologist for HSV conjunctivitis. Do not prescribe ocular corticosteroids.
- Consider acyclovir resistance if there is no improvement with acyclovir or valacyclovir. Foscarnet is alternate therapy.
- Consider psychological sequelae when disclosing HSV diagnosis due to incurability.
- Patients will often inquire about the incubation period and infectivity in order to ascertain from whom they contracted the STI. Disclose factual information, and avoid involvement in determining source of infection.

# HIRSCHSPRUNG DISEASE

Sage Myers

## BASICS

### DESCRIPTION

In Hirschsprung disease, there is an absence of parasympathetic enteric ganglion cells in variable lengths of the colon leading to functional bowel obstruction.

### EPIDEMIOLOGY

#### Incidence

~1/5,000 live births (1):

- Short-segment Hirschsprung disease is much more common than that involving the long segment (~80% of total cases) (1,2).

### RISK FACTORS

- Short-segment disease has a male to female ratio of 4:1.
- Long-segment disease with less male predominance (2:1–1:1) (1):
  - Most common in Asians (2)
  - Least common in Hispanics (1)

### PATHOPHYSIOLOGY

- Arrest of the progression of the vagal neural crest cells in their caudal migration to form the enteric nervous system during development (neurocristopathy)
- Neurocristopathy caused by arrest of neural crest cell migration at 5–12 wk of gestation
- Leads to segments of aganglionic bowel (both in the submucosal and myenteric plexuses):
  - The aganglionic section begins at the anal sphincter.
  - Short segment: The aganglionic section does not extend beyond the upper sigmoid.
  - Long-segment: The aganglionic section extends beyond the sigmoid and may include the entire large intestines (total colonic aganglionosis), occasionally extending into the small intestines and rarely including the entire bowel (total intestinal aganglionosis).

### ETIOLOGY

- Congenital anomaly:
  - Most often presents sporadically
  - May be familial in up to 20% of cases
  - Complex pattern of inheritance with low, sex-dependent penetrance and variability in the affected bowel-segment length (2)
- Associated mutations have been found in multiple genes, many of which code for proteins important in signaling pathways for ganglia of the GI system.

### COMMONLY ASSOCIATED CONDITIONS

May be associated with chromosomal abnormalities (12%) or congenital anomalies (18%) (1):

- The most commonly associated chromosomal abnormality is trisomy 21 (1).
- Associated congenital anomalies include polydactyly, cleft palate and other craniofacial anomalies, septal defects of the heart, and GI issues.
- May also be associated with other neurocristopathies, including cancer syndromes, such as MEN2 and neuroblastoma, as well as congenital central hypoventilation syndrome and Waardenburg syndrome (1,3)
- May be associated with specific genetic syndromes, including:
  - Mowat-Wilson syndrome, an autosomal dominant disorder that includes mental retardation, delayed motor development, and epilepsy (3)
  - Goldberg-Shprintzen megacolon syndrome, an autosomal recessive disorder of neurologic abnormalities and Hirschsprung disease (3)

## DIAGNOSIS

### HISTORY

- Often diagnosed in neonatal period with delayed passage of meconium
- Later in infancy, patients will often have history of constipation since birth.
- Vomiting is common.
- Those diagnosed later in childhood or adulthood may have a history of poor growth, severe recalcitrant constipation, and intermittent vomiting.
- Patients may present more urgently with signs of enterocolitis:
  - Abdominal distention, poor feeding, and foul-smelling watery stool

### PHYSICAL EXAM

- May find abdominal distention, which can be relieved by enemas or rectal stimulation to promote passage of stool
- Stool may be palpable on abdominal exam.
- Tight anal sphincter can be present.
- In patients diagnosed later in childhood or adulthood, evidence of failure to thrive may be found in addition to chronic abdominal distention.
- Patients presenting with enterocolitis at the time of diagnosis may appear lethargic with abdominal distention and signs of dehydration.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- Plain films of the abdomen may show distended loops of bowel, which lead into an area with a paucity of gas:
  - The gasless area will include the rectum and variable length of bowel proximal to it.
- Occasionally, plain films may show a narrowing cone of gas between the dilated section and the gasless section of bowel, representing the transition zone between normal (dilated) and aganglionic (gasless) bowel.
- Barium enema shows the small rectum and can more clearly display the transition zone between the small, compressed segment of affected bowel and the dilated normal bowel:
  - Barium enema may also display uncoordinated contractions within the affected bowel segment.
  - In a systematic review of diagnostic testing for Hirschsprung disease, contrast enema was found to have a sensitivity of 70% and a specificity of 83% (4).

#### Diagnostic Procedures/Other

Anorectal manometry:

- In patients with Hirschsprung disease, manometry shows absence of usual relaxation of the internal anal sphincter in response to rectal distension.
- May not be sensitive in young neonates
- Overall, sensitivity of anorectal manometry is 91%, with a specificity of 94% (4).

#### Pathological Findings

- Rectal suction biopsy is often undertaken to confirm the diagnosis of Hirschsprung disease:
  - Has the advantage of being minimally invasive and not requiring sedation
  - However, there have been reports of perforation, significant rectal bleeding, and sepsis complicating rectal suction biopsy.
  - Affected individuals will display lack of enteric ganglion cells and an increase in acetylcholinesterase activity by specific staining.
  - Rectal suction biopsy was found to have a sensitivity of 93% and a specificity of 98% in a recent systematic review (4).
- Full-thickness rectal biopsy can also be done but carries more risk than the partial-thickness rectal suction biopsy, as it requires general anesthesia and suturing of the biopsy site.
- Pathologic evaluation is also necessary at the time of corrective surgery to determine the proximal limit of the affected aganglionic segment to guide resection.

**DIFFERENTIAL DIAGNOSIS**

Other causes of obstruction:

- Functional intestinal obstruction from sepsis
- Functional intestinal obstruction from toxic exposures
- Congenital hypothyroidism decreasing gut motility
- Meconium ileus secondary to cystic fibrosis
- Congenital stenosis/atresia of the intestines
- Botulism
- Meconium plug syndrome
- Small left colon syndrome
- Chronic intestinal pseudo-obstruction (enteric motility disorders) (5)

**TREATMENT****INITIAL STABILIZATION/THERAPY**

For those patients who have developed enterocolitis, treatment includes rectal irrigations several times a day, which promote the passage of gas and stool, as well as broad-spectrum antibiotic therapy.

**MEDICATION**

Ampicillin, gentamicin, and metronidazole are commonly used:

- Ampicillin 100–200 mg/kg/day IV divided q.i.d.
- Gentamicin 7.5 mg/kg/day IV as single daily dose or divided t.i.d.
- Metronidazole 30 mg/kg/day IV divided q.i.d.

**SURGERY/OTHER PROCEDURES**

- If diagnosed early with short-segment disease, 1-step surgical resection is possible.
- If diagnosed later in childhood/adulthood or with long-segment disease, an ostomy may need to be placed to allow for decrease in dilation of the proximal normally everted bowel before reattachment of the normal bowel to the anus.
- Laparoscopic and transanal techniques may be used to decrease scarring and recovery time, and such minimally invasive techniques are becoming the most common strategy for surgical management (6).
- Initial research in the prospect of stem cell transplantation for the treatment of Hirschsprung disease is ongoing (7).

**DISPOSITION****Admission Criteria**

- Patients who are obstructed but not septic may require admission to the general ward.
- Critical care admission criteria:
  - Patients with sepsis or perforation, either as a result of complications of biopsy or surgery or as a result of enterocolitis, should be monitored in an intensive care setting.

**Discharge Criteria**

If patients are able to tolerate feeding and are able to maintain adequate caloric intake and hydration, they may be discharged home.

**Issues for Referral**

Children without signs of enterocolitis at the time of suspected diagnosis should be referred to outpatient pediatric surgery for evaluation.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Patients must be counseled in the continued risk of enterocolitis and the need to seek care quickly if symptoms develop.
  - Regular postsurgical outpatient visits should be undertaken to monitor for complications.
- Activity:
  - Regular activity can be resumed as tolerated.

**PROGNOSIS**

- The majority of patients have near-normal GI function after surgical repair (8).
- An assessment of long-term outcome showed that 75% of patients had excellent anorectal function and were well adjusted:
  - Of the remaining 25%, > 19% had only minor problems including constipation and minor soiling (9).
  - Psychologically, 94% of patients were found to be “well adjusted” (9).

**COMPLICATIONS**

Postsurgical complications include:

- Stenosis of the anal anastomosis
- Fistula formation at the anastomosis site
- Continued chronic constipation
- Fecal incontinence
- Enterocolitis
- Bleeding
- Infection
- Risks of anesthesia

**ICD9**

751.3 Hirschsprung's disease and other congenital functional disorders of colon

**PEARLS AND PITFALLS**

- Failure to pass meconium in the 1st 24 hr of life, abdominal distension, and severe constipation should increase concern for the possibility of Hirschsprung disease.
- Enterocolitis is a severe complication that can be seen both before and after surgical correction and must be managed aggressively.
- Pathologic evaluation from biopsy specimens with acetylcholinesterase staining is the most sensitive and specific means for diagnosis.

## BASICS

### DESCRIPTION

- HIV causes a chronic RNA virus infection in humans.
- When the HIV-infected person develops opportunistic infections, certain malignancies, or immune dysfunction, that person is defined as having AIDS.
- Prenatal testing and perinatal treatment have made new cases of perinatally acquired HIV rare.
- Due to advances in HIV treatment, children with congenital HIV are now surviving into adolescence.

### EPIDEMIOLOGY

#### Incidence

- <200 new cases per year of perinatally acquired HIV infection in the U.S.
- In 2006, there were >2,000 new cases reported in people 13–24 yr of age.
- 25% of all people are unaware of their HIV infection; 50% of adolescents are unaware that they are infected.
- Worldwide, > 1,000 children are infected with HIV each day.

#### Prevalence

The World Health Organization estimates that there are >30 million HIV-infected individuals in the world; 2 million are children.

### RISK FACTORS

- Females: Heterosexual intercourse
- Males: Male to male sexual contact (75% of cases):
  - <20% of cases in males are due to heterosexual contact.
- IV drug use
- In adolescents, use of other illicit drugs and alcohol
- High number of sexual partners
- Adolescents living in poverty or who are homeless

### GENERAL PREVENTION

Use of condoms

### PATHOPHYSIOLOGY

- The HIV virus binds to CD4 receptors on T lymphocytes and enters the host cell.
- Viral RNA is transcribed to viral DNA, which enters the host cell nucleus and becomes part of the host cell genome.
- Viral proteins are produced, as well as viral genomic RNA, and complete virions are released.
- An initial viremic phase occurs before the host antibody response; it is now that the infected person has the highest potential to infect others.
- Immune dysfunction results from destruction of CD4+ T lymphocytes.
- In children, humoral immunity is also affected, leading to recurrent episodes of common bacterial infections.

### ETIOLOGY

HIV is a lentivirus in the retrovirus family.

### COMMONLY ASSOCIATED CONDITIONS

- *Pneumocystis jiroveci* pneumonia
- Lymphoid interstitial pneumonitis (LIP)
- Recurrent bacterial infections (otitis, sinusitis, pneumonia, bacteremia)
- HIV wasting syndrome or encephalopathy
- Candidal infections (persistent thrush)
- *Mycobacterium avium* complex (MAC) infections
- Severe or unusual viral infections (eg, severe *Herpes simplex* or *CMV retinitis*)
- Severe or difficult to control seborrhea, eczema, or other skin conditions

## DIAGNOSIS

### HISTORY

- In infants and young children: Small for gestational age, failure to thrive, developmental delay, or recurrent serious bacterial infections
- After 12 mo of age: Recurrent or persistent thrush
- Unexpectedly severe complications of routine viral infections (eg, varicella or herpes simplex virus), recurrent or persistent diarrhea or rashes
- Respiratory distress as the 1st sign of *Pneumocystis* pneumonia. Hypoxia is worse than expected from the amount of distress or changes on CXR.
- Respiratory distress and recurrent wheezing may be seen in children with LIP.
- History of parental risk factors: History of HIV infection, IV drug use, other substance abuse or addiction, multiple sexual partners, and prostitution:
  - Increased prenatal screening has made unknown parental infection less common than in the past.
- In adolescents, 2–6 wk after acute infection: An acute retroviral syndrome with sore throat, fever, myalgia, swollen lymph nodes, rash, and fatigue
- Adolescents who were infected more remotely may present with symptoms of opportunistic infections including *Candida* esophagitis, pneumonia, or severe vaginitis; severe varicella zoster virus (VZV); *Pneumocystis* pneumonia; MAC infections; cryptosporidiosis; and parotid gland swelling

### PHYSICAL EXAM

- Infants and young children may have recurrent fevers, failure to thrive, and severe wasting; extensive or persistent lymphadenopathy; hepatosplenomegaly; or parotid swelling.
- Pulmonary findings may include digital clubbing, episodes of respiratory distress, and hypoxia.
- Severe oral thrush after age 1 yr
- Recurrent otitis media or sinusitis
- Severe cases of VZV, varicella, rubeola, molluscum contagiosum, eczematous or seborrheic dermatitis

- Older children and adolescents with a recent infection with HIV may appear to have infectious mononucleosis: Fever, adenopathy, hepatosplenomegaly, and a nonspecific rash
- Children and adolescents with known HIV infection may present with physical signs of serious bacterial illness including severe pneumonia and sepsis, opportunistic infections, and pulmonary (eg, lymphoid interstitial pneumonitis) or neurologic involvement.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Diagnosis of HIV:
  - ELISA and Western blot tests for antibodies to HIV are used to screen for and diagnose HIV infection:
    - ELISA is used as a screening test; if positive, a Western blot is done for confirmation.
    - Both results must be positive for the overall test to be considered positive.
  - Newer, rapid tests for HIV antibodies are available, which can be performed on either blood or saliva. If positive, these must be confirmed using ELISA and Western blot:
    - These are now widely available in emergency departments.
  - Infants born to HIV-infected mothers will have antibodies to HIV present due to transplacental transfer of IgG.
  - The presence of HIV antibodies in the blood of a patient > 18 mo of age is diagnostic.
  - Patients with recent infection may not have developed an antibody response to the virus, so ELISA may be negative.
  - For young infants or children with a recent infection, polymerase chain reaction (PCR) testing for HIV DNA or RNA may be used.
  - HIV culture and HIV p24 antigen detection may also be used in some situations.
  - To definitively diagnose HIV infection, a patient must have 2 confirmatory tests that are positive (eg, a positive HIV antibody test after age 18 mo plus the presence of HIV RNA or DNA or 2 positive antibody tests after age 18 mo).
  - Antibody testing after an exposure to HIV is not to be considered negative until negative at least 6 mo after the exposure.
  - If HIV testing is to be done in the emergency department, arrangements must be made for contacting the patient with the result and for appropriate pre- and post-test counseling.
- Lab assays for patients with known HIV:
  - CBC to detect anemia, neutropenia, or thrombocytopenia
  - Urinalysis to detect urinary tract infection, hematuria, proteinuria
  - Comprehensive chemistry panel with LFTs to detect hepatitis, associated hypoalbuminemia, and/or renal injury
  - Consider obtaining a CBC with blood culture, urinalysis, and urine culture in febrile patients with known HIV infection.

- If ill appearing, consider lumbar puncture with standard CSF evaluation including culture for mycobacterium in addition to standard pathogens and staining for *Cryptococcus* in addition to Gram stain.
- Assay CD4+ T lymphocyte count and viral load for comparison with previous results
- Patients with known HIV infection who are ill appearing should also have coagulation studies and a lumbar puncture.
- Consider stool for WBCs and culture, and ova and parasite and *Clostridium difficile* testing for those with diarrhea.
- In patients with respiratory distress, lactate dehydrogenase (elevated) and arterial blood gas (high alveolar–arterial oxygen gradient) may help in the diagnosis of *Pneumocystis* pneumonia.

### Imaging

- Use of imaging should be guided by the clinical presentation of the patient.
- Consider head CT to detect lesions due to toxoplasmosis, *Cryptococcus*, or CNS lymphoma; also useful to evaluate for elevated intracranial pressure prior to lumbar puncture.
- All with respiratory distress should have a CXR:
  - LIP: A diffuse interstitial process often with a reticulonodular pattern
  - *Pneumocystis* pneumonia: Diffuse interstitial pattern, lobar infiltrates or changes consistent with acute respiratory distress syndrome

### DIFFERENTIAL DIAGNOSIS

- Congenital immunodeficiency syndromes
- Viral illnesses
- Malignancy
- Failure to thrive

### TREATMENT

#### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- For very ill patients with advanced disease, clarify the extent to which the family wants resuscitation efforts to be performed.
- For ill patients with fever, obtain IV access and begin fluid resuscitation.
- Contact with physician who regularly manages the patient's HIV may be extremely helpful and is recommended.

#### MEDICATION

- Empiric broad-spectrum antibiotic therapy for ill patients with suspected bacterial infections
- Coverage for *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Staphylococcus aureus*, gram-negative enterics, and *Pseudomonas* species:
  - Cefepime 50 mg/kg/dose IV q12h
  - Vancomycin 10 mg/kg/dose IV q6–8h
- In patients suspected of *Pneumocystis* pneumonia, therapy should be begun immediately with IV trimethoprim/sulfamethoxazole:
  - Dose: 15–20 mg/kg/day in 3–4 doses

### DISPOSITION

#### Admission Criteria

- Young children who are ill appearing, have failure to thrive, or neurologic abnormalities in whom HIV infection is suspected should be admitted for additional testing to determine immune status, antiretroviral therapy, and level of family support.
- Patients suspected to have opportunistic infections should also be admitted.
- Critical care admission criteria:
  - Severe respiratory distress, sepsis, meningitis, shock, or intractable seizures

#### Discharge Criteria

Febrile patients known to be HIV infected may be discharged if they appear well and initial testing (CBC, CXR) is normal:

- If the presumed diagnosis is a viral infection, antibiotics are not needed.
- Localized bacterial infections (eg, otitis media or sinusitis) may be treated with oral antibiotics.

#### Issues for Referral

Children newly diagnosed with HIV disease should be referred to an immunologist or infectious diseases specialist.

### FOLLOW-UP

#### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- Prior to emergency department discharge, families should be clear about what symptoms should prompt them to return, and they must have a way to return.
- In patients in which a diagnosis of presumed perinatally acquired HIV infection is made, referral of the mother and/or father to a primary HIV provider for adults should be facilitated.

#### PROGNOSIS

When treatment consists of multidrug, antiretroviral therapy, >95% of children with perinatally acquired HIV survive to 16 yr of age; compliance with such regimens preserves immune function:

- Onset of opportunistic infections (especially *Pneumocystis*, progressive neurologic diseases, and severe wasting) are associated with worse prognosis.

#### COMPLICATIONS

- LIP
- *Pneumocystis* pneumonia
- Thrush
- Failure to thrive
- Recurrent and persistent infections

#### ICD9

042 Human immunodeficiency virus (HIV) disease

### PEARLS AND PITFALLS

- Adolescents with newly acquired HIV infection may have a clinical picture similar to infectious mononucleosis.
- Consider HIV infection in children with persistent parotid swelling, adenopathy, and hepatosplenomegaly.
- Include HIV in the differential diagnosis for children with recurrent infections, failure to thrive, or developmental delay.
- Aggressively treat possible opportunistic infections (especially *Pneumocystis* pneumonia) even before a definitive diagnosis is established.

# HYDROCARBON POISONING

Robert J. Hoffman

## BASICS

### DESCRIPTION

- Hydrocarbons are molecules consisting of a carbon backbone in aliphatic (straight) or aromatic/cyclic structure, typically with predominantly hydrogen and oxygen attached.
- Hydrocarbons are often heterogeneous; a given substance, paraffin for example, consists of carbon chains of lengths varying from 6–10 carbons.
- Other attached atoms, such as halogens, or substances dissolved or suspended in the hydrocarbon, such as pesticides or camphor, may impart additional toxicity.
- Halogenated hydrocarbons and cyclical hydrocarbons have greater relative toxicity than aliphatic hydrocarbons due to systemic effects.
- Hydrocarbons are ubiquitous in industrialized societies, used to power combustion engines, in cleaning agents, and in manufacturing processes.
- This topic will focus on hydrocarbon ingestion and aspiration, though inhalation and transdermal toxicity may occur.

### EPIDEMIOLOGY

#### Incidence

Hydrocarbons regularly rank as the 2nd or 3rd leading cause of poisoning death in the U.S. in both children and adults.

### RISK FACTORS

- Access to hydrocarbons is a risk factor for toddler and school-aged poisoning.
- Intentional abuse as an inhalant is a risk factor for adolescent poisoning.

### GENERAL PREVENTION

- Make poisons inaccessible to children.
- Do not store poisons in containers other than their original, properly labeled container.
- Do not siphon gasoline by mouth.

### PATHOPHYSIOLOGY

- Properties of the hydrocarbon as well as characteristics of the poison exposure impart risk:
  - Five “V’s” of predicting adverse events:
    - Volume >30 mL ingested
    - Vomiting subsequent to ingestion
    - Volatility: Higher volatility increases risk of aspiration.
    - Viscosity: Low viscosity is greater risk for aspiration.
    - Van der Waals forces: Low surface tension increases risk of aspiration.
- Aliphatic hydrocarbons effectively lack systemic toxicity; if they are ingested without aspiration, they will pass through the GI tract without being absorbed and without causing systemic effects.
- Massive ingestion of long-chain aliphatic hydrocarbons may result in systemic symptoms, typically inebriation:
  - Terpenes or wood alcohols commonly cause inebriation.
  - Terpenes are absorbed from the GI tract and in large doses cause inebriation as ethanol or other alcohols.

- Halogenated hydrocarbons and aromatic/cyclical hydrocarbons have unique ability to sensitize the myocardium to endogenous catecholamines:
  - This may result in premature ventricular contractions, ventricular tachycardia, ventricular fibrillation, or asystole.
  - This is the putative mechanism underlying “sudden sniffing death,” in which a patient abusing these substances may have sudden cardiac dysrhythmia or death, often as a result of suddenly being startled or surprised.

### ETIOLOGY

- Aliphatic hydrocarbons
- Aromatic hydrocarbons
- Halogenated hydrocarbons
- Hydrocarbons admixed with other substances

## DIAGNOSIS

### HISTORY

- History of exposure to hydrocarbon is usually readily given by caretaker or patient:
  - Older school-age children and adolescents may abuse hydrocarbons regularly to get high.
  - This is typically done by children who do not have access to more serious drugs of abuse or by persons such as homeless who lack funds to purchase more expensive street drugs:
    - Bagging: Placing hydrocarbon onto a paper bag and rebreathing
    - Ragging: Wetting a rag with hydrocarbon and inhaling
    - Huffing: Directly inhaling fumes from a container such as a glass jar
  - GI: Oral irritation or pain, abdominal pain, nausea, vomiting, or even rectal irritation if hydrocarbon has fully transited GI tract
  - It is critical to inquire about episodes of choking, coughing, or vomiting to assess for likelihood of aspiration.
  - Respiratory: Dyspnea, cough, tachypnea, wheeze
  - Neurologic: Somnolence or CNS depression

### PHYSICAL EXAM

- Patients will often have obvious hydrocarbon smell on the body or breath.
- Assess vital signs: Tachypnea or hypoxia is suggestive of aspiration; tachycardia is suggestive of systemically active hydrocarbon.
- Mental status: Dose-dependent sedation or CNS depression may occur.
- Respiratory: Assess respiratory rate, effort, and breath sounds:
  - Hydrocarbon aspiration into the lung, even a small volume, often causes pneumonitis indistinguishable from pneumonia.
- HEENT: Evidence of exposure may include dribble marks, pharyngeal erythema, increased salivation, conjunctival injection, or lacrimation if there is ocular exposure.
- Dermatologic: Erythema, contact dermatitis, or frosting of skin may occur from dermal exposure. Rarely, with prolonged topical contact, 2nd-degree burn or skin necrosis may occur.

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- Lab testing is not routinely indicated and is usually unnecessary.
- If an intentional ingestion, obtain screening acetaminophen level.
- Pregnancy test as indicated
- If respiratory symptoms are present, obtain blood gas:
  - Initially venous sample and arterial sampling only if necessary
- Chronic abusers of hydrocarbons have unique risks and considerations:
  - CBC to assess for bone marrow suppression
  - BUN and creatinine to assess renal function
  - Hepatic function tests to assess for hepatic injury

### Imaging

CXR should be obtained immediately if respiratory symptoms are present or develop:

- Routine CXR in patients without respiratory symptoms is not recommended.
- In young children with hydrocarbon ingestion and respiratory symptoms, CXR at 6 hr should be performed to confirm lack of pneumonitis. If initial symptoms are very mild or after initial brief symptomatic period, it is acceptable to simply wait 6 hr and obtain a single CXR.

### DIFFERENTIAL DIAGNOSIS

Respiratory symptoms:

- Irritant gas inhalation
- Caustic exposure
- Aspiration
- Upper respiratory infection
- Pneumonia or bronchiolitis
- Asthma attack
- Hypoxia
- Methemoglobinemia

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation:
  - Do not administer activated charcoal.
- If grossly contaminated, decontaminate patient in field:
  - Fumes from hydrocarbon-soaked clothing may become overwhelming in the closed space of ambulance and may affect prehospital staff.

### ALERT

- Even a faint smell of hydrocarbon inside the emergency department may result in exaggerated response in both staff and other patients with varied complaints of headache, nausea, chest pain, and difficulty breathing.
- These can be avoided by disrobing and decontaminating the patient as well as physical separation or isolation of the patient to contain any smell.

**INITIAL STABILIZATION/THERAPY**

- Perform skin decontamination prior to entrance in emergency department if necessary:
  - Fumes from hydrocarbon-soaked clothing may become bothersome to staff and other patients.
- Assess and stabilize airway, breathing, and circulation:
  - Do not administer activated charcoal or syrup of ipecac.
  - Use of an NG tube to aspirate liquid may rarely outweigh risk of the procedure, as procedure may cause vomiting or aspiration:
    - Massive ingestion
    - Hydrocarbon containing heavy metal
    - Hydrocarbon containing pesticide
    - Hydrocarbon containing camphor
    - Hydrocarbon containing halogens
- Supportive care usually requires no specific intervention other than observation.
- Respiratory support is the most commonly needed intervention:
  - Administer oxygen as necessary.
  - Endotracheal intubation is sometimes needed for severe respiratory distress or respiratory failure.
  - Standard mechanical ventilation or high-frequency jet ventilation may be used.
  - Extracorporeal membrane oxygenation is rarely required for severe respiratory insufficiency.
- At the earliest possible convenient time, report the case to the appropriate local poison center:
  - Reporting serves a vital epidemiologic public health purpose.
  - Reporting cases ensures that subsequent caregivers will have access to expert advice by a toxicologist.

**ALERT**

- Hydrocarbon pneumonitis causes cough, hypoxia, infiltrate on CXR, leukocytosis, and pyrexia.
- As these pneumonitis findings are identical to pneumonia, clinicians often manage this condition as they do infectious pneumonia.
- Antibiotics are not routinely necessary and will not alter the course of pneumonitis.
- With significant aspiration of gastric contents, there is potential benefit from antibiotics.
- Corticosteroids are often administered but are not proven to be of benefit.

**MEDICATION**

**First Line**

- Albuterol for wheezing or bronchoconstriction:
  - Albuterol 0.15 mg/kg/dose, min 2.5 mg:
    - Increased risk of cardiac dysrhythmia if albuterol is used in cases involving systemic toxicity from halogenated or cyclical hydrocarbon
- In rare cases of myocardial sensitization to halogenated or cyclical hydrocarbons, beta-adrenergic antagonists (beta-blockers) should be used to decrease myocardial hyperreactivity:
  - Relatively contraindicated in asthmatics

**Second Line**

- Ondansetron 0.15 mg/kg IV q8h, max single dose 8 mg:
  - Give if nausea or vomiting to prevent potential aspiration of vomited hydrocarbon
- If asthmatic with bronchoconstriction, use a burst dose of steroid as for asthma exacerbation:
  - Prednisone 1–2 mg/kg, max single dose 60 mg PO per day for 3–7 days
  - Dexamethasone 0.15 mg IM/IV × 1 dose, max single dose 10 mg

**DISPOSITION**

**Admission Criteria**

- Critical care admission criteria:
- Those with pneumonitis, cardiac symptoms, or severe toxicity such as coma or unstable vital signs should be admitted to a critical care unit.
  - Admissions for medical purposes should be made to a critical care unit; only social admissions are suitable for the general ward.

**Discharge Criteria**

- Normal vital signs
- Minimal symptoms that are stable or improving and normal CXR 6 hr after ingestion

**Issues for Referral**

- Follow-up for substance abuse counseling for hydrocarbon abusers
- Follow up for psychiatric care for patients with exposure with intent of self-harm

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Return for re-evaluation if respiratory symptoms develop within 24 hr
- Keep poisons inaccessible to children.

**PROGNOSIS**

Prognosis varies depending on type of aspiration as well as systemic toxicity.

**COMPLICATIONS**

- Pneumonitis/Respiratory failure
- Coma
- Hepatitis
- Renal tubular acidosis (chronic use)
- Renal failure
- Cardiac dysrhythmia
- Cardiac arrest

American Association of Poison Control Centers: 1-800-POISONS (764-7667)

**ICD9**  
987.0 Toxic effect of other gases, fumes, or vapors: liquefied petroleum gases

**PEARLS AND PITFALLS**

- Respiratory symptoms should be presumed to indicate aspiration until CXR and clinical status demonstrate otherwise.
- Pneumonitis from hydrocarbon aspiration is clinically identical to pneumonia, but there is no benefit from antibiotic use.
- Morbidity and mortality from hydrocarbons is predominantly from pulmonary complications.
- GI decontamination is not routinely indicated and may result in aspiration.
- Five V's predictive of aspiration risk: Volume, vomiting, volatility, viscosity, Van der Waals (surface tension)
- All poison exposures should be reported to the appropriate poison control center for epidemiologic purposes and to ensure that ongoing monitoring and guidance by a toxicologist is available.

# HYDROCEPHALUS

Amy D. Thompson

## BASICS

### DESCRIPTION

- Hydrocephalus is an accumulation of CSF within the ventricles and subarachnoid spaces that can lead to increased intracranial pressure (ICP) and dilatation of the cerebral ventricular system (1).
- Hydrocephalus may be acute, subacute, or chronic.
- The symptoms and signs of hydrocephalus are secondary to the degree and duration of increased ICP and ventricular dilatation.
- Death occurs from tonsillar herniation with brainstem compression and subsequent respiratory arrest.

### EPIDEMIOLOGY

#### Prevalence

The prevalence of pediatric hydrocephalus has been estimated to be as high as 0.9 per 1,000 children (2).

### RISK FACTORS

- Prematurity
- Congenital syndromes
- Genetic
- CNS infections
- Head injury

### PATHOPHYSIOLOGY

- CSF is produced in ventricles' choroid plexus.
- CSF is absorbed into the systemic circulation by subarachnoid granulations located along the sagittal sinus and major cortical veins.
- Hydrocephalus results from a disturbance of either the production, flow, or absorption of CSF:
  - Excessive production: Rare; occurs in the case of a functional choroid plexus papilloma
  - Flow obstruction: Occurs secondary to either anatomic or functional obstruction to CSF flow
  - Impaired absorption: Occurs secondary to inflammation of the subarachnoid granulations
- The terms *communicating hydrocephalus* and *noncommunicating hydrocephalus* have no prognostic significance but are often seen in the literature and refer to the use of pneumoencephalography (2).

### ETIOLOGY

- Congenital:
  - Neural tube defects: Myelomeningocele
  - CNS malformations: Dandy-Walker malformation, Arnold-Chiari malformation, vein of Galen malformation, agenesis of the foramen of Monro, aqueductal stenosis
  - Intrauterine infections: Toxoplasmosis, rubella, syphilis, cytomegalovirus
  - Syndromes: X-linked and autosomal dominant hydrocephalus, achondroplasia, Apert syndrome, Crouzon syndrome, Cockayne syndrome, Pfeiffer syndrome
  - Idiopathic

- Acquired:
  - Mass lesions: Tumor, cyst, abscess, vascular malformation
  - Intraventricular hemorrhage: Prematurity, head injury, vascular malformation, systemic bleeding disorders
  - Infections: Meningitis, cysticercosis, mumps, encephalitis
  - Increased venous sinus pressure: Achondroplasia, craniostenoses, venous thrombosis
  - Iatrogenic: Hypervitaminosis A
  - Idiopathic

## DIAGNOSIS

### HISTORY

- Symptoms in infants may include decreased feeding, increased somnolence, apnea, irritability, and vomiting.
- Acute symptoms in older children may include headache, neck pain, vomiting, blurred vision, and diplopia.
- Chronic complaints in older children may include developmental regression, personality changes, delayed growth, accelerated puberty, and difficulty walking.
- Headaches and vomiting are more prevalent in the morning because CSF is resorbed less efficiently in the recumbent position.
- Past medical history should include prior infections and past head injuries.
- Prenatal history should include maternal infections, prematurity, and jaundice.
- Family history should focus on inherited syndromes and bleeding disorders.
- Social history should include foreign travel.
- Medication history should include all prescribed and over-the-counter medications, including vitamin and herbal supplements.

### PHYSICAL EXAM

- The Cushing triad (HTN, bradycardia, alterations in respiration) may be present in cases of severely increased ICP.
- Increased head circumference, widened sutures, frontal bossing, prominent scalp veins, and a tense fontanelle may be present in infants.
- Ocular findings include papilledema, failure of upward gaze, unilateral or bilateral abducens and trochlear palsies, and the "setting-sun" sign:
  - The setting-sun sign refers to downward deviation of the eyes with retraction of the upper lids, allowing the sclera to be visible above the iris.
- Neurologic findings include irritability, lethargy, altered sensorium, increased limb tone, unsteady gait, and hyperreflexia:
  - Increased limb spasticity preferentially affects the lower limbs because ventricular dilatation causes stretching of the corticospinal fibers originating from the leg region of the motor cortex.

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

No specific blood tests are recommended in the workup of hydrocephalus.

### Imaging

- Noncontrast head CT is the image of choice for the unstable patient:
  - A normal CT does not conclusively rule out hydrocephalus, especially in a patient with clinical exam findings of increased ICP.
  - The best evidence for increased ICP on CT scan is effacement of the lateral ventricles or basilar cisterns (3).
- MRI is superior to CT in detecting posterior fossa masses and developmental malformations and is highly sensitive in detecting cerebral edema.
- Head US is the standard screening test for stable neonates with suspected hydrocephalus or intraventricular hemorrhage:
  - The anterior fontanelle must be patent.

### DIFFERENTIAL DIAGNOSIS

- See the Etiology section for a complete listing of diagnoses associated with hydrocephalus.
- Other causes of macrocephaly include familial macrocephaly, head-sparing intrauterine growth retardation, pericerebral effusions, intracranial cysts, tumors, or metabolic degenerative disorders (leukodystrophies, lysosomal diseases, aminoacidurias).
- A thickened cranium from chronic anemia, rickets, or osteogenesis imperfecta may also cause the head to appear enlarged.
- Other causes of ventriculomegaly include brain atrophy, benign external hydrocephalus, and chronic ethanol or corticosteroid exposure:
  - In benign external hydrocephalus, both the ventricles and the extra-axial CSF spaces are proportionately enlarged. The patients are largely asymptomatic, and the condition typically resolves spontaneously.
  - In cases of cerebral atrophy and focal destructive lesions, CSF passively fills the vacant space left by loss of the cerebral tissue.

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Hydrocephalus can lead to critical elevations of ICP, subsequent tonsillar herniation, and death.
- Medical management in the emergency department for increased ICP may include (4):
  - Endotracheal intubation with mild hyperventilation (PaCO<sub>2</sub> 30–35 mm Hg) to cause cerebral vasoconstriction
  - Elevation of the head of the bed to 30 degrees
  - Controlling agitation and movement with adequate sedatives and analgesics:
    - Fentanyl 1–2 µg/kg IV q2h PRN:
      - Initial dose of 1 µg/kg IV may be repeated q15–20min until pain controlled, then q2h PRN
    - Midazolam 0.05–0.1 mg/kg/dose IV

- Titrating IV fluids to maintain adequate tissue and cerebral perfusion
- Administering hyperosmolar therapy using either mannitol or hypertonic saline (3% NaCl)
- Mannitol 0.25–1 g/kg/dose
- 3% NaCl 1–6 mL/kg/dose

### MEDICATION

Medical treatment has been trialed in neonates with posthemorrhagic hydrocephalus to delay surgical intervention:

- Acetazolamide and furosemide have been used to decrease CSF secretion by the choroid plexus (5).
- Furosemide 1 mg/kg/day PO b.i.d.
- Acetazolamide 25–50 mg/kg/day PO given in divided doses q8–12h

### SURGERY/OTHER PROCEDURES

- Most cases of hydrocephalus require extracranial shunts.
- Ventricular shunting is performed on the majority of patients with progressive hydrocephalus (6).
- An endoscopic 3rd ventriculostomy may be used as an alternative to CSF ventricular shunt placement in case of myelomeningocele, pineal tumors, and aqueductal stenosis (7).
- Rapid-onset hydrocephalus with increased ICP is a surgical emergency, and the following may be lifesaving:
  - Ventricular or subdural puncture (infant)
  - Open ventricular drainage (children)
  - Lumbar puncture (posthemorrhagic or postmeningitic hydrocephalus)
- Ventricular shunt puncture may be required as a temporizing measure until surgical repair can be performed in the patient with shunt malfunction and severely increased ICP (8):
  - The patient is placed supine for a frontal shunt and lateral for a posterior parietal shunt.
  - The shunt site is cleared with an antiseptic solution using strict sterile technique.
  - If the patient has a Rickham or “button” reservoir, a 23-gauge butterfly needle is inserted perpendicular to the skin.
  - If the patient has a dome-shaped pumping reservoir, the needle is inserted tangentially 2–5 mm.
  - Remove CSF until ventricular pressure is at ~10 cm H<sub>2</sub>O (5–20 mL).
  - If flow is poor, adjust the angle or depth of the needle. Poor flow is correlated with proximal shunt obstruction.
  - The needle is then withdrawn, and gentle pressure is applied over the entry site.

### DISPOSITION

#### Admission Criteria

Critical care admission criteria:

- Patients with rapidly progressive or symptomatic hydrocephalus require admission.

#### Discharge Criteria

Asymptomatic patients with chronic hydrocephalus and normal neurologic exams may be discharged home with close follow-up.

### Issues for Referral

- A pediatric neurosurgeon and/or neurologist should be consulted on all patients with newly diagnosed hydrocephalus.
- Pediatric patients with hydrocephalus also often require referral to ophthalmology and neurorehabilitation.

### FOLLOW-UP

#### FOLLOW-UP RECOMMENDATIONS

It is important to follow clinical status, head circumference, and ventricular size on all patients with hydrocephalus, particularly in those with whom the need for shunting is unclear.

#### PROGNOSIS

- Dependent on the severity and etiology of hydrocephalus as well as the presence of concomitant neurologic disorders
- In shunt-treated patients, significant associated morbidity and mortality from shunt complications such as malfunctions or infections may occur (9).
- Long-term intelligence for children with congenital hydrocephalus appears to be more favorable as compared to those with hydrocephalus from infection or intraventricular hemorrhage (10,11).

#### COMPLICATIONS

- Acute hydrocephalus: Increased ICP leading to tonsillar herniation, respiratory arrest, and death
- Chronic hydrocephalus: Macrocephaly, spastic paraplegia, visual loss, incontinence, cognitive delay, and premature sexual development
- Complications of ventricular shunt placement include infection and malfunction (6).

#### ICD9

- 331.3 Communicating hydrocephalus
- 331.4 Obstructive hydrocephalus
- 742.3 Congenital hydrocephalus

### PEARLS AND PITFALLS

- Children with hydrocephalus may have more prominent symptoms, such as headaches and vomiting, in the morning because CSF is resorbed less efficiently in the recumbent position.
- In untreated progressive hydrocephalus, death may occur by tonsillar herniation secondary to raised ICP with compression of the brain stem and subsequent respiratory arrest.
- Macrocephaly and ventriculomegaly can be seen in disorders other than hydrocephalus.
- Noncontrast head CT is the imaging test of choice for the patient with suspected hydrocephalus.
- Medical therapy for progressive hydrocephalus provides only temporary relief, and surgical intervention in the form of ventricular shunting is performed on the majority of patients.

# HYDRONEPHROSIS

Colette C. Mull

Nathalie Degaffier

## BASICS

### DESCRIPTION

- Hydronephrosis (HN) is the dilatation of the collecting system of the kidney.
- A patient may be referred to the emergency department specifically for HN, or it may be discovered in the process of evaluating a patient for a related complaint.

### RISK FACTORS

See Etiology.

### PATHOPHYSIOLOGY

- Obstruction (1):
  - Congenital or acquired anatomic or functional obstruction of urinary flow anywhere between the kidney and the urethral meatus (eg, nephrolithiasis, posterior urethral valves)
  - The rise in ureteral pressure leads to the dilatation of the collecting system and reductions in the glomerular filtration rate (GFR), tubular function, and renal perfusion:
    - Leads to acid base and electrolyte disturbances and disruption in the kidney's ability to concentrate urine
  - GFR can remain low even weeks after relief of the anatomic or functional obstruction.
  - The duration of obstruction dictates reversibility of kidney dysfunction.
- Reflux:
  - Vesicoureteral reflux occurs most commonly from incomplete closure of the ureterovesical junction (a congenital defect), a 1-way valve promoting forward flow from the ureter to the bladder. Less commonly, reflux results from a neuropathic bladder (1).
- Nonobstruction, nonreflux:
  - Primary abnormalities in structure and/or function of urinary tract elements (eg, diabetes insipidus) (1)
- Obstruction and reflux:
  - The most commonly occurring example is that of a complete duplex system: Upper pole ureter obstruction and lower pole ureter reflux (1).

### ETIOLOGY

- Upper urinary tract obstruction:
  - Renal calculus: Admission rate: 4.7/100,000 (2)
  - Ureteropelvic junction obstruction (UPJO): Intrinsic stenosis or extrinsic obstruction by an accessory artery to the lower kidney (3):
    - Most common site of upper urinary tract obstruction in infants and children (4)
    - 1/500 births, males > females (5)
  - Less common (4):
    - Congenital megaureter: Dilatation of ureter with or without reflux
    - Ureterocele: Cystic dilatation of terminal ureter
    - Ureterovesical junction obstruction

- Lower urinary tract obstruction:
  - Severe constipation
  - Painful genital problem (eg, vaginitis, injury)
  - Posterior urethral valves:
    - Congenital membranous folds obstruct urethra
    - Classic finding: Bilateral HN and hydroureter (HU) (1)
    - 1/5,000–8,000 male births (6)
  - Other: Ectopic ureter, hydrocolpos, prolapsing ectopic ureteroceles, pelvic tumors, neuropathic bladder, pelvic trauma (eg, straddle injuries), meatal stenosis, bladder calculi, iatrogenically acquired urethral strictures (eg, catheterization) (1)
- Vesicoureteral reflux: 1/100 newborns (7):
  - 35–45% of children with urinary tract infection (UTI)
  - Whites, females > males
- Nonobstruction, nonreflux:
  - Prune belly syndrome (3):
    - 1/40,000 births, male predominance
    - Congenital, intrinsic, structural urinary tract abnormalities result in HN and HU.
  - Conditions with high urinary flow rates (1) (eg, diabetes insipidus, single kidney)
- Obstruction and reflux:
  - Duplex system (7)

### COMMONLY ASSOCIATED CONDITIONS

- See Etiology.
- Chronic granulomatous disease (3)
- Cystinuria (1)

## DIAGNOSIS

### HISTORY

- Early HN can be asymptomatic (3).
- Elicit history of prenatal HN, prior UTI, abdominal trauma (1,3).
- Ascertain presence and character of pain:
  - Renal colic (1,3): Abdominal, flank, and/or back pain; unable to find comfortable position
  - Location of pain helps localize obstruction (1):
    - Flank pain: Upper ureter, renal pelvis
    - Radiation to ipsilateral testis or labia: Lower ureter
- Nausea and vomiting (1,3)
- Hematuria (1,3)
- Symptoms of infection (1,3): Dysuria, urgency, frequency, fever, chills:
  - Enuresis, weak urinary stream, or urinary retention with frank anuria are seen more often with lower urinary tract obstruction (eg, posterior urethral valves) (1,3).
  - Infants: Failure to thrive, vomiting, diarrhea (3)

### PHYSICAL EXAM

- Tachycardic, tachypneic (pain, sepsis) (1,3)
- HTN or hypotension (sepsis) (1,3)
- Abdominal tenderness (1,3)
- Costovertebral angle/flank tenderness (1,3)
- Abdominal mass (1): May be palpable and tender
- "Dietl crisis": Acute abdomen associated with HN (1)
- Posterior urethral valves:
  - Neonates (1): Respiratory distress due to lung hypoplasia from associated oligohydramnios
  - Infants (3): Palpably distended bladder, difficulty voiding with straining, or grunting while voiding
- Prune belly syndrome (1): Abdominal wall deficiency, bilateral cryptorchidism
- Urethral obstruction from anterior urethral valves: A soft mass on the ventral surface at the penoscrotal junction
- Urethral obstruction from prolapse of ectopic ureterocele may present as a vaginal mass (8).

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Urinalysis and culture:
  - If considering urinary obstruction in a non-toilet-trained patient, consult with a pediatric urologist prior to catheterization.
- Serum electrolytes, BUN, creatinine
- Additional testing is guided by the history and physical exam (eg, for sepsis, obtain CBC and blood culture).

#### Imaging

- US:
  - Detects size and shape of kidney, duplicated or dilated ureters, and gross anatomic abnormalities (1,9)
  - Useful in diagnosis of HN; often determines its cause (1,9)
  - Urinary tract obstruction can be ruled out if US shows no HN, no HU, normal size bladder, and normal bladder emptying (1,9,10).
  - Concurrent Doppler exam may help assess the integrity of renal blood flow (9,10).
  - Not useful for detection of scarring or vesicoureteral reflux
  - Use of routine prenatal US has dramatically increased diagnosis of HN antenatally
    - Many such cases involve minimal enlargement of questionable clinical significance.
- CT:
  - Provides complementary information
  - Used if better resolution than US is needed
  - More sensitive for evaluation of renal mass
  - Non-contrast-enhanced helical CT is the gold standard for radiologic diagnosis of nephrolithiasis (2,3).
- It is rare that other imaging studies such as radionuclide scintigraphy (definition of structure and function of kidney) or voiding cystourethrogram (diagnosis of vesicoureteral reflux) would be ordered during the patient's emergency department visit (2).

**DIFFERENTIAL DIAGNOSIS**

- Given that HN is a radiologic and a pathophysiologic finding, its differential diagnosis encompasses all its etiologies (see Etiology).
- Abdominal mass
- Abdominal neoplasm, Wilms tumor
- Intussusception
- Constipation
- Ovarian cyst

**TREATMENT**

- Acute upper urinary tract obstruction:
  - Conservative management initially (1)
  - Bed rest, analgesia (1)
  - Antibiotics (1)
  - Forced diuresis, in case of ureteric stones (1)
  - Consult pediatric urologist and nephrologist
  - Indications for acute surgical intervention (1):
    - Pyonephrosis (ie, obstruction, pyelonephritis)
    - Deteriorating renal function
    - Acute UPJO, ureterovesical obstruction
    - Impacted calculi
    - Failure of conservative management
- Acute lower urinary tract obstruction:
  - Resuscitation as needed (1)
  - Treat underlying etiology when possible (1):
    - Enemas for constipation (1)
    - Analgesia for painful genital problems (1)
    - Otherwise, treat obstruction emergently (1):
      - Can be performed by emergency department physician
      - Consult pediatric urologist
      - Urethral catheterization (1)
      - 8 French Foley catheter (1)
      - 5 French feeding tube for small male infant (1)
      - Suprapubic catheterization if necessary (1):
        - 4 French feeding tube (1)
        - Through a wide angiocatheter into bladder (1)
  - Posterior urethral valves (1):
    - Emergent catheterization
    - IV antibiotics
    - Consult pediatric urologist and nephrologists.
    - Replace salt and water loss carefully.
  - Prune belly syndrome:
    - Resuscitation as needed (1)
    - Prophylactic antibiotics
    - Consult pediatric urologist and nephrologists (1).
    - Indications for surgical intervention (1):
      - Renal failure
      - Intractable UTI
      - Anuria

**SURGERY/OTHER PROCEDURES**

- Acute upper urinary tract obstruction (1):
  - Percutaneous nephrostomy
  - US-guided lithotripsy for impacted calculi
- Acute lower urinary tract obstruction:
  - Catheterization is rarely required (1).
  - See Treatment.
- All other surgeries can be performed on a semiemergent basis (1).

**DISPOSITION****Admission Criteria**

- Sepsis
- Deteriorating renal function; renal failure
- Emergent surgical intervention is required.
- Failure of conservative management

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- If patient is being discharged from the emergency department, consult with a pediatric nephrologist or urologist to define the follow-up interval and the need for outpatient imaging studies.
- All patients with HN must follow up with a pediatric urologist and/or nephrologist.
- Discharge medications and diet are determined by the etiology of the patient's HN and by the involved specialist's recommendations.
- Monitoring for stability of renal function and BP is necessary.
- The emergency department physician should communicate discharge instructions and follow-up plans with the primary care physician.

**PROGNOSIS**

- Acute upper urinary tract obstruction (1,4):
  - Conservative management is successful in the majority of children with acute unilateral obstruction.
  - Obstructive calculi will typically clear the urinary tract spontaneously.
  - The majority of obstructed kidneys experience full functional recovery after treatment.
  - Nephrectomy is rarely required.
- Acute lower urinary tract obstruction (1):
  - Treatment of the 2 most common causes of obstruction, constipation and local genital problems, results in rapid resolution of urinary retention.
  - Prompt drainage of serious urinary retention is typically successful.
  - Despite early diagnosis and treatment, a significant number of patients with posterior urethral valves will have renal dysfunction and require renal transplantation. A persistently elevated creatinine level post-ablation is highly predictive for end-stage renal disease.

**COMPLICATIONS**

- Infection:
  - If acute lower urinary tract obstruction is not treated emergently, pyelonephritis and sepsis ensue. Death or renal scarring can occur (1).
- Deteriorating renal function; renal failure
- HTN
- Surgical complications

**CODES**

- ICD9
- 591 Hydronephrosis
- 753.29 Other obstructive defect of renal pelvis and ureter

**PEARLS AND PITFALLS**

- A careful and complete history and physical exam will often yield the underlying etiology of HN:
  - Always check BP.
  - Always examine genitalia.
  - Respiratory signs and symptoms in infants may signal the presence of renal disease.
  - HN may be asymptomatic.
- Consider common etiologies of HN before uncommon ones (eg, constipation).
- Consider US as the imaging method of choice in the initial evaluation of suspected HN.
- Obtain serum creatinine to measure renal function.
- Involve a subspecialist early in the evaluation.

# HYPERCALCEMIA

Manoj K. Mittal

## BASICS

### DESCRIPTION

- Hypercalcemia is defined as a plasma level >11 mg/dL. Severe hypercalcemia is defined as a level >13.5 mg/dL (1).
- The severity of disease varies depending on absolute elevation and rate of change.
- Mild cases are asymptomatic and found incidentally, while severe cases may result in cardiac and respiratory compromise.
- Hypercalcemia may be an incidental finding or may be a harbinger of serious conditions like primary hyperparathyroidism or malignancies like acute lymphoblastic leukemia (ALL).

### RISK FACTORS

- Malignancy: Hypercalcemia is the most common life-threatening metabolic complication of malignancy in adults (5–20% of cases) but is extremely rare in children (0.4–1.3%) (2,3).
- Occurs in children with both hematologic malignancies and with solid tumors, with ALL accounting for majority of cases

### PATHOPHYSIOLOGY

- The skeleton contains 98% of body calcium.
- Most calcium outside bone is intravascular; half is free or ionized, the other half is bound to albumin, globulin, and other inorganic molecules:
  - The ionized form has physiologic effects.
- Intracellular calcium is very low. Gradient in calcium concentration across cell membranes is maintained by voltage- and ligand-gated calcium channels.
- Hypercalcemia leads to hyperpolarization of cell membranes and effects in multiple organ systems as listed in the Diagnosis section.
- Plasma calcium concentration is closely controlled through a delicate interplay between parathyroid hormone (PTH), calcitonin, and vitamin D acting on target organs such as bone, kidney, and the GI tract.
- Hypercalcemia in patients with cancer is caused by increased bone resorption and release of calcium from bone (2,3). This can occur by:
  - Localized bone destruction by cancer cells, as in breast cancer and multiple myeloma
  - Osteolytic metastases with local release of cytokines, as happens with most solid tumors
  - Tumor secretion of parathyroid hormone–related protein (PTHrP), as is the case with most leukemias and in many patients with solid tumors with bone metastases; the PTHrP can bind to the PTH receptor causing increased bone resorption and decreased renal calcium excretion.

- PTH increases bone resorption by activating osteoclasts. This leads to activation of osteoblasts and, thus, bone formation. Resulting hypercalcemia in hyperparathyroidism is usually mild.
- The PTHrP uncouples bone resorption and bone formation and does not promote osteoblastic activity. The hypercalcemia mediated by PTHrP is therefore more severe (3).
- Tumor production of calcitriol, as in patients with Hodgkin disease or non-Hodgkin lymphoma (3)

### ETIOLOGY

- Increased bone resorption, as in primary hyperparathyroidism (rare in childhood), secondary parathyroidism (as in renal failure), malignancies like ALL, hyperthyroidism, and hypervitaminosis A
- Increased intestinal calcium absorption, as in milk alkali syndrome, hypervitaminosis D, lymphoma, TB, and sarcoidosis
- Miscellaneous conditions such as familial hypocalciuric hypercalcemia, idiopathic hypercalcemia of infancy (William syndrome), immobilization, total parenteral nutrition, and chronic intake of some medications such as lithium and thiazides
- Primary hyperparathyroidism and malignancy account for >80% of cases of hypercalcemia in children (1,2).

### COMMONLY ASSOCIATED CONDITIONS

See Etiology.

## DIAGNOSIS

### HISTORY

- Mild hypercalcemia may be asymptomatic, whereas moderate to severe hypercalcemia may affect multiple systems and present in myriad ways (1,2).
- Clinical features of hypercalcemia: “Bones, groans, moans, stones” for bone pain, abdominal pain, depression/psychosis, and renal stones, respectively (2).
- Nonspecific symptoms: Fatigue, weakness, and weight loss
- GI symptoms result from smooth muscle relaxation, anorexia, nausea, vomiting, abdominal pain, and constipation.
- Bone pain and, rarely, pathologic fractures associated with increased bone resorption
- Renal: Abdominal pain because of renal stones (due to hypercalciuria), polyuria and polydipsia related to decreased renal tubular concentrating ability
- Cardiac: Chest pain, palpitations as manifestation of dysrhythmias
- Underlying malignancy is usually clinically evident by the time hypercalcemia results.
- History of fever, weight loss, night sweats, bone pain, unexplained bleeding, or bruising
- Inquire about intake of vitamin A or D or any other medications, such as thiazides or lithium.

### PHYSICAL EXAM

- Patients with hypercalcemia from primary hyperparathyroidism usually appear well, unlike those with an underlying malignancy (2).
- Features of dehydration: Dry mucous membranes, delayed capillary refill, poor skin turgor
- Cardiac: Rarely bradycardia, HTN
- Neurologic: Anxiety, depression, cognitive dysfunction, hallucinations, somnolence, or coma
- Musculoskeletal: Hypotonia, hyporeflexia
- Presenting features of malignancies, such as hepatosplenomegaly, lymphadenopathy, or petechial rash

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Plasma calcium, ionized calcium: Both will be raised in true hypercalcemia.
- Primary hyperparathyroidism usually causes mild hypercalcemia; severe hypercalcemia is more often related to malignancies (4).
- CBC: Pancytopenia may be present with malignancy.
- Serum phosphate:
  - Often low normal in hyperparathyroidism and in humoral hypercalcemia of malignancy
  - High serum phosphate is seen in vitamin D–mediated hypercalcemia (vitamin D–mediated increased intestinal absorption), thyrotoxicosis, milk alkali syndrome, immobilization, and metastatic bone disease.
- Serum PTH levels:
  - High PTH level suggests hyperparathyroidism; an inappropriately normal or increased 24-hr urine calcium excretion is confirmatory.
  - Low PTH is not typical of primary hyperparathyroidism and is suggestive of underlying malignancy.
- Serum calcidiol: Elevated with excess intake of vitamin D or of calcidiol itself
- Serum calcitriol: Elevated in cases of direct intake, extrarenal production as in granulomatous disease or lymphoma, or increased renal production induced by primary hyperparathyroidism
- PTHrP level useful; usually elevated in malignancies (2,3):
  - As opposed to PTH, PTHrP does not induce increased calcitriol secretion. Thus, in malignancies, calcitriol level is usually low, its production being appropriately suppressed by the hypercalcemia.
- Amylase, lipase: Assess for associated pancreatitis.
- Urinalysis: May show reduced specific gravity, presence of blood
- Plasma electrolytes, BUN, creatinine: May be affected if hypercalcemia is complicated by renal insufficiency or dehydration.

**Imaging**

- Chest radiograph: Evidence of TB or mediastinal mass in leukemia/lymphoma
- Abdominal radiograph, sonogram, or CT may show nephrocalcinosis or urolithiasis.
- Primary hyperparathyroidism: Technetium sestamibi scintigraphy may show parathyroid tumors better than conventional imaging techniques.

**Diagnostic Procedures/Other**

- ECG:
  - Shortened QT interval
  - There also may be shortening of the ST segment, prolongation of the PR interval and QRS interval, and occasionally 2nd- or 3rd-degree heart block (1).
- Bone marrow aspiration or biopsy may be considered in children with clinical or lab features suspicious of ALL.

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Administer fluid resuscitation to treat dehydration and hypotension and to correct hypercalcemia:
  - Rehydration achieves intravascular volume expansion and increases urinary calcium excretion (1,2).
- Symptomatic patients, especially those with neurologic symptoms or with hypercalcemia > 14 mg/dL (3.5 mmol/L) regardless of symptoms, need immediate, aggressive treatment.
- Saline rehydration is the mainstay of initial therapy. There is no indication for additional saline beyond that to restore euolemia.

**MEDICATION****First Line**

- Bisphosphonates:
  - Pamidronate 0.5–1 mg/kg IV infusion given over 2–24 hr (4):
    - Pamidronate has been shown to correct hypercalcemia in 90% of cases within 3–4 days, with the duration of effect being 3–4 weeks (2,4).
    - May have anaphylactoidlike or histaminelike reaction that is rate related
  - Zoledronic acid 4 mg IV infused over 30 min; administer to adolescent/adult only:
    - May have anaphylactoid-like or flu-like reaction that may be ameliorated by premedication with acetaminophen
- Bisphosphonates are the most effective agents to correct severe hypercalcemia.
- Mechanism of action: Analogs of inorganic pyrophosphate bind hydroxyapatite and inhibit osteoclastic function.
- Adverse effects: Mild to moderate hypophosphatemia, hypomagnesemia, and transient hypocalcemia at 2–10 days after administration. Plasma levels of these electrolytes should therefore be monitored for up to 2 wk after the administration of these agents.

- Calcitonin 4 IU/kg IM/SC q12h, may increase up to 6–8 IU/kg IM/SC q6h:
  - Inhibits bone resorption by suppressing osteoclast activity, increases urinary calcium excretion
  - Rapid onset of action, relatively nontoxic
  - A weak agent, and tachyphylaxis develops rapidly, limiting its effectiveness when used on its own (2).
  - Bisphosphonates (delayed onset but long duration of action) are often combined with calcitonin (quick onset, short duration of action) for best effect in cases of severe or symptomatic hypercalcemia (2).

**Second Line**

- Furosemide 1–2 mg/kg IV q6h:
  - May be used after correction of dehydration with strict fluid and electrolyte monitoring
  - Due to electrolyte imbalance that may result from furosemide and effectiveness of bisphosphonates, loop diuretics are no longer the initial treatment of choice.
- Prednisone 2 mg/kg PO per day, max single dose 60 mg
- Hydrocortisone 2–4 mg/kg/dose IV q8h:
  - Inhibits vitamin D, used in granulomatous diseases and lymphoma with increased calcitriol level

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

Rarely, hypercalcemia due to malignancies may be resistant to conventional treatment and only responds to specific anticancer treatment.

**SURGERY/OTHER PROCEDURES**

- Hemodialysis with little or no calcium in the dialysis fluid or peritoneal dialysis:
  - Used in patients with severe hypercalcemia associated with renal failure or heart failure
  - When volume expansion is contraindicated and the commonly used drugs may cause cumulative toxicity
- Primary hyperparathyroidism: Surgery to remove parathyroid adenoma or subtotal excision of hyperplastic parathyroid glands as indicated

**DISPOSITION****Admission Criteria**

- Symptomatic patients with hypercalcemia or those with severe hypercalcemia
- Critical care admission criteria:
  - Patients with significant cardiac or renal involvement may require admission to an ICU.

**Issues for Referral**

- Endocrinology, renal, cardiology, neurology, or surgery teams may be consulted as needed.
- Consult an oncologist if a malignancy is suspected.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- After surgery for primary hyperparathyroidism, there is increased uptake of calcium by bones, which may result in hypocalcemia.
- The patient should take a diet rich in calcium and vitamin D until serum calcium levels are normal and stable.

**COMPLICATIONS**

- Pancreatitis
- Renal: Nephrolithiasis, renal tubular dysfunction, particularly decreased concentrating ability, and renal insufficiency
- Cardiac: Severe hypercalcemia may rarely be associated with life-threatening arrhythmias.
- CNS: Mild hypercalcemia can lead to anxiety, depression, and cognitive dysfunction, whereas levels > 16 mg/dL have been known to cause confusion, organic psychosis, hallucinations, somnolence, and coma.

**CODES**

ICD9

275.42 Hypercalcemia

**PEARLS AND PITFALLS**

- Calcium is essential for the smooth functioning of multiple organ systems; hence, hypercalcemia can have wide-ranging manifestations.
- The most common cause of hypercalcemia is hyperparathyroidism or malignancy.
- Management depends on the severity and may include correction of dehydration and use of bisphosphonates and calcitonin.

# HYPEREMESIS GRAVIDARUM

Kai M. Stürmann  
Mary T. Ryan

## BASICS

### DESCRIPTION

- Hyperemesis gravidarum is defined during pregnancy as:
  - Persistent vomiting
  - Weight loss >5% of prepregnancy body weight
  - Ketonuria not attributable to a different cause
- Nausea and vomiting in pregnancy is common and affects up to 80% of all pregnancies.

### EPIDEMIOLOGY

- 50–80% of pregnant women will experience some degree of nausea with or without vomiting.
- 0.3–2% of pregnant women will meet the definition of *hyperemesis*.

### RISK FACTORS

- Tendency to develop nausea and vomiting with migraine headache, motion sickness, or certain gustatory stimuli
- History of hyperemesis in a previous pregnancy
- 1st pregnancy
- Presence of a multiple pregnancy
- Female sex of the fetus
- Absence of multivitamin therapy in early pregnancy or periconception
- The presence of GERD may increase the severity of symptoms.

### GENERAL PREVENTION

- Daily multivitamin therapy beginning at or near conception
- Avoidance of environmental triggers (eg, visual or physical motion, heat, humidity, offensive odors).

### PATHOPHYSIOLOGY

- Decreased PO intake and loss of fluids through vomiting causes hypovolemia.
- Persistent vomiting causes electrolyte imbalance, characteristically metabolic alkalosis and hypokalemia.
- The lack of available carbohydrate leads to starvation ketosis.

### ETIOLOGY

- Exact cause unknown
- Pregnancy:
  - Mean onset of symptoms at ~5–6 wk of gestation
  - Peak severity at ~9 wk
  - Usually resolves by ~16–18 wk
  - May persist throughout pregnancy

- The cause of nausea and vomiting in pregnancy is not well established:
  - Hormonal influence: hCG, estrogen, and progesterone likely play a part.
  - Psychologic factors and pre-existing disorders of gastric motility may be involved.
- Molar pregnancy (hydatidiform mole) is associated with a high incidence of hyperemesis gravidarum and must be ruled out.

### COMMONLY ASSOCIATED CONDITIONS

- Pregnancy
- Multiple pregnancy
- Molar pregnancy

## DIAGNOSIS

### HISTORY

- By nature, hyperemesis is a pregnancy-related complication and therefore requires utmost consideration of patient privacy and familiarity with local state laws regarding consent and duty to inform.
- Pregnancy: Incidence of unrecognized pregnancy in eligible emergency department patients is estimated to be between 2.3 and 13% but is likely much higher in the subset of adolescent emergency department patients.
- Obtain gynecologic history including date of the last normal menstrual period and the presence or absence of abdominal/pelvic pain or vaginal bleeding.
- Historical feature of the disease is nausea, usually of several days to weeks duration prior to presentation. Although it may be more severe or frequent in the morning, symptoms may occur at any time of day and in the majority of patients (80%) persists throughout the day.
- Dizziness or light-headedness may be present in cases of significant dehydration.
- Abdominal pain and fever are usually *not* present:
  - If present, strongly consider other diagnoses.

### PHYSICAL EXAM

- Obtain the patient's weight
- Vital signs may reveal tachycardia and mild hypotension beyond what would be expected for the early pregnant state. Check for orthostasis.
- Look for objective signs of dehydration by examining skin and mucous membranes.
- A ketotic odor may be present in the patient's breath.
- A pelvic exam is *not* indicated unless the patient has pelvic pain or vaginal bleeding.

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

- Hyperemesis gravidarum is a clinical diagnosis.
- Pregnancy testing: UCG for screening, quantitative serum beta-hCG if pregnancy has been confirmed
- Serum electrolytes; consider serum acetone.
- Urine ketones
- The following tests are not necessary but may be obtained based on clinician preference:
  - CBC: May reveal hemoconcentration (elevated hematocrit; be sure to use appropriate reference values—physiologic hemodilution in early pregnancy is expected)
  - Liver enzyme panel: ALT, AST, bilirubin may be elevated <4 mg/dL
  - Amylase of nonpancreatic origin may be elevated.
  - Lipase to evaluate for pancreatitis
  - Thyroid function panel: Will help to distinguish secondary hyperthyroidism (if present) from primary hyperthyroidism

### Imaging

- Pelvic US exam is necessary to rule out a molar pregnancy but can be performed on follow-up.
- Not essential for emergency department management unless other complications of pregnancy are a concern
- Evidence of trophoblastic disease on US is a specific finding for hydatidiform mole.

### DIFFERENTIAL DIAGNOSIS

- Differential diagnosis of nausea and vomiting in pregnancy includes the entire differential diagnosis of nausea and vomiting in the nonpregnant patient:
  - Gastroenteritis
  - Pyelonephritis
  - Pancreatitis
  - Diabetic ketoacidosis
- Nausea and vomiting developing after 10 wk of gestation are not likely due to hyperemesis gravidarum. Consider especially:
  - Preeclampsia
  - HELLP syndrome (hemolysis, elevated liver function tests, low platelets)
  - Fatty liver of pregnancy
- Strongly consider a different diagnosis in the presence of abdominal pain, diarrhea, constipation or fever, HTN, headache, goiter, and neurologic abnormalities.

## TREATMENT

### PRE HOSPITAL

- Avoid use of lights, sirens, and high speed unless the patient is medically unstable.
- Administer a normal saline bolus of 1 L IV, not to exceed 20 mL/kg, if possible.

### INITIAL STABILIZATION/THERAPY

- IV hydration with lactated Ringer or normal saline; using dextrose supplement, such as D<sub>5</sub>NS, and adding potassium replacement as necessary once urine output is established:
  - Calculate the fluid deficit, and replace half of the deficit in the 1st 8 hr.
  - For patients whose weight is >50 kg, 1–2 L as an IV bolus is safe and effective (standard 20 mL/kg dose).
- Consider antiemetic therapy (see below).

### MEDICATION

#### First Line

- Continued IV rehydration as above.
- Thiamine 100 mg IV single dose
- Multivitamin formulation, 1 single-use ampule IV
- Antiemetic therapy:
  - Pyridoxine 25 mg IV q6h PRN AND/OR
  - Diphenhydramine 25 mg IV q6h PRN OR
  - Metoclopramide 5–10 mg IV q6h PRN

#### Second Line

- Antiemetic therapy:
  - Ondansetron 4 mg IV/IM q6–8h PRN
- Methylprednisolone 16 mg IV/PO single dose:
  - Demonstrated to help vomiting in small pilot studies

### COMPLEMENTARY & ALTERNATIVE THERAPIES

Other therapies may be efficacious but generally are considered more appropriate for prevention than for emergency intervention and treatment:

- Ginger-containing foods (eg, lollipops and naturally flavored ginger ale)
- Acupressure at the P6 acupressure point; may be easily accessed via commercially available nonprescription devices (wristbands)
- Hypnosis by qualified medical hypnotist

### DISPOSITION

#### Admission Criteria

- Persistent vomiting despite appropriate emergency department treatment and period of observation
- Persistent vomiting despite close compliance with appropriate outpatient management
- Weight loss and ketonuria
- Concern for patient safety at home
- Critical care admission criteria:
  - Frank hypotension or severe electrolyte abnormality with ECG abnormalities
  - GI complications from severe emesis; esophageal perforation or unstable GI bleeding
  - Other associated conditions that would warrant ICU care

### Discharge Criteria

Fluid, electrolyte, and nutritional (vitamin) deficits corrected:

- Ability to tolerate PO fluids
- Relevant psychosocial issues addressed

### Issues for Referral

- All pregnant patients should be promptly referred to specialized prenatal care.
- Appropriate psychosocial agencies as indicated

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Pyridoxine 25 mg PO t.i.d., first-line, taken to prevent nausea
  - Doxylamine 10 mg PO q6h PRN
  - Metoclopramide 10 mg PO q6–8h PRN
  - Ondansetron 2–4 mg PO q6–8h PRN
  - Avoid known triggers:
    - Motion or flickering lights
    - Hot, humid, or stuffy environments
    - Offensive chemicals or smoke
    - Offensive odors or food
  - Get plenty of rest and avoid prolonged periods without sleep.
- Activity:
  - As tolerated. Avoid activities that will:
    - Aggravate dehydration (heavy exercise)
    - Aggravate nausea (time on boats, carnival rides, etc)

### Patient Monitoring

- Weight should be closely monitored by primary/obstetric physician.
- Patient should develop an inventory of known triggers to aid in avoidance.

### DIET

- Eat early (at 1st sign of hunger), frequently, and in small quantities.
- Diet should be high in carbohydrates and low in fat content.
- Iron may contribute to gastric irritation; therefore, prenatal vitamins may be taken before bedtime with a snack.

### PROGNOSIS

- Symptoms in most patients resolve within 6 wk of onset.
- Most cases respond well to treatment, but resistant cases may require prolonged periods of hospitalization.
- The ultimate prognosis is excellent.
- The outcome for the fetus tends to be better in women with nausea and vomiting during pregnancy (statistically significant lower rates of miscarriages and stillbirths).

### COMPLICATIONS

- Few, if successfully treated
- Fluid and electrolyte imbalance:
  - Metabolic alkalosis
  - Hypokalemia
- Nutritional depletion and weight loss
- Wernicke encephalopathy
- Uncommon but serious: Mallory-Weiss esophageal tear or perforation (Boerhaave)
- Direct adverse effects on fetus have not been identified.

### See Also (Topic, Algorithm, Electronic Media Element)

- Dehydration
- Gastrointestinal Bleeding: Upper
- Pregnancy
- Sexual Assault
- Vomiting

### ICD-9 CODES

#### ICD9

- 643.00 Mild hyperemesis gravidarum, unspecified as to episode of care
- 643.03 Mild hyperemesis gravidarum, antepartum
- 643.10 Hyperemesis gravidarum with metabolic disturbance, unspecified as to episode of care

### PEARLS AND PITFALLS

- Be certain to consider a broad differential diagnosis. Symptoms may not be pregnancy related.
- Be certain to consider sexual abuse and sexual assault by obtaining a thorough and reliable history.
- If concern exists that this pregnancy is the result of sexual assault or abuse, appropriate steps should be taken.
- Always include vitamin repletion in treatment.

# HYPERGLYCEMIA

Catherine H. Chung

## BASICS

### DESCRIPTION

- Hyperglycemia is defined as serum glucose  $>150$  mg/dL.
- Hyperglycemia is most commonly associated with diabetes mellitus (DM).
- Type 1 DM is due to insulin deficiency, while type 2 DM is due to insulin resistance.
- Once rare in children, type 2 DM is increasingly diagnosed as a result of childhood obesity.
- According to the American Diabetes Association, for the diagnosis of DM type 1 or 2 (1):
  - Random glucose  $\geq 200$  mg/dL plus symptoms of DM (polyuria, polydipsia, recent weight loss)
  - Fasting glucose  $>126$  mg/dL
  - 2-hour glucose tolerance test glucose  $>200$  mg/dL

### EPIDEMIOLOGY

#### Prevalence

- Type 1 DM: One in every 400–600 people  $<20$  yr of age (0.22%) (2)
- Prediabetes type 2: 2 million people 12–19 yr of age and 1 in 6 overweight adolescents (2)
- Type 2 DM: Prevalence data unknown

### RISK FACTORS

- Risk factors for hyperglycemia are mostly linked to risk factors for DM.
- Obesity: 85% of children with type 2 DM are overweight (1).
- Family history:
  - Type 1 DM: 5% have 1st- or 2nd-degree relative with the disease (2)
  - Type 2 DM: 45–80% have 1 parent with the disease (1)
- Medications:
  - Corticosteroids
  - Antipsychotics
  - Beta-blockers
  - Thiazide
  - Niacin
  - Pentamidine
  - Protease inhibitors
- Intercurrent illness such as sepsis, trauma, or seizures due to catecholamine surge
- Emotional or physical stress or pain

### GENERAL PREVENTION

- Directly linked to etiology
- Type 1 DM: Regular glucose monitoring, carbohydrate count, and insulin therapy
- Type 2 DM: Regular exercise, weight loss

### PATHOPHYSIOLOGY

- Glucose is regulated by glucose intake, gluconeogenesis, insulin secretion, and catecholamine production.
- Excess glucose intake: If chronically elevated, insulin receptors become less sensitive to insulin, resulting in high serum glucose levels.
- Gluconeogenesis: Accelerated from substrates from lipolysis, proteolysis, and catecholamines
- Insulin: Regulates peripheral glucose consumption; its deficiency or ineffectiveness can result in serum hyperglycemia.
- Catecholamines (cortisol, growth hormone) are released during times of illness/emotional/physical stress to enhance gluconeogenesis.

### ETIOLOGY

- Hyperglycemia often results from insulin deficiency (type 1 DM) or insulin resistance (type 2 DM)
- Excess glucose intake
- Excessive glycogen breakdown

### COMMONLY ASSOCIATED CONDITIONS

- Medication use
- Stress
- Pain

## DIAGNOSIS

### HISTORY

- May be asymptomatic if transient hyperglycemia or chronic low-grade hyperglycemia
- Classic triad of type 1 DM: Polydipsia, polyphagia, and polyuria
- Recent illness
- Weight loss
- Dry mouth
- Weakness and fatigue
- Recurrent urinary tract infections, yeast infections
- Inquire about medication use.
- Inquire about family history of DM.

### PHYSICAL EXAM

- Most children with type 2 DM are obese.
- Check for signs of diabetic ketoacidosis (DKA), reflecting poor glucose control in a child with type 1 DM:
  - Significant dehydration marked by tachycardia, fatigue, dry mucous membranes, sunken eyes, delayed capillary refill
  - Fruity breath
  - Hypernea and tachypnea: Kussmaul respirations
  - Stupor/Coma
- Acanthosis nigricans often seen with type 2 DM
- Hyperadrenergic state: Sweating, tremors, flushing, HTN
- Physical findings associated with pain: Abdominal tenderness, orthopedic injury

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Bedside glucose test and a urine dipstick to detect hyperglycemia and ketonuria
- If suspecting type 1 DM: Serum electrolytes, calcium, magnesium, phosphorus, venous blood gas, and urinalysis
- If suspecting type 2 DM, an oral glucose tolerance test may be done if the fasting or random glucose is normal but suspicion is high.
- Diabetic ketoacidosis is loosely defined by these abnormal lab parameters: serum glucose  $>300$  mg/dL, bicarbonate level  $<15$  mEq/L, and pH  $<7.30$ , with ketonemia and ketonuria.

#### Diagnostic Procedures/Other

- C-peptide, insulin, and hemoglobin A1c levels may be obtained if initial investigation suggests DM as the etiology for hyperglycemia.
- If suspecting type 2 DM, an oral glucose tolerance test may be done if the fasting or random glucose is normal but suspicion is high.

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation
- If dehydrated, as in DKA, administer a 20 cc/kg bolus of normal saline.
- In patients without known DM, the primary goals of investigation with lab assays are to determine if the patient is diabetic and if DKA is present.

### MEDICATION

#### First Line

- Patients with mild hyperglycemia associated with pain, stress, or infection do not typically require specific therapy:
  - The chief management goal is to correct the underlying condition.
- If the patient has type 1 DM and has DKA, therapy will include providing a continuous infusion of IV fluids as well as a continuous insulin drip, usually at a rate of 0.1 unit/kg/hr (3).
- After the initial normal saline bolus, the patient in DKA should receive normal saline with potassium supplementation and without dextrose
  - Patients in DKA are potassium depleted and typically need to receive a minimum of 40 mEq/L of potassium.
  - The potassium may be given in equal parts potassium chloride and potassium phosphate, if serum phosphate levels are low.
  - Patients in DKA typically require these IVFs at a rate of at least 1.5 maintenance, after the initial fluid bolus.
- The patient's serum glucose must be monitored frequently during the insulin infusion.
- Once the serum glucose level drops to 225–275 mg/dL, dextrose (D5) may be added to the IVFs.

#### Second Line

- Manage potassium and phosphate levels, as they are directly related to fluctuations in glucose levels.
- Consider antibiotics for possible sepsis.
- Oral hypoglycemic agents may be indicated for type 2 DM.

### DISPOSITION

#### Admission Criteria

- Children newly diagnosed with presumed type 1 DM who are well appearing and not in DKA may be admitted to a general ward or receive follow-up with an endocrinologist within 24 hr.
- Critical care admission criteria:
  - For patients with type 1 DM, strongly consider admission to the ICU for any of the following reasons (3):
    - Age <1 yr
    - pH <7.0
    - Glasgow Coma Score <12
    - Hemodynamically instable
    - Concern for sepsis

#### Discharge Criteria

Patients with mild degrees of hyperglycemia associated with pain, stress, or infection do not typically require hospitalization, depending on the etiology.

#### Issues for Referral

Children with type 1 or 2 DM may follow up with their primary care provider or with an endocrinologist.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Regular glucose monitoring
- Activity:
  - Regular exercise

### DIET

- Type 1 DM: Dietary restrictions with carbohydrate counting
- Type 2 DM: High-fiber, low-carbohydrate diet

### PROGNOSIS

Dependent on etiology

### COMPLICATIONS

- Uncontrolled hyperglycemia may result in DKA or hyperosmolar ketoacidosis.
- The most serious complication of DKA is cerebral edema
- Other DKA complications include severe dehydration, stroke, hyponatremia, hypokalemia, and dysrhythmias.
- Long-term complications of DM may include retinopathy, cataracts, stroke, peripheral vascular disease, HTN, and neuropathy.

- Diabetic Ketoacidosis

### CODES

#### ICD9

- 250.00 Diabetes mellitus without mention of complication, type ii or unspecified type, not stated as uncontrolled
- 250.01 Diabetes mellitus without mention of complication, type I (juvenile type), not stated as uncontrolled
- 790.29 Other abnormal glucose

### PEARLS AND PITFALLS

- Hyperglycemia in children is most often associated with type 1 or 2 DM.
- Children with mild hyperglycemia without ketonuria or a history of polydipsia or polyuria are likely to have an etiology other than DM.

# HYPERKALEMIA

Suzanne Schmidt

## BASICS

### DESCRIPTION

- Hyperkalemia is an elevation in serum potassium (K<sup>+</sup>) defined as a level >5.5 mEq/L in children (>6.0 mEq/L in a neonate).
- Pseudohyperkalemia is an artificial elevation of measured K<sup>+</sup> level in the blood sample with normal plasma K<sup>+</sup>:
  - Caused by lysis of blood cells and is more common with thrombocytosis, leukocytosis, hemolysis, or inappropriate venipuncture
  - Measured K<sup>+</sup> can be >2 mEq/L higher than actual plasma K<sup>+</sup> from these effects.

### RISK FACTORS

- Renal insufficiency or failure
- Adrenal insufficiency or deficiency of mineralocorticoid or aldosterone
- Insulin deficiency
- Cell lysis or tissue breakdown
- Medications

### GENERAL PREVENTION

Monitoring serum K<sup>+</sup> and limiting use of medications that cause hyperkalemia in at-risk patients

### PATHOPHYSIOLOGY

- Potassium homeostasis:
  - 98% of body potassium is intracellular.
  - 2% is in the extracellular fluid (ECF).
  - The balance of potassium in intracellular fluid (ICF) to ECF is influenced by pH, insulin, and catecholamines.
  - Acidosis causes K<sup>+</sup> to shift out of cells into the ECF through a potassium–hydrogen ion exchange. For every 0.1 decrease in blood pH, the ECF K<sup>+</sup> concentration increases by ~0.6–1.5 mEq/L.
  - Insulin and catecholamines (eg, beta<sub>2</sub>-adrenergic agonists) stimulate cellular uptake of K<sup>+</sup> via a sodium-potassium ATPase, lowering ECF K<sup>+</sup> concentration.
  - Any process causing cell lysis can release a large amount of potassium from the ICF into the blood and result in hyperkalemia.
  - K<sup>+</sup> elimination is primarily renal (90%) and is dependent on adequate glomerular filtration, tubular secretion, and urine flow. A small amount (10%) of K<sup>+</sup> is excreted in the GI tract. With impaired renal function, GI elimination is responsible for a greater proportion of K<sup>+</sup> excretion.
- Hyperkalemia is caused by a disturbance in one or more of these processes of K<sup>+</sup> homeostasis.

### ETIOLOGY

- Hyperkalemia can be broken down into 3 general causes: Increased K<sup>+</sup> load, transcellular shift of K<sup>+</sup> from ICF to ECF, and decreased renal excretion of K<sup>+</sup>.

- Often more than one of these mechanisms is involved in the development of significant hyperkalemia.
- Increased K<sup>+</sup> load:
  - Exogenous: K<sup>+</sup> supplements, K<sup>+</sup>-containing penicillins, stored blood
  - Endogenous: Rhabdomyolysis, hemolysis, tumor lysis, tissue breakdown (burns, trauma, infection, starvation)
- Transcellular K<sup>+</sup> shift from ICF to ECF:
  - Acidosis, insulin deficiency, beta-blockers, succinylcholine, digoxin toxicity, familial hyperkalemic periodic paralysis
- Decreased renal K<sup>+</sup> excretion:
  - Renal failure, severe volume depletion, adrenal insufficiency, hypoaldosteronism, renal tubular disease
  - Medication induced: K<sup>+</sup>-sparing diuretics, angiotensin-converting enzyme inhibitors, NSAIDs, trimethoprim, heparin, cyclosporine, tacrolimus

### COMMONLY ASSOCIATED CONDITIONS

- Renal insufficiency or failure
- Metabolic acidosis
- Adrenal insufficiency

## DIAGNOSIS

### HISTORY

- Patients with hyperkalemia are usually asymptomatic, and the abnormality may be discovered on routine lab testing.
- When present, the predominant symptoms of hyperkalemia are neuromuscular:
  - Patients may have paresthesias, myalgias, and skeletal muscle weakness, followed by ascending flaccid paralysis (sparing respiratory muscles and trunk/neck muscles).
- Inquire about the use of medications that alter K<sup>+</sup> homeostasis, K<sup>+</sup> supplements, and K<sup>+</sup> load in the diet.
- Evaluate for associated symptoms or predisposing conditions, including decreased urine output, excessive exercise, burns, trauma, or muscle pain.

### PHYSICAL EXAM

- Check BP and growth parameters.
- Evaluate hydration status, and look for signs of chronic illness and underlying disease.
- Evaluate neurologic exam for weakness and paralysis.
- Cardiac exam is nonspecific unless there is an associated dysrhythmia.

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- Check K<sup>+</sup>. Repeat if pseudohyperkalemia is suspected. Gross hemolysis reported by the lab increases suspicion of pseudohyperkalemia.
- Complete basic metabolic panel, including BUN and creatinine to evaluate renal function
- Consider:
  - Blood gas to evaluate for acidosis
  - Creatine phosphokinase for rhabdomyolysis
  - CBC, uric acid, lactate dehydrogenase for hemolysis or tumor lysis
  - Urinalysis for renal function, myoglobinuria
  - Urine electrolytes and osmolality

### Imaging

If renal insufficiency or failure is suspected, a renal US may be indicated.

### Diagnostic Procedures/Other

- Obtain ECG on all patients with known or suspected hyperkalemia since associated changes can be seen with mildly elevated K<sup>+</sup> levels:
  - ECG changes are more important than actual serum K<sup>+</sup> concentration in determining the need to treat hyperkalemia.
  - ECG changes are generally related to the degree of hyperkalemia if the increase in K<sup>+</sup> is acute, though effects at a specific level may be highly variable depending on the chronicity of K<sup>+</sup> rise and other electrolyte levels.
- Expected ECG findings:
  - K<sup>+</sup> >6 mEq/L: Tall, peaked T waves, followed by prolonged PR and widened QRS
  - K<sup>+</sup> >8 mEq/L: Decreased amplitude of P wave followed by atrial standstill, sine wave pattern
  - K<sup>+</sup> >10 mEq/L: Ventricular fibrillation or asystole

### DIFFERENTIAL DIAGNOSIS

Pseudohyperkalemia

## TREATMENT

### PRE HOSPITAL

Support airway, breathing, and circulation as needed; dysrhythmias may cause cardiovascular compromise.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- A patient with significant hyperkalemia should be placed on a cardiac monitor throughout treatment.
- Treatment is based on the cause and severity of potassium elevation.
- Treatment of hyperkalemia has 2 goals: Decreasing serum K<sup>+</sup> and preventing cardiac toxicity.
- Serum K<sup>+</sup> can be decreased by redistributing K<sup>+</sup> into cells, which temporarily lowers serum K<sup>+</sup>, but definitive treatment requires removal of K<sup>+</sup> from the body.

- Cardiac toxicity is possible at K<sup>+</sup> levels <7 mEq/L if there is an acute increase in K<sup>+</sup> or in the setting of acidosis or hypocalcemia (1).
- Treatment should begin at K<sup>+</sup> >6.5 mEq/L or at lower levels if there are ECG changes.
- Follow serum potassium levels q2–4h during treatment.

## MEDICATION

### First Line

- Treatment algorithm (doses below):
  - K<sup>+</sup> >8 mEq/L or K<sup>+</sup> <8 with significant ECG changes (prolonged PR, wide QRS):
    - Calcium gluconate IV with ECG monitoring
    - Glucose with or without insulin
    - Consider sodium bicarbonate.
    - Albuterol may be given concomitantly.
    - Consider dialysis if renal failure is present.
  - K<sup>+</sup> 6.5–8 mEq/L with early ECG changes (peaked T waves only):
    - Sodium bicarbonate if acidosis is present
    - Consider nebulized albuterol.
    - Sodium polystyrene resin
    - Treat more aggressively if K<sup>+</sup> is likely to continue to rise.
  - K<sup>+</sup> 6.5–8 mEq/L with normal ECG or K<sup>+</sup> <6.5 with early ECG changes (peaked T waves):
    - May require only sodium polystyrene resin
  - K<sup>+</sup> <6.5 without ECG changes may not require treatment.
  - For all patients: Stop hyperkalemia-causing medications and consider more aggressive treatment with renal failure or rhabdomyolysis.
- Medications:
  - Calcium chloride is an alternative but is not preferred due to the accompanying risk of tissue necrosis with extravasation.
  - Calcium gluconate and calcium chloride each:
    - Have an onset of 1–3 min, duration 30–60 min
    - Should be given if ECG changes are present
    - May be repeated, if needed
    - May cause hypercalcemia or bradycardia; monitor ECG during infusion.
    - Should be used with caution in the setting of digitalis toxicity; administer over 20–30 min.
  - Glucose 0.5 g/kg (2 mL/kg of 25% dextrose or 5 mL/kg of 10% dextrose) IV over 15–30 min (adult dose 50 g) with regular insulin 0.1 units/kg (adult dose 10 units):
    - Onset 15–30 min, duration 1–4 hr
    - May give insulin alone if the patient is hyperglycemic
    - Watch for hyper- and hypoglycemia, especially late hypoglycemia.
    - Lowers K<sup>+</sup> by 0.5–1 mEq/L
  - Albuterol (0.5%) 2.5–5 mg for children (adult dose 10–20 mg) nebulized over 10 min:
    - Onset within 30 min, duration 2–4 hr
    - Side effects include tachycardia and tremor.
    - A single dose can lower plasma K<sup>+</sup> by 0.5–1 mEq/L.
    - May repeat as needed
    - A subset of patients may be unresponsive to the K<sup>+</sup>-lowering effects of albuterol.

- Sodium bicarbonate 1–2 mEq/kg IV over 5–10 min (adult dose 1–2 amps, 1 amp = 44 mEq):
  - Onset 10–30 min, duration 1–4 hr
  - More useful if acidosis is present but may have effect even without acidosis
  - Effect is variable based on the underlying cause and may be useful as an adjunct but should not be used as primary therapy alone.
  - Watch for hyponatremia and volume overload.
- Furosemide 1–2 mg/kg IV/IM (adult dose 40–80 mg):
  - Onset 15–30 min, duration 4–6 hr
  - Promotes renal potassium excretion, but good renal function is necessary.
  - Monitor volume status and other electrolytes.
- Sodium polystyrene resin (Kayexalate) 1 g/kg (adult dose 50 g) PO/PR in sorbitol (25–70%):
  - Onset in 1–2 hr, duration 4–6 hr
  - 1 g/kg reduces plasma K<sup>+</sup> by 1 mEq/L
  - Binds potassium in the intestine to increase GI excretion
  - May cause increased sodium, alterations in other electrolytes, constipation, and rarely intestinal necrosis

### Second Line

Treat underlying disorder. Follow serum K<sup>+</sup> levels, as hypokalemia may result due to total body K<sup>+</sup> depletion:

- For known or suspected adrenal insufficiency, give corticosteroid replacement.
- Correct metabolic acidosis.

### SURGERY/OTHER PROCEDURES

Hemodialysis or hemofiltration may be necessary in the setting of renal failure.

### DISPOSITION

#### Admission Criteria

- Most patients with significant hyperkalemia should be admitted, since removal of body K<sup>+</sup> is a slow process and most treatment effects are temporary.
- Critical care admission criteria:
  - Hyperkalemia with ECG changes requires continuous ECG monitoring.
  - In the setting of renal insufficiency or failure, if hemodialysis or hemofiltration may be necessary

#### Discharge Criteria

- Asymptomatic patient with only mild elevation of K<sup>+</sup> (<6.5 mEq/L) and normal ECG
- Renal function intact
- No concern for ongoing process that will cause K<sup>+</sup> to continue to rise
- Follow-up for repeat K<sup>+</sup> levels established

#### Issues for Referral

- Pediatric nephrology consultation or referral for diagnosis and management of renal disease or implementation of hemodialysis
- Pediatric endocrinology consultation or referral for diagnosis and management of adrenal insufficiency

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- Discontinue potassium supplements and hyperkalemia-inducing medications.

### Patient Monitoring

Continued monitoring of serum K<sup>+</sup> may be needed on an outpatient basis, depending on the cause of hyperkalemia.

### DIET

A potassium-restricted diet may be necessary for hyperkalemia with renal failure.

### PROGNOSIS

- If identified and treated early, fatal arrhythmias may be prevented.
- Prognosis depends on the etiology of hyperkalemia.

### COMPLICATIONS

- The most significant and life-threatening complications of hyperkalemia are cardiac dysrhythmias, including ventricular fibrillation and asystole.
- Neuromuscular weakness

## CODES

ICD9

276.7 Hyperpotassemia

## PEARLS AND PITFALLS

- If hyperkalemia is suspected in an unstable patient, empiric treatment should be initiated immediately while awaiting lab results.
- ECG changes are more important than actual serum K<sup>+</sup> concentration in determining the need to treat hyperkalemia.
- Pseudohyperkalemia is likely if the blood sample is hemolyzed and the patient does not have risk factors for hyperkalemia.

# HYPERNATREMIA

Halden F. Scott

## BASICS

### DESCRIPTION

*Hypernatremia* is defined as a serum sodium >145 mEq/L.

### RISK FACTORS

- Impaired thirst or inability to access water, such as children with medical conditions that limit their ability to self-feed
- Infants: Either inadequately breast-fed or with improperly mixed formula
- Hospitalization is a risk factor for iatrogenic hypernatremia in patients maintained on inappropriate parenteral fluids.
- Diarrhea, especially osmotic diarrhea

### GENERAL PREVENTION

Dehydration-related hypernatremia in infants can be prevented by:

- Education in proper formula mixing
- Education in proper breast-feeding techniques
- Frequent follow-up visits with the pediatrician after newborn hospital discharge, particularly in first-time breast-feeding mothers (1)

### PATHOPHYSIOLOGY

- Hypernatremia is the result of either a net free water loss or sodium gain or a combination of both:
  - Impairments in normal functioning of thirst and the endocrine or renal systems
  - Extreme salt intoxication or water deprivation where thirst is intact but access to water is impaired, such as hospitalization
- Hypernatremia causes initial cellular dehydration and shrinkage, with manifestations across organ systems:
  - In cases of slow and prolonged rise in serum sodium, compensatory mechanisms attenuate these effects.
- Cerebral bleeding and subarachnoid hemorrhage can result from brain shrinkage and vascular rupture.

### ETIOLOGY

See Differential Diagnosis .

### COMMONLY ASSOCIATED CONDITIONS

- Hospitalization
- Impaired mental status
- Heat stroke, heat exhaustion
- Dependency on gastrostomy tube feeds
- Hypothalamic structural lesions, including holoprosencephaly, may cause diabetes insipidus (DI).
- Intentional salt poisoning, Munchausen by proxy, suicidality

## DIAGNOSIS

### HISTORY

- The duration of hypernatremia should be assessed by determining the presence and duration of any mental status changes and duration of any causative events.
- Obtain a very detailed history of the patient's feeding regimen.
- Infants and children who cannot access fluid themselves and children dependent on gastrostomy tube feeds or total parenteral nutrition without free water access
- Breast-feeding: Infant's latch, suck, feeding patterns, quantity of diapers, whether the mother has felt her milk "come in," and any history of maternal breast surgery
- Inquire about high volumes of insensible losses such as vomiting, diarrhea, or burns.
- A previously well patient who has been hospitalized or unable to access fluid due to injury or environmental circumstances should be suspected of water deprivation.
- Patients may initially report thirst, but this often decreases as hypernatremia persists.
- Patients with DI will have a history of polyuria and polydipsia:
  - If familial, this history may be present for other family members.
- Inquire about diuretic or other medication use and comorbidities.

### PHYSICAL EXAM

- Mental status may range from restlessness and decreased sleep to lethargy and coma.
- When hypernatremia is due to free water loss, signs of dehydration including tachycardia and orthostatic hypotension will be present. "Doughy" skin has been described.
- Hyperpnea
- Fever
- Muscle weakness
- Vomiting
- Seizures, rarely
- If a recent weight is available, weight can be used to assess the degree of dehydration. Weight gain indicates salt intoxication; weight loss indicates dehydration (2).

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- Serum electrolytes, including sodium, chloride, potassium, bicarbonate, BUN, creatinine, glucose
- Urine sodium and creatinine should be measured at the same time as serum values.
- Simultaneous serum, urine osmolality
- Basic principles can be used to interpret these tests to determine the etiology, although caution should be used in rigidly applying these principles since they are not universally true. Only by following electrolyte levels over time (and after resuscitation) can disorders of the antidiuretic hormone (ADH) axis, dehydration, and salt intoxication be differentiated with certainty:
  - Hypernatremia should cause thirst and ADH release, resulting in maximally concentrated urine, confirmed by a urine osmolality >700 mosmol/kg (although nonelectrolyte osmoles such as urea can cause urine to appear less than maximally concentrated, even in the presence of appropriate ADH).
  - With intact ADH function thus proven, urine sodium <25 mEq/L indicates free water deprivation is the cause, and urine sodium >100 mEq/L indicates salt intoxication is the cause (2).
  - Urine osmolality < serum osmolality suggests central or nephrogenic DI.
- Fractional excretion of sodium (FENa) =  $(\text{urine Na} \times \text{plasma Cr}) / (\text{plasma Na} \times \text{urine Cr}) \times 100$ :
  - FENa should be >2% in cases of salt poisoning and <1% in dehydration, but in cases with a mixed picture of water and sodium loss, FENa may also be elevated (2).
- Hyperglycemia and hypocalcemia can occur and will resolve with correction of hypernatremia.

### Imaging

Head CT is indicated for patients with altered mental status or seizures.

### Diagnostic Procedures/Other

- If urine osmolality < serum osmolality, a dose of ADH (dDAVP) can be administered diagnostically:
- In central DI, dDAVP will increase urine osmolality by 50%, and no change will be seen in cases of nephrogenic DI.

### DIFFERENTIAL DIAGNOSIS

- Hypernatremia is the result of either a net free water loss or sodium gain.
- Water loss: This may be pure water loss or accompanied by sodium loss that is less than the amount of water loss:
  - Neurogenic DI
  - Nephrogenic DI (primary or lithium induced)
  - Impaired thirst or access to water
  - Insensible losses: Sweat, respiratory, burns
  - GI loss: Vomiting, NG drainage, diarrhea
  - Renal loss: Diuretics, acute tubular necrosis, glucosuria, osmotic load (mannitol, glucosuria)

- Sodium gain:
  - Improperly mixed enteral feeds
  - Medications: Excessive sodium bicarbonate, sodium chloride, saline enemas, hypertonic saline, dialysate
  - Hyperaldosteronism
  - Cushing syndrome
  - Ingestions: Salt, sea water
  - Transient hypernatremia with exercise; lactate enters cells and water follows
  - Hospitalization: Inappropriate fluid therapy in a patient not allowed to drink or inadequate replacement of insensible free water loss

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Coma, seizure, and dehydration may require rapid correction and stabilization. Intubation, mechanical ventilation, and antiepileptics may be required.
- If cerebral edema, altered mental status, or seizures develop while correcting serum sodium, 3% saline should be given emergently to increase the serum sodium and reverse cerebral edema:
  - Each mL/kg of 3% NaCl typically raises serum sodium by 1 mEq/L and, similar to the treatment of hyponatremia, 4–6 mL/kg of 3% NaCl is recommended to reverse symptoms of too rapid a correction of hypernatremia (3).
- Patients in shock should receive normal saline boluses to reverse hypotension before initiating more carefully directed fluid therapy to reduce serum sodium levels.
- Therapy for severe, acute-onset hypernatremia should aim to reduce serum sodium rapidly:
  - Risk of iatrogenic cerebral edema during correction is much lower in this setting because idiogenic osmoles have not yet accumulated.

### MEDICATION

#### First Line

- Identification of the underlying cause will guide treatment
- For stable children, therapy should aim to decrease the serum sodium not faster than 12 mEq/L/day:
  - If acute ingestion of salt has led to hypernatremia over several hours, the sodium concentration may be safely decreased faster, 0.5 mEq/L/hr.
- In cases of water deficit, fluid is the mainstay of therapy and is most safely administered orally when possible. A rate should be chosen by estimating volume of free water lost and replacing it over 48 hr, in addition to maintenance requirements.
- The following formula has been empirically recommended to calculate a water deficit in cases of hypernatremic dehydration, but it has never been formally validated for efficacy in correction of hypernatremia:
  - To correct to a goal of 145 mEq/L Na: Water deficit (in L) = body weight (kg) × 0.6 [1 – (145/current sodium)] (3)
  - This water deficit should be added to maintenance fluids and be replaced over 48 hr.
- In lieu of following the above formula, a generally safe choice is 1/4–1/2 normal saline fluid at 20–50% greater than maintenance, with frequent repeat serum sodium checks to ensure appropriate rate of decline.

- In cases of acute sodium intoxication, more aggressive treatment with D5W is indicated.
- Any fluid choice may require reduced dextrose content due to association of hypernatremia and hyperglycemia. 2.5% dextrose is often chosen (4).

### Second Line

- In cases of DI, antidiuresis with medications such as dDAVP is sometimes indicated after appropriate replacement of free water loss:
  - These medications should always be used in consultation with an endocrinologist and usually not emergently.
- Calcium gluconate may be required to treat associated hypocalcemia (4).

### DISPOSITION

#### Admission Criteria

- All patients with sodium >155 mEq/L require admission.
- If intentional salt intoxication/water deprivation is suspected, patients should be admitted until a safe discharge environment is assured.
- Critical care admission criteria:
  - Altered mental status in the context of hypernatremia
  - Shock
  - Intracranial hemorrhage
  - Patients with severely elevated serum sodium, which will require great care to lower at an appropriate rate, may require critical care admission.

#### Discharge Criteria

A patient with mild hypernatremia who demonstrates improvement while in the emergency department and is able to tolerate enteral fluids may be considered for discharge:

- Close follow-up must be ensured and an underlying cause for the hypernatremia identified and resolved.

#### Issues for Referral

- Disorders of the endocrinologic or renal systems require subspecialty care.
- Hypothalamic lesions or tumors may require neurologic or neurosurgical consultation.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

#### Patient Monitoring

Patients should be maintained on a cardiorespiratory monitor until sodium levels normalize and mental status returns to normal.

#### DIET

Enteral and parenteral feed regimens should be carefully reviewed, and family understanding of feed schedule should be assessed.

#### PROGNOSIS

- Prognosis is variable and depends on severity and duration and the underlying cause of the hypernatremia.
- For patients with acute sodium intoxication, prognosis improves with rapid correction of hypernatremia.
- Rapid correction is contraindicated in patients with hypernatremia of gradual onset.

### COMPLICATIONS

- Sinus venous thrombosis
- Rapid correction of hypernatremia of prolonged duration can lead to cerebral edema due to the idiogenic osmoles the brain cells have generated to retain fluid during the time of hypernatremia. This cerebral edema can lead to coma, seizure, and death.
- The cellular dehydration of hypernatremia can cause cerebral and subarachnoid hemorrhage due to tearing of cerebral vessels as brain cells shrink.

## CODES

#### ICD9

276.0 Hyperosmolality and/or hypernatremia

### PEARLS AND PITFALLS

- Hypernatremia may result from water deficit or sodium excess.
- Frequent repeat tests of serum sodium level are critical to monitoring the rate of fall of the serum sodium.
- Water deficit hypernatremia of slow onset must be corrected over 48 hr to avoid cerebral edema.

# HYPERTENSION

Besh Barcega  
Emily Rose

## BASICS

### DESCRIPTION

- HTN is indicated by BP measurements that are >95th percentile based on normative data according to gender, age, and height (1).
- Formula to estimate BP for age:
  - Systolic =  $90 + (3 \times \text{age in years})$
  - Diastolic =  $50 + (1.5 \times \text{age in years})$
- BP measurements between the 90th and 95th percentiles are considered pre-HTN. Adolescents with BP levels  $\geq 120/80$  should be considered prehypertensive.
- Severe HTN is a BP >99th percentile accompanied by abnormal physical exam and lab findings (hypertensive urgency).
- A hypertensive emergency is severe HTN with evidence of target-organ damage such as altered mental status, seizures, and CHF.

### EPIDEMIOLOGY

- HTN occurs in up to 4.5% of children.
- Increasing related to the increasing prevalence of childhood obesity (2)

### RISK FACTORS

- Obesity and family history are the main risk factors for primary HTN.
- Mechanical, structural and hormonal mechanisms are the most common risk factors for secondary HTN.

### GENERAL PREVENTION

Weight reduction by dietary and lifestyle modification is recommended for primary HTN.

### PATHOPHYSIOLOGY

- Unclear and most likely multifactorial in primary HTN
- Mechanism of secondary HTN varies depending on the underlying disease process:
  - Alteration in the renin-angiotensin system
  - Fluid overload
  - Sympathetic stimulation
  - Endothelial dysfunction
  - Mechanical obstruction
- Persistent elevations in BP have been linked to left ventricular hypertrophy, increased carotid intima-media thickness, and decreased cognitive function.

### ETIOLOGY

- Primary HTN is the most common cause of HTN for children >10 yr of age without any underlying renal or cardiac conditions.
- No identifiable cause has been found for primary HTN (also called *essential* HTN).

- Renal, cardiac, and endocrine disorders are the most common causes for HTN in infants and young children (secondary HTN):
  - Coarctation of the aorta is the most common cardiac etiology in infants and children.
  - Congenital renal disease and renal artery thrombosis or stenosis are the most common renal etiologies in newborns and infants.
  - Glomerulonephropathies and uropathies are the most common renal causes in children.
  - Congenital adrenal hyperplasia, hyperthyroidism, and neurofibromatosis are the most common endocrine disorders causing HTN in infants and children.
  - Wilms tumor, neuroblastoma, and pheochromocytoma are the most common malignancies that cause HTN in infants and children.
  - Renal vein thrombosis is a rare cause of HTN that can be found in children who have severe dehydration.
- Methamphetamine, cocaine, and over-the-counter medications with sympathomimetics can cause HTN.

### ALERT

The Cushing triad (elevation of the systolic pressure, bradycardia, and irregular respirations) found with increasing intracranial pressure from an intracranial injury or mass should be recognized as a separate entity and is a neurosurgical emergency.

### COMMONLY ASSOCIATED CONDITIONS

- Renal diseases
- Endocrine tumors and diseases
- Sleep apnea
- Pregnancy
- Illicit drug use

## DIAGNOSIS

### HISTORY

- Inquire about the family history for essential HTN and inherited conditions such as polycystic kidney disease and neurofibromatosis.
- Past medical history should look for:
  - Extreme prematurity and use of umbilical catheters
  - History of frequent urinary tract infections
- Inquire about medications and substance abuse.
- If the patient has known HTN, ask about compliance with medication(s).
- Infants in hypertensive emergencies often have symptoms of CHF such as irritability, difficulty breathing, and failure to thrive.
- Children with hypertensive emergencies will often have symptoms of hypertensive encephalopathy such as severe headache, vomiting, seizures, ataxia, lethargy, confusion, and/or visual disturbances.

### PHYSICAL EXAM

- Findings suggestive of hypertensive urgency and emergency:
  - Altered mental status
  - Papilledema
  - CHF: Hepatomegaly, rales, dyspnea
- Diminished lower extremity pulses will be found in coarctation of the aorta.
- A palpable abdominal mass may be suggestive of Wilms tumor or neuroblastoma.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- For all patients with confirmed HTN, obtain the following:
  - Serum electrolytes including BUN and creatinine
  - Microscopic urinalysis
- If indicated from history and/or exam:
  - Urine culture
  - Pregnancy test

#### Imaging

- Head CT if neurologic signs and symptoms are found, such as the Cushing triad
- For nonemergent HTN, the following studies can be obtained as an outpatient or part of the inpatient workup:
  - Echo if suspicion for coarctation of the aorta
  - Renal US if a urinalysis, electrolyte, or creatinine abnormality is found
  - Abdominal US and/or abdominal CT if a mass is found on abdominal exam
  - Chest radiograph for patients with presumed essential HTN

#### Diagnostic Procedures/Other

Angiography may be needed upon admission for suspicion for renal vascular disease such as renal vein thrombosis or renal artery stenosis.

### DIFFERENTIAL DIAGNOSIS

- Pain, anxiety, and agitation may elevate BP measurements.
- Use of an inappropriately sized BP cuff is the most common cause of factitious HTN.

## TREATMENT

### PRE HOSPITAL

Treatment of severe HTN or hypertensive emergency should be under the direct supervision of the base-station physician.

### INITIAL STABILIZATION/THERAPY

Assess and stabilize airway, breathing, and circulation.

### ALERT

Avoid lowering BP more than 25% in the 1st 8 hr to avoid irreversible target organ damage.

**MEDICATION****First Line**

- There is limited data on many antihypertensive medications for pediatric hypertensive crises.
- Labetalol: 0.2–1 mg/kg/dose IV (up to 40 mg/dose), followed by infusion of 0.25–3 mg/kg/hr; relative contraindication for asthma and CHF
- Fenoldopam: 0.1–2  $\mu\text{g/kg/min}$  IV:
  - Has received FDA approval for pediatric labeling
- Nicardipine: 0.5–1  $\mu\text{g/kg/min}$  IV titrated up to 5  $\mu\text{g/kg/min}$ :
  - Ineffective in renin-mediated HTN
  - May cause increased intracranial pressure
- Nifedipine: 0.2 mg/kg/dose sublingual:
  - Use if unable to establish IV
  - Add long-acting agent when IV is established.

**Second Line**

- For hypertensive emergencies:
  - Sodium nitroprusside: 0.3–8  $\mu\text{g/kg/min}$  IV; very short acting and should only be delivered as an infusion
  - Hydralazine: 0.1–0.5 mg/kg/dose IV, max single dose 20 mg
  - Esmolol: 100–500  $\mu\text{g/kg}$  loading dose, then infusion of 50–300  $\mu\text{g/kg/min}$ ; relative contraindication for asthma and may cause profound bradycardia
  - Enalaprilat: 5–10  $\mu\text{g/kg/dose}$  IV (up to 125  $\mu\text{g/dose}$ ); useful in high renin states
  - Phentolamine: 0.1 mg/kg/dose IV, max single dose 5 mg; primarily used for hypertensive crises from excessive circulating catecholamines
  - Benzodiazepines are the drug of choice for hypertensive emergency due to stimulant drugs such as cocaine and amphetamines:
    - Diazepam 0.1 mg/kg IV (max initial dose 10 mg):
      - May be repeated every 5–10 min PRN
      - If repeated dosing is necessary to control HTN, every 4th dose should be doubled (max single dose 50 mg).
    - Lorazepam 0.1 mg/kg IV, max initial dose 5 mg:
      - May be repeated every 5–10 min PRN
      - If repeated dosing is necessary to control HTN, every 4th dose should be doubled (max single dose 10 mg).
- For hypertensive urgencies, medication selection should be based on underlying etiology:
  - Consult with the nephrologist for renal and endocrine causes.
  - Consult with cardiology if coarctation of the aorta is suspected.
- Management of nonurgent and nonemergent HTN does not need to be initiated in the emergency department setting and should be left to the discretion of the primary care physician or subspecialist.

**SURGERY/OTHER PROCEDURES**

Surgical intervention may be required for identifying the underlying etiology of secondary HTN.

**DISPOSITION****Admission Criteria**

- Signs and symptoms of end organ damage despite resolution of the hypertensive emergency
- Newly diagnosed severe HTN should be admitted for diagnostic evaluation and treatment, especially if prompt outpatient follow-up cannot be arranged.
- Critical care admission criteria:
  - Patients with a hypertensive emergency requiring continuous infusion of an antihypertensive medication should be admitted to the ICU.

**Discharge Criteria**

Patients with known HTN who present with severe HTN that has been stabilized in the emergency department may be sent home provided:

- Reliable 24-hr follow-up with a primary care physician or subspecialist can be arranged
- Consultation with a nephrologist or cardiologist may be needed prior to discharge.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Patients with known HTN should follow up with their subspecialist or primary care physician within 24 hr.
- Medications should be reviewed and compliance should be stressed.
- Patients with an incidental finding of pre-HTN should have reliable follow-up made within a few days to obtain a repeat BP measurement.

**DIET**

Patients with renal disease or essential HTN may need salt and water restriction.

**PROGNOSIS**

- For secondary HTN, the prognosis is dependent on the underlying etiology.
- The prognosis for primary HTN is dependent on compliance with lifestyle modifications.

**COMPLICATIONS**

- Poorly controlled HTN can lead to:
  - Encephalopathy
  - MI
  - Seizure
  - Stroke
  - Death
- Overly rapid pressure correction may result in cerebral hypoperfusion and ischemia.

**See Also (Topic, Algorithm, Electronic Media Element)**

Normative data Web site: <http://www.nhlbi.nih.gov/guidelines/HTN/child.tbl.pdf>

**ICD9**

- 401.9 Unspecified essential hypertension
- 405.99 Other unspecified secondary hypertension

**PEARLS AND PITFALLS**

- Pearls:
  - Obtain a BP reading on any newborn or infant presenting with failure to thrive and irritability.
  - Obtain a BP reading on both upper and lower extremities when an elevated BP is found.
  - Triage BP measurements may be factitiously elevated and should always be repeated.
  - “White coat” HTN should not be discounted, and follow-up with a primary care physician is recommended (3).
- Pitfalls:
  - Failure to obtain the BP measurement using an appropriately sized cuff in the right arm
  - Failure to recognize hypertensive encephalopathy in a child presenting with altered mental status

# HYPERTHERMIA

Lauren S. Chernick  
Anupam Kharbanda

## BASICS

### DESCRIPTION

- Hyperthermia occurs when the body temperature elevates above the hypothalamic set point secondary to excessive heat gain or inadequate heat loss. This is different from fever, which occurs when the hypothalamic set point is increased.
- Hyperthermia syndromes are classified as:
  - Heat-related illness:
    - Heat exhaustion: Mild dehydration and temperature 38°C (100.4°F) to 40°C (104°F)
    - Heat stroke: Severe dehydration with mental status changes and body temperature >40°C (104°F)
  - Drug induced:
    - Malignant hyperthermia (MH): A genetic condition triggered by an exposure to anesthetics
    - Neuroleptic malignant syndrome (NMS): Extrapyramidal syndrome associated with the use of antipsychotic drugs or withdrawal of dopaminergic agents
    - Serotonin syndrome (SS): A spectrum of clinical findings due to excess serotonergic agonism of CNS receptors and peripheral serotonergic receptors
    - Medications that increase heat production and/or uncouple oxidative phosphorylations, such as salicylates or dinitrophenol
  - Genetic/Unknown origin

### EPIDEMIOLOGY

#### Incidence

- Heat-related illnesses are the most common cause of hyperthermia:
  - Incidence of heat stroke varies because of underdiagnosis and differing definitions of heat-related death.
  - During heat waves in the U.S., the incidence of heat stroke varied from 17.6–26.5 cases per 100,000 population (1).
- MH: Most common in 1st 3 decades of life; ~50% of cases occur in children
- NMS: Occurs in 0.02–3% of patients taking neuroleptic agents (2,3)
- SS: Rising incidence due to increased use of serotonergic agents

### RISK FACTORS

- Heat-related illness:
  - Heat waves
  - Very young age
  - Poor and limited access to air-conditioning (4)
  - Athletes
- MH: Children with muscular dystrophy and congenital myotonia

### GENERAL PREVENTION

- Heat-related illnesses:
  - Avoid outdoor activities in hot weather.
  - Never leave children unattended in a car.
  - Prevent dehydration.
  - Acclimate children to hot surroundings.

- Drug-induced hyperthermia:
  - Review personal and family history for adverse reactions to anesthesia.
  - Pay close attention to the medication list.
  - Refrain from using succinylcholine for rapid sequence induction in patients with muscular dystrophies or myotonias.
  - Refrain from use of succinylcholine for elective intubation in children <8 yr of age.

### PATHOPHYSIOLOGY

- Hyperthermia occurs when there is excess heat gain or production, inadequate heat loss, or both.
- Heat-related illness requires the following:
  - Failure of thermoregulation:
    - A rise in body temperature shifts blood to the periphery by vasodilation.
    - Intestinal perfusion is reduced.
  - Abnormal inflammatory response
  - Increased intestinal permeability causes endotoxins to leak into systemic circulation resulting in hyperthermia and hypotension.
- MH:
  - Genetic abnormality in ryanodine receptor
  - Abnormal calcium release upon exposure to a triggering medication
  - Generates heat and increased muscle metabolism
- NMS: Due to decreased availability of dopamine or blockage of the dopamine receptor
- SS: Secondary to excessive serotonin stimulation causing fever as by-product
- End organ damage as well as disseminated intravascular coagulation may result from hyperthermia:
  - Rhabdomyolysis
  - Renal failure
  - Hepatic failure

### ETIOLOGY

- Heat-related illness:
  - Classic or nonexertional (eg, baby left in a car)
  - Exertional (eg, athlete)
- MH:
  - Due to halothane, isoflurane, sevoflurane, and/or succinylcholine exposure
  - ~50% of patients inherit a point mutation as an autosomal dominant trait.
- NMS: Offending medications include haloperidol, prochlorperazine, clozapine, risperidone, or olanzapine.
- SS: Associated with monoamine oxidase inhibitors (MAOIs), selective serotonin reuptake inhibitors, tricyclic antidepressants, dietary supplements, and methamphetamines
- Conditions and medications that impair heat dissipation, such as psoriasis, eczema, and anticholinergic medications
- Conditions and medications that increase metabolism or uncouple oxidative phosphorylation such as hyperthyroidism, thyroid stimulants, salicylates, or dinitrophenol

## DIAGNOSIS

### HISTORY

- Heat-related illness:
  - Heat exhaustion:
    - Feeling overheated or faint
    - Nausea, vomiting, headache
  - Heat stroke:
    - Dizzy, confused, delirious
    - Diarrhea
    - Seizures
- MH:
  - Exposure to anesthetic within previous 24 hr, usually occurs soon after medication exposure
  - Family history of adverse reaction to anesthesia
- NMS:
  - Usually in young to middle-aged adults
  - History of ingesting offending medication, usually within previous 7 days
  - Slow progression of symptoms over 1–3 days
  - Muscle rigidity
  - Cognitive or behavior dysfunction, autonomic instability
- SS:
  - History of ingesting the offending medication, usually within the preceding weeks
  - Rapid progression of symptoms usually within 6 hr of initial use of the medication, overdose, or dosing change
  - Cognitive or behavior dysfunction, autonomic instability
  - Characteristic shivering or torso shuddering

### PHYSICAL EXAM

- Assess vital signs.
- Perform a full neurologic exam to detect neurologic impairment.
- Heat-related illness:
  - Heat exhaustion:
    - Temperature 38–40°C (100.4–104°F), tachycardia, normotensive
    - Increased pallor, cool moist skin
  - Heat stroke:
    - Temperature >40°C (104°F), tachycardia, hypotensive
    - Altered mental status or loss of consciousness
    - Delayed capillary refill
- MH:
  - Temperature >40°C (104°F), tachycardia, tachypnea
  - Muscle rigidity
  - Sweating, skin mottling, usually an absence of shivering (late sign)
  - Tenderness and swelling of muscles, especially the thighs
- NMS:
  - Temperature >40°C (104°F), tachycardia, hypotension or HTN, tachypnea, hypoxemia, autonomic dysfunction
  - Diaphoresis or sialorrhea
  - Muscle rigidity
  - Altered mental status (confusion, agitation, catatonia), tremor

- SS:
  - Mild: Afebrile, tachycardia, shivering, diaphoresis, mydriasis, tremor, hyperreflexia
  - Moderate: Temperature >40°C, HTN, hyperactive bowel sounds, agitation, slurred speech, autonomic dysfunction
  - Severe: Temperature >41.1°C, muscular rigidity, akathisia, hypertonicity, shock, seizures
  - Hyperthermia in ~50% of cases

**DIAGNOSTIC TESTS & INTERPRETATION**

**Lab**

**Initial Lab Tests**

- No specific lab value is unique for heat-related illnesses.
- Heat exhaustion: Labs should be relatively normal with the exception of possible dehydration
- Heat stroke, MH, NMS, or SS:
  - CBC for leukocytosis, anemia, or thrombocytopenia
  - Serum electrolytes, phosphorous, magnesium, and calcium for electrolyte abnormalities
  - AST, ALT for liver transaminitis
  - PT/PTT/INR and split products, d-dimer for signs of disseminated intravascular coagulation
  - Urine myoglobin and creatine kinase for signs of myoglobin-induced renal injury

**Diagnostic Procedures/Other**

**ECG:**

- Heat stroke: Findings similar to a myocardial ischemia
- Drug-induced hyperthermia: Dysrhythmias

**DIFFERENTIAL DIAGNOSIS**

- Drugs: Anticholinergics, antidepressants, amphetamines, hallucinogens, phencyclidine (PCP), MAOIs, neuroleptics, salicylates
- Infectious: Meningitis, encephalitis, sepsis
- Thyroid: Graves disease, thyroid storm

**TREATMENT**

**PRE HOSPITAL**

- Remove the patient from the circumstances causing the hyperthermia.
- Apply ice or cold packs.
- Provide oxygen and secure the airway if necessary.
- Secure a large-bore IV catheter.
- Cardiac monitoring to evaluate for ECG changes
- Benzodiazepines for seizures or severely agitated patients
- Rapid transport to an emergency department greatly improves outcome in heat stroke patients (5).

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation:
  - Provide supplemental oxygen.
  - If intubating, use nondepolarizing paralytic if suspicious of MH
- Continuously monitor the core temperature.
- Cool the patient (5):
  - Passive/Evaporative cooling: Spray the patient with tepid water and fan to maximize air circulation.
  - External:
    - Place ice packs over the groin, axilla, and neck.
    - Cooling blankets
    - Patients with a core temperature 41.7°C (107°F) should have ice or cold water immersion.

- Cold water immersion: immerse patient's body in an ice water bath.
  - If an appropriate bed, such as a cholera bed, is unavailable for ice immersion, a body bag may be used to contain the ice and patient.
- Internal:
  - Cold water lavage via NG tube, Foley catheter, and rectal tubes
  - Cold IV fluid administration
- Perfusion status:
  - Fluid resuscitate with normal saline 20 mL/kg
  - Bolus to maintain urine output over 1 cc/kg/hr (if rhabdomyolysis, maintain urine output >3 cc/kg/hr). Consider vasopressor agents for hypotension.
  - Place a Foley catheter to monitor urine output.
- Other:
  - Treat electrolyte abnormalities.
  - Monitor for ECG changes.

**MEDICATION**

- Heat exhaustion/stroke: Treatment goal is largely supportive.
- Reversal of offending agent:
  - MH: Dantrolene 2.5 mg/kg IV repeated until disappearance of symptoms (typically 1–4 doses)
  - NMS:
    - Bromocriptine (dopamine agonist) 7.5–30 mg PO divided t.i.d. (2.5–10 mg/dose); max 100 mg/day in patients > 15 yr of age
    - Dantrolene (see above)
  - SS: Cyproheptadine (0.25 mg/kg divided q6h PO/NG)
- Treat agitation or shivering with diazepam 0.1 mg/kg IV q10–15min until controlled.

**DISPOSITION**

**Admission Criteria**

- Inpatient admission criteria:
  - Patients diagnosed with heat exhaustion should be admitted if they are unable to tolerate PO or need continued rehydration.
- Critical care admission criteria:
  - Children with hyperthermia, evidence of end organ dysfunction, and mental status changes should be admitted to the ICU.

**Discharge Criteria**

Patients who have normal vital signs, are able to drink fluids, and have a normal physical exam can be discharged home.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Patients should return for headache, altered mental status, dark urine, vomiting, or syncope.
- Avoid outdoor activities in warm, humid weather.
- Drink fluids.
- Stop offending medications.

**PROGNOSIS**

- The length of hyperthermia and height of temperature determine the prognosis.
- Body temperatures between 41°C and 42°C (105.8°F and 107.6°F) can cause tissue injury in hours, while temperatures >49°C (>120°F) can induce tissue injury in minutes.

**CODES**

**ICD9**

- 778.4 Other disturbances of temperature regulation of newborn
- 780.60 Fever, unspecified
- 995.86 Malignant hyperthermia

**PEARLS AND PITFALLS**

- Antipyretics play no role in treatment.
- Do not presume temperature >41°C is due to infection.
- Heat stroke is differentiated from heat exhaustion by the presence of severe dehydration and mental status changes. Cooling is essential.
- MH, NMS, and SS similarly cause rigidity, hyperpyrexia, and dysautonomia but can be distinguished by the implicated medication.

# HYPERTHYROIDISM

John M. Loissele

## BASICS

### DESCRIPTION

- Hyperthyroidism is a disorder resulting from the excess production and secretion of thyroid hormones.
- Graves disease is the predominant cause.
- Clinical features are independent of the etiology.
- Thyroid storm is a potentially life-threatening syndrome consisting of extreme symptoms of hyperthyroidism.

### EPIDEMIOLOGY

#### Incidence

- Hyperthyroidism is rare in children, although the incidence increases with age:
- 0.1/100,000 per year in young children
- 3/100,000 per year in adolescents
- 4–5 times higher in girls than boys:
  - Thyroid storm occurs in 1% of patients with hyperthyroidism.

### RISK FACTORS

- Female gender
- Family history of autoimmune disorders
- A genetic susceptibility may exist.

### PATHOPHYSIOLOGY

- In Graves disease, thyroid-stimulating hormone (TSH) receptor autoantibodies mimic TSH and stimulate production of thyroid hormone.
- In Hashimoto thyroiditis, early disease can result in the disruption of thyroid follicles, which release thyroid hormones into the circulation.
- In neonatal Graves disease, transplacental passage of maternal thyroid-stimulating antibodies stimulate production of thyroid hormone.

### ETIOLOGY

- Graves disease is by far the predominant cause of hyperthyroidism in children.
- Neonatal Graves disease in infants of hyperthyroid mothers

- Hashimoto thyroiditis (chronic lymphocytic thyroiditis)
- McCune-Albright syndrome
- Postpartum thyroiditis
- Neck-trauma induced
- Medication induced:
  - Amiodarone
  - Lithium
  - Iodine
  - Thyroid hormone

### COMMONLY ASSOCIATED CONDITIONS

- Autoimmune diseases:
  - Diabetes mellitus
  - Celiac disease
  - Primary adrenal insufficiency
  - Vitiligo
  - Systemic lupus erythematosus
  - Rheumatoid arthritis
  - Myasthenia gravis
- Trisomy 21
- Mitral valve prolapse

## DIAGNOSIS

### HISTORY

- Symptoms are typically of insidious onset.
- Hyperactivity, nervousness, irritability, and emotional lability
- Difficulty concentrating in school, deterioration of handwriting
- Palpitations
- Increased appetite with poor weight gain, or weight loss
- Heat intolerance, increased sweating
- Proximal muscle weakness
- Growth acceleration

### PHYSICAL EXAM

- Tachycardia with widened pulse pressure, systolic murmur
- Proptosis: Staring expression with eyelid retraction and conjunctival injection can occur but is less common than in adults.
- Goiter: Symmetric, nontender enlargement of the thyroid gland is present in almost all patients.
- Palpable thrill or audible bruit over the thyroid

- Warm and moist skin
- Tremor
- Proximal muscle weakness
- Brisk tendon reflexes
- Thyroid storm is severe thyrotoxicosis:
  - Hyperthermia
  - Tachycardia
  - Tachydysrhythmia
  - High-output cardiac failure
- Neurologic alterations: Agitation, confusion, psychosis
- GI symptoms: Vomiting, diarrhea

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

TSH assay and thyroid function tests:

- Assays are dependent on the underlying etiology of the hyperthyroidism.
- In the majority of cases of hyperthyroidism, an elevated total T3 and T4 in the setting of a low TSH is diagnostic.
- Free T3 and T4 are more accurate as only unbound hormone is active, but levels are more difficult to obtain in the acute setting.
- TSH receptor antibodies (TRAb) are elevated in the setting of Graves disease, but levels are not available acutely.

#### Imaging

A CXR is indicated in the setting of thyroid storm to assess for findings consistent with CHF.

#### Diagnostic Procedures/Other

EKG

### DIFFERENTIAL DIAGNOSIS

- Pheochromocytoma
- Hypoglycemia
- Sepsis
- Sympathomimetic drug use
- Sedative-hypnotic withdrawal

## TREATMENT

### PRE HOSPITAL

- Address issues of airway, breathing, and circulation according to Pediatric Advanced Life Support (PALS) guidelines.
- Treat thyroid storm with supplemental oxygen and cooling if necessary.

### INITIAL STABILIZATION/THERAPY

- Address issues of airway, breathing, and circulation according to PALS.
- Administer supplemental oxygen.
- Administer IV fluid.
- Apply cooling techniques appropriate for temperature.
- Cardiopulmonary monitoring

### MEDICATION

#### First Line

- To treat extreme tachycardia, consider esmolol 100–500  $\mu\text{g}/\text{kg}$  IV over 1 min followed by 25–100  $\mu\text{g}/\text{kg}/\text{min}$  infusion:
  - If inadequate control, loading dose may be readministered and infusion dose increased in 25–50  $\mu\text{g}/\text{kg}/\text{min}$  increments. The usual maintenance dose range is 50–500  $\mu\text{g}/\text{kg}/\text{min}$ .
- Propranolol: Neonate/Child, 2 mg/kg/24 PO divided q6–12h; adolescent, 1–3 mg/dose IV over 10 min, repeat in 4–6 hr

#### Second Line

- Methimazole 0.4–0.7 mg/kg/24 hr divided q8h:
  - Inhibits hormone synthesis
- Propylthiouracil (PTU): Neonates, 5–10 mg/kg/24 hr divided q8h PO; children 6–10 yr of age, 50–150 mg/24 hr divided q8h PO; > 10 yr of age, 150–300 mg/24 hr divided q8h PO:
  - Inhibits hormone synthesis
- Methimazole is now preferred over PTU due to the more frequent and severe side effects associated with PTU. PTU may be used in those who cannot tolerate methimazole.
- Potassium iodide: Neonatal, 1 drop Lugol solution PO q8h; other ages, 50–250 mg PO t.i.d. (~1–5 drops of saturated solution of potassium iodide (SSKI) PO t.i.d.):
  - Blocks hormone release
- Dexamethasone 0.15 mg/kg IV single dose:
  - Prevents peripheral conversion of T4–T3

### SURGERY/OTHER PROCEDURES

Thyroidectomy if intensive therapy fails

### DISPOSITION

#### Admission Criteria

Critical care admission criteria:

- Thyroid storm with cardiovascular or neurologic instability
- Symptomatic patients requiring medication to control symptoms should be admitted for observation until stable on medications.

#### Discharge Criteria

Patients with minimal symptoms who do not require medications to control may be discharged from the emergency department with follow-up scheduled with an endocrinologist.

#### Issues for Referral

- Children with hyperthyroidism should be referred to a pediatric endocrinologist.
- Ophthalmology evaluation is indicated in children with proptosis or visual complaints.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- Patients should be maintained on a regular dose of PTU or methimazole as well as a beta-blocker if necessary.
- Modifications of dosage should be performed under the guidance of the endocrinologist.

### PROGNOSIS

- Spontaneous remission without need for continued medication occurs in 25% of cases every 2 yr
- The overall remission rate on antithyroid medications is 30–60%.
- No predictive prognostic factors have been identified.

### COMPLICATIONS

- Thyroid storm
- Cardiac dysrhythmia
- Seizure
- Cerebrovascular hemorrhage
- Disseminated intravascular coagulation
- Hyperthermic end organ damage
- Cardiac failure
- Growth failure

## ADDITIONAL READING

## CODES

### ICD9

- 242.00 Toxic diffuse goiter without mention of thyrotoxic crisis or storm
- 242.90 Thyrotoxicosis without mention of goiter or other cause, and without mention of thyrotoxic crisis or storm
- 242.91 Thyrotoxicosis without mention of goiter or other cause, with mention of thyrotoxic crisis or storm

## PEARLS AND PITFALLS

- Medications that block thyroid hormone synthesis will not benefit patients acutely because preformed hormone will continue to be released for several weeks.
- Neonatal hyperthyroidism can occur even when maternal symptoms are not present if the mother has undergone surgical thyroidectomy or radioactive iodine ablation therapy.
- Hyperthyroidism is rarely diagnosed early in the clinical course, and it mimics common behavioral disorders in children.

# HYPERVENTILATION

In K. Kim

## BASICS

### DESCRIPTION

- Hyperventilation syndrome is a condition, often provoked by anxiety, in which minute ventilation exceeds metabolic demands.
- A constellation of light-headedness, dizziness, anxiety, paresthesias, and sense of impending doom may result.
- Pathologic or physiologic disease, such as CNS disease, may also cause hyperventilation and should be ruled out before a diagnosis of anxiety-associated hyperventilation is made.

### EPIDEMIOLOGY

#### Incidence

- Acute form: <1% of all children
- Chronic form from respiratory, cardiac, neurologic, and GI diseases
- Chronic form is less common than acute.
- Female to male ratio of 7:1
- Pediatric peak incidence in teenagers

#### Prevalence

6% of the general population experience hyperventilation.

### RISK FACTORS

- Panic disorder and hyperventilation overlap: 50% of patients with panic disorder manifest hyperventilation.
- Diabetic ketoacidosis (DKA)
- CHF
- Severe pain
- Aspirin overdose
- Head injuries
- Pregnancy
- Asthma

### PATHOPHYSIOLOGY

- The underlying mechanism is not well defined.
- Stressors provoke an exaggerated respiratory response.
- Normal tidal volume is 35–45% of vital capacity. With hyperventilation, upper thorax breathing results in overinflated lungs. Deep breathing is then perceived as dyspnea, creating anxiety.
- Hyperventilation-induced alkalosis causes vasoconstriction. Diminished blood flow to the brain leads to a sensation of light-headedness.
- Alkalinization of plasma proteins such as albumin increases their calcium binding. The subsequent reduction in free ionized calcium can cause paresthesias and tetany.

### ETIOLOGY

- Believed to result from psychological stress, but the exact cause is unknown. Some persons appear to have an abnormal response to stress, with lactate and chemical or emotional triggers.
- With hyperpnea and thoracic breathing resulting in a hyperexpanded chest and high residual lung volume, proprioceptors in the chest wall may signal suffocation. This trigger may release neurotransmitters that cause palpitations, tremor, and anxiety.
- *Ataque de nervios* (“attack of nerves”) is a culture-bound phenomenon in which Hispanics, in response to shock or grief, may hyperventilate or engage in violent or bizarre behavior:
  - This is distinct from hyperventilation or panic attack but is very similar and may be treated similarly.

### COMMONLY ASSOCIATED CONDITIONS

- Anxiety disorder
- Panic disorder
- Agoraphobia

## DIAGNOSIS

### HISTORY

- Following a stressful event, sudden onset of dyspnea, chest pain, dizziness, weakness, paresthesias, near syncope
- Agitation and anxiety
- Sense of suffocation
- Tetanic cramps, carpopedal spasm
- Paresthesias
- Perioral numbness
- Symptoms of bloating and belching from aerophagia
- Dry mouth from mouth breathing
- Syncope or seizure
- Feelings of depersonalization, hallucination

### PHYSICAL EXAM

- Check for signs of underlying respiratory, cardiac, or metabolic diseases.
- Tachypnea and hyperpnea:
  - Breath sounds should be clear; wheezing or other abnormal breath sounds do not occur with hyperventilation.
- Chest wall tenderness
- Carpopedal spasm from reduced ionized calcium and phosphate levels:
  - Positive Chvostek sign: Tapping over the facial nerve ~2 cm anterior to the tragus of the ear leads to twitching at the angle of the mouth, then by the nose, the eye, and facial muscles.
  - Positive Trousseau sign: Inflation of a BP cuff causes local ulnar and median nerve ischemia, resulting in carpal spasm.
- Tremor
- Mydriasis
- Pallor
- Hallucination or seizure
- Chronic hyperventilation: Frequent sighing respirations and yawning; chest wall tenderness, numbness, and tingling

**DIAGNOSTIC TESTS & INTERPRETATION****Lab****Initial Lab Tests**

- Lab testing is not helpful in the assessment of most children with anxiety-induced hyperventilation.
- Depending on presentation, consider:
  - ECG
  - Chest radiograph
  - Venous or arterial blood gas

**Imaging**

Imaging studies are not indicated when the diagnosis is clear.

**DIFFERENTIAL DIAGNOSIS**

- Asthma
- Pneumonia
- Pulmonary embolism
- Angina
- Pleural effusion
- Pneumothorax
- Atrial flutter/fibrillation
- Cardiomyopathy
- Myocarditis
- Costochondritis
- DKA
- Metabolic acidosis
- Salicylate toxicity
- Ethanol or sedative-hypnotic withdrawal
- Carbon monoxide poisoning
- Panic disorders
- Nasopharyngeal stenosis

**TREATMENT****ALERT**

Having patients rebreathe into a paper bag has been the traditional treatment for hyperventilation. This practice is unsafe and may result in fatality. Rebreathing should not be performed under any circumstances.

**PRE HOSPITAL**

Assess and stabilize airway, breathing, and circulation.

**INITIAL STABILIZATION/THERAPY**

After airway stabilization, support circulatory status.

**MEDICATION**

Rarely, benzodiazepines may be of use:

- There is significant risk of inappropriate reinforcement to the patient that an emergency department visit or medical treatment is necessary.
- These should only be used in extreme circumstances.
- Diazepam 0.1 mg/kg PO/IV; adolescent or adult, 2–5 mg/dose IV/PO
- Alprazolam 0.005 mg/kg/dose; adolescent or adult, 0.25–0.5 mg/dose PO

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Breathing retraining may reduce symptoms.
- Consider acupuncture: Useful in reducing anxiety, and the frequency of attacks may be reduced

**DISPOSITION****Admission Criteria**

Hospitalization is not usually indicated unless there is a serious underlying organic etiology.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Consider a psychiatrist or psychologist referral.

**PROGNOSIS**

- Patients with chronic hyperventilation syndrome may experience multiple exacerbations.
- Those with episodes that begin in childhood often have hyperventilation as adults.
- Management of underlying organic disease, if any, will decrease the frequency of episodes.
- Patients with breathing retraining, stress reduction, and medication experience significant reductions in frequency and severity.

**COMPLICATIONS**

- Hypocalcemia
- Patients often undergo unnecessary testing and may have complications from medical interventions.

**See Also (Topic, Algorithm, Electronic Media Element)**

Panic Attack

**CODES****ICD9**

- 306.1 Respiratory malfunction arising from mental factors
- 786.01 Hyperventilation

**PEARLS AND PITFALLS**

- Panic attacks and hyperventilation are not synonymous, although there is considerable overlap:
  - ~50% of panic disorder and 60% of agoraphobia manifest as hyperventilation.
- Kussmaul respirations with DKA can mimic hyperventilation. With DKA, patients will have signs of dehydration and a fruity smell to the breath.
- Failure to consider a CNS lesion, medication toxicity, DKA, or another severe cause for hyperventilation

# HYPHEMA

Sandra H. Schwab

## BASICS

### DESCRIPTION

Hyphema is an accumulation of blood between the cornea and the iris, in the anterior chamber of the eye:

- It is usually a result of blunt trauma.
- *Microhyphema* is defined as circulating RBCs that do not layer out to form a fluid level.

### EPIDEMIOLOGY

#### Incidence

Hyphema occurs in 12–17 per 100,000 children annually (1,2):

- Males are 3–5 times more likely to sustain a traumatic hyphema.
- Peak incidence is 10–20 yr of age.
- The majority of hyphemas are monocular.

### RISK FACTORS

- Occupation such as construction or factory worker
- Sporting activity, especially with projectiles, sticks, or racquets
- Improper or no eye protective equipment
- Bleeding disorder
- Patients on anticoagulant medications
- Air bag deployment during motor vehicle crash
- Assault or child abuse
- Sickle cell trait or disease

### GENERAL PREVENTION

- Properly fitted and worn eye equipment has been shown to reduce eye injuries in the occupational and sport settings.
- Avoidance of high-risk behaviors and activities if known predisposition to bleeding

### PATHOPHYSIOLOGY

Damage to the small blood vessels of the iris or ciliary body of the eye results in bleeding into the anterior chamber.

### ETIOLOGY

- The usual cause of hyphema is blunt trauma to the eye.
- Rarely, spontaneous hyphema can result when an underlying disease or tumor is present.

### COMMONLY ASSOCIATED CONDITIONS

- Sickle cell trait or disease
- Immune thrombocytopenic purpura, hemophilia, or von Willebrand disease
- Anticoagulant use

## DIAGNOSIS

### HISTORY

- Eye trauma
- Projectile contacting the eye
- Eye pain
- Impaired vision
- Photophobia
- History regarding participation in a high-risk occupation or activity should be elicited:
  - Details such as eye protection, projectiles, and force should be included.
  - Past medical history should include questions about bleeding disorders, anticoagulation, or sickle cell disease or trait.

### PHYSICAL EXAM

- The patient should be examined in the upright position with the head angled at 30 degrees.
- Layering of blood behind the cornea, creating a fluid level in front of the iris and/or pupil, is diagnostic of hyphema.

- A universal grading system to describe the extent of hyphema has been established:
  - Grade 0: Microhyphema, seen with slit lamp
  - Grade 1: <33% of anterior chamber filling
  - Grade 2: 33–50% of anterior chamber filling
  - Grade 3: >50% of anterior chamber filling
  - Grade 4: Complete filling of anterior chamber
- Visual acuity should be assessed and is an important factor in determining the prognosis.
- Regularity of eye movements and pupil size and shape should be confirmed:
  - Ophthalmoplegia would be suggestive of entrapment of an extraocular muscle, as might be seen with an associated orbital fracture.
  - An irregularly shaped pupil could be indicative of an open globe injury.
- Other eye injuries such as lacerations, abrasions, fractures, or foreign bodies should be noted.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- A CBC to confirm platelet count
- PT/PTT to evaluate for an underlying bleeding disorder
- Sickle cell preparation if status is unknown

#### Imaging

- CT scan to evaluate for other injuries is the current standard and should be considered; CT may be omitted if exam reveals hyphema alone.
- US by an experienced clinician may be helpful to determine the presence of foreign body, hemorrhage, lens dislocation, or retinal detachment.

### DIFFERENTIAL DIAGNOSIS

- Corneal or sclera laceration
- Open globe injury
- Child abuse

## TREATMENT

### PRE HOSPITAL

- A hard shield should be placed over the bony prominences of the eye to minimize any further damage or injury.
- The patient should be made nonambulatory and transported only via stretcher or wheelchair.

### INITIAL STABILIZATION/THERAPY

- Pain control and anxiolysis may be necessary in order to fully evaluate the eye, especially in pediatric patients.
- An ophthalmologist should be consulted early in the care of these patients. A full exam, including intraocular pressures, by a specialist determines important treatment and prognostic information.

### MEDICATION

#### First Line

Cycloplegics may be used for comfort:

- Atropine eyedrops:
  - <1 yr of age: 0.25% 1 drop t.i.d.
  - 1–5 yr: 0.5% 1 drop t.i.d.
  - >5 yr (or younger if dark irides): 1% 1 drop t.i.d.

#### Second Line

- Topical corticosteroids have been shown to reduce inflammation and rebleeding (4).
- Topical and systemic antifibrinolytics, such as aminocaproic acid (ACA) have been shown to reduce rebleeding (3,4):
  - For dosing of ACA or corticosteroid, consult an ophthalmologist.
- Mannitol 0.25–0.5 g/kg IV q4–6h

### SURGERY/OTHER PROCEDURES

Surgical intervention is usually needed only if complications arise:

- Anterior chamber washout or iridectomy is performed to increase drainage and reduce intraocular pressure.

### DISPOSITION

#### Admission Criteria

- Patients with >50% hyphema, underlying bleeding disorder, visual loss, rebleeding, or risk for noncompliance should be admitted for frequent exams and enforcement of bed rest.

- Results of recent studies have determined that many children can be successfully managed as outpatients (3,4).

#### Discharge Criteria

- Stable exam without rebleeding
- Normal or controlled intraocular pressure

#### Issues for Referral

All patients with hyphema should be followed by an ophthalmologist.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Medications should be prescribed and managed by the specialist.
- Activity:
  - Bed rest, preferably with head elevated, until cleared by the ophthalmologist

#### Patient Monitoring

Patients should be monitored for changes in intraocular pressure, vision, and corneal staining

### PROGNOSIS

Prognosis depends on initial severity of hyphema, rebleeding, and increased intraocular pressure:

- Patients with grade 0–1 hyphema have a 90% chance of 20/50 or better vision (4).
- Patients with grade 3–4 hyphema have only a 50% chance of 20/50 or better vision (4).

### COMPLICATIONS

- Rebleeding, usually between 2 and 5 days after initial injury:
  - Patients with more severe hyphema on presentation or underlying blood dyscrasia are at greatest risk.
- Glaucoma, or increased intraocular pressure, resulting from abnormal drainage of aqueous humor and blood products from the anterior chamber
- Corneal staining resulting from increased fragility and abnormal leakage of blood cells into the corneal tissue

## CODES

### ICD9

- 364.41 Hyphema of iris and ciliary body
- 921.3 Contusion of eyeball

## PEARLS AND PITFALLS

- Patients with hyphema should always be referred for specialist evaluation and treatment.
- Delay in diagnosis or treatment may result in devastating complications and vision loss.
- Patients with sickle cell disease or trait are at greatest risk of vision loss due to increased intraocular pressure and rebleeding.
- Proper use of eye protective equipment significantly reduces the incidence of hyphema and traumatic vision loss.

# HYPOCALCEMIA

Brenda J. Bender

## BASICS

### DESCRIPTION

- *Hypocalcemia* is defined as a total serum calcium <7.0 mg/dL or an ionized calcium <3.5 mg/dL.
- Mild symptoms of hypocalcemia can occur with a total serum calcium of 7.5 mg/dL in neonates and 8.5 mg/dL in older children.

### EPIDEMIOLOGY

#### Incidence

Most pediatric patients with hypocalcemia are newborns.

### RISK FACTORS

- Prematurity/Low birth weight
- No sex predilection

### PATHOPHYSIOLOGY

- Calcium is the most abundant mineral in the body.
- Of the body's total calcium, 99% is in bone.
- Total calcium levels include both the ionized fraction and the bound fraction.
- The ionized calcium is the active and physiologically important component.
- At a physiologic pH of 7.4, 40% of the total calcium is bound to albumin; 10% is complexed with bicarbonate, phosphate or citrate; and 50% is free ionized calcium (1).
- In the emergency department, most cases are due to hyperventilation-induced alkalosis, which causes increased calcium binding to protein, thereby decreasing the serum ionized calcium (2).
- In renal failure, hypocalcemia is due to inadequate 1-hydroxylation of 25-hydroxyvitamin D and hyperphosphatemia due to diminished glomerular filtration (3).

### ETIOLOGY

- Early neonatal (within 48–72 hr of birth):
  - Prematurity
  - Birth asphyxia
  - Gestational diabetes
  - Intrauterine growth retardation
- Late neonatal (3–7 days after birth to 6 wk of age):
  - Exogenous phosphate load
  - Magnesium deficiency
  - Transient hypoparathyroidism of newborn
  - Hypoparathyroidism due to other causes
  - Gentamicin use
- Infants and children:
  - Hypoparathyroidism: Decreased parathyroid hormone levels or ineffective parathyroid response:
    - There are numerous forms of hypoparathyroidism, including idiopathic, pseudo, transient neonatal, post-thyroid surgery, hemochromatosis, and autoimmune.
  - Abnormal vitamin D production or action, which includes vitamin D deficiency (eg, rickets), acquired or inherited disorders of vitamin D metabolism, resistance to actions of vitamin D, liver disease
  - Hyperphosphatemia, which may be due to excessive use of sodium phosphate enemas, improper formula mixing, renal failure, anoxia, chemotherapy, or rhabdomyolysis

- Alkalosis, especially respiratory alkalosis
- Pseudohypocalcemia (ie, hypoalbuminemia)
- Pancreatitis
- Malabsorption states
- Drug therapy (anticonvulsants, cimetidine, aminoglycosides, calcium channel blockers)
- Hypomagnesemia or hypermagnesemia
- Calcitriol (activated vitamin D) insufficiency
- Tumor lysis syndrome
- Ethylene glycol ingestion
- Hydrofluoric acid or ammonium bifluoride toxicity
- Rattlesnake bite
- Renal failure
- Massive transfusion

## DIAGNOSIS

### HISTORY

- The severity, rate of development, and chronicity of hypocalcemia determines the clinical manifestations.
- In a newborn, there may be a history of poor feeding, vomiting, lethargy, and cyanosis.
- Children may have a history of seizures, twitching, cramping, or laryngospasm.
- A hyperventilating adolescent may present with a history of anxiety, tachypnea, labored breathing, recent emotional upset, or past history of anxiety or psychiatric disorders.

### PHYSICAL EXAM

- Tetany
- Lethargy
- Hyperreflexia
- Neuromuscular irritability with weakness
- Paresthesias
- Fatigue
- Cramping
- Altered mental status
- Emotional lability
- Irritability
- Impaired cognition
- Vomiting and diarrhea
- Seizures
- Laryngospasm
- Cardiac dysrhythmias
- Trousseau sign: Carpopedal spasm after arterial occlusion of an extremity for 3 min (4)
- Chvostek sign: Muscle twitching with percussion of facial nerve (5)
- In patients with long-standing hypocalcemia, there can be cataracts, metastatic calcifications, dry and brittle hair and nails, and dry coarse skin.
- In autoimmune hypoparathyroidism, a patient may present with candidiasis or increased skin pigmentation (2).
- In pseudohypoparathyroidism, patients may present with a round face, stocky build, mental retardation, and short 4th and 5th metacarpals and metatarsals (2).

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- Obtain electrolytes, glucose, calcium (total and ionized), phosphorus, alkaline phosphatase, magnesium, total protein, albumin, BUN, creatinine, venous blood gas, lipase, parathyroid hormone, and 25-OH vitamin D levels:
  - In hypoalbuminemic states, total serum calcium decreases 0.8 mg/dL for every 1 g/dL reduction in serum albumin.
  - The use of ionized calcium measurement is preferable for determination of the degree of hypocalcemia.
- Obtain urine levels of calcium, phosphorus, magnesium, and creatinine.
- In hypoparathyroidism, phosphorus is elevated and alkaline phosphatase is normal.
- In vitamin D deficiency, phosphorus is low and alkaline phosphatase is elevated.
- In hyperventilation-induced hypocalcemia, a blood gas analysis demonstrates an increased pH, decreased PCO<sub>2</sub>, and a normal PO<sub>2</sub>.

### Imaging

- Consider CXR (to visualize thymus).
- Consider ankle and wrist films (to assess for changes suggestive of rickets).

### Diagnostic Procedures/Other

ECG: Changes may include prolonged QT interval, prolonged ST, and T-wave abnormalities (2,3).

### DIFFERENTIAL DIAGNOSIS

- Common associated conditions: Hypoparathyroidism, pseudohypoparathyroidism, malabsorption syndromes, renal failure, rickets, and hyperventilation syndrome
- The differential diagnosis is dependent on the clinical presentation.
- Hyperventilation: Panic attack, asthma, pneumonia, foreign body, sepsis
- Carpopedal spasm: Seizure, dystonia
- Dysrhythmia or ECG changes: Congenital prolonged QT, other electrolyte disturbances such as hypokalemia

## TREATMENT

### INITIAL STABILIZATION/THERAPY

Assess and stabilize airway, breathing, and circulation:

- Laryngospasm, dysrhythmia, or seizures

### MEDICATION

- For acute symptomatic hypocalcemia, treat with IV forms of calcium: Calcium gluconate or calcium chloride (6).
- Calcium gluconate is strongly recommended for use rather than calcium chloride. If calcium chloride is used, it is critical to assure IV placement of catheter by documenting back flash of blood into catheter and the securing catheter or central venous line so dislodgement is not possible:
  - Extravasation of calcium chloride can result in devastating tissue necrosis and loss, including loss of hand function or digits in affected region of extravasation.

- Calcium gluconate: Dosing below is expressed as milligrams of calcium gluconate; this is not elemental calcium dosing:
  - 10% calcium gluconate contains 100 mg/mL calcium gluconate
  - For reference, a 10 mL vial of 10% calcium gluconate contains 90 mg of elemental calcium. Note that elemental calcium dosing is not discussed here.
  - Solution is constituted by adding desired dose of 10% calcium gluconate to 50 mL of 5% dextrose (D5W).
  - Neonates, infants, children: 50–100 mg/kg given over 5–20 min:
    - For cardiac arrest or tetany, use 100 mg/kg.
  - Adolescents, adults: 500 mg to 2 g over 10–30 min (0.5–2 ampules of 10 mL):
    - For cardiac arrest, use 1–2 g (1–2 ampules of 10 mL)
  - Generally, IV push rate should be <100 mg/min.
  - Generally, IV infusion rate should be <200 mg/kg/hr, and concentration should not exceed 50 mg/mL.
- Calcium chloride: Dosing below is expressed as mg of calcium chloride; this is not elemental calcium dosing:
  - Use of calcium gluconate is highly recommended rather than calcium chloride:
    - Calcium chloride is only preferable in rare cases when rapid infusion of more concentrated calcium is necessary.
    - Massive tissue necrosis may result from extravasated calcium chloride.
  - 10% calcium chloride contains 100 mg/mL of calcium chloride.
  - For reference, a 10-mL vial of 10% calcium chloride contains 272 mg of elemental calcium; this is 3 times more concentrated than calcium gluconate. Note that elemental calcium dosing is not discussed here.
  - Solution is constituted by diluting desired dose of 10% calcium chloride into 100 mL of 5% dextrose (D5W).
  - Neonates, children: 10–20 mg/kg/dose over 5–20 min:
    - For cardiac arrest or tetany, use 20 mg/kg.
  - Adolescent, adult: 1–3 g/dose (1–3 ampules of 10 mL each) over 10–30 min:
    - For cardiac arrest or tetany, use minimum of 1 g/dose (1 ampule of 10 mL)
  - Generally, the IV push rate should be <100 mg/min.
  - Generally, IV infusion rate should be <200 mg/kg/hr, and concentration should not exceed 20 mg/mL.
- For chronic hypocalcemia, use oral calcium supplements (75 mg/kg/day of elemental calcium divided into 4 doses) in the form of calcium carbonate, calcium gluconate, calcium glubionate, or calcium lactate (6).

- Contraindications for calcium therapy include renal calculi, hypercalcemia hypophosphatemia, ventricular fibrillation during cardiac arrest, or digitalis toxicity (3).
- Rare cases of poisoning by calcium channel blocker overdose, hydrofluoric acid, ammonium bifluoride, or rattlesnake bite may require massive calcium far in excess of doses recommended above given at a much more rapid rate by central venous access.

## DISPOSITION

### Admission Criteria

- Admit patients with symptomatic hypocalcemia and all those with a first episode of hypocalcemia, especially if the etiology is unclear.

### Issues for Referral

- Depending on the cause, patients may need to follow up with an endocrinologist, nephrologist, or geneticist.
- For hydrofluoric acid, ammonium bifluoride, or rattlesnake toxin–induced hypocalcemia, consult a toxicologist.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Patients often are discharged on oral calcium supplementation.
- At times, patients need supplemental magnesium or phosphate-lowering agents.
- Other therapies, such as vitamin D, are based on the underlying etiology.

### DIET

- Patients must maintain a diet high in calcium and low in phosphate.
- Infants drinking regular cow's milk or evaporated milk must be given formula that more closely resembles human milk.
- Breast milk is low in vitamin D, so those with rickets who are breast-fed will need vitamin D.
- Patients with renal failure need a low-solute, low-phosphate formula.

### PROGNOSIS

Prognosis depends on the underlying cause of hypocalcemia.

### ICD9

- 275.41 Hypocalcemia
- 775.4 Hypocalcemia and hypomagnesemia of newborn

## PEARLS AND PITFALLS

- Common causes of hypocalcemia in children include hypoparathyroidism, malabsorption, renal failure, rickets, and hyperventilation syndrome.
- Symptoms of hypocalcemia that are refractory to calcium supplementation may be caused by hypomagnesemia (6).
- Significant hyperphosphatemia should be corrected before the correction of hypocalcemia because soft tissue calcification may occur if total calcium times phosphorous exceeds 80 (7).
- Heart rate and rhythm need to be closely monitored during IV calcium infusion because of the potential cardiac complications.
- Seizures caused by hypocalcemia are often refractory to anticonvulsants; calcium must be given (3).
- If a patient is also acidemic, hypocalcemia should be corrected 1st. Acidemia increases the ionized calcium levels by displacing calcium from albumin (3).
- IV infusion with calcium-containing solutions may cause severe tissue necrosis (6).

# HYPOGLYCEMIA

Halden F. Scott

## BASICS

### DESCRIPTION

- Hypoglycemia is low blood sugar, definitions of which vary, but serum glucose  $<50$  mg/dL is the most widely accepted definition.
- Normal serum glucose varies by age, with healthy neonates having a lower "normal" serum blood sugar, particularly in the 1st week of life.
- Hypoglycemia may result in severe morbidity and mortality, with the most prominent adverse event being permanent neurologic injury.

### EPIDEMIOLOGY

- A chart review of pediatric emergency department patients found diagnoses of hypoglycemia in 6.54 of 100,000 visits.
- 1 study found that 18% of critically ill children in the emergency department were hypoglycemic.

### RISK FACTORS

- Neonates: Low birth weight, polycythemia, environmental or infectious stress, and inborn errors of glucose metabolism
- Ketotic hypoglycemia is most common in thin children  $<6$  yr of age with intercurrent illness.
- Children with diabetes are more likely to have hypoglycemic events the younger they are, when events also carry the greatest neurocognitive consequences.
- Gastroenteritis is frequently associated with hypoglycemia.

### PATHOPHYSIOLOGY

- Hypoglycemia results from an inability to convert stored energy in the body into glucose. This can result from inadequate intake combined with depleted glycogen stores or inborn deficiencies in enzymes in metabolic pathways of energy production, specifically defects of glycogenolysis, the urea cycle, fatty acid oxidation, or the mitochondria.
- Deficiencies in hormones that regulate the process of gluconeogenesis and exogenous ingestions also lead to hypoglycemia.
- The brain depends on a steady supply of glucose. Sometimes children's brains are able to better use alternate energy sources such as ketones and free fatty acids for limited periods of time.
- The clinical manifestations of hypoglycemia are driven by neurologic failure resulting from loss of energy to the brain.

### ETIOLOGY

See Differential Diagnosis.

## COMMONLY ASSOCIATED CONDITIONS

- Gastroenteritis
- Sepsis
- Respiratory failure
- CHF
- Inborn errors of metabolism
- Toxic ingestion
- Small for gestational age
- Failure to thrive
- Beckwith-Wiedemann syndrome

## DIAGNOSIS

### HISTORY

- Nausea, vomiting, dizziness, diaphoresis and disorientation, or confusion may precede more severe problems:
  - Older children often report adrenergic manifestations, including diaphoresis, tachycardia, weakness, and nervousness
  - Infants display nonspecific symptoms, including irritability, lethargy, poor feeding, apnea or tachypnea, hypothermia, and hypotonia.
- Lethargy, loss of consciousness, unresponsiveness, coma, seizure, and focal neurologic deficit occur with more severe or prolonged hypoglycemia.
- In patients without known etiology for hypoglycemia, some clues that there might be an underlying metabolic cause include recurrent episodes after fasting, infection, or exposure to specific foods (eg, introduction of fruits or high-protein foods).
- A detailed history may reveal an unintentional medication ingestion.

### PHYSICAL EXAM

- The most common presenting symptoms in the pediatric emergency department are emesis, seizures, unresponsiveness, and lethargy.
- Hepatomegaly: Glycogen storage disease (GSD)
- Neonatal obesity: Hyperinsulinism
- Myopathy: Fatty acid oxidation disorder and GSD
- Micropenis, midline facial defects, microcephaly: Hypopituitarism.

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- Immediate bedside assessment of blood glucose should be performed:
  - If hypoglycemia is confirmed, any critical labs should be drawn before treatment is initiated.
  - Critical labs are institution dependent but often include serum insulin, C-peptide, cortisol, growth hormone (GH), beta-hydroxybutyrate, lactate, free fatty acids, ammonia, carnitine, and acylcarnitine.
  - If in question, draw blood samples and hold.
- Next-void urine should be sent for ketones, organic acids, and reducing substances.
- If indicated by precipitating event, other lab tests, such as serum toxicology screening for medication ingestion, blood culture, urinalysis, and urine culture, may be sent.

- Additional blood and urine specimens should be frozen and saved for further diagnostics if possible:
  - Beta-hydroxybutyrate of  $<2.5$  mEq/L at the time of hypoglycemia suggests inappropriate ketosis, seen in hyperinsulinism, fatty acid oxidation disorders, and GSD type I.
  - High insulin ( $>6$  mU/mL) at the time of hypoglycemia suggests hyperinsulinism.
  - Hyperammonemia and acidosis are seen in some inborn errors of metabolism and intoxications.
  - Hypoglycemia in the setting of large urinary ketones and without hepatomegaly, hyperammonemia, or acidosis suggests idiopathic ketotic hypoglycemia; in this setting, it may be appropriate to limit the workup for inborn errors of metabolism.

## DIFFERENTIAL DIAGNOSIS

- Increased energy utilization:
  - Neonates: Sepsis, seizure, high or low environmental temperatures, hyperinsulinism (including Beckwith-Wiedemann syndrome, erythroblastosis fetalis, perinatal asphyxia)
  - Tumors: Islet-cell adenomas, hepatoblastomas, Wilms tumors, Hodgkin lymphomas
- Decreased energy production:
  - Ketotic hypoglycemia in children with infection and decreased oral intake
  - Fatty acid oxidation disorders
  - Diarrhea
  - Cortisol and GH deficiencies: Cortisol deficiency can be primary (adrenal hyperplasia) or secondary (adrenocorticotropic hormone deficiency).
  - Amino acidopathy
  - GSD
- Ingestions and complex mechanism:
  - Insulin, oral hypoglycemic agents
  - Alcohol intoxication
  - Beta-blockers
  - Salicylates
  - Reye syndrome
  - Akee fruit ("Jamaican vomiting sickness"), atractyloside (Mediterranean thistle): Mimic fatty acid oxidation disorders
  - Liver disease, heart failure

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation.
- Immediate assessment of blood glucose and administration of dextrose or glucagon if hypoglycemic:
  - See dextrose and glucagon administration information in the Medication, "First Line" section.

### INITIAL STABILIZATION/THERAPY

- As with any patient, attention to airway, breathing, and circulation is warranted.
- However, in the absence of additional processes, reversal of hypoglycemia alone will correct impaired respiratory drive and perfusion; thus, immediate correction of hypoglycemia is of utmost importance.

**MEDICATION****First Line**

- Patients with a normal level of consciousness should drink simple carbohydrates such as juice or glucose gel immediately. If hypoglycemia does not improve, they should receive parenteral glucose immediately.
- Dextrose: 0.25 g/kg of dextrose is a resuscitative dose for hypoglycemia:
  - D50 50% dextrose 1 ampule (25 g) 1–2 mL/kg IV q5–10min PRN:
    - Given to adolescents and older children
  - D25 25% dextrose 2–4 mL/kg IV q5–10min PRN:
    - Given for ages from toddler to adolescent
  - D10 10% dextrose 4–5 mL/kg IV q5–10min PRN
  - D5 5% dextrose 5 mL/kg IV q5–10min PRN:
    - Preferred for infants
- Higher concentrations of dextrose, such as D50 and D25, may cause phlebitis if prolonged infusion or tissue damage if extravasated.
- Glucagon may be dosed 0.03 mg/kg SC/IM/IV q20min PRN:
  - Used if vascular access is unavailable to give IV dextrose
  - Empiric dosing of 1 mg SC/IM/IV q20min PRN can be used.
  - Glucagon should cause a rise of at least 25 mg/dL in hyperinsulinemic patients. If no response is seen after administration, dextrose should be given immediately.

**Second Line**

- A dextrose infusion should be started after initial glucose correction:
  - A glucose infusion rate (GIR) of 6–9 mg/kg/min should be maintained. D10 at 1.5 times maintenance rates usually achieves an adequate GIR.
  - $GIR = [\% \text{ dextrose} \times \text{infusion rate} \div (6 \times \text{weight})]$
- Octreotide 1  $\mu\text{g}/\text{kg}$  IV/SC q6–12h, indicated for sulfonyleurea-induced hypoglycemia, insulinoma, or other hyperinsulinemic state, for hypoglycemia refractory to dextrose administration and as adjunctive therapy. (See Complementary & Alternative Therapies.)
- Specific etiologies respond to treatment:
  - Hyperinsulinism can be controlled with diazoxide and octreotide.
  - GSD: NG tube feedings and cornstarch throughout the day
  - Sulfonyleurea overdose: Octreotide

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

Octreotide 1  $\mu\text{g}/\text{kg}$  SC/IV may be used to prevent further pancreatic insulin release:

- This may be useful in preventing rebound hypoglycemia after bolus dextrose.

**SURGERY/OTHER PROCEDURES**

Partial pancreatectomy may be performed for hyperinsulinism.

**DISPOSITION****Admission Criteria**

- Patients with new onset of hypoglycemia with unknown etiology for whom observation or diagnostic evaluation is needed
- Critical care admission criteria:
  - Persistent hypoglycemia, sulfonyleurea ingestion, or persistently depressed mental status or hemodynamic instability might warrant critical care admission.

**Discharge Criteria**

- Diabetics with mild insulin overdose or inadequate oral intake may be discharged after blood glucose is normal and stable.
- Hypoglycemia reversed and stable
- Other patients with underlying cause identified and reversed without concern for recurrence, such as an adolescent with a skipped meal

**Issues for Referral**

- Ketotic hypoglycemia may be managed without subspecialty support.
- Pediatric endocrinologist, metabolic specialist, or toxicologist as appropriate

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS****Patient Monitoring**

Patients should remain on continuous cardiorespiratory monitoring until resolution of hypoglycemia and its underlying cause.

**DIET**

- In all cases, the patient must be able to maintain enteral nutrition prior to discharge.
- Patients with inborn errors of metabolism may require specialized diets. Patients with ketotic hypoglycemia may have only a limited amount of time that they can safely fast before requiring medical attention.

**PROGNOSIS**

Degree of hypoglycemia and duration and frequency of episodes determine the degree of long-term effects. The etiology will influence whether other energy sources are available during the episode and thus also affect outcome.

**COMPLICATIONS**

- Severe hypoglycemic episodes can cause brain damage, including central pontine myelinolysis and movement disorders.
- The sequelae of hypoglycemia depend on the severity, duration, and frequency of hypoglycemia as well as availability and the brain's ability to use alternate energy sources such as ketone bodies and free fatty acids. Thus, disorders such as hyperinsulinism, which suppress ketone production at the time of hypoglycemia, carry greater consequences.
- Frequent neonatal hypoglycemic episodes have been negatively associated with neurodevelopmental outcome.

**ICD9**

- 251.2 Hypoglycemia, unspecified
- 775.6 Neonatal hypoglycemia

**PEARLS AND PITFALLS**

- Blood glucose should be immediately assessed in any patient with acute alteration of mental status or neurologic function.
- Untreated hypoglycemia may result in permanent neurologic injury.
- Collection of critical labs before correction of blood glucose is crucial to the diagnosis and may obviate the need for a future risky fasting study.
- Hypoglycemia should be considered in the differential diagnosis for all children presenting with altered mental status, seizures, or syncope.

# HYPOGLYCEMIC AGENTS POISONING

Beth Y. Ginsburg

## BASICS

### DESCRIPTION

- The clinical presentation of medication-induced hypoglycemia is extremely variable and may mimic other conditions, including viral syndromes and neurovascular events.
- Undiagnosed hypoglycemia may lead to significant morbidity and mortality depending on the duration and degree of hypoglycemia:
  - Permanent neurologic injury may occur from a single significant hypoglycemic event.
- A bedside blood glucose concentration should be obtained along with the other vital signs in any case suspicious for hypoglycemia:
  - This includes any altered mental status or behavioral changes.

### EPIDEMIOLOGY

#### Incidence

- Oral hypoglycemics are a common pediatric pharmaceutical exposure.
- In 2007, oral hypoglycemics resulted in 20,000 single-substance pharmaceutical exposures in children <6 yr of age and ~3,000 single-substance pharmaceutical exposures in the 6–19-yr age group in the U.S.

### PATHOPHYSIOLOGY

- Different categories of antidiabetic agents have different mechanisms of action.
- Medications that promote insulin secretion are likely to cause hypoglycemia.
- Medications that increase insulin sensitivity are unlikely to cause hypoglycemia.
- Hypoglycemia results in decreased glucose delivery to the brain. This leads to activation of the sympathetic arm of the autonomic nervous system with symptoms typical of catecholamine release.
- The brain relies almost entirely on glucose for energy. Therefore, manifestations of hypoglycemia are typically characterized by neuroglycopenic symptoms.
- Insulin exposure reliably causes hypoglycemia:
  - Insulin, a pancreatic hormone, acts on insulin receptors to control the uptake, storage, and usage of glucose.
  - Synthetic insulin used for management of type 1 diabetes commonly results in overdose.
- Endogenous insulin release in response to dextrose boluses or infusion may complicate treatment of any toxin-induced hypoglycemia by adding to the factors driving hypoglycemia. Octreotide may aid in suppressing this endogenous insulin release.
- Sulfonylureas (eg, glimepiride, glipizide, glyburide) increase insulin release from the beta islet cells of the pancreas. Sulfonylureas may also improve sensitivity to insulin outside the pancreas:
  - Sulfonylureas often cause significant hypoglycemia, which may be delayed in onset and prolonged in duration.

- Meglitinides (eg, repaglinide, nateglinide) improve insulin release from the beta islet cells of the pancreas in a similar manner as sulfonylureas.
- Incretins are gut hormones that stimulate insulin secretion from the pancreas via interaction with G-protein coupled receptors on pancreatic beta islet cells. Incretin mimetics (eg, exenatide) are agonists at the pancreatic beta islet cell G-protein coupled receptors. Incretin enhancers (eg, sitagliptin) inhibit the enzymatic breakdown of incretins.
- Biguanides (eg, metformin) increase sensitivity to insulin by decreasing hepatic gluconeogenesis and glucose output and by enhancing peripheral glucose uptake.
- Thiazolidinediones (eg, pioglitazone, rosiglitazone) increase insulin sensitivity by decreasing hepatic gluconeogenesis and by enhancing glucose uptake into adipose tissue and skeletal muscle.
- Beta-glucosidase (eg, acarbose) inhibitors inhibit beta-glucosidase in the intestine, thereby leading to decreased absorption of glucose following oral ingestion of carbohydrates.
- The onset and duration of hypoglycemia depends on the particular hypoglycemic agent involved:
  - Insulin:
    - Duration and severity of symptoms depend on amount of insulin injected and formulation.
    - Longer-acting insulin results in more prolonged hypoglycemia.
    - In significant overdose, pharmacokinetics are altered, and even regular insulin may cause prolonged hypoglycemia far beyond the expected duration of action for half-life.
    - Following a large overdose, hypoglycemia may persist beyond the expected duration of effect. This may partly be due to a depot effect following a large SC injection.
    - Hypoglycemia does not occur following insulin ingestion because insulin is destroyed in the stomach.
  - Sulfonylureas:
    - Sulfonylureas have a variable duration of action of about 24 hr.
    - Following overdose, patients may have hypoglycemia ranging from hours to several days.
    - Onset of hypoglycemia may be delayed. Ingestion of any quantity may result in severe hypoglycemia in children.
  - Meglitinides have a relatively short duration of action of only 1–4 hr. However, the duration of action following overdose may be prolonged.
  - Incretin mimetics and incretin enhancers are relatively new agents. There is little data available on clinical effects following overdose. However, hypoglycemia should be anticipated.

- Nonhypoglycemic toxicity may occur from the following:
  - Biguanide ingestions have been associated with development of severe lactic acidosis (ie, metformin-associated lactic acidosis, MALA). This may be due to inhibition of hepatic lactate uptake and inhibition of conversion of lactate to glucose. Lactic acidosis is more likely to occur in the setting of comorbidities, particularly renal failure in which there is an increased tissue burden of the biguanide.
  - Thiazolidinediones have been associated with the development of liver toxicity, even in the setting of therapeutic dosing.
  - Beta-glucosidase inhibitors are associated with GI side effects including nausea, bloating, flatulence, abdominal pain, and diarrhea.

## DIAGNOSIS

### HISTORY

- A history of exposure is helpful but may not be available in patients with altered mental status.
- Inquire about medication, dose, route, if insulin-specific type (regular, long-acting), and diabetes status of patient.
- Hypoglycemia should be suspected in patients presenting with altered mental status.
- Hypoglycemia should always be considered in cases of neurologic symptoms, even those suggestive of a stroke such as a focal neurologic deficit.

### PHYSICAL EXAM

- Patients with hypoglycemia may demonstrate signs on physical exam consistent with a sympathomimetic toxidrome:
  - Vital signs: Tachycardia, HTN
  - HEENT: Mydriasis
  - Skin: Diaphoresis, piloerection
  - CNS: Agitation, tremor
- Other symptoms due to increased catecholamine release include anxiety, palpitations, chest pain, nausea, and headache.
- Neuroglycopenic signs and symptoms predominate in the setting of hypoglycemia:
  - Altered mental status, difficulty concentrating, confusion, agitation
  - Generalized weakness, fatigue, lethargy
  - Blurred vision
  - Focal neurologic deficits (eg, hemiplegia), loss of coordination
  - Hypothermia
  - Seizure
  - Coma

**DIAGNOSTIC TESTS & INTERPRETATION**

**Lab**

- Immediately assess bedside capillary glucose measurement regardless of symptoms:
  - A serum glucose concentration may be more accurate, but bedside glucose testing typically guides management.
  - Frequent bedside glucose assessment should be continued for the duration of time that the patient is at risk for hypoglycemia.
- C-peptide: Obtain if surreptitious or malicious insulin overdose is suspected or to guide octreotide administration:
  - When proinsulin is secreted, it is cleaved to insulin and C-peptide in equimolar amounts:
    - Exogenous insulin does not contain C-peptide; high insulin concentrations and low C-peptide concentrations corroborate exogenous insulin administration.
  - C-peptide levels may be used to guide octreotide therapy to treat hypoglycemia associated with elevated C-peptide levels:
    - This role is not clearly defined.
- Venous blood lactate concentration should be obtained in cases of metformin overdose.
- Hepatic and renal function tests may be sent to uncover other causes of hypoglycemia.
- Serum ethanol concentration may be assayed to detect cause of hypoglycemia.

**Imaging**

Obtain CT of the brain if there is any concern about neurologic injury as a cause of symptoms.

**DIFFERENTIAL DIAGNOSIS**

Other exogenous causes of hypoglycemia include:

- Ackee fruit
- Ethanol
- Medications (eg, beta-adrenergic antagonists, propoxyphene, quinine, quinidine, salicylates, streptozocin, sulfonamides, valproic acid)
- Hypoglycemic agents mentioned here

**TREATMENT**

**PRE HOSPITAL**

- Assess and stabilize airway, breathing, and circulation.
- If normal mental status, glucose-rich food and drink should be given.
- If hypoglycemic, administer oral or IV dextrose; if indicated by local protocol, administer glucagon.

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Immediately assess the blood glucose level:
  - Treat symptomatic hypoglycemia immediately, even before results of bedside glucose testing are unavailable.
- Carbohydrate-rich food and drink may be given if normal mental status and no concerns regarding ability to maintain an airway.
- Consider treatment with a bolus of IV dextrose.

**MEDICATION**

- Dextrose:
  - Infants: D10W, 0.5 g/kg IV
  - Children: D10W–D25W, 0.5 g/kg IV
  - Adults: D50W, 0.5–1.0 g/kg IV
  - Repeat as necessary.

- Treatment of insulin-induced hypoglycemia involves continuous infusion of IV dextrose with either D5W or D10W titrated to maintain euglycemia.
- Glucagon: <20 kg, 0.5 mg/dose or 0.02 mg/kg/dose IM/IV/SC q20min PRN (max 3 doses); 20–40 kg, 1 mg/dose IM/IV/SC q20min; adult, 2 mg/dose IM/IV/SC q20min PRN (max 3 doses)
- Octreotide 1 μg/kg SC q6–8h; adult dose, 50–100 μg q8h:
  - Inhibits pancreatic insulin release
  - Is most typically indicated for hypoglycemia secondary to sulfonylurea toxicity:
    - Patients should be treated for a minimum of 24 hr with continued blood glucose concentration monitoring. Treatment should continue >24 hr if hypoglycemia persists.
    - Frequent blood glucose concentrations should be monitored for an additional 12–24 hr after termination of octreotide prior to discharge.
    - Infusion of IV dextrose in the setting of sulfonylurea-induced hypoglycemia will stimulate the pancreas to release insulin, thereby causing recurrent hypoglycemia, and is therefore not recommended.
  - May be used to treat hypoglycemia associated with meglitinides, incretin, and incretin enhancers
  - May be used adjunctively to treat recurrent hypoglycemia requiring bolus or infusion dextrose resulting from long-acting insulin overdose in patients without type 1 diabetes:
    - Use in patients with type 1 diabetes is expected to be futile, as they are unable to release endogenous insulin.

**SURGERY/OTHER PROCEDURES**

Surgical excision or ice applied to area of SC insulin overdose is of potential but unproven benefit.

**DISPOSITION**

**Admission Criteria**

- All cases of toxin-induced hypoglycemia:
  - Type 1 diabetics taking therapeutic doses of insulin who become hypoglycemic upon missing a meal are an exception; they may be discharged from the emergency department when stable.
- All cases of intentional overdoses
- Pediatric ingestion of any nontherapeutic sulfonylureas always requires admission regardless of whether hypoglycemia is present:
  - Asymptomatic patients should be admitted for 24 hr of observation and blood glucose monitoring.
- Recommended for exposures to meglitinides and incretin mimetics and incretin enhancers
- Although hypoglycemia is not expected to occur following thiazolidinedione exposure, clinical experience is limited and hospital admission for observation is recommended.

**Discharge Criteria**

- Insulin toxicity:
  - Type 1 diabetics taking therapeutic doses of insulin with hypoglycemia after missing a meal may be discharged when stable.
  - Long-acting insulin overdose may be discharged after blood sugar is stable without administration of parenteral glucose or glucagon for 12–24 hr.

- Metformin/Phenformin:
  - Patients should be observed in the emergency department for at least 6 hr following any large metformin or phenformin exposure. May be discharged if they remain euglycemic and do not develop lactic acidosis during this time.
- Acarbose does not cause systemic toxicity, and patients may be discharged.
- Patients treated for hypoglycemia may be safely discharged upon maintaining euglycemia for 12–24 hr after discontinuation of dextrose, glucagon, or octreotide therapy.

**Issues for Referral**

- Consult a poison control center or medical toxicologist for assistance in management.
- Patients who present following an intentional overdose require a psychiatric evaluation.

**FOLLOW-UP**

**PROGNOSIS**

- Varies depending on agent and dose
- Insulin reliably causes hypoglycemia; sulfonylureas often cause delayed and/or prolonged hypoglycemia.

**COMPLICATIONS**

- Seizure
- Permanent neurologic injury

**ADDITIONAL READING**

- Bronstein AC, Spyker DA, Cantilena JR, et al. 2007 Annual Report of the American Association of Poison Control Centers' National Poison Data System (NPDS): 25th Annual Report. *Clin Toxicol*. 2008;46:927–1057.
- Seltzer HS. Drug-induced hypoglycemia. A review of 1418 cases. *Endocrinol Metab Clin North Am*. 1989;18:163–183.
- Spiller HA, Sawyer TS. Toxicology of oral antidiabetic medications. *Am J Health Syst Pharm*. 2006;63:929–938.

**CODES**

**ICD9**

- 251.1 Other specified hypoglycemia
- 962.3 Poisoning by hormones and synthetic substitutes: insulines and antidiabetic agents

**PEARLS AND PITFALLS**

- Even brief periods of significant hypoglycemia may result in permanent neurologic injury. It is critical to frequently assess blood glucose levels and respond to hypoglycemia by administration of glucose and other medications as indicated.
- Insulin overdose in type 1 diabetics is usually well tolerated and does not usually necessitate hospital admission.
- Ingestion of sulfonylureas warrants prolonged observation and hospital admission even if initially asymptomatic.

# HYPOKALEMIA

Teresa M. Romano  
Colette C. Mull

## BASICS

### DESCRIPTION

- Hypokalemia is defined as a serum potassium concentration  $<3.5$  mEq/L (1).
- One of the most common electrolyte disturbances in sick children
- Mild hypokalemia ( $K^+ = 3.0$ – $3.5$  mEq/L) is well tolerated, but severe hypokalemia may be associated with a high mortality rate.

### RISK FACTORS

- Renal disease
- Dehydration
- Medications, especially diuretics and beta-adrenergic agonists

### PATHOPHYSIOLOGY

- The ratio of intracellular to extracellular potassium is the major determinant of the resting membrane potential and results in the generation of the action potential in nerve and muscle cells (2).
- Abnormalities in serum potassium may have deleterious effects on cardiac and neuromuscular function.
- Potassium concentration is regulated by the kidney under the influence of various hormones:
  - Aldosterone release results in increased potassium excretion from the kidney
  - Glucocorticoids, antidiuretic hormone, high urinary flow rate, and increased sodium delivery to the distal nephron will also increase potassium excretion (2).

### ETIOLOGY

- Transcellular shifting:
  - Potassium moves into cells in alkalotic states and out of cells in acidotic states.
  - For every 0.1 unit change in pH, there is a reciprocal change in serum potassium of  $\sim 1$  mEq/L (2,3).
  - Insulin administration results in potassium movement into cells via stimulation of the sodium-potassium ATPase pump on the cellular membrane (2,3).
  - Beta-adrenergic agonists (exogenous albuterol or endogenous epinephrine) stimulate the sodium-potassium ATPase (2,3) pump, causing cellular uptake of potassium.
  - Toluene intoxication (paint or glue sniffing) can result in transcellular shifting and hypokalemia: Mechanism unclear (4).

- Decreased intake (2,3):
  - Anorexia nervosa
  - Bulimia
  - Habitual clay eating: Binds potassium and inhibits absorption
- Extrarenal losses (2,3):
  - Diarrhea
  - Laxative abuse
  - Extreme perspiration
- Renal losses (2,3):
  - Diuretic use (loop and thiazide diuretics)
  - Diabetic ketoacidosis (DKA)
  - Renal tubular acidosis (RTA) (distal, proximal)
  - Acute tubular necrosis
  - Hyperaldosteronism
  - Bartter syndrome
  - Gitelman syndrome
  - Magnesium deficiency

### COMMONLY ASSOCIATED CONDITIONS

- Gastroenteritis (2,3)
- Chronic use of loop diuretics for treatment of congenital heart disease or bronchopulmonary dysplasia
- DKA or nonketotic hyperglycemia
- Posttraumatic states
- Hyperthyroidism
- Familial periodic paralysis

## DIAGNOSIS

- Mild hypokalemia ( $K^+ = 3.0$ – $3.5$  mEq/L) is usually asymptomatic, and the diagnosis is based on the serum potassium value (2,3).
- Moderate and severe hypokalemia are typically diagnosed subsequent to lab investigation of the following clinical manifestations (2):
  - Dysrhythmias, conduction defects
  - Weakness, paralysis
  - Rhabdomyolysis
  - Constipation, ileus
  - Polyuria

### HISTORY

- Diarrhea
- Vomiting
- Constipation
- Polyuria
- Muscle weakness
- Medication use: Diuretics, beta-adrenergic agonists, laxatives
- Past medical history: Asthma, anorexia nervosa, bulimia, RTA, acute tubular necrosis, DKA, Bartter syndrome, Gitelman syndrome, hyperaldosteronism, magnesium deficiency

### PHYSICAL EXAM

- Confusion or lethargy
- Urinary retention
- Hypoactive bowel sounds
- Hyporeflexia
- Flaccid paralysis
- Acute respiratory failure
- Dysrhythmia

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Electrolytes:
  - Serum potassium levels only reflect extracellular potassium and therefore will not reflect total body potassium deficits.
- Blood gas:
  - In metabolic acidosis and DKA, serum potassium may underestimate the total body potassium deficit.
  - A combination of hypokalemia and metabolic acidosis supports a diagnosis of diarrhea, RTA, or DKA (2).
  - A combination of hypokalemia and metabolic alkalosis supports a diagnosis of emesis or NG losses, mineralocorticoid excess, or use of diuretics (2).
- Creatine phosphokinase and urinary myoglobin to evaluate for rhabdomyolysis
- BUN and creatinine
- Glucose

##### Diagnostic Procedures/Other

#### ECG:

- Changes consistent with hypokalemia include prolonged PR interval, flattened T wave, depressed ST segment, and U waves (2).
- Ventricular fibrillation and torsades de pointes can occur in hypokalemic patients with underlying heart disease.

### DIFFERENTIAL DIAGNOSIS

See Etiology.

## TREATMENT

### PRE HOSPITAL

Assess and stabilize airway, breathing, and circulation.

#### Initial Stabilization and Therapy

- Hypokalemia resulting from transcellular shifting is transient and rarely requires replacement because total body potassium remains normal (2,5).
- Potassium correction is based on the potassium level, presence of clinical symptoms, and baseline renal function as well as continued potassium losses (2,3):
  - Decreased renal function limits the kidneys' ability to excrete excess potassium. Providing supplementation to such a patient may result in hyperkalemia.

- Oral, as opposed to IV, potassium supplementation is safer, as the potassium is slower to enter the circulation, allowing for ease of titration to effect.
- IV administration is necessary in patients with severe symptoms requiring emergent or urgent correction.
- Hypokalemia associated with cardiac dysrhythmia or severe hypokalemia (potassium concentration <2.2–2.5 mEq/L), even without cardiac dysrhythmia, should be treated with parenteral potassium therapy.
- Other hypokalemia may be treated with oral potassium.

## MEDICATION

### First Line

- IV fluid administration with added potassium chloride may be sufficient in the setting of gastroenteritis-induced hypokalemia (5).
- 3 salts are available for IV potassium administration. Selection of the appropriate salt depends on the identity of the anion lost with the potassium:
  - Potassium phosphate for cases associated with hypophosphatemia
  - Potassium bicarbonate or potassium acetate for cases of concurrent metabolic acidosis
  - In all other clinical settings, potassium chloride is the preferred salt.
  - Potassium dosing is the same independent of the associated salt. For simplicity, potassium chloride dosing is provided here.
- Potassium chloride oral dose: 1–2 mEq/kg/dose PO:
  - Typical oral dose for older children or adolescents 20 mEq/kg, max oral dose 40 mEq/dose
  - May repeat oral dosing q4–8h.
- Potassium chloride IV dose 0.5–1 mEq/kg/dose infused over a minimum of 1 hr:
  - Dilution of the potassium solution is required to prevent phlebitis.
  - Typically, potassium chloride is added to normal saline; 20–40 mEq KCL added to 1 L of normal saline
  - For use in peripheral veins, 20 mEq/hr is the maximum feasible dosing, but lower infusion rates are better tolerated.
  - Rarely, such as in cases of ventricular dysrhythmia, higher infusion rates and dosing are necessary:
    - This may be possible through a central venous or intraosseous line; up to 200 mEq/L potassium chloride in normal saline.
    - These high concentrations cannot be delivered via peripheral venous lines.
  - Empiric dose of 10 mEq/dose may be used for large children, adolescents, or adults.
  - Continuous ECG monitoring is required.
  - When providing IV potassium, administration of excess potassium and creation of hyperkalemia may occur quickly.

### Second Line

- In patients with ongoing losses of potassium secondary to diuretic use, the addition of a potassium-sparing diuretic (eg, spironolactone) can be used to restore serum levels to normal (3):
  - 1.5–3 mg/kg/day PO divided t.i.d.
  - Monitor renal function and serum potassium to avoid hyperkalemia.
- Magnesium deficiency will cause potassium secretion by the kidney through an unknown mechanism. Therefore, it is important to correct any magnesium deficiency in the setting of hypokalemia:
  - Magnesium sulfate 50 mg/kg IV, max single dose 2 g
  - The magnesium infusion rate should not exceed 1 mEq/kg/hr.
- Chloride: Hypokalemia with alkalosis may be resistant to treatment unless volume repletion and hypochloremia is corrected by normal saline.

## DISPOSITION

### Admission Criteria

- Requirement for IV potassium replacement
- Patients with decreased renal function who require potassium supplementation should be admitted for electrolyte monitoring.
- Patients with ongoing potassium losses
- Critical care admission criteria:
  - Cardiac dysrhythmia

### Issues for Referral

Consider consultation with a nephrologist or cardiologist prior to initiating any oral potassium supplementation in patients with hypokalemia from ongoing renal losses.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

#### DIET

For patients with continued potassium losses, a diet rich in potassium can help to increase serum potassium levels: Dried fruits, nuts, avocados, spinach, tomatoes, broccoli, bananas, cantaloupe, kiwis, red meat.

#### COMPLICATIONS

- Cardiac dysrhythmia as a result of hypokalemia or secondary to overcorrection and hyperkalemia
- Correction of hypokalemia resulting from transcellular shifting can result in hyperkalemia because total body potassium stores (in the case of transcellular shifting) are normal.
- Phlebitis from IV infusion

## CODES

### ICD9

276.8 Hypopotassemia

## PEARLS AND PITFALLS

- For every 0.1 unit change in pH, there is a reciprocal change in serum potassium of ~1 mEq/L.
- Mild hypokalemia (K<sup>+</sup> = 3.0–3.5 mEq/L) is usually asymptomatic, and the diagnosis is based on the serum potassium value.
- Serum potassium levels only reflect extracellular potassium and therefore will not reflect total body potassium deficits.
- ECG changes consistent with hypokalemia include prolonged PR interval, flattened T wave, depressed ST segment, and U waves.
- When repleting potassium, repeated measurement of serum potassium levels is necessary. If using an IV potassium infusion, measurement after each IV infusion run of potassium should be performed.
- When administering IV potassium, keep the patient on continuous ECG monitoring.

# HYPONATREMIA

Masafumi Sato

Christopher J. Haines

## BASICS

### DESCRIPTION

- *Hyponatremia* is defined as a measured serum sodium (Na) level <130 mEq/L.
- Symptoms are typically vague and dependent upon the Na concentration, rate of decrease, and duration (acute vs. chronic).
- The most common electrolyte abnormality among hospitalized patients (1)

### RISK FACTORS

- Children <6 mo of age
- Burns
- Medications

### GENERAL PREVENTION

Parents of young infants should receive anticipatory guidance to prevent hyponatremia including:

- Instructions to properly mix formula
- Avoidance of intake of free water to prevent water intoxication

### PATHOPHYSIOLOGY

- Hyponatremia is a state of low Na relative to total body water (TBW).
- Total body Na determines extracellular fluid volume.
- Serum Na is regulated by the interplay of:
  - Hypothalamic osmoreceptors
  - Thirst mechanism
  - Antidiuretic hormone (ADH) levels
  - Renin-angiotensin-aldosterone system
  - Kidneys work to prevent hyponatremia through urinary dilution and excretion of free water.
- Acute hyponatremia is a rapid Na decrease in 24–48 hr.
- Chronic hyponatremia is a slow Na decrease over days to weeks.
- See Etiology.

### ETIOLOGY

- Mechanisms responsible for the development of hyponatremia:
- Hypovolemic hyponatremia (decreased TBW and Na):
  - GI loss: Vomiting, diarrhea
  - Renal losses: Diuretics, renal tubular acidosis, nephropathy
  - 3rd space losses: Burns, ascites, pancreatitis, peritonitis
  - Adrenal: Mineralocorticoid deficiency
- Hypervolemic hyponatremia (increased TBW, edema-forming states):
  - Iatrogenic, SIADH
  - Water intoxication
  - Hypothyroidism
  - Glucocorticoid deficiency
  - Nephrotic syndrome
  - Congestive heart failure (CHF)
  - Cirrhosis
  - Psychogenic polydipsia
- Hyperosmolar hyponatremia (normal TBW and Na):
  - Hyperglycemia
  - Mannitol therapy

- Pseudohyponatremia (normal total body Na):
  - Hyperlipidemia
  - Hyperproteinemia
  - Diabetic ketoacidosis (DKA)
- Drug and medication induced:
  - Stimulation of ADH:
    - Clofibrate
    - Cyclophosphamide
    - Carbamazepine
    - Vincristine, vinblastine
    - Oxytocin
    - Bromocriptine
    - Ecstasy (MDMA)
  - Increased sensitivity to ADH:
    - Chlorpropamide
    - NSAIDs

### COMMONLY ASSOCIATED CONDITIONS

- Acute gastroenteritis (AGE)
- Water intoxication
- CHF
- Liver failure
- Pancreatitis
- DKA
- Congenital adrenal hyperplasia (CAH)
- Renal failure
- Nephrotic syndrome
- Conditions associated with SIADH:
  - Intracranial pathology: Meningitis, bleeding
  - Pulmonary pathology: Pneumonia, abscess
  - Use of medications associated with SIADH

## DIAGNOSIS

### HISTORY

- Presentation of hyponatremia is nonspecific and dependent upon the serum Na level and rate of decrease.
- Children usually present with symptoms related to the condition causing the hyponatremia rather than with symptoms directly related to the hyponatremia itself.
- Na level 125–130 mEq/L:
  - GI symptoms predominate
  - Weakness, anorexia, muscle cramps, and headache may also be present.
- Na level <125 mEq/L:
  - Neurologic symptoms including seizures, confusion, lethargy, altered mental status, coma, abnormal respiratory pattern
- Assessment of intake and output should be made including a detailed dietary history, fluid intake, and urinary and GI output.
- Assessment should be directed toward the suspected primary etiology as well as past medical problems and medications:
  - AGE: Amount of vomiting and diarrhea, history of weight loss or poor urine output
  - CAH: Feeding difficulties, abnormal appearance of genitalia, weight loss
  - Pneumonia/Abscess: Length of illness, severity of illness
  - Meningitis: History of fever, neck pain, headache, photophobia
  - Medications: Dose, concentration, duration

- Young infants presenting with new-onset seizures should be assessed for water intoxication–induced hyponatremia:
  - Assess the formula type, amount of water added, other fluid types (teas), and additional water given to the infant.
- Past medical history should focus on heart, renal, or liver disease.

### PHYSICAL EXAM

- Na level 125–130 mEq/L:
  - Physical findings are generally nonspecific, including weakness, muscle tenderness on palpation, and signs of dehydration.
- Na level <125 mEq/L:
  - Neurologic signs begin to predominate including seizures, gait abnormalities, altered mental status, Cheyne-Stokes respirations
- Severe hyponatremia (Na level <120 mEq/L or a rapid decline) may present with signs of cerebral herniation, including:
  - Coma, abnormal posturing, pupillary dilation, bradycardia, HTN
- The exam should be directed at identifying the underlying etiology:
  - Meningitis/Intracranial pathology:
    - Altered mental status, meningismus, petechia, purpura
  - Pneumonia/Abscess:
    - Crackles, decreased airflow
  - AGE:
    - Dry mucous membranes, sunken eyes, poor skin turgor
  - CHF:
    - Crackles, gallop rhythm, peripheral edema, hepatomegaly
  - CAH:
    - Ambiguous genitalia in female, signs of dehydration
  - Nephrotic syndrome:
    - Weight gain and pitting edema in periorbital, scrotal, or pretibial regions
  - Liver disease:
    - Icteric sclera, ascites, hepatomegaly
  - DKA:
    - Altered mental status, severe dehydration with dry mucous membranes and poor skin turgor, Kussmaul respirations

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Serum:
  - Electrolytes, BUN/creatinine (Cr)
  - Osmolality
  - LFTs
  - Serum glucose
- Urine:
  - Urinalysis with specific gravity
  - Urine osmolality
  - Urine Na
  - Urine Cr
- CSF should be sent for analysis if meningitis is suspected.
- A venous blood gas should be ordered if DKA is suspected.

- Total protein and albumin levels will be helpful to assess for nephrotic syndrome.
- A random serum cortisol level should be obtained if adrenal hyperplasia is suspected.
- Correction of measured Na level is required in the presence of hyperglycemia:
  - 1.6 mEq/L of Na should be added for each 100 mg/dL increase of glucose above normal.

### Imaging

- Imaging studies should be obtained selectively.
- CXR:
  - May assist with diagnosis of pneumonia (SIADH) or CHF
- Head CT scan:
  - Should be emergently obtained in children with acute onset of altered mental status, seizure with associated hyponatremia, or a precipitous drop in Na

### DIFFERENTIAL DIAGNOSIS

- Pseudohyponatremia:
  - Hyperlipidemia, hyperproteinemia, hyperglycemia
- Altered mental status and seizures:
  - Hypoglycemia
  - Hypocalcemia
  - Medication/Drugs
  - Metabolic diseases
  - Nonaccidental head injury
- SIADH

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Prompt evaluation of airway, breathing, and circulation
- Treatment of respiratory arrest, seizure, coma, or cerebral herniation warrants immediate, definitive therapy:
  - Endotracheal intubation, administration of hypertonic saline
- Continuous cardiopulmonary monitoring should be implemented.
- Supplemental oxygen and airway management should be provided as needed.
- Establish IV access.
- Measure serum glucose for altered mental status or seizure.
- Acute correction:
  - If the child is symptomatic (eg, seizures) with a serum Na < 125 mEq/L, treatment using 3% hypertonic saline (513 mEq/L) is indicated (2).
  - 2 mL/kg doses should be given up to 3 doses over 15 min (max 5–6 mL/kg) with a reassessment after each dose (3).
  - Hypertonic replacement should be discontinued if the patient becomes asymptomatic.
  - 1 mL/kg of 3% saline will raise the serum Na ~1 mEq/L.
  - The initial target Na level should be 125–130 mEq/L.
  - Hypertonic saline is the treatment of choice in seizures associated with low Na levels.
  - Frequently, hyponatremic seizures will be refractory to anticonvulsants.

- Chronic correction:
  - Early consultation with a nephrologist is recommended after acute correction, as rapid correction of chronic hyponatremia increases the risk of central pontine myelinolysis.
  - Na deficiency can be calculated by the following equation:  $0.6 \text{ (volume of distribution)} \times \text{weight (kg)} \times (\text{target Na} - \text{measured Na})$
  - Following the acute correction, Na should be raised gradually at ~0.5 mEq/L/hr (or 10–12 mEq/L/day).
- Hypovolemic hyponatremia:
  - Restore cardiac output and organ perfusion.
  - Isotonic volume expansion with 0.9% normal saline IV
- Euvolemic and hypervolemic hyponatremia:
  - Initial complete fluid restriction followed by restriction to 1,000 mL/m<sup>2</sup>/day
- Pseudohyponatremia, hypertonic hyponatremia:
  - Treatment of the underlying etiology

### MEDICATION

- Acute correction:
  - 3% saline
- Hypovolemic, hyponatremia:
  - 0.9% saline
- Hypervolemic, hyponatremic:
  - Furosemide 1–2 mg/kg IV

### DISPOSITION

#### Admission Criteria

- Critical care admission criteria:
  - Intensive care admission is recommended for:
    - Initial serum Na levels of < 120 mEq/L
    - Symptomatic patients with altered mental status, status epilepticus, signs of respiratory insufficiency, hemodynamic instability, signs of cerebral edema
- Disposition is dependent on the underlying etiology, but patients with the following Na levels should be considered for admission:
- Serum Na level < 130 mEq/L
- Mild to moderately symptomatic patients with a serum Na of 131–134 mEq/L

#### Discharge Criteria

- Asymptomatic patients with a serum Na level > 120 mEq/L, known underlying etiology, no comorbid factors, close follow-up
- Asymptomatic patients with a serum Na > 130 mEq/L of unknown etiology

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Provide instructions for continued monitoring of daily intake and output.
- Provide parameters in which patients should return and/or follow up with their pediatrician.

### PROGNOSIS

- Dependent on underlying cause
- Rapid development of hyponatremia (< 48 hr) is associated with higher incidence of permanent neurologic sequelae (4).

### COMPLICATIONS

- Seizure
- Status epilepticus:
  - Published literature has described an association between hyponatremic seizures and low core temperature (< 36.5°C) (5).
- Cerebral edema and herniation
- Central pontine myelinolysis:
  - Associated with rapid correction of hyponatremia (5)

### CODES

#### ICD9

- 276.1 Hyposmolality and/or hyponatremia
- 775.5 Other transitory neonatal electrolyte disturbances

### PEARLS AND PITFALLS

- Suspect hyponatremia in seizing infants < 6 mo of age, especially if they are hypothermic or refractory to anticonvulsant therapy (5).
- Use 3% saline for the acute correction of symptomatic hyponatremia.
- After acute correction of hyponatremia, the Na level should be raised slowly to avoid severe complications.

# HYPOPARATHYROIDISM

Amy D. Thompson

## BASICS

### DESCRIPTION

Hypoparathyroidism is a condition of decreased levels or effectiveness of parathyroid hormone (PTH).

### EPIDEMIOLOGY

#### Incidence

Hypoparathyroidism most commonly occurs as transient neonatal hypoparathyroidism.

### RISK FACTORS

- Prematurity
- Genetic
- Neck surgery or irradiation
- Medications

### PATHOPHYSIOLOGY

- PTH functions to maintain serum calcium levels and manage bone metabolism.
- The plasma calcium level is the prime regulator of PTH secretion.
- PTH acts on bone to release calcium and phosphorus, on the kidney to decrease calcium clearance and inhibit phosphate reabsorption, and in the gut to indirectly stimulate calcium and phosphorus absorption by converting 25-hydroxyvitamin D to 1,25 dihydroxyvitamin D.
- The net effects of PTH activity are an increase in serum calcium levels and a decrease in serum phosphorus levels.
- Insufficient production of PTH is known as hypoparathyroidism, while target organ resistance to PTH is known as pseudohypoparathyroidism.

### ETIOLOGY

- Hypoparathyroidism may be transient, inherited/congenital, acquired, or idiopathic.
- Transient neonatal hypoparathyroidism:
  - May occur during the 1st 3 wk of life due to parathyroid gland immaturity; preterm infants are at increased risk.
  - Maternal hyperparathyroidism can cause transient hypoparathyroidism in the newborn when maternal PTH suppresses neonatal parathyroid activity.
  - Infants of diabetic mothers are at risk for hypomagnesemia, which can impair PTH release and function
- Inherited/Congenital hypoparathyroidism:
  - There are autosomal dominant, autosomal recessive, and x-linked recessive forms of familial PTH deficiency.
  - Arises from genetic mutations that impair PTH synthesis, secretion, function, or regulation
  - Hypoparathyroidism in DiGeorge syndrome is secondary to developmental hypoplasia of the parathyroid gland.
  - Hypoparathyroidism in autosomal dominant hypercalciuric hypocalcemia is caused by activating mutations of the parathyroid and renal calcium-sensing receptor.

- Acquired hypoparathyroidism:
  - Surgery or irradiation of the neck
  - Disorders of deposition or infiltration impairing PTH secretion include metastatic carcinoma, Wilson disease, thalassemia, and hemochromatosis.
  - Destruction of the parathyroid gland occurs in autoimmune disorders such as autoimmune polyglandular syndrome type I.
  - In mitochondrial encephalomyopathy (ie, Kearns-Sayre syndrome), PTH secretion can be affected by the intracellular metabolic abnormality.
  - Functional deficiency occurs in the case of both hypermagnesemia and hypomagnesemia through attenuation of PTH secretion.
- Medication-induced hypoparathyroidism: Aluminum, doxorubicin, omeprazole, aminoglycoside, cimetidine, or alendronate

### COMMONLY ASSOCIATED CONDITIONS

- See Complications.
- DiGeorge syndrome
- Kenny-Caffey syndrome
- Kearns-Sayre syndrome
- Blomstrand chondrodysplasia
- Autoimmune polyglandular syndrome type I
- Albright hereditary osteodystrophy

## DIAGNOSIS

### HISTORY

- The predominant historical features of hypoparathyroidism are secondary to hypocalcemia, most notably tetany.
- The severity of symptoms depends upon the absolute level of calcium as well as the rate of decrease.
- Symptoms of tetany include perioral and acral numbness, paresthesias, muscle cramps, myalgias, intestinal and biliary colic, laryngospasm, bronchospasm, and seizures.
- Additional symptoms of hypocalcemia include lethargy, irritability, psychosis, anxiety, and depression.
- Symptoms of chronic hypocalcemia include dry skin, brittle nails, recurrent dental caries, visual changes, dementia, and movement disorders.
- A past medical history or family history of sensorineural deafness, renal dysplasia, chronic candidiasis, vitiligo, recurrent infections, congenital heart disease, and mental retardation are associated with syndromes that include hypoparathyroidism.

### PHYSICAL EXAM

- Vital signs with attention to:
  - Respiratory insufficiency, bradycardia, and hypotension.
- The prevailing clinical manifestations of hypoparathyroidism are the same as those of hypocalcemia.
- Additional exam findings may be indicative of syndromes that include hypoparathyroidism.
- Ophthalmologic: Cataracts, keratoconjunctivitis, and papilledema

- Cardiovascular: Dysrhythmias, hypotension, and heart failure
- Pulmonary: Stridor, wheezing, and apnea
- GI: Abdominal distention and vomiting
- Ectodermal: Candidiasis, xerosis, coarse hair, dental hypoplasia, and alopecia
- Psychiatric: Psychosis, depression, and anxiety
- Neurologic: Hyperreflexia, paresthesias, tremors, dystonia, ataxia, seizures, papilledema, and altered mental status
- Classic exam findings that may indicate tetany include the Trousseau sign and the Chvostek sign:
  - Chvostek sign: Contraction of the facial muscles following tapping on the facial nerve anterior to the ear
  - Trousseau sign: Contraction of the hand and forearm muscles following occlusion of the brachial artery above systolic BP
  - The Trousseau sign has both a higher sensitivity and specificity than the Chvostek sign.
- Features of DiGeorge syndrome include cleft palate, micrognathia, ear anomalies, short philtrum, conotruncal cardiac defects, and thymus aplasia.
- Features of Albright hereditary osteodystrophy include round facies, dental anomalies, short distal thumb phalanges, obesity, short stature, and developmental delay.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Total and ionized serum calcium: Low in hypoparathyroidism and pseudohypoparathyroidism
- Albumin level: Required to correct for total serum calcium
  - Corrected calcium =  $[0.8 \times (\text{normal albumin} - \text{patient's albumin})] + \text{patient's calcium}$
- Serum phosphorus: Elevated
- Serum magnesium: Normal
- Intact PTH: Low in hypoparathyroidism and elevated in pseudohypoparathyroidism; may be inappropriately normal in calcium-sensing receptor mutations
- 1,25-dihydroxyvitamin D: Low in hypoparathyroidism but may be normal to elevated in pseudohypoparathyroidism
- If an autoimmune process is suspected, thyroid studies, adrenal antibody levels, and adrenocorticotropic hormone levels may be considered.

#### Imaging

- A chest radiograph and echocardiogram should be performed in all patients in whom DiGeorge syndrome is being considered.
- While a head CT is not routinely recommended in the workup of hypoparathyroidism, intracranial calcifications may be seen in patients with long-standing disease.

#### Diagnostic Procedures/Other

ECG may show bradycardia or a prolonged QT interval; ST segment elevation mimicking MI have also been reported.

**DIFFERENTIAL DIAGNOSIS**

- Hypocalcemia of other etiology
- Hypomagnesemia
- Hyperventilation syndrome
- Renal failure
- Vitamin D deficiency
- Addison disease
- Osteoblastic activity, including carcinoma

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Symptomatic hypocalcemia is a medical emergency.
- Assess and stabilize airway, breathing, and circulation.
- Respiratory arrest and cardiac dysrhythmia are complications of hypocalcemic hypoparathyroidism.
- Vascular access should be promptly obtained.
- The patient should be placed on continuous cardiac monitoring.

**MEDICATION****First Line**

- Calcium gluconate 10%: 0.5–1.0 mL/kg given over 3–5 min:
  - Administer for severe, symptomatic hypocalcemia; prolonged QT interval; and acute decreases in total serum calcium  $\leq 7.5$  mg/dL.
  - If necessary, may be repeated or started on a continuous 1–3 mg/kg/hr elemental calcium infusion of 10% calcium gluconate
  - Extravasation may lead to local tissue necrosis.
  - The calcium infusion should be stopped if heart rate is  $< 60$  bpm.
  - Once serum calcium levels are in a safe range ( $> 7.5$  mg/dL) and the patient is asymptomatic, transition is made to oral calcium.
- Oral calcium gluconate, calcium citrate, and calcium carbonate can be used for maintenance therapy or to correct mildly symptomatic hypocalcemia:
  - The dose of oral calcium gluconate is 50–75 mg/kg/day of elemental calcium divided into 4–6 doses per day.

**Second Line**

- Treatment of chronic hypoparathyroidism involves vitamin D and oral calcium.
- Calcitriol (1,25-dihydroxyvitamin D) is 0.01–0.04  $\mu\text{g}/\text{kg}/24$  hr:
  - Calcitriol's action begins in 1–2 days and ceases after 2–4 days.
- Calcium and vitamin D supplementation should be administered cautiously to patients with calcium-sensing receptor mutations. These patients rarely have symptomatic hypocalcemia and are at increased risk for nephrocalcinosis.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Early work on replacement PTH as an alternative to calcitriol has been promising but is not currently the standard of care in children.
- Relative to vitamin D, treatment with PTH would avoid the harmful side effects of hypercalcemia.

**DISPOSITION****Admission Criteria**

- Symptomatic hypocalcemia patients
- Patients with acute decreases in serum calcium to  $\leq 7.5$  mg/dL
- Patients unable to tolerate oral supplements
- Critical care admission criteria:
  - Patients with cardiac dysrhythmia other than mild sinus bradycardia, hypocalcemic seizures, tetany, or respiratory compromise should be managed in a critical care setting.

**Discharge Criteria**

Stable patients without significant or symptomatic hypocalcemia

**Issues for Referral**

A pediatric endocrinologist should be consulted.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Follow-up is dependent on the causative agent of hypoparathyroidism.
- To avoid harmful effects of hypercalcemia, serum calcium levels should be monitored closely until stable.
- Families should be aware of the symptoms and signs of hypocalcemia.

**DIET**

A formula with a low phosphate content supplemented with calcium such as Similac PM 60/40 can be used for infants with associated hyperphosphatemia.

**COMPLICATIONS**

- Respiratory insufficiency
- Respiratory arrest
- Bradycardia
- Cardiac dysrhythmia
- Tetany
- Seizure

**CODES****ICD9**

- 252.1 Hypoparathyroidism
- 775.4 Hypocalcemia and hypomagnesemia of newborn

**PEARLS AND PITFALLS**

- Hypoparathyroidism is insufficient production of PTH, while target organ resistance to PTH is considered pseudohypoparathyroidism.
- Symptomatic hypocalcemia is a medical emergency.
- The most significant clinical finding related to hypoparathyroidism are secondary to hypocalcemia.

# HYPOTENSION

Jeranil Nunez

## BASICS

### DESCRIPTION

- *Hypotension* is defined as a systolic BP <5th percentile for age:
  - Newborn (0–1 mo): <60 mm Hg
  - Infant (1 mo to 1 yr): <70 mm Hg
  - Child (>1 yr):  $<70 + [2 \times (\text{age in years})]$  (1)
  - >10 yr of age: <90 mm Hg
- Hypotension is a late finding in children with cardiopulmonary compromise and signifies impending decompensated shock, which results in end organ dysfunction.
- Once hypotension is identified, treatment should be initiated to stabilize the symptomatic patient while an underlying etiology is sought.
- Asymptomatic hypotensive patients should be evaluated for potential causes, but this topic will focus on acute symptomatic hypotension.
- Inappropriate BP cuff size is one of the most common reasons for low BP readings. Abnormal measurements should be repeated for accuracy.

### EPIDEMIOLOGY

#### Incidence

Depends on the underlying etiology. See specific topics for precise incidence.

### PATHOPHYSIOLOGY

- A change in any of the components that affect BP (blood volume, cardiac output, systemic vascular resistance) can lead to hypotension.
- Hypovolemia: A decrease in blood volume and central venous pressure leads to decreased cardiac output. In an attempt to normalize perfusion pressure, there is normally a compensatory increase in heart rate and systemic vascular resistance.
- Cardiogenic: Hypotension results from a decrease in cardiac output secondary to:
  - Cardiac dysfunction with reduced contractility
  - Obstruction to blood flow into the heart
  - Obstruction to outflow of blood from the heart
- Distributive: A decrease in normal peripheral vascular tone leads to decreased preload and cardiac output. Causes include:
  - Drugs/Toxins
  - Antigen exposure (anaphylaxis) or sepsis leading to release of vasoactive mediators (eg, histamine, leukotrienes, prostaglandins) from inflammatory cells causing vasodilation and increased vascular permeability
- Neurologic or spinal cord injury resulting in an interruption in sympathetic signals to vasomotor neurons causing vasodilation and/or unopposed parasympathetic stimulation
- Shock occurs when there is inadequate perfusion of tissues with a subsequent decrease in the delivery of oxygen and required nutrients and uptake of toxic metabolites.

### ETIOLOGY

- Shock:
  - Hypovolemic:
    - Abdominal trauma
    - Adrenal insufficiency, Addisonian crisis
    - Anemia
    - Methemoglobinemia
    - Aneurysms
    - Anorexia, bulimia
    - Arteriovenous malformations
    - Burns
    - Dehydration: Vomiting, diarrhea, diuretics, diabetes, poor oral intake, heat intolerance
    - Hemorrhage: Blunt or penetrating trauma, fractures, hemoptysis, hemorrhagic disease of the newborn, hemothorax, GI bleed, placenta previa, retroperitoneal bleed, ruptured ectopic pregnancy or hemorrhagic ovarian cyst, splenic rupture, traumatic brain injury in infants, vascular injuries
    - Intestinal obstruction
    - Severe ascites
  - Cardiogenic/Obstructive:
    - Cardiomyopathy
    - Conduction abnormalities/arrhythmia
    - Congenital heart disease, cardiac surgery
    - Esophageal rupture
    - MI
    - Myocardial contusion
    - Myocarditis
    - Pericardial tamponade
    - Pulmonary or air embolism
    - Tension pneumothorax
    - Valvular insufficiency
  - Distributive:
    - Anaphylaxis (food, drugs, latex, venom)
    - Neurogenic (head injury, spinal cord insult)
  - Sepsis:
    - Any infection or abscess
    - Bowel perforation
    - Infected indwelling prosthetic device
- Pharmacologic/Toxins:
  - Antihypertensives
  - Antidepressants
  - Barbiturates
  - Cholinergics
  - Digoxin
  - Narcotics
  - Nitrates
  - Sedative hypnotics

## DIAGNOSIS

### HISTORY

- A careful, detailed history can often help elucidate the etiology for hypotension.
- Newborn specific:
  - Gestational age
  - Prenatal screen or sonogram abnormalities
  - Perinatal/Postnatal infections or complications
  - Birth trauma
  - Excessive bleeding (vitamin K deficiency)
  - Cyanosis, tachypnea, diaphoresis with feeds
  - Failure to gain weight or weight loss
  - Maternal medications (breast-fed infants)

- Ambiguous genitalia
- Abnormal body odor (inborn error of metabolism)
- General history:
  - Trauma, spinal cord injury
  - Ingestions (medications, toxins)
  - Coagulopathy
  - Surgeries
  - Prior allergic reactions or antigen exposure
  - Fever or exposure to communicable disease
  - General symptoms can include:
    - Anxiety, irritability, lethargy
    - Dizziness, light-headedness
    - Diaphoresis
    - Difficulty breathing
    - Chest pain
    - Fatigue
    - Hemorrhage
    - Nausea
    - Vomiting, diarrhea
    - Abdominal pain
    - Increased or decreased urine output
    - Palpitations, tachycardia
    - Rash (urticarial, petechial, purpuric)

### PHYSICAL EXAM

- Signs of decreased cardiac output/perfusion:
  - Altered mental status (irritability, lethargy)
  - Tachycardia
  - Tachypnea
  - Diaphoresis
  - Pallor or mottled, ashen skin
  - Delayed capillary refill
  - Decreased peripheral pulses
  - Temperature instability: Hypo-/Hyperthermia
  - Extremities: Cool, clammy
- Cardiogenic shock:
  - Jugular venous distention
  - Lungs: Rales, rhonchi, crackles, wheeze
  - Cardiac: S3 gallop, murmur
  - Abdomen: Organomegaly
- Anaphylactic shock:
  - Respiratory compromise (stridor, hoarseness)
  - Urticaria, angioedema
- Neurogenic shock:
  - Flaccid paralysis, loss of rectal tone
  - Hypotension with bradycardia

### DIAGNOSTIC TESTS & INTERPRETATION

Lab evaluation and diagnostic testing is based on the suspected etiology. The following tests can help guide the initial patient management.

#### Lab

- CBC and C-reactive protein
- Capillary glucose measurement (bedside)
- Electrolytes
- Blood gas analysis
- Coagulation studies, disseminated intravascular coagulation panel
- Urinalysis
- Urine beta-hCG
- Cultures as indicated: Blood, urine, respiratory, wound, indwelling catheter, CSF

- Further tests based on suspected etiology:

- Cardiac enzymes
- Alcohol level
- Urine toxicology screen
- Lipase
- LFTs
- Lactic acid (elevated in shock)
- Ammonia level (urea cycle defects)
- Cortisol level (adrenal insufficiency)
- Drug/Medication specific levels

### Imaging

- CXR: Cardiomegaly, hemothorax, pneumonia, pneumothorax, pulmonary edema, widened mediastinum
- Brain CT: Intracranial hemorrhage, mass
- Abdominal US: Intraabdominal bleed, ectopic pregnancy, ovarian pathology, malignancy
- Abdominal CT: Abdominal aortic aneurysm, appendicitis, pancreatitis, traumatic injuries

### Diagnostic Procedures/Other

- ECG: Conduction abnormalities, ischemia, infarction, pulmonary embolism, tamponade
- Echo: Aortic coarctation, aortic dissection, cardiac tamponade, congenital heart lesions, wall motion abnormalities, MI
- Angiography: Pelvic fracture, retroperitoneal hemorrhage, lower GI bleeding, vascular injury:
  - Embolization of arterial bleed

### DIFFERENTIAL DIAGNOSIS

See Etiology.

## TREATMENT

### PRE HOSPITAL

- ABCs:
  - Administration of oxygen
  - IV/IO access: Crystalloid fluid resuscitation
  - Rapid 20 cc/kg bolus in noncardiogenic shock
- Tamponade active bleeding:
  - Direct manual pressure or pressure dressing
  - Long bone traction
  - External fixation of pelvis
- Capillary glucose measurement

### INITIAL STABILIZATION/THERAPY

- Supplemental oxygen (100%) via face mask
- Intubation for airway compromise, impending respiratory failure, or obtundation
- IV/IO access for immediate fluid resuscitation in most cases of hypotension
- Continuous cardiac monitoring
- Cardioversion/Defibrillation if indicated:
  - Unsynchronized: Start 2 joules/kg/dose
  - Synchronized: Start 0.5–1.0 joules/kg/dose

### MEDICATION

#### First Line

- Crystalloid fluid resuscitation IV/IO:
  - Normal saline/Lactated Ringer: 20 mL/kg rapid bolus × 3 as needed
  - Goal is to give 60 mL/kg within the 1st hour for patients with shock.
  - Use cautiously in patients with cardiogenic shock. Start with 10 mL/kg bolus if needed.

- Hypoglycemia (glucose <40 mg/dL):
  - Dextrose IV/IO:
    - Neonates: D10W 1–2 mL/kg bolus
    - Children: D25W 1–2 mL/kg bolus OR
  - Glucagon IM/IV/SQ, may repeat q20min:
    - <20 kg: 0.5 mg or 0.02–0.03 mg/kg, max single dose 1 mg
    - >20 kg: 1 mg

- Obtundation/Narcotic overdose:
  - Naloxone (Narcan): IV/IM/ET:
    - <20 kg: 0.1 mg/kg, max single dose 2 mg
    - >20 kg: 2 mg/dose
    - May repeat q2–3min
- Anaphylactic shock:
  - Epinephrine: IM 0.01 mg/kg (1:1,000 solution), may repeat q5–20min × 3, max single dose 0.5 mg
  - Albuterol/Racemic epinephrine nebulized PRN

### Second Line

- Obstructive shock: Patent ductus arteriosus–dependent lesions (newborn):
  - Prostaglandin E1: 0.05–0.1  $\mu$ g/kg/min IV
- Sepsis/Shock:
  - Early broad-spectrum antimicrobial coverage
  - Inotropic support:
    - Dopamine: 5–20  $\mu$ g/kg/min IV
    - Dobutamine: 5–20  $\mu$ g/kg/min IV
    - Norepinephrine 0.05–0.1  $\mu$ g/kg/min IV
    - Epinephrine 0.1–1  $\mu$ g/kg/min IV
  - PRBC: Transfuse cross-matched, type-specific, or O-negative blood 10 mL/kg IV
  - Blood products: Platelets, cryoprecipitate, fresh frozen plasma as indicated
- Addisonian crisis/Adrenal insufficiency:
  - Hydrocortisone 1–2 mg/kg bolus IV/IM
- Diabetic ketoacidosis:
  - Insulin infusion 0.05–0.1 units/kg/hr
- Specific treatment for electrolyte disturbances
- Drug-specific antidotes for known overdose

### SURGERY/OTHER PROCEDURES

- Needle thoracostomy: Tension pneumothorax
- Pericardiocentesis: Pericardial tamponade

### DISPOSITION

#### Admission Criteria

- All patients in shock
- Persistent electrolyte disturbances
- Etiology identified in a hemodynamically stable patient that requires further monitoring or more extensive evaluation/treatment
- Critical care admission criteria:
  - Respiratory failure necessitating intubation
  - Massive hemorrhage, persistent hemodynamic instability, need for inotropic support, life-threatening conduction abnormalities
  - Mental obtundation or coma
  - Severe metabolic acidosis pH <7.0
  - Multiorgan system failure

#### Discharge Criteria

- Non-life-threatening etiology
- Hemodynamic stability without end organ symptoms after initial stabilization and observation
- Appropriate outpatient follow-up

#### Issues for Referral

Subspecialty referral as indicated by etiology

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

As indicated by specific etiology

### PROGNOSIS

End organ dysfunction can be prevented or reversed if hypotension is recognized early and effective treatment of shock is quickly initiated.

### COMPLICATIONS

- Disseminated intravascular coagulation
- Acute respiratory distress syndrome
- End organ dysfunction
- Multiorgan system failure
- Death

## CODES

### ICD9

- 458.9 Hypotension, unspecified
- 779.89 Other specified conditions originating in the perinatal period

### PEARLS AND PITFALLS

- Hypotension is a late finding in children with cardiopulmonary compromise. For the symptomatic hypotensive patient, stabilization treatment should be initiated immediately to prevent progression to shock.
- Early recognition and effective treatment of shock are essential to prevent progression to irreversible multisystem organ failure and death.
- The main goals in the emergency department are appropriate treatment to prevent end organ injury and diagnosis of underlying cause of hypotension.

# HYPOTHERMIA

Masafumi Sato

Christopher J. Haines

## BASICS

### DESCRIPTION

- *Hypothermia* is defined as a reduction in core body temperature  $<35^{\circ}\text{C}$  ( $<95^{\circ}\text{F}$ ).
- Severity classification:
  - Mild:  $32\text{--}35^{\circ}\text{C}$  ( $90\text{--}95^{\circ}\text{F}$ )
  - Moderate:  $28\text{--}32^{\circ}\text{C}$  ( $82\text{--}90^{\circ}\text{F}$ )
  - Severe:  $<28^{\circ}\text{C}$  ( $<82.4^{\circ}\text{F}$ )
- Mechanisms of heat loss include:
  - Radiation, conduction, convection, evaporation

### EPIDEMIOLOGY

- Accounts for ~700 deaths each year (1)
- Mortality is estimated to be 0.3–0.4 per 100,000 persons in the U.S. (1).

### RISK FACTORS

- Pediatric population:
  - Large surface to volume ratio, especially among neonates
  - Immature thermoregulatory system
- Physical disability (immobilization)
- Disruption in the integumentary system
- Drug and alcohol ingestion
- Cold weather sports/activities
- Motor vehicle accidents/breakdown
- Wet, windy conditions even in a temperate environment
- Underlying medical conditions

### GENERAL PREVENTION

Hypothermia can be prevented by:

- Identifying vulnerable populations
- Providing education and anticipatory guidance
- Ensuring adequate nutrition
- Avoiding prolonged exposure to cold stress

### PATHOPHYSIOLOGY

- Change in environmental temperature is sensed by peripheral thermoreceptors and transmitted to the hypothalamus.
- The hypothalamus can also sense a change in core temperature directly responding via various mechanisms including:
  - Shivering, vasoconstriction, increased hormone release (thyroid, adrenal, epinephrine), piloerection, loss of sweating
- When these regulatory mechanisms fail and homeostasis is disrupted, hypothermia can result.

### ETIOLOGY

- Environmental exposure:
  - Most common mechanism: Immersion in cold water (conductive loss) and exposure to cold air (convective loss)
  - Drowning victims may experience more severe hypothermia secondary to the increased heat conductivity of water.
  - Neonates left unbundled in a cool environment
- Decreased production:
  - Malnutrition
- Increased loss:
  - Burns

- Infection/Sepsis
- Metabolic/Endocrine:
  - Adrenal insufficiency, hyponatremia, hypothyroidism, hypopituitarism
- CNS disease:
  - Head trauma, tumors, and strokes
  - Muscular dystrophies, amyotrophic lateral sclerosis, spinal muscular atrophy, cerebral palsy
- Toxins/Ingestions:
  - Ethanol (ETOH), sedative hypnotics, and narcotics

## DIAGNOSIS

### HISTORY

- Typically, a history of cold exposure is present.
- If history of prolonged cold or environmental exposure is not present, inquire about an underlying medical disorder.

### PHYSICAL EXAM

- Assess vital signs and respiratory and mental status; it is necessary to use a core-temperature thermometer capable of accurate low temperature measurements.
- The following signs/symptoms may be seen with the different stages of hypothermia:
  - Mild hypothermia— $32\text{--}35^{\circ}\text{C}$  ( $90\text{--}95^{\circ}\text{F}$ ):
    - Shivering, tachycardia, tachypnea
    - Confusion, amnesia, ataxia
  - Moderate hypothermia— $28\text{--}32^{\circ}\text{C}$  ( $82\text{--}90^{\circ}\text{F}$ ):
    - Lethargy, stupor, respiratory insufficiency
    - Loss of shivering reflex, muscle rigidity
    - Bradycardia, atrial/ventricular dysrhythmias
    - Pupillary dilatation
  - Severe hypothermia— $<28^{\circ}\text{C}$  ( $<82.4^{\circ}\text{F}$ ):
    - Appearance may mimic that of death with fixed/dilated pupils and rigor.
    - Coma, apnea
    - Decreased/Loss of reflexes, apnea
    - Hypotension, oliguria, pulmonary edema
    - Ventricular dysrhythmias (common with core temperature  $<28^{\circ}\text{C}$ )
    - Asystole (with core temperature  $<20^{\circ}\text{C}$ )

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Lab testing is not routinely necessary.
- The following lab studies should be obtained in patients with moderate or severe hypothermia:
  - CBC, coagulation panel, electrolytes including glucose, calcium, magnesium, phosphorous, creatine phosphokinase
  - Liver enzymes, amylase/lipase
  - Arterial blood gas with serum lactate
- Consider ETOH level, toxicologic screen, fibrinogen, thyroid function tests

#### Imaging

Chest radiograph may be useful in identifying aspiration pneumonia and pulmonary edema.

### Diagnostic Procedures/Other

ECG:

- Decreased sinus rate
- T-wave inversion
- Interval prolongation: RR, PR, QRS, QT
- J (Osborn) waves: Convex upward deflections (hump) at junction of QRS and ST segment
- Seen with core temperature  $<32^{\circ}\text{C}$
- Size correlates with the degree of hypothermia.

## TREATMENT

### PRE HOSPITAL

- Prompt assessment of ABCs with supplemental oxygen and airway support as needed
- Continuous cardiac monitoring
- Gentle handling of the patient, as ventricular fibrillation may occur spontaneously with trivial stimulation at temperatures  $<28^{\circ}\text{C}$
- Immediate passive rewarming
- Obtain a core temperature, if available.
- Check blood sugar.

### INITIAL STABILIZATION/THERAPY

- Continued management of the ABCs with supportive care
- Cardiac arrest and dysrhythmia are treated uniquely:
  - Cardiac arrest:
    - Return of circulation with no neurologic deficit has been reported after prolonged cardiac arrest due to hypothermia, such as with cold water drowning.
    - Resuscitation should continue until the patient's core temperature has been restored to that of mild hypothermia, or  $32\text{--}35^{\circ}\text{C}$  ( $90\text{--}95^{\circ}\text{F}$ ).
    - Defibrillation success with a hypothermia-induced arrhythmia and a core temperature  $<30^{\circ}\text{C}$  is rare but may be attempted.
    - Resuscitative measure should continue until the core temperature is  $>32^{\circ}\text{C}$  if hypothermia is believed to be the cause, rather than the result, of the arrest.
  - Dysrhythmia:
    - Ventricular dysrhythmia is common during rewarming and may be induced by rough handling or jostling the patient, chest compressions, or intracardiac pacing wire placement due to an irritable myocardium.
    - Electrical defibrillation attempts are usually unsuccessful at temperatures  $<30^{\circ}\text{C}$ .
    - Once  $>30^{\circ}\text{C}$ , amiodarone may be used effectively; avoid lidocaine use.
- Core temperature should be obtained upon arrival and continued through the emergency department course:
  - Low-reading thermometers should be used (rectal, bladder, or esophageal)
- Continuous cardiorespiratory monitoring
- Multiple large IV access sites
- Assess for and correct the following:
  - Hypoxemia/Hypercarbia, hypoglycemia, hypokalemia, hypocalcemia

- Supplemental oxygen should be continued, and early intubation may be necessary for:
  - Altered mental status, increased secretions, respiratory depression
  - Intubation should be done gently secondary to the risk of arrhythmia.
- Passive rewarming (temperature  $<32^{\circ}\text{C}$ ):
  - Minimize the heat loss, and allow the body to rewarm spontaneously.
  - Dry the patient, and cover the head and body with blankets.
  - Most cases of mild hypothermia can be safely managed with passive external warming.
- Rewarming technique depends on the degree of hypothermia, but faster rewarming yields better results than slower rewarming.
- Active external rewarming (temperature  $<32^{\circ}\text{C}$ ):
  - Overhead warming lights, forced heated air, thermal blankets, warm packs
  - Warm water baths
- Active internal rewarming ( $<32^{\circ}\text{C}$ ):
  - Warm IV fluids: The ideal fluid temperature used in active internal rewarming is between  $42^{\circ}\text{C}$  and  $44^{\circ}\text{C}$ .
  - Peritoneal lavage: 10–20 mL/kg of warmed normal saline is infused and drained after 20 min.
  - Pleural/Mediastinal lavage
  - 2 thoracostomy tubes are needed for infusion and drainage.
  - Successful case series have employed fluids warmed to  $41^{\circ}\text{C}$ , with 40 L infused over 20 min (3).
  - Extracorporeal rewarming
  - This is accomplished by several methods: Cardiopulmonary bypass, continuous arteriovenous rewarming, hemodialysis, venovenous hemofiltration.
- If sepsis is suspected, prompt initiation of antibiotics therapy is indicated.
- Decreased core temperature and severe hypotension secondary to peripheral vasodilatation (afterdrop phenomenon) can occur with all rewarming techniques when cold, acidic blood is shunted to the core.
- This should be anticipated and addressed with adequate fluid replacement to maintain mean arterial pressures.
- All labs should be checked in a serial fashion while in the emergency department.

#### MEDICATION

- Normal saline (0.9%) IV boluses (20 mL/kg):
  - Lactated Ringer solution should not be used in the resuscitation of hypothermic patients secondary to depressed hepatic function.
- IV dextrose 0.5–1 g/kg
- Amiodarone 5 mg/kg:
  - If pulseless, given as IV push
  - If pulse, infused over 20 min
  - Followed by continuous infusion beginning at  $5\ \mu\text{g}/\text{kg}/\text{min}$  and increasing up to  $15\ \mu\text{g}/\text{kg}/\text{min}$ , max single dose 20 mg/kg/24 hr

#### SURGERY/OTHER PROCEDURES

- Foley catheter
- NG tube
- Thoracostomy tube placement

#### DISPOSITION

##### Admission Criteria

- Critical care admission criteria:
  - Severe hypothermia, hemodynamic instability, respiratory insufficiency, signs of organ failure or dysfunction
- Symptomatic patients with mild hypothermia and all patients with moderate hypothermia should be admitted for further care and observation.

##### Discharge Criteria

Asymptomatic patients without an underlying medical disorder who have experienced mild hypothermia, have been successfully rewarmed, and have maintained their temperature in the emergency department for several hours may be considered for discharge.

#### FOLLOW-UP

##### FOLLOW-UP RECOMMENDATIONS

- Patients should be instructed to return immediately for recurrent symptoms, signs of cold injury, lethargy, altered mental status, pallor, or change in urine output/color.
- Education and anticipatory guidance should be given prior to discharge to prevent recurrence.

##### Patient Monitoring

Specific monitoring is not required for patients who have experienced mild hypothermia.

##### PROGNOSIS

- Full recovery from hypothermia-induced prolonged cardiac arrest has been documented (5).
- Case reports have documented survival of an infant with core temperatures as low as  $14.2^{\circ}\text{C}$  ( $57.6^{\circ}\text{F}$ ) (6).

##### COMPLICATIONS

- Acidosis:
  - Secondary to lactic acid production and respiratory insufficiency
  - Hypokalemia/Hypocalcemia secondary to cellular shifts and urinary loss
- Increased capillary leak with volume loss, with resultant increase in blood viscosity and hematocrit
- Splenic sequestration may occur with a decrease in both WBCs and platelets.
- CNS dysfunction:
  - Decreased cerebral blood flow, nerve conduction, deep tendon reflexes, and pupillary response
- GI dysfunction with decreased:
  - GI motility
  - Liver function with decreased ability to process and detoxify drugs/products of metabolism
  - Pancreatic function with a subsequent decrease in insulin production with resultant hyperglycemia
  - Stress ulcers, GI bleeding, pancreatitis
- Renal hypoperfusion, oliguria, and renal failure
- Coagulopathy
- Cardiac arrhythmia
- Infection, sepsis
- Rhabdomyolysis, compartment syndrome
- Frostbite, frostnip, gangrene
- Rewarming shock, refractory hypotension

#### ICD9

- 778.3 Other hypothermia of newborn
- 991.6 Hypothermia

#### PEARLS AND PITFALLS

- Hypothermia is most commonly the result of environmental exposure but may result from medical disorders.
- Return of circulation with no neurologic deficit has been reported after prolonged cardiac arrest due to hypothermia, such as with cold water drowning.
- Resuscitation in such cases should continue until the core temperature has been restored to  $32\text{--}35^{\circ}\text{C}$  ( $90\text{--}95^{\circ}\text{F}$ ).
- After death from other causes, such as sudden infant death syndrome, a drop in temperature of the corpse is expected. Continuing resuscitative measures until the patient is rewarmed is not indicated.
- Standard Pediatric Advanced Life Support and Advanced Cardiac Life Support guidelines may not be effective in moderate to severe hypothermia.

# IDIOPATHIC THROMBOCYTOPENIC PURPURA

Arezoo Zomorodi

## BASICS

### DESCRIPTION

- Idiopathic thrombocytopenic purpura (ITP) is an acquired autoimmune disorder characterized by a platelet count  $<150 \times 10^9/L$ , a purpuric rash, and normal bone marrow without another identifiable cause.
- Also called autoimmune thrombocytopenic purpura or isoimmune thrombocytopenic purpura.
- Even if no purpura are present, the disease is still referred to as ITP:
  - Up to 30% of patients are discovered by abnormal platelet count with CBC obtained for other reasons and have no symptoms.
- 80% of childhood ITP is acute.
- Chronic thrombocytopenia is characterized by persistence of thrombocytopenia for  $>6$  mo and is more common in adolescents.
- Most cases of ITP are primary, but secondary causes include collagen vascular disorders, immune deficiencies, and chronic infections.

### EPIDEMIOLOGY

- Most common cause of thrombocytopenia in children; annual incidence of 3–8 per 100,000
- The average age of presentation is between 2 and 10 yr of age, with a peak between 2 and 5 yr.
- The slightly higher incidence in males is more pronounced in infants.
- Severe bleeding in 3% of cases; risk decreases after the 1st month of illness
- 80% of childhood ITP is acute.
- Chronic ITP occurs in ~20% of children with ITP, is more common in adolescents and females, and is more likely to have an underlying autoimmune disorder.

### PATHOPHYSIOLOGY

- Autoantibodies bind platelet membrane glycoproteins to form antibody-coated platelets, which are destroyed by macrophages in the reticuloendothelial system.
- Platelet survival is significantly shortened.
- Infectious agents or toxins trigger the production of antiplatelet antibodies in acute ITP.

### ETIOLOGY

Idiopathic

### COMMONLY ASSOCIATED CONDITIONS

- Acute ITP follows a viral illness by a few days to a few weeks in 50–80% of cases.
- ITP follows administration of mumps-measels-rubella vaccination once every 40,000 doses.
- Secondary causes of chronic thrombocytopenia include autoimmune disorders, immune deficiencies, and chronic infections.

## DIAGNOSIS

### HISTORY

- ITP often presents as acute onset of bruising or petechiae in previously healthy children.
- 1/3 of patients have a history of bleeding from mucous membranes including the gums, nose, GI tract, vaginal mucosa, urinary tract, or conjunctiva.
- The risk for intracranial hemorrhage (ICH) is greatest in patients with a platelet count  $<20 \times 10^9/L$  and should be considered when a patient has a persistent headache or an abnormal neurologic exam. Although the incidence of ICH is  $<1\%$ , the mortality rate is high among those with ICH.
- Systemic symptoms such as fever, anorexia, joint pain, or weight loss are rare in ITP and suggest other causes of thrombocytopenia.
- Family history is typically negative for bleeding disorders.
- Inquire about medications that may be associated with thrombocytopenia.

### PHYSICAL EXAM

- While almost all patients have cutaneous bleeding marked by petechiae, ecchymoses, or purpura at the time of presentation, some also have mucosal bleeding.
- A spleen tip is palpable in ~8% of cases.
- Significant lymphadenopathy, marked hepatosplenomegaly, jaundice, or pallor suggests other causes of thrombocytopenia.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC is the only necessary lab assay.
- Pregnancy testing should be performed in sexually mature females.
- The key lab feature is isolated thrombocytopenia; other cell lines are typically normal.
- Bleeding is more frequent when the platelet count is  $<20 \times 10^9/L$ .
- Mild anemia from bleeding may also be seen with normal RBC indices.
- Mild eosinophilia may be present.
- PT and PTT are normal and do not need to be routinely checked if thrombocytopenia is present.
- Bleeding time is usually prolonged but does not need to be checked for the diagnosis.
- Abnormal leukocyte count and/or RBCs should prompt further diagnostic evaluation for leukemia or aplastic anemia.
- A peripheral blood smear will show increased platelet size due to rapid platelet turnover and the release of younger, larger platelets.
- The presence of immature nucleated WBCs or abnormal RBC morphology suggests other diagnoses.
- Additional tests in chronic thrombocytopenia should include evaluation for autoimmune thyroid disease, other autoimmune diseases, infection, and immunodeficiency.

### Imaging

Head CT should be obtained if suspicion of ICH exists.

### Diagnostic Procedures/Other

Bone marrow aspiration is not needed for the diagnosis of ITP but should be considered in the presence of unusual history and physical exam, abnormal WBC or RBC indices, thrombocytopenia refractory to typical ITP treatment, or chronic thrombocytopenia:

- Some hematologists routinely sample bone marrow to rule out leukemia prior to commencing steroid treatment.
- If bone marrow sampling is planned, administration of corticosteroids should be delayed until this aspiration if possible.

### DIFFERENTIAL DIAGNOSIS

- Congenital disorders of decreased platelet production include thrombocytopenia-absent radius syndrome, Fanconi anemia, and amegakaryocytic thrombocytopenia.
- Acquired disorders of decreased platelet production include leukemia, aplastic anemia, neuroblastoma, and nutritional deficiencies.
- Drugs associated with decreased platelet production include thiazide diuretics, alcohol, estrogen, chloramphenicol, and ionizing radiation.
- Increased platelet destruction can occur from neonatal alloimmune thrombocytopenia, posttransfusion purpura, collagen-vascular disease, hemolytic uremic syndrome, and disseminated intravascular coagulation.
- Drugs causing increased platelet destruction include sulfonamides, digoxin, heparin, valproic acid, quinine, quinidine, and carbamazepine.
- Infectious causes of acute thrombocytopenia include human immunodeficiency syndrome, hepatitis, and infectious mononucleosis.
- Some inherited causes of ITP include Wiskott-Aldrich syndrome, Bernard-Soulier syndrome, and gray platelet syndrome.

### Pregnancy Considerations

Causes of gestational thrombocytopenia:

- Gestational thrombocytopenia (75%)
- HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets)
- ITP (15%):
  - Maternal platelet count does not predict neonatal platelet count.
  - Maternal treatment does not alter the thrombocytopenia in the newborn.
  - Neonatal cranial US should be performed to evaluate for ICH.

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Local measures to control active bleeding should be instituted promptly.
- Heavy menstrual bleeding may require administration of hormonal therapy.
- For severe thrombocytopenia, therapy to prevent ICH is necessary.

**MEDICATION**

- 70% of patients will completely recover within 6 mo without treatment:
  - Pharmacologic management of acute ITP remains controversial; treatment side effects vs. potential benefits must be weighed.
- Though therapy may decrease the duration of thrombocytopenia, studies have not clearly evaluated effects on morbidity or mortality.
- Pharmacotherapy shortens the time period of dangerous thrombocytopenia but is not curative.
- The American Society of Hematology recommends treatment for:
  - Any patient with life-threatening hemorrhage
  - Any patient with a platelet count  $< 10 \times 10^9/L$
  - Patients with platelet count  $10\text{--}30 \times 10^9/L$  and active bleeding
  - Common treatment thresholds are platelet counts between  $10\text{--}30 \times 10^9/L$ .
- Intravenous immunoglobulin (IVIG):
  - IVIG blocks Fc receptors on macrophages in the reticuloendothelial system and inhibits destruction of antibody-coated platelets.
  - The initial dose is 0.8–1 g/kg IV. A 2nd dose may be indicated 24 hr later depending on the initial clinical response.
  - Mean time to raising platelet counts  $20 \times 10^9/L$  ranges from 24–72 hr.
  - More rapid response and less side effects than with corticosteroids
  - 95% of patients will have a significant elevation in platelet count within 2–3 days of IVIG therapy that peaks at 1 wk and lasts 3–4 wk.
  - Disadvantages include aseptic meningitis, hemorrhage, neutropenia, and hemolytic anemia.
- Corticosteroids (CS):
  - CS block the Fc receptors of splenic macrophages.
  - Various dosing regimens, usually oral prednisone 1–2 mg/kg PO daily for several weeks with tapering dose:
    - Higher doses increase platelet counts faster.
  - Some hematologists prefer bone marrow aspiration prior to CS use to definitively rule out leukemia:
    - Long-term outcome may be adverse if a patient with leukemia is erroneously diagnosed with ITP and treated with CS.
  - 75% of patients will have significant elevation in platelet count within 2–3 days.
  - Potential side effects of CS include hyperglycemia, weight gain, and mood/behavioral changes. Prolonged CS use can also cause Cushing syndrome and stunted growth.

- Anti-Rh(D):
  - Competitively inhibits antibody-coated platelet destruction by preferential sequestration of immunoglobulin-coated RBCs
  - The dose of Anti-Rh(D) is 50–75  $\mu\text{k}/\text{kg}$  IV.
  - Anti-Rh(D) can only be used in patients who are Rh positive.
  - Side effects include mild hemolysis, fevers, chills, nausea, and vomiting. Due to the risk of hemolysis, it should not be given to patients who are Coombs positive or who have hemoglobin levels  $< 10$  g/dL.
  - Peak platelet counts rise slightly slower and are lower than IVIG therapy.
  - Compared to IVIG, there is lower risk of headache, faster administration time, and lower cost. However, the risk of anemia is greater.
- Platelet transfusions alone are not useful, because the autoimmune process will continue destroying the transfused platelets.
- If severe uncontrollable bleeding or in cases of ICH, IV hydrocortisone and IVIG should be administered, followed by a platelet transfusion. If the platelet count does not improve, emergent splenectomy may be considered.
- If the patient is asplenic, exchange transfusion or plasmapheresis may be considered.

**SURGERY/OTHER PROCEDURES**

- Craniotomy for ICH
- Splenectomy may induce complete remission:
  - Risk and benefit must be carefully weighed.

**DISPOSITION**

**Admission Criteria**

- Increased risk of bleeding, including patients whose platelet count is  $< 20 \times 10^9/L$
- ITP-related bleeding, regardless of their platelet count
- Poor compliance or follow-up
- Additional bleeding risk factors
- Critical care admission criteria:
  - Hemorrhage with hemodynamic compromise
  - ICH
  - Patients requiring plasmapheresis

**Discharge Criteria**

- Healthy asymptomatic patients with a platelet count  $> 30 \times 10^9/L$  who have adequate follow-up
- Consultation with a hematologist may help determine which patients to discharge.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Restrict physical activity, and avoid medications that suppress platelet function.
- It is critical that caregivers are aware of symptoms of ICH, elevated intracranial pressure, and GI hemorrhage:
  - Seek medical care for increased bruising or petechiae, bleeding, new headaches, or any head trauma.

**Patient Monitoring**

- Platelet counts should be checked once or twice weekly until recovery is detected.
- Monitor platelet counts at lengthening intervals until normal. Resolution occurs within 3 mo in 70% of patients.

**PROGNOSIS**

- Most patients have a benign course.
- Within 3 mo, 60% of children will have a normal platelet count.
- The risk for ICH is  $< 1\%$ .
- The risk for life-threatening bleeding is 3%.
- $< 5\%$  of children who recover from ITP will have a recurrence of the disease that is also usually benign and self-limited.
- $\sim 20\%$  of children with ITP will develop chronic thrombocytopenia.

**COMPLICATIONS**

- ICH
- Hypovolemic shock or anemia

**CODES**

ICD9  
287.31 Immune thrombocytopenic purpura

**PEARLS AND PITFALLS**

- Excessive bleeding that requires RBC transfusion is rare with ITP.
- Acute, isolated thrombocytopenia in previously healthy children is usually due to ITP.
- Systemic symptoms suggest a diagnosis other than ITP.
- Consultation with a hematologist is recommended, particularly before beginning CS treatment.

# IMMOBILE ARM

John T. Kanegaye

## BASICS

### DESCRIPTION

- Unexplained limitation of arm movement is most common in infants and younger children with limited ability to communicate verbally.
- Pain, weakness, contractures, or joint deformities may limit arm movement.
- Most arm complaints are related to minor trauma, and the diagnosis is made or suggested by clinical evaluation.
- A small number of patients will have clinically inapparent diagnoses or limb- or life-threatening conditions.
- Further complicating the evaluation is the possibility of inflicted injury and falsified reporting of injury mechanism.

### EPIDEMIOLOGY

#### Incidence

- Upper extremity impairment in children <6 yr of age accounts for 8/1,000 pediatric emergency department visits. The most common diagnoses are radial head subluxation (63%), fractures (22%), and soft tissue injuries (13%) (1).
- Brachial plexus injury occurs in 0.1–0.4% of live births.
- Infants <18 mo of age incur 80% of abusive fractures but only 2% of accidental fractures.

### PATHOPHYSIOLOGY

- The pathophysiology of the immobile arm is diverse and beyond the scope of this topic. See relevant topics on Nursemaid's Elbow; Brachial Plexus Injury; fractures and trauma (multiple topics); Osteogenesis Imperfecta; Osteosarcoma; Osteomyelitis; Arthritis, Septic; Leukemia; Child Abuse; and Conversion Disorder.
- Radial head subluxation results from sudden, usually unexpected, traction on the arm causing entrapment of the annular ligament between the radial head and the capitellum. Less common mechanisms, such as falling onto an extended arm or rolling over the arm, also occur.
- Although inoculation by direct puncture may cause osteomyelitis, hematogenous seeding is most common.
- Abusive injuries may result from a direct blow, traction, or torsion to the arm or from rotational force transmitted from the trunk. Injuries range from nonspecific transverse diaphyseal, greenstick, and torus fractures to more suspicious metaphyseal-physeal injuries ("corner" and "bucket handle" fractures) and subperiosteal hemorrhages.
- Traction on the brachial plexus during delivery may produce variable injury patterns:
  - Upper roots (C5–7, Erb palsy): Shoulder adduction and internal rotation, elbow extension, wrist flexion (waiter's tip posture)
  - Lower roots (C7–T1, Klumpke palsy): Wrist and hand weakness (claw-hand deformity)
  - Entire plexus (C5–T1): Total paralysis

### ETIOLOGY

- Traumatic:
  - Brachial plexus palsy
  - "Stinger" or "burner" is a brachial plexus injury most commonly occurring in high school or college football or wrestling and may result in burning pain, weakness, or numbness of the affected arm that typically resolves without sequelae.
  - Radial head subluxation may be difficult to detect if the mechanism is unknown or atypical, or if the parent suspects shoulder or wrist pain.
  - Fractures are more common than dislocations. Clavicle, supracondylar, and distal forearm injuries predominate. Torus and nondisplaced physeal injuries may be clinically and even radiographically occult. Clavicle fractures sometimes present as pain when carried.
  - Inflicted (abusive) injury
  - Pathologic fracture through pre-existing lesion (cyst, malignancy, osteogenesis imperfecta)
  - Overuse injuries: Little League elbow (traction apophysitis of medial epicondyle), intra-articular loose body, Panner disease (capitellar osteochondrosis), osteochondritis dissecans
- Infectious:
  - Skin/Soft tissue infection (cellulitis, abscess, fasciitis, pyomyositis)
  - Septic (pyogenic) arthritis or osteomyelitis may produce pseudoparalysis in the neonate.
  - Lyme arthritis
- Neurologic: Neuropathy, radiculopathy, plexopathy, demyelination
- Neoplastic/Infiltrative:
  - Leukemia
  - Metastatic neuroblastoma
  - Primary bone tumor (Ewing sarcoma, osteosarcoma, chondrosarcoma)
  - Rhabdomyosarcoma, fibrosarcoma
  - Osteoid osteoma
- Congenital conditions include deformities obvious at birth and others that may cause functional limitation later in childhood:
  - Arthrogryposis: Multiple neurogenic, myopathic, or skeletal causes of newborn rigid-joint deformities
  - Congenital radial head dislocation
  - Congenital synostoses (radioulnar synostosis leads to a pronation deformity; elbow synostosis results in flexion deformity)
- Somatoform disorders/Pain syndromes:
  - Conversion reaction
  - Complex regional pain syndrome (reflex sympathetic dystrophy) may follow minimal trauma and manifests with pain and change of color and temperature. Initial warmth and edema are followed by cool and clammy skin. Disuse atrophy may occur.
  - Fibromyalgia
  - Neuropathic pain
- Other diseases for which arm immobility is a component of systemic disease:
  - Nutritional (rickets, scurvy)
  - Inflammatory arthritides: Post-infectious/reactive (following hepatitis B, streptococcal, enteric, or chlamydial infections), juvenile idiopathic arthritis (JIA), psoriatic arthritis, various spondyloarthropathies, inflammatory bowel disease, juvenile dermatomyositis, Kawasaki disease, scleroderma, rheumatic fever

## DIAGNOSIS

### HISTORY

- Onset of limitation and prior level of function
- Degree of arm dysfunction and disturbance in social, academic, and athletic activities
- Birth weight, difficulty with delivery
- Injury mechanism and associated features (audible or palpable snap/pop sensation):
  - Locking with joint movement suggests loose body.
- Fever; constitutional, GI, and genital symptoms
- Presence and diurnal pattern of pain and limitation (eg, morning stiffness)
- Pain migration suggests a systemic inflammatory process.
- Social stressors and variation of disability with school and parenting schedule
- Modifying factors: Lack of relief with rest and analgesics is concerning for a more serious process such as neoplasm.

### PHYSICAL EXAM

- Observation of spontaneous use of arm while the patient is unaware may help localize the disease process or may reveal conversion reaction.
- A nonthreatening general exam and exam of the unaffected arm reassures the apprehensive child and provides a basis for comparison of differential response (grimace, withdrawal, or cry) in the preverbal child.
- Inspection: Posture of the arm may suggest brachial plexus injury (adducted, internally rotated shoulder with extended elbow and flexed wrist) or a subluxed radial head (slight elbow flexion with pronation).
- Palpation of bone and joints for localized tenderness or crepitus. Disappearance of the normal dimple behind the radiocapitellar articulation suggests effusion due to fracture or inflammation:
  - Fearful children may prefer to have a parent palpate the arm or shoulder to assess for tenderness.
- Changes in overlying skin
- Mucocutaneous changes: Palpable purpura (Henoch-Schönlein purpura), Gottron papules (dermatomyositis), plaques and nail pitting (psoriasis), stomatitis
- Neurologic exam: Motor deficits, Horner syndrome (brachial plexus injury), primitive reflexes (Moro, asymmetric tonic neck reflex, and palmar grasp are altered in brachial plexus injury)
- Lymphadenopathy, hepatosplenomegaly

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Obtain lab assays if injuries are not readily apparent:
  - Inflammatory indices for the evaluation of occult infection or neoplasm (CBC, ESR, C-reactive protein). Anemia may be present in neoplasm or other chronic disease.
  - Coagulation evaluation for unexplained bleeding, bruising, hemarthroses (platelet count, PT, PTT, bleeding time)

- Specialized tests may be recommended by specialty consultant (eg, antinuclear antibody in lupus and pauciarticular JIA, rheumatoid factor in JIA) but have no impact on emergency department management.

### Imaging

- If the abnormality remains unexplained after clinical evaluation (and reduction maneuver for radial head subluxation, if age appropriate), radiographs may be focused on a single painful region or encompass the entire clavicle and arm.
- If inflicted injury is possible, a plain film survey of the entire skeleton may be necessary. The yield of this study decreases above 2 yr of age.
- Follow-up radiographs or skeletal surveys may be useful in documenting occult or initially equivocal fractures, particularly in suspected abuse (2).
- Scintigraphy may identify subtle fractures, foci of infection, or infiltration.
- MRI is useful for detection of osteomyelitis.

### Diagnostic Procedures/Other

- Aspiration of synovial, subperiosteal, or intramedullary fluid at site of suspected infection
- Cytological exam of bone marrow for suspected leukemia, lymphoma, or neuroblastoma

### DIFFERENTIAL DIAGNOSIS

See Etiology.

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation; spinal immobilization if needed.
- For severe trauma: Oxygen and IV access
- Volume expansion if perfusion is compromised
- Direct pressure to external bleeding sites

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation; splint immobilization if necessary.
- In severe trauma or sepsis, respiratory and hemodynamic stability must be restored.
- Administer analgesics as necessary.
- Orthopedic consultation for vascular compromise, compartment syndrome, and open fractures or joint injuries

### MEDICATION

#### First Line

- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation.
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine/Acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone/Acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN

### Second Line

Anti-inflammatory, antibiotic, immunosuppressive, and antineoplastic agents as necessary

### SURGERY/OTHER PROCEDURES

- Brachial plexus injury: Observation and range of motion are recommended. If no recovery, the patient may require exploration and repair of the plexus. In long-standing injury, repair of joint deformity or tendon transfer is needed.
- Reduction of subluxation of the radial head by pronation is less aggressive and may be more successful than supination-flexion (3). Overly aggressive and rapid reduction maneuvers are unnecessary. Close outpatient observation and re-examination are appropriate if reduction fails.
- Immobilization by splint or cast is traditional for most minimally displaced or minimally angulated fractures. Notable exceptions: Clavicle (sling or sling-swath) and buckle fractures (removable splints may lead to faster recovery and return to activity) (4).
- Reduction and casting is indicated for most significantly angulated or displaced fractures. Reduction is often done with procedural sedation in the emergency department but may require operative reduction.
- Some fractures require operative management:
  - Supracondylar fractures: Type II or type III
  - Open fractures

### DISPOSITION

#### Admission Criteria

- Major extremity and extraskelatal trauma and hemorrhage
- Inability to discharge to safe environment
- Suspected malignancy or bone/joint infection
- Sickle cell vasoocclusive crisis with inadequately controlled pain
- Critical care admission criteria:
  - Cardiorespiratory instability

#### Discharge Criteria

- Hemodynamically normal
- Medical follow-up assured

#### Issues for Referral

- Orthopedic: Acute fractures, brachial plexus palsy, overuse injury, primary bone lesions
- Rheumatology: Noninfectious inflammatory arthritis associated with extraskelatal manifestations or which fails to resolve with supportive therapy

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Activity:

- For most minor injuries, advance activity as tolerated after a brief immobilization period.
- A prolonged rest or immobilization may be needed for overuse injuries and osteochondroses.

### COMPLICATIONS

- Residual deficits occur in 30–40% with brachial plexus palsy. Spontaneous recovery is unlikely if there is no movement in the affected motor groups by 3–6 mo.

- Bone or joint infection may lead to deformity, destruction, or chronic infection.
- Fractures, particularly of elbow, are at risk for malunion, nerve or vascular injury, and compartment syndrome and its sequelae (Volkmann contracture).

## CODES

### ICD9

- 729.89 Other musculoskeletal symptoms referable to limbs
- 959.2 Other and unspecified injury to shoulder and upper arm

## PEARLS AND PITFALLS

- Skeletal injuries suspicious for abuse: Metaphyseal-physeal, scapular, medial and lateral clavicle, newborn clavicle fractures identified after 10 days of age without signs of healing, or unexplained periosteal bone formation
- Pain may be absent or referred.
- Growth arrest lines may be mistaken for metaphyseal fractures associated with abuse.
- Absence of systemic symptoms or radiographic abnormalities should not dissuade the clinician from pursuing possible bone or joint infection.
- Bone tumor is suggested by night-time pain, constitutional symptoms, a palpable mass, or pain without localizing tenderness.

# IMPERFORATE HYMEN

Jeffrey A. Seiden

## BASICS

### DESCRIPTION

*Imperforate hymen* refers to the abnormal persistence of the central portion of the hymen, resulting in vaginal outflow obstruction.

### EPIDEMIOLOGY

#### Incidence

- Occurs in ~0.1% of newborn females
- Imperforate hymen is the most common cause of vaginal outflow obstruction.
- ~40% of cases are diagnosed prior to age 4 yr, while nearly 60% are diagnosed after age 10 yr.

### RISK FACTORS

Most cases are sporadic, though there are case reports of familial occurrences.

### PATHOPHYSIOLOGY

- The hymen develops as a solid membrane separating the proximal vaginal tract and the introitus. Failure of the central area of the hymen to degenerate, or canalize, prior to birth results in an imperforate hymen.
- Imperforate hymen causes vaginal outflow obstruction, resulting in the retention of vaginal and uterine secretions.

### ETIOLOGY

- The etiology of imperforate hymen is unclear.
- Proposed hypotheses include a failure of cellular apoptosis secondary to either an abnormal genetic signal or an inappropriate hormonal environment.

### COMMONLY ASSOCIATED CONDITIONS

- Mucocolpos: Vaginal retention of mucoid secretions
- Hematocolpos: Vaginal retention of menstrual products
- Pyocolpos: Vaginal retention of infectious material

## DIAGNOSIS

### HISTORY

- Imperforate hymen can be asymptomatic.
- In the newborn period, parents may report seeing a whitish bulge at the vaginal introitus.
- When diagnosed in adolescence, it may present with primary amenorrhea, abdominal pain, back pain, urinary retention, or constipation.
- Symptoms may be cyclical, corresponding to the patient's menstrual period.

### PHYSICAL EXAM

- At any age, an imperforate hymen appears as a solid membrane proximal to the vaginal introitus.
- Newborns often present with signs of mucocolpos, which appears as a white bulging membrane between the labia. Occasionally, the uterus may be palpable as a lower abdominal mass.
- Adolescents often present with signs of hematocolpos, which appears as a bluish bulging membrane at the introitus. Appreciation of this finding may be facilitated by asking the patient to perform a Valsalva maneuver.
- This physical finding highlights the importance of examining the external genitalia of adolescent girls presenting with abdominal pain and tenderness, particularly in those reporting primary amenorrhea.
- Imperforate hymen can be differentiated from labial adhesions on physical exam:
  - With labial adhesions, the labia minora are completely or partially fused (typically starting posteriorly), while in imperforate hymen, the labia minora are separated.

## DIAGNOSTIC TESTS & INTERPRETATION

### Imaging

- Pelvic US is reliable in visualizing retained vaginal and uterine secretions.
- MRI may be helpful if a more complex anatomic anomaly is suspected.

### DIFFERENTIAL DIAGNOSIS

- Vaginal cyst
- Transverse vaginal septum
- Labial adhesions
- Sarcoma botryoides

## TREATMENT

### MEDICATION

- Initial medical therapy should focus on pain management.
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
    - Ketorolac 0.5 mg/kg IV/IM q6h PRN
    - Naproxen 5 mg/kg PO q8h PRN
  - Some clinicians prefer to avoid due to theoretical concern over influence on coagulation and callus formation.
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2  $\mu$ g/kg IV q2h PRN:
    - Initial dose of 1  $\mu$ g/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.

- Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
- Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- Other medical therapy such as IV antibiotics are generally not indicated unless the patient is febrile and/or infection is suspected.

#### SURGERY/OTHER PROCEDURES

- Definitive surgical repair involves excising the central hymenal tissue and evacuating any retained material.
- The hymenal ring is then sutured to the vaginal mucosa to prevent adhesions and resultant obstruction.

#### DISPOSITION

##### Admission Criteria

- Patients with severe pain may need inpatient hospitalization for pain management and immediate surgical treatment.
- Patients with suspected infection (pyocolpos or pyometras) should be admitted and treated with antibiotics along with immediate surgical treatment.

##### Issues for Referral

Refer patients to a gynecologist. Consider a pediatric gynecologist referral for younger children.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- Pain management with acetaminophen or NSAIDs is usually sufficient.

#### Patient Monitoring

Monitor for fever or worsening of pain.

#### PROGNOSIS

Outcomes after surgical repair are excellent.

#### COMPLICATIONS

- Recurrent obstruction
- Ascending pelvic infection: Rare unless there have been prior attempts at nonsurgical drainage of retained secretions
- Secondary endometriosis secondary to retrograde menstruation: Thought to be self-limited once imperforate hymen is repaired

#### ADDITIONAL READING

- Posner JC, Spandorfer PR. Early detection of imperforate hymen prevents morbidity from delays in diagnosis. *Pediatrics*. 2005;115:1008–1012.
- Sakalke R, Samarakkody U. Familial occurrence of imperforate hymen. *J Pediatr Adolesc Gynecol*. 2005;18:427–429.

### See Also (Topic, Algorithm, Electronic Media Element)

Amenorrhea

### CODES

#### ICD9

752.42 Imperforate hymen

### PEARLS AND PITFALLS

- Simple aspiration and drainage of retained vaginal contents should not be performed, as it does not obviate the need for definitive surgical intervention and increases the risk for iatrogenic infection.
- Physicians should examine the external genitalia of adolescent girls presenting with abdominal pain and tenderness, particularly in those reporting primary amenorrhea.

# IMPETIGO

Lauren Daly

## BASICS

### DESCRIPTION

- Impetigo is a superficial skin infection caused by *Streptococcus pyogenes* or *Staphylococcus aureus* and is categorized into 2 forms—bullous and nonbullous:
  - In bullous impetigo, there are fluid-filled blisters containing serous or seropurulent fluid.
  - The blisters in bullous impetigo are >1 cm in diameter.
  - In nonbullous impetigo, a small vesicopustule with a seropurulent exudate evolves to form a honey-colored crust.
- Ecthyma gangrenosum is a deeper variety of impetigo that involves the dermis, whereas simple impetigo is restricted to the epidermis.

### EPIDEMIOLOGY

#### Incidence

- Impetigo is a very common contagious infection seen most frequently in children <6 yr of age, though older age groups may be affected.
- It is more common in the warm, humid summer months, especially in crowded or unsanitary environments.
- Nonbullous impetigo is more common than bullous impetigo.

### RISK FACTORS

- Poverty
- Crowding
- Day care attendance
- Poor hygiene (1)
- Those who harbor group A streptococcus and *S. aureus* in the nasopharynx are predisposed as well (2).

### GENERAL PREVENTION

- Maintenance of proper hygiene, such as frequent hand washing, may aid in reducing the spread of impetigo.
- Use of antibacterial soap may aid in prevention.

### PATHOPHYSIOLOGY

- Bacteria invades nonintact skin.
- Exfoliative toxin of *S. aureus* may cause bullous impetigo.

### ETIOLOGY

- All cases of bullous impetigo and most cases of nonbullous impetigo are caused by *S. aureus* (3).
- *S. pyogenes* (group A streptococcus) is the sole pathogen in <5% of cases; more commonly, it causes coinfections with *S. aureus*.
- In contrast, ecthyma is more typically associated with *Pseudomonas aeruginosa*.

## DIAGNOSIS

### HISTORY

- The typical history offered by the parent is of “sores” on the child’s body in the absence of fever or other systemic symptoms.
- Nares, upper lip, and face are common locations for these “sores” to arise.

### PHYSICAL EXAM

- Nonbullous impetigo lesions begin as papules that progress to vesicles surrounded by erythema:
  - The vesicles evolve into pustules that rupture and leave a thick, honey-colored crust.
- Lesions are often clustered on the face or extremities.

- In bullous impetigo, the vesicles enlarge to the size of bullae and are full of turbid yellow fluid:
  - Bullae are more commonly on the trunk.
- Ecthyma appears as “punched out” ulcerations that have infiltrated both the epidermis and dermis and are covered with a yellow crust:
  - Ecthyma lesions are characterized by a necrotic center.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Diagnosis is clinical, but the lab assay may definitively diagnose *S. aureus* or *S. pyogenes*.
- Lesions that are unresponsive to conventional treatment may need to be cultured since community-acquired MRSA is becoming a significant pathogen in skin and soft tissue infections (3).
- Community-acquired MRSA typically causes subcutaneous abscesses but may also cause impetigo.

### DIFFERENTIAL DIAGNOSIS

- Other rashes may be confused with impetigo:
  - Herpes simplex
  - Tinea corporis
  - Contact dermatitis
  - Nummular eczema
  - Pemphigus foliaceus
  - Subcorneal pustular dermatosis
  - Pyoderma gangrenosum
- In contrast to cellulitis, impetigo tends to be less erythematous or tender.
- In contrast to furuncles or abscesses, impetigo is more superficial and nonfluctuant.

## TREATMENT

### MEDICATION

#### First Line

- Topical therapy with mupirocin 3 times a day is appropriate treatment if there are a limited number of lesions without bullae (4).
- Oral antibiotics:
  - With extensive skin lesions, difficulty in application of topical medication, or parenteral clinician preference, PO antibiotics may be used.
  - Nonbullous impetigo was previously streptococcal predominant and now is staphylococcal predominant.
  - With the increasing prevalence of MRSA as a causative organism, antibiotics effective against MRSA such as clindamycin or trimethoprim/sulfamethoxazole may be best (3).
- Other antibiotic considerations include:
  - Cephalexin 50 mg/kg PO divided b.i.d.–q.i.d., max single dose 500 mg.
  - Clindamycin 10–30 mg/kg/day PO divided t.i.d., max single dose 300 mg.
  - Dicloxacillin 25–50 mg/kg/day PO divided b.i.d.–q.i.d., max single dose 500 mg
  - Trimethoprim/Sulfamethoxazole 10 mg/kg PO divided b.i.d., based on trimethoprim component:
    - Particularly recommended for high MRSA incidence or suspicion of MRSA impetigo

#### Second Line

Other topical medications may be used:

- Hydrogen peroxide cream b.i.d.
- Povidine b.i.d.

## DISPOSITION

### Admission Criteria

Young infants with bullous impetigo should be admitted for parenteral antibiotic therapy.

### Issues for Referral

For cases that do not resolve with standard therapy, consider an alternative antibiotic or referral to a dermatologist if the diagnosis is in doubt.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- The patient should have follow-up with the pediatrician toward the end of the antibiotic course to ensure resolution.

### PROGNOSIS

Impetigo typically resolves rapidly with therapy.

### COMPLICATIONS

- Cellulitis
- Rheumatic fever
  - Antibiotic treatment lowers the likelihood of developing rheumatic fever.
- Glomerulonephritis:
  - Follows impetigo caused by a nephritogenic strain of *S. pyogenes*
  - This may lead glomerulonephritis 7–14 days later (5).
  - Antibiotic treatment does not appear to lower the likelihood of postinfectious glomerulonephritis.

## ADDITIONAL READING

### See Also (Topic, Algorithm, Electronic Media Element)

- Cellulitis
- Glomerulonephritis

## CODES

ICD9  
684 Impetigo

## PEARLS AND PITFALLS

- Antibiotic coverage for impetigo may need to include coverage for MRSA, depending on the community prevalence of MRSA.
- Ecthyma gangrenosum may be the initial manifestation of an immunosuppressive condition such as leukemia.

# INBORN ERRORS OF METABOLISM

Derek A. Wong

Ilene Claudius

Richard G. Boles

## BASICS

### DESCRIPTION

- Inborn errors of metabolism (IEM) are congenital deficiencies of an enzyme or enzyme system resulting in abnormal synthesis or breakdown of important molecules.
- This topic covers the subset of IEM that are due to defective intermediate metabolism:
  - In these conditions, a block in a metabolic pathway leads to the accumulation of small toxic metabolic intermediates.
  - The most common types of IEM due to intermediate metabolism include:
    - Amino acid disorders (AADs)
    - Organic acid disorders (OADs)
    - Fatty acid oxidation disorders (FAODs)
    - Urea cycle disorders (UCDs)
- Several IEMs are not discussed in this topic, including carbohydrate disorders, storage disorders, and mitochondrial disorders (the latter are covered in a separate topic).

### EPIDEMIOLOGY

#### Prevalence

- Individually rare, but overall prevalence is ~1/3,000–1/5,000 in the U.S.
- Although the majority present in infancy, many IEMs in older children and adults are underdiagnosed.

### GENERAL PREVENTION

- Genetic counseling for families with affected relatives
- Newborn screening (NBS) programs detect many IEMs but vary by state and country. Many IEMs, especially urea cycle defects, are not picked up by NBS.

### PATHOPHYSIOLOGY

- Elevated metabolite levels from impaired pathways lead to a wide variety of toxic effects, especially in the brain, resulting in acute (eg, altered mental status, vomiting) or chronic (eg, mental retardation, seizures) central neurologic symptoms:
  - Some IEMs can also affect the heart, skeletal muscle, liver, pancreas, and/or bone marrow.
- FAOD: The lack of an essential product results in energy deficiency, especially after a period without adequate oral intake.

### ETIOLOGY

Most IEMs are autosomal recessive, with some notable exceptions, such as the UCD ornithine transcarbamoylase deficiency, that are X-linked.

## DIAGNOSIS

### HISTORY

- Acute altered mental status: Lethargy, irritability, coma, psychosis
- Acute neurologic dysfunctions: Apnea, seizures, ataxia, loss of milestones (transient or long term)
- Chronic neurologic dysfunctions: Ataxia, developmental delay, hypotonia, hemiparesis, dystonia, abnormal movements
- Feeding intolerance, poor growth
- Concomitant viral infection (results in fasting, which is the usual trigger of a metabolic crisis)
- Positive NBS (often asymptomatic)
- Family history of IEM, mental retardation, or neonatal deaths

### PHYSICAL EXAM

- Altered mental status: Lethargy, irritability, coma, psychosis
- Neurologic findings: Hypotonia, dystonia, ataxia, lethargy, movement disorder
- Signs of heart failure (cardiomyopathy)
- Muscle weakness
- Hepatomegaly, jaundice
- Abnormal odor (in rare cases)

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Anion gap metabolic acidosis (OAD)
- Respiratory alkalosis (some UCD)
- Hypoglycemia (OAD/FAOD, often not present)
- Hyperammonemia (UCD, OAD, some FAOD):
  - Levels >250 micromol/L:
    - Often IEM
    - Usually UCD and OAD
  - Levels 100–250 micromol/L:
    - Some IEM (UCD/OAD/FAOD)
    - Lab technique resulting in a false positive
    - Age-related changes (normal newborns may have levels >100 micromol/L)
  - Levels <100 micromol/L:
    - Nondiagnostic, but other IEMs still possible
- Neutropenia or pancytopenia (OAD)
- Urine ketosis (except FAOD)
- Elevated ALT (some AAD, UCD, FAOD)
- Elevated creatine kinase (FAOD)
- Elevated lipase (some OAD)
- Abnormal specialized studies such as plasma amino acids, urine organic acids, plasma acylcarnitines, plasma carnitines, lactate/pyruvate

#### Initial Lab Tests

- Electrolytes, BUN, creatinine, glucose
- Plasma ammonia
- CBC with differential
- Urine dipstick
- ALT, lipase, creatine kinase
- Blood gas if seriously ill

### Imaging

Imaging is usually not necessary if the patient has a known diagnosis of IEM. Imaging may be performed to exclude other diagnoses. Imaging findings for IEM:

- Brain MRI may show infarcts, especially in the basal ganglia.
- Head CT may show cerebral edema.

### Diagnostic Procedures/Other

Diagnosis will usually require specialized testing in consultation with a geneticist or other physician with an expertise in metabolic disease.

### DIFFERENTIAL DIAGNOSIS

- Infection
- External toxins/poisonings
- Mitochondrial disorders
- Cyclic vomiting syndrome
- Spurious lab values:
  - Ammonia levels must be placed on ice and processed immediately to avoid spuriously high values.
  - Lactic acid and ammonia can be fictitiously elevated by:
    - Use of a tourniquet with phlebotomy
    - Improper specimen handling, especially in infants and toddlers

## TREATMENT

### PRE HOSPITAL

- Avoid fasting by administration of calories.
- Oral supplementation with 1 of the following solutions:
  - 8 ounces Pedialyte plus 1/3 cup Polycose
  - 8 ounces Pedialyte plus 2 heaping tbs sugar
- Note that the patients may have an alternate “sick day” diet prescribed by their metabolic team.

### INITIAL STABILIZATION/THERAPY

- IV fluids with 10% dextrose 0.45% normal saline at a high rate of 1.5–2 times maintenance:
  - This therapy will increase available energy and stop catabolism, thereby reducing production of toxic intermediates.
- If the patient is dehydrated, add a normal saline bolus through a “Y” connector to the above D10 regimen:
  - Giving isolated normal saline boluses without D10 as described will not be effective in stopping catabolism.
- Glucose bolus of 0.25–0.5 g/kg dextrose for patients with any of the following:
  - Significant hypoglycemia
  - Severe metabolic acidosis
  - Altered mental status
- Use insulin in case of substantial hyperglycemia (>200 mg/dL):
  - Do not lower the glucose infusion rate.

**MEDICATION**

**First Line**

- Hyperammonemic patients will require:
  - Sodium benzoate
  - Sodium phenylbutyrate:
    - o If the patient is alert, can tolerate enteral intake, and plasma ammonia is <200–250 micromol/L, give an extra oral dose of these medications at the regular prescribed dose on presentation.
  - Patients with ammonia levels >250 micromol/L may need immediate IV infusion of these medications, in consultation with an expert in metabolic disease, and likely will require immediate transfer to a tertiary care facility:
    - o The usual starting dose is IV sodium benzoate plus sodium phenylbutyrate at 250 mg/kg apiece, up to a max single dose of 5.5 g/m<sup>2</sup>.
- Insulin at a starting rate of 0.05 units/kg/hr will stop catabolism and will treat hyperglycemia resulting from the high glucose rate:
  - Insulin dosages of 0.2–0.5 units/kg/hr are often needed.
- Carnitine is helpful in many IEMs to allow excretion of toxic intermediates and to transport fatty acids into the mitochondria. Carnitine has low toxicity and may be used empirically in some cases:
  - In sick patients, give 50 mg/kg/dose (max single dose 2 g) q6h IV
  - In other patients, continue their outpatient carnitine regimen.

**Second Line**

- Metabolic patients on glucose only for >12–24 hr will require additional protein to prevent catabolism. The protein may be in the form of special formulas or total parenteral nutrition to limit offending substrates. Consultation with a metabolic specialist and metabolic dietician is critical.
- Home medications such as cofactors should be given as soon as tolerated.

**SURGERY/OTHER PROCEDURES**

Dialysis for severe hyperammonemia (>500–1,000 micromol/L) in consultation with a metabolic expert and nephrologist

**DISPOSITION**

**Admission Criteria**

- Patients with IEM who have vomiting or otherwise decreased enteral intake may require admission despite “good” clinical appearance.
- Failure to tolerate adequate caloric intake in a patient on fasting avoidance:
  - Less than half of the usual caloric intake often requires admission
- Serum anion gap  $\geq 20$  mM (sodium minus chloride minus HCO<sub>3</sub>):
  - A serum anion gap of 18–19 is borderline.
- Large urine ketones (>40 mg/dL):
  - Moderate is borderline.
- Loss of abilities, altered mental status (relative to baseline), or new neurologic finding
- Significant hyperammonemia (>100 micromol/L), acidosis, or hypoglycemia after initial stabilization
- Pancreatitis (lipase >400 units/dL)

**Discharge Criteria**

- Ability to tolerate adequate enteral intake
- Negative urine ketones
- Normal serum anion gap (<14 mM)
- At baseline ammonia level
- In most cases, the approval of a metabolic specialist should be obtained, especially if any of the above criteria are not met.

**Issues for Referral**

- Neurology for seizures not associated with hypoglycemia or new focal findings
- Gastroenterology for severe dysmotility

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Follow the management plan recommended by the specialist, including diet, activity, medications, and cofactors:
  - Adequate hydration and caloric intake are essential.
- The patient/family should contact the specialist or his or her office the following day.
- Return for:
  - Altered mental status (eg, lethargy, excessive irritability, loss of abilities)
  - Significant vomiting, signs of dehydration, poor enteral intake
  - Increased urine ketones not responding to sugar solutions
  - Other worrisome findings

**Patient Monitoring**

- Urine ketones every void
- Serum anion gap
- Plasma ammonia
- Mental status
- Caloric and fluid intake and outtake

**DIET**

Patients on special formula preparations may require altered diets until they are stabilized.

**PROGNOSIS**

Variable; depends on severity of illness, compliance, and degree of metabolic control

**COMPLICATIONS**

- Stroke
- Seizures
- Movement disorders
- Developmental delay, mental retardation
- Cataracts
- Liver failure or hepatomegaly
- Rhabdomyolysis
- Pancreatitis
- GI dysmotility at all levels
- Renal tubular dysfunction, acidosis
- Cardiomyopathy
- Arrhythmias
- Pancytopenia, or any element(s) thereof
- Immune deficiency
- Hypoglycemia
- Hypotonia and/or muscle weakness
- Coma
- Cerebral edema
- Multisystem failure
- Sudden death

**See Also (Topic, Algorithm, Electronic Media Element)**

- Disorders of Energy Metabolism (Mitochondrial Disease)
- <http://genes-r-us.uthscsa.edu> (ACT sheets and NBS algorithms)
- <http://www.genereviews.org>

**ICD9**

- 270.6 Disorders of urea cycle metabolism
- 277.9 Unspecified disorder of amino-acid metabolism
- 277.6 Other deficiencies of circulating enzymes

**PEARLS AND PITFALLS**

- Have a low threshold for checking ammonia levels in lethargic newborns undergoing evaluation for sepsis
- Have a low threshold for admitting a well-appearing child with vomiting who has an IEM, especially FAODs, and those <4 yr of age.
- Delayed treatment of IEMs may lead to catastrophic outcomes, including mental retardation or death.
- A normal NBS does not rule out an IEM.
- Many metabolic patients have an emergency department letter:
  - Please ask for and pay close attention to this document, as it may contain extremely important patient-specific information.
- The published literature in rare metabolic disorders is lacking in controlled studies, and treatment is often based on expert opinion:
  - Therefore, there is a considerable amount of variation in the treatment of these patients between metabolic practitioners.

# INFANTILE SPASM

Manoj K. Mittal

## BASICS

### DESCRIPTION

- Infantile spasms (IS) are an age-related epileptic syndrome affecting infants and young children marked by clusters of spasms and an EEG abnormality called *hypsarrhythmia*.
- The triad of IS, arrest of psychomotor development, and *hypsarrhythmia* is known as West syndrome.
- IS are different from usual seizures in that they are usually refractory to conventional antiepileptic drugs but responsive to adrenocorticotropic hormone (ACTH).

### EPIDEMIOLOGY

The most common epilepsy syndrome in infancy, affecting about 3/10,000 births

### RISK FACTORS

- Developmental delay
- Structural brain malformation
- Family history of IS or other types of seizure disorders
- Tuberous sclerosis (TS)

### PATHOPHYSIOLOGY

- The exact pathophysiology of IS is not understood.
- Low CNS concentrations of depressant neurotransmitters such as GABA and high concentrations of stimulants such as lysine and glutamate have been implicated.
- Based on the efficacy of hormonal treatments, abnormalities in the hypothalamic-pituitary-adrenal axis may also play a role.

### ETIOLOGY

- Symptomatic: Those with a known organic disease or developmental delay at the onset, accounting for ~2/3 of affected infants. It results from a CNS disorder that develops from a prenatal, perinatal, or early postnatal insult:
  - Prenatal:
    - CNS malformation: Cortical dysplasia, cerebral dysgenesis (eg, Aicardi syndrome), lissencephaly, holoprosencephaly
    - Chromosome abnormalities: Trisomy 21, 18q duplication, 1p36 deletion, Aristales-related homeobox gene (ARX) or STK9 mutations, and mitochondrial diseases.
    - Patients with these genetically determined conditions often do not show any structural lesions on neuroimaging.

- Neurocutaneous disorders: TS, incontinentia pigmenti, and neurofibromatosis type 1 (NF1).
- Inborn errors of metabolism: Untreated phenylketonuria, Menkes disease, Leigh syndrome, pyridoxine deficiency, urea cycle disorders
- Intrauterine infections: Toxoplasmosis, syphilis, cytomegalovirus
- Perinatal: Hypoxic-ischemic encephalopathy, periventricular leukomalacia associated with prematurity, birth trauma
- Postnatal: Meningoencephalitis, CNS trauma (accidental or inflicted), intracranial hemorrhage, near-drowning
- Cryptogenic or idiopathic: Normal development at the time of onset of IS, no other seizures, normal exam and neuroimaging, and *hypsarrhythmic* EEG pattern without focal epileptiform abnormalities

### COMMONLY ASSOCIATED CONDITIONS

- See Etiology.
- Developmental delay
- Structural brain malformation
- Family history of IS or other types of seizure disorders

## DIAGNOSIS

### HISTORY

- Peak age of onset: 2–7 mo
- In the beginning, spasms may be mild, limited to eye movements and crying, and infrequent.
- Over a few days to weeks, they become more obvious and easy to identify, occurring in clusters.
- Spasms usually involve the muscles of neck, trunk, and extremities. They may be flexor (simulating the prayer posture in Islam, leading to the moniker “Salaam spells”), extensor, or mixed. They may be symmetrical, asymmetrical, or mixed.
- Eye deviation to 1 side or nystagmoid eye movement is common. Affected infants often cry after an attack.

### PHYSICAL EXAM

Look for signs of developmental delay, micro- or macrocephaly, neurologic abnormalities, and stigmata of associated conditions as delineated in the Etiology section.

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- No lab tests are diagnostic.
- Evaluation of serum glucose and electrolytes may be indicated.
- Metabolic screening including lactate, pyruvate, amino acids, and ammonia

### Imaging

- CT may show gross structural malformations related to an underlying organic disease.
- MRI is the imaging modality of choice for infants with IS. Besides showing cerebral malformations and cerebral atrophy, it may also reveal delay or defect of myelination and small focal lesions not seen well on CT scan.
- Positron emission tomography (PET) scan may be useful for cases with a normal MRI scan, identifying abnormalities in a substantial proportion of such cases.

### Diagnostic Procedures/Other

- Electroencephalography testing is diagnostic.
- Most patients have the characteristic EEG pattern known as *hypsarrhythmia* during the inter-ictal state—very high voltage/amplitude random delta theta slow waves and spikes in all cortical areas.
- The spikes vary from moment to moment in location and duration, giving a chaotic or disorganized appearance to the EEG. Some patients may show variations including more synchronization, asymmetry, consistent focus of abnormal discharge, episodes of attenuation, or periodic flattening similar to the suppression burst pattern.
- EEG during the spasm may reveal a high-amplitude slow wave, low-amplitude fast activity, or a combination followed by attenuation of activity.
- Focal findings on EEG may be related to focal brain lesions.
- Video EEG may be helpful when the spasms are subtle.

### Pathological Findings

Several parts of the brain may be affected depending on the condition associated with IS, although the idiopathic cases may have no structural malformation.

**DIFFERENTIAL DIAGNOSIS**

- Infantile colic
- Gastroesophageal reflux
- Exaggerated Moro or startle reflex
- Benign myoclonus of early infancy: Tonic/Myoclonic spasms affecting truncal or limb muscles; associated with normal development, exam, and EEG; spontaneous remission in a few months
- Benign neonatal sleep myoclonus: Jerky movements during sleep starting in the 1st month of life; not associated with any other abnormality on exam or EEG; subside spontaneously in a few months.
- Tonic reflex seizures of early infancy: Episodes of tonic spasm with extension of all limbs, sometimes accompanied by apnea, presenting at 1–3 mo of age; associated with normal exam, development, and EEG; subside spontaneously in a few months.
- Myoclonic epilepsy syndromes

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

The airway and breathing of patients who are actively seizing must be supported with supplemental oxygen or positive pressure ventilation.

**DISPOSITION**

**Admission Criteria**

An infant with history consistent with IS should be admitted to the hospital under pediatric neurology service for urgent EEG and neuroimaging to establish the diagnosis and to start drug treatment if indicated.

**MEDICATION**

**First Line**

ACTH:

- Mechanism of action: Not yet established. It may act by suppressing the release of corticotrophin-releasing hormone (CRH), an endogenous neuropeptide (secreted by hypothalamus) that may provoke seizures in immature brain.
- Dose: Optimal dose not clear. It has been used in doses ranging from 20–150 units/m<sup>2</sup>/day, given parenterally (IV, IM, or SC).
- Duration of therapy: Not clear. The effect of ACTH persists after discontinuation of therapy following resolution of IS and hypersarrhythmia.

**Second Line**

- Vigabatrin:
  - Mechanism of action: It inhibits the enzyme GABA-transaminase, thus raising the CNS concentration of GABA, a neuroinhibitory compound.
  - Dose: Not clearly established. It has been used in doses varying from 18–200 mg/kg/day.
- Oral corticosteroids
- Topiramate
- Zonisamide
- Pyridoxine

**OTHER MEDICAL THERAPIES**

Ketogenic diet

**SURGERY/OTHER PROCEDURES**

- Surgery may be considered for patients not responding to either medication or who develop focal seizures following usual drug treatment.
- Surgery is more likely to be beneficial in the presence of an excisable cortical brain lesion demonstrated on an MRI or PET scan.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

The infant needs to be monitored carefully for cessation of IS, developmental delay, and any drug-related adverse effects.

**PROGNOSIS**

- IS stops in most children by 3 yr of age and in almost all children by 5 yr. A substantial proportion may, however, develop other kinds of seizures.
- Most patients are developmentally delayed at diagnosis and will be permanently mentally retarded.
- Outcome can vary from total recovery to severe mental retardation with persistent seizures. It is generally better in cryptogenic than in symptomatic forms.
- Duration of epileptic encephalopathy may contribute to the development of autism, particularly in TS and trisomy 21.
- ARX mutations are often associated with autistic behavior.
- Among patients with IS and TS, 2/3 may develop mental retardation. The rate of MR may be higher with prolonged duration of IS from onset to cessation, increased time from treatment initiation until IS cessation, and poor control of other seizures after IS.
- Outcome is better in patients with IS associated with NF1, with resolution of seizures in 90% of cases.
- 1/3 of patients with symptomatic IS go on to develop Lennox-Gastaut syndrome (a severe form of epilepsy that includes characteristic types of seizures, including drop attacks and tonic seizures, and characteristic EEG patterns).

**CODES**

**ICD9**

- 345.60 Infantile spasms, without mention of intractable epilepsy
- 345.61 Infantile spasms, with intractable epilepsy

**PEARLS AND PITFALLS**

- Suspicion of IS should lead to emergent referral to a pediatric neurologist.
- IS do not respond to usual antiepileptic drugs.
- Once treatment with ACTH begins, the infant needs to be monitored carefully not only for cessation of the spasms but also for potential adverse effects related to the medication.

# INFECTIOUS MONONUCLEOSIS

Neil G. Uspal

## BASICS

### DESCRIPTION

- Infectious mononucleosis (IM) is an infectious illness caused by the Epstein-Barr virus (EBV).
- Other pathogens may cause an IM-like illness indistinguishable from classic mononucleosis.
- Symptoms often include fever, malaise, pharyngitis, and lymphadenopathy.
- Rare complications may include splenic rupture, airway compromise, anemia, hepatitis, and neurologic sequelae.

### EPIDEMIOLOGY

#### Incidence

- Greatest in individuals 10–19 yr of age (6–8 cases per 1,000 persons per year) (1).
- In younger and older populations, <1 case per 1,000 persons per year (1)
- In the U.S., incidence of clinical infection is up to 30 times higher in whites vs. blacks (2).

### RISK FACTORS

- Through school age, primary EBV infection is typically subclinical.
- Persons of higher socioeconomic status in developed countries are more likely to acquire primary symptomatic infection later in life.
- Greatest rates of clinical infection in populations living in close quarters (college dormitories, military barracks, etc.)

### GENERAL PREVENTION

Viral shedding in salivary secretions in patients following IM for up to 32 wk (3):

- Household contacts of patients with IM are no more likely to get IM than others.
- Increased rate of disease in sexually active individuals

### PATHOPHYSIOLOGY

- Infection typically is transmitted through saliva to epithelial cells of the buccal mucosa or salivary glands.
- Subsequent infection of B lymphocytes
- Incubation period of 4–8 wk prior to onset of symptoms
- Up-regulation of nonspecific circulating antibodies, termed *heterophile antibodies*, during 1st to 2nd week of illness
- Activation of suppressor T lymphocytes, causing atypical lymphocytosis

### ETIOLOGY

- EBV, a herpesvirus, is the etiologic agent of classic IM:
  - Humans are the only natural reservoir of EBV.
  - Infects only B lymphocytes and squamous epithelial cells
  - Lifetime latent presence of virus in B cells
  - Periodic reactivation of virus to lytic form results in infectious shedding beyond initial infection
- Mononucleosis-like illnesses present similarly to IM but are caused by agents such as cytomegalovirus, human herpesvirus 6, HIV, and adenovirus

### COMMONLY ASSOCIATED CONDITIONS

- Burkitt lymphoma is associated with EBV in areas with high prevalence of *Plasmodium falciparum* malaria.
- Nasopharyngeal carcinomas are associated with EBV in areas of Asia.
- Lymphomas and lymphoproliferative disorders are associated with EBV infection in immunosuppressed individuals.
- Streptococcal pharyngitis

## DIAGNOSIS

### HISTORY

- 3–5 day prodrome of headache, anorexia, and malaise
- Subsequent development of fever, sore throat, and lymphadenopathy
- Fevers last for a week or more, typically >39.0°C, although some patients may have fevers >40.0°C for weeks.
- Malaise and fatigue may continue for weeks to months after onset of clinical symptoms.

### PHYSICAL EXAM

- Symmetric anterior and posterior cervical lymphadenopathy; may also be present in axillary and inguinal distributions
- Lymph nodes usually 2–4 cm in diameter, single, mildly tender, and firm (4)
- Pharyngitis usually exudative, indistinguishable from streptococcal pharyngitis
- Palatal petechiae may be present.
- Splenomegaly is present in 50% of patients during the 2nd and 3rd week of illness, usually is asymptomatic, is more frequent in younger patients, and may be difficult to detect clinically (5).
- Hepatomegaly is less common.
- Rash may be present and can be maculopapular, petechial, or morbilliform; likelihood of rash is significantly increased if the patient is placed on antibiotics.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC:
  - Leukopenia or leukocytosis
  - Occasionally, leukopenia is severe enough to cause severe neutropenia (5).
  - Younger children tend to have higher elevations of WBC counts.
  - Presence of atypical lymphocytes usually begins in the 2nd week of illness; more frequent in older children and adults.
  - Atypical lymphocytes are usually >10% of WBCs; higher numbers of atypical lymphocytes are more specific for mononucleosis.
- Rapid streptococcal screen/throat culture:
  - To rule out potential bacterial pharyngitis
  - Concomitant streptococcal pharyngitis with IM is common.

- Liver transaminases:
  - May be elevated but typically are <600
  - Not routinely indicated
- Heterophile antibody (Monospot) test:
  - Heterophile antibodies appear during 1st or 2nd week of illness; test may be negative if performed in the early stage of illness.
  - Young children often have false-negative results; 25–50% sensitivity for IM in children under age 12 yr of age (6).
  - False-positive tests can occur in patients with leukemia, lymphoma, systemic lupus erythematosus, and HIV disease (4).
- Viral capsid antibodies (VCA):
  - Present at the onset of clinical illness
  - VCA-IgM antibodies disappear months after acute infection; VCA-IgG antibodies persist for life.
  - More highly sensitive than heterophile antibody test but similar specificity
  - Similar sensitivity in younger and older children
- Epstein-Barr virus nuclear antigen antibodies (EBNA):
  - IgG antibodies appear 6–12 wk after onset of symptoms and persist throughout life.
  - Presence excludes acute EBV infection
  - Presence of VCA-IgG in the absence of EBNA-IgG is diagnostic for IM.
- EBV PCR:
  - Shown to be 75% sensitive for acute infection (7)
  - More likely to be positive early in the course of illness, then less likely to be positive as viral load decreases
  - Often used in immunocompromised patients; limited utility in classic IM

### DIFFERENTIAL DIAGNOSIS

- Viral pharyngitis
- Group A streptococcal pharyngitis
- Malignancy (leukemia/lymphoma)
- Mononucleosis-like illnesses:
  - Cytomegalovirus
  - Primary HIV infection
  - Adenovirus
  - Human herpesvirus 6
  - Herpes simplex virus
  - Toxoplasmosis

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Consider potential complications to airway and circulation as above.
- Most patients will not require specific stabilization measures.
- Consider IV rehydration if the severity of pharyngitis limits fluid intake.

### MEDICATION

#### First Line

- Supportive care is the primary treatment for IM.
- Analgesics/Antipyretics for fever, throat pain, and myalgia:
  - Ibuprofen 10 mg/kg/dose PO/IV q6h
  - Naproxen 5 mg/kg PO q8h PRN
  - Acetaminophen 15 mg/kg/dose PO q4h

**Second Line**

Corticosteroids may improve symptoms; however, no demonstrated evidence of prolonged symptom relief (8):

- Dexamethasone 0.6 mg/kg/dose PO or IV q24h, max single dose 10 mg
- Prednisone or prednisolone 1–2 mg/kg/day PO × 5–7 days
- Not recommended for routine use. Consider in patients with severe pharyngitis where oral intake or airway is compromised.
- There is theoretical concern for long-term adverse sequelae, but no proven adverse effects are known.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

Acyclovir has been shown to reduce viral shedding in IM but shows no significant clinical benefit (9).

**DISPOSITION**

**Admission Criteria**

- Inability to maintain adequate hydration or concern for potential airway obstruction
- Critical care admission criteria:
  - Airway obstruction

**Discharge Criteria**

When patients are able to maintain adequate hydration and there are no concerns for airway obstruction, they may be safely discharged.

**Issues for Referral**

- Immunocompromised at baseline with active EBV infection
- Neutropenia or concern for potential malignancy
- Airway management concerns
- Prolonged illness or concerns regarding diagnosis

 **FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Patients should be seen within a few days of discharge by their primary pediatrician to monitor progression of symptoms and provide continued expectant management.

- Discharge instructions and medications:
  - Keep well hydrated.
  - Ibuprofen or acetaminophen as needed for fever/pain
- Activity:
  - No indication for bed rest
  - Patients, regardless of whether they have clinically detectable splenomegaly, should avoid both contact and noncontact sports for 3 wk.
  - More prolonged avoidance of contact sports is indicated if splenomegaly is slow to resolve.

**DIET**

Patients may return to a regular diet as tolerated:

- Families should ensure adequate hydration until resolution of pharyngitis.

**PROGNOSIS**

- The vast majority of patients with IM recover without complications.
- Most major symptoms, such as fever and pharyngitis, resolve within 1–2 wk.
- Families should be advised that it may take weeks to months for other symptoms, such as fatigue and malaise, to fully resolve.

**COMPLICATIONS**

- Splenic rupture:
  - Occurs in ~0.1% of patients (1)
  - Usually occurs in the 1st 3 wk of illness
  - 50% of cases are atraumatic.
  - Usually managed nonoperatively
- Neurologic:
  - Occurs in 1–5% of patients (10)
  - Meningoencephalitis, neuropathies, cerebellitis, myelitis, and Guillain-Barré
- Hematologic:
  - Autoimmune hemolytic anemia: Self-resolving over 1–2 mo; usually asymptomatic
  - Neutropenia: Short-lived and rarely associated with infection
  - Thrombocytosis: Usually mild
- Hepatitis: Self-limited
- Upper airway obstruction

ICD9  
075 Infectious mononucleosis

**PEARLS AND PITFALLS**

- While IM is caused by EBV, a number of mononucleosislike illnesses are caused by other viral agents.
- Heterophile antibody tests may give false-negative results in young patients and those early in the course of their illness.
- Consider IM for patients who develop a dense maculopapular rash while receiving antibiotics for pharyngitis.
- Corticosteroids are only indicated for patients with severe pharyngitis causing dehydration or potential airway compromise.
- Even in the absence of clinically apparent splenomegaly, children should be advised to avoid all sports for at least 3 weeks, with longer avoidance of contact sports if splenomegaly has not resolved.

# INFECTIVE ENDOCARDITIS

Travis K.F. Hong  
Calvin G. Lowe

## BASICS

### DESCRIPTION

- Infective endocarditis is infection of the endothelial surface of the heart, usually due to bacterial, and less commonly, fungal microorganisms.
- Severity can range from an indolent course to fulminant sepsis and cardiac failure.

### EPIDEMIOLOGY

- Reported incident rates vary widely, ranging from 0.2–1.2 cases per 1,000 pediatric hospital admissions (1,2).
- Declining rates of rheumatic heart disease coupled with improved survival in children with congenital heart disease (CHD) have caused shifts in incidence.
- In a study of 51 children with *Staphylococcus aureus* bacteremia, 11.8% developed infective endocarditis, of whom 53% had CHD (3).

### RISK FACTORS

- CHDs, especially those with high-velocity or turbulent blood flow such as aortic valve stenosis, mitral valve regurgitation, ventricular septal defect (VSD), patent ductus arteriosus (PDA), and tetralogy of Fallot
- Implanted devices such as prosthetic valves, systemic-pulmonary shunts (eg, Blalock-Taussig shunt or Rastelli shunt), and septal defect patches
- Indwelling venous catheters
- Rheumatic heart disease
- IV drug use

### GENERAL PREVENTION

- Maintenance of good oral health and hygiene
- Antibiotic prophylaxis in patients with:
  - Prosthetic valves
  - Acquired valvular abnormalities (eg, rheumatic heart disease)
  - Systemic-pulmonary shunts
  - Hypertrophic cardiomyopathy
  - Previous history of bacterial endocarditis
  - Repair of an atrial septal defect (ASD), VSD, or PDA within 6 mo of surgery
  - Any unrepaired congenital cardiac malformations, except:
    - Secundum ASD
    - Mitral valve prolapse without regurgitation

### PATHOPHYSIOLOGY

- Endothelium damaged by turbulent or high-velocity blood flow, surgical manipulation, or indwelling catheters induces thrombogenesis.
- Sterile vegetations composed of platelets, fibrin, and RBCs form, leading to nonbacterial thrombotic endocarditis.
- Transient bacteremia from dental, respiratory tract, or genitourinary tract procedures causes colonization of the vegetations, with subsequent deposition of additional platelets and fibrin.

- Microbial colonies are shielded from normal phagocytic mechanisms, reaching high growth densities and then becoming metabolically inactive.
- Depending on its intracardiac location, vegetations may embolize to the systemic or pulmonary circulation, leading to neurologic, renal, GI, pulmonary, cutaneous, or fulminant manifestations.

### ETIOLOGY

- Improved survival among neonates and children with CHD has led to a shift in etiologic factors:
  - 22% cyanotic CHD
  - 13% nosocomial infections
  - 9% unrepaired VSD
  - 6% community acquired
  - 5% acyanotic CHD
  - 4% mitral valve prolapse with regurgitation
  - 3% rheumatic heart disease
- The vast majority of infective endocarditis is caused by  $\alpha$ -hemolytic viridans group streptococci (eg, *Streptococcus mutans*, *Streptococcus sanguinis*, *Streptococcus mitis*) and *S. aureus*:
  - Together, these organisms cause 59–76% of cases (1).
  - *S. aureus* is the most common cause of acute bacterial endocarditis.
- Infections associated with prosthetic material such as valves, indwelling catheters, and systemic-pulmonary shunts are usually due to *S. aureus* or coagulase-negative staphylococci (eg, *Staphylococcus epidermidis*).
- Other organisms include *Streptococcus pneumoniae*, *Streptococcus bovis*, and *Enterococcus* species.
- HACEK group bacteria (*Haemophilus parainfluenzae*, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* species, *Kingella kingae*) are less common causes in pediatric patients.
- Fungal endocarditis is caused by *Candida* or *Aspergillus* species; seen in neonates or associated with central venous catheters with parenteral nutrition.
- Fungal vegetations can grow to large sizes and frequently embolize, causing grave complications including mycotic aneurysms.

## DIAGNOSIS

### HISTORY

- The typical presentation is indolent and often consists of nonspecific complaints:
  - Unexplained or prolonged fever  $\geq 38^{\circ}\text{C}$
  - Fatigue or weakness
  - Myalgias or arthralgias
  - Diaphoresis
  - Weight loss
  - Rigors

- Unexplained specific complaints:
  - New neurologic deficits
  - New-onset hematuria
  - Cutaneous lesions
  - Conjunctival hemorrhages
  - Hemoptysis or respiratory distress
- Patients with CHD and a persistent fever should be evaluated for infective endocarditis.

### PHYSICAL EXAM

- The cardiac exam varies with the type of underlying CHD and the specific site of infection.
- New regurgitant murmurs may be auscultated when valve leaflet destruction is present.
- However, an unchanged cardiac exam does not rule out infective endocarditis.
- Decreasing oxygen saturation levels due to flow obstruction may occur in patients with systemic-pulmonary shunts or conduits.
- Signs of heart failure may occur with severe valvular involvement or dehiscence of prosthetic material.
- Arthritis or arthralgias can be found especially in older children.
- Tachypnea, respiratory distress, hypoxemia, or pneumonia can develop from septic pulmonary embolization.
- Focal neurologic deficits or meningismus occur from embolic events or aneurysms.
- Neonates may present with tachycardia, hypotension, respiratory distress, apnea, seizures, or focal neurologic deficits.
- Classically described extracardiac findings, such as Roth spots, Janeway lesions, Osler nodes, hemorrhages, or splenomegaly are uncommon in children.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Aerobic blood culture with antibiotic susceptibility testing:
  - It is critically important to obtain this prior to initiation of antibiotics.
  - 1–3 mL in infants and 5–7 mL in children is optimal, and 3 serial blood cultures via separate venipunctures should be obtained if possible.
  - Timing of blood culture draws need not coincide with fever spikes since bacteremia is usually constant.
  - If unusual or fastidious organisms are suspected, use appropriate culture media.
- CBC may show a bandemia, but leukocytosis is not always present. Anemia of chronic inflammation or hemolytic anemia may be present.
- $\uparrow$  ESR,  $\uparrow$  C-reactive protein, and hypergammaglobulinemia are nonspecific but helpful indicators.
- Urinalysis to determine the presence of microscopic hematuria
- Cutaneous emboli scrapings may be cultured.

**Imaging**

- Echo is the imaging mainstay of diagnosis and monitoring in infective endocarditis.
- Echo provides a quick, noninvasive, method for evaluation of infected sites:
  - Findings include vegetations, abscesses, or associated pericardial effusion. Cardiac function and ventricle size should be noted.
  - Color Doppler is used to detect acute changes in valvular insufficiency and intracardiac flow patterns.
- Transthoracic echocardiography (TTE) has a reported 51% sensitivity and 92% specificity in detecting vegetations in adults (5). Sensitivity of 81% has been reported in pediatric patients (6).
- Transesophageal echocardiography (TEE) may be preferred in children who are obese, very muscular, or have pulmonary hyperinflation. TEE is recommended in patients with suspected endocarditis involving the aortic valve (1).

**DIFFERENTIAL DIAGNOSIS**

- Viral syndrome
- Bacterial sepsis
- Meningitis
- Pneumonia
- Osteomyelitis
- Septic arthritis
- Myocarditis or pericarditis
- CHF
- Kawasaki disease
- Rheumatic heart disease
- Oncologic conditions (eg, leukemia)

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- IV fluid resuscitation as needed to maintain an adequate BP
- Consultation with a pediatric cardiologist and/or infectious disease (ID) specialist is recommended.

**MEDICATION****First Line**

- A prolonged course ( $\geq 2$ –6 wk) of antibiotics is always indicated in infective endocarditis due to poor penetration into the fibrin-coated thrombus.
- The low metabolic rate of embedded bacteria also make them less susceptible to  $\beta$ -lactam antibiotics.
- Antibiotic regimens are chosen based on the isolated microorganism and the presence of prosthetic material.
- Streptococcus* species susceptible to penicillin: Penicillin G 50,000 U IV q6h or ampicillin 50 mg/kg IV q6h or ceftriaxone 100 mg/kg IV q24h
- Streptococcus* species susceptible to penicillin with prosthetic material: Penicillin G 50,000 U IV q6h or ampicillin 50 mg/kg IV q6h or ceftriaxone 100 mg/kg IV q24h and gentamicin 3 mg/kg IV q8h
- Streptococcus* species not susceptible to penicillin or *Enterococcus* species: Penicillin G 50,000 U IV q6h or ampicillin 50 mg/kg IV q6h and gentamicin 3 mg/kg IV q8h

- MSSA: Nafcillin 50 mg/kg IV q6h or oxacillin 50 mg/kg IV q6h with or without gentamicin 3 mg/kg IV q8h
- MRSA: Vancomycin 10 mg/kg IV q6h
- MSSA with prosthetic material: Nafcillin 50 mg/kg IV q6h or oxacillin 50 mg/kg IV q6h or cefazolin 25 mg/kg IV q6h and gentamicin 3 mg/kg IV q8h and rifampin 7 mg/kg PO q8h
- MRSA with prosthetic material: Vancomycin 10 mg/kg IV q6h and gentamicin 3 mg/kg IV q8h and rifampin 7 mg/kg PO q8h
- HACEK group bacteria: Ampicillin 50 mg/kg IV q6h and gentamicin 3 mg/kg IV q8h or a 3rd-generation cephalosporin
- For other gram-negative bacteria, consultation with an ID specialist is recommended.
- Fungal endocarditis:
  - Amphotericin B 0.25 mg/kg IV over 6 hr, then gradually increase to 1 mg/kg qd
  - Surgical resection of the thrombus is usually required. Efficacy of fluconazole is unclear. Medical therapy alone is rarely successful.

**Second Line**

If allergy to  $\beta$ -lactams, the following may be used. Dosages should be adjusted accordingly in patients with abnormal renal function:

- Streptococcus* species and native cardiac valves: Vancomycin 10 mg/kg IV q6h
- Enterococcus* species or *Streptococcus* species with prosthetic material: Vancomycin 10 mg/kg IV q6h and gentamicin 3 mg/kg IV q8h
- S. aureus*: Vancomycin 10 mg/kg IV q6h with or without gentamicin 3 mg/kg IV q8h

**SURGERY/OTHER PROCEDURES**

Indications for surgical intervention are progressive heart failure, perivalvular abscess or fistula, valve obstruction, prosthetic dehiscence, ruptured ventricular septum or sinus of Valsalva, embolic events, fungal endocarditis, and persistence of bacteremia despite antibiotic therapy.

**DISPOSITION****Admission Criteria**

- All patients with suspected endocarditis should be admitted for IV antibiotic therapy and serial blood cultures.
- Critical care admission criteria:
  - Consider critical care admission in patients with hemodynamic instability or fulminant endocarditis.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

All patients should be admitted for ID and cardiology evaluation.

**COMPLICATIONS**

CHF, embolic events, perivalvular extension of infection, arrhythmia, heart block, prosthetic valve dehiscence, prosthetic shunt obstruction, mycotic aneurysm, glomerulonephritis, seeding of microorganisms, persistent bacteremia

**CODES****ICD9**

- 041.10 *Staphylococcus* infection in conditions classified elsewhere and of unspecified site, *staphylococcus, unspecified*
- 421.0 Acute and subacute bacterial endocarditis

**PEARLS AND PITFALLS**

- Infective endocarditis requires prolonged treatment courses.
- Correct management in the emergency department has a critical impact on subsequent diagnostic procedures.
- Be aware of the need for serial blood cultures from different venipuncture sites.
- Patients recently treated with antibiotics present a diagnostic dilemma, as negative cultures may not rule out infective endocarditis.

# INFLAMMATORY BOWEL DISEASE

Kyle A. Nelson

## BASICS

### DESCRIPTION

- Inflammatory bowel disease (IBD), usually Crohn's disease (CD) or ulcerative colitis (UC), is an immune-mediated disorder of chronic inflammation in the GI tract (1).
- Due to disease variability and limitations of diagnostic testing, some patients may be diagnosed with "indeterminate" colitis (2).
- Emergency department physicians may encounter patients undiagnosed with IBD having acute symptoms or patients with IBD exacerbations or complications.

### EPIDEMIOLOGY

#### Incidence

- Bimodal: 1st peak begins in 2nd decade of life (3).
- CD and UC incidences in U.S. children are estimated at 4.5 and 2.1 per 100,000 (3).
- 15–25% have onset at <20 yr of age (3).

#### Prevalence

- IBD is more common in industrialized nations in the Northern Hemisphere (2).
- ~140,000 U.S. children and adolescents have IBD; the prevalence may be rising (1).
- Specific IBD type may vary by age. Children <2 yr of age predominantly have "indeterminate" colitis, those age 3–5 yr have UC, and those >6 yr have CD (1).

### RISK FACTORS

- CD is more common in males <16 yr of age and in older females (1).
- UC has no gender predilection (2).
- 30% have a family history of IBD, indicating genetic risk factors (4).
- Other specific risk factors remain unclear.

### GENERAL PREVENTION

- Preventive measures are not established.
- Among those with IBD, medication and nutrition adherence may prevent or delay disease progression and complications.

### PATHOPHYSIOLOGY

- Chronic inflammation develops after an environmental or infectious trigger (1).
- Enteric bacterial flora play a role in IBD development; specific mechanisms are unclear (5,6).
- CD: Inflammation may occur at any point in the GI tract (terminal ileum affected in 50–70%) (4). Inflammation may be transmural with thickened bowel wall; unaffected areas may be interspersed between inflamed areas (skip lesions) (5,7).
- UC: Inflammation is usually limited to the mucosa and restricted to the colon. The rectum is affected with uninterrupted extension proximally to variable distances (4,5,7).

### ETIOLOGY

- Multifactorial: Occurs in genetically susceptible individuals whose immune systems react abnormally to environmental or infectious stimuli (1,2).
- Genetic association studies are ongoing.

### COMMONLY ASSOCIATED CONDITIONS

- 25–35% of children with IBD have extraintestinal manifestations (EIMs) that may precede GI symptoms (4,8,9).
- EIMs included: Arthritis, nephrolithiasis, erythema nodosum, pyoderma gangrenosum, recurrent fevers, oral ulcers, oral cheilitis, recurrent pancreatitis, cholangitis, choledocholithiasis, delayed puberty (4,8,9)

## DIAGNOSIS

### HISTORY

- IBD diagnosis and differentiation from acute self-limited colitis can be challenging.
- Most with IBD have GI symptoms >2 wk, with or without specific infections (7).
- IBD may be suspected if >2 GI illnesses occur within a 6-mo period (10).
- Symptoms may differ depending on areas of inflammation and extent of disease (2).
- 25–80% of children and adolescents with CD have the classic presentation of abdominal pain, diarrhea, poor appetite, and weight loss, though pain may precede diarrhea by weeks or months (8,10):
  - Other CD symptoms: Weight loss, blood in stool, fever, oral ulcer, arthralgia, perianal lesion (2,8)
- Bloody diarrhea is a typical symptom of UC:
  - Other UC symptoms: Pain at time of defecation, weight loss, fever (2)
- Acute severe pain may indicate severe toxic colitis, intestinal obstruction, or perforation.
- Consider serious infection in febrile patients on immunosuppressive therapy.

### PHYSICAL EXAM

- Most children have abdominal tenderness that is often vague and periumbilical, but it may localize:
  - CD: Commonly in the right middle quadrant (9)
  - UC: Commonly in the lower abdomen (9)
- Significant intravascular volume depletion may be present in patients with peritonitis, sepsis, hemorrhage, and obstruction.
- Carefully examine for EIMs, including perineum and perianal areas; findings increase suspicion for IBD (4).
- Many children have growth impairment at the time of diagnosis; assess weight and height (4).

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab Tests

- Lab tests lack sensitivity/specificity for IBD but are used to assess disease and complications.
- CBC may reveal microcytic hypochromic anemia and thrombocytosis (4,10).
- ESR and C-reactive protein may be elevated (more common in CD) but can be normal in mild disease (4,11,12).
- Albumin, prealbumin, and transferrin may be abnormal as acute-phase reactants and reflect poor nutritional status (4).
- Perinuclear neutrophil cytoplasmic antibody (pANCA) is positive in ~20% of CD patients and 80% of UC patients (4).

- Antisaccharomyces cerevisiae antibody (ASCA) is commonly positive in CD (2,4).
- Fecal inflammatory markers (lactoferrin, calprotectin, PMN-elastase, lysozyme) may correlate with disease activity (11,12).
- Consider infectious disease testing of stool in acute exacerbations.

### Imaging

- Abdominal radiography, CT, and US will not definitively diagnose IBD but may help to evaluate the differential diagnoses and complications.
- Radiography can often be rapidly obtained to assess for perforation or obstruction.
- CT is helpful in diagnosing fistulae and/or abscesses and obstruction.
- Though not diagnostic, CT findings suggestive of CD are mural thickening >2 cm, mesenteric fat stranding, adenopathy, abscesses, fistulae, and perianal disease (2).
- Upper GI study with small bowel follow-through can identify stricture in CD (4).
- Enterography using CT or MRI and enteroclysis using CT or MRI are being studied in IBD (13).

### Diagnostic Procedures/Other

- Flexible colonoscopy with ileoscopy and multiple biopsies is used for IBD diagnosis and for differentiating CD from UC (4,14).
- Esophagogastroduodenoscopy is also usually completed during the diagnostic workup (11).
- Flexible sigmoidoscopy and capsule endoscopy may be considered if colonoscopy is contraindicated (14).

### Pathological Findings

- IBD can be differentiated histologically from acute self-limited colitis if there are findings of chronic colitis (distorted crypt architecture, basal lymphoplasmacytosis, Paneth cell metaplasia) (7).
- CD features: Chronic colitis and/or ileitis with granulomatous inflammation, possibly transmural and discontinuous with skip lesions (7)
- UC features: Chronic colitis with nongranulomatous inflammation limited to mucosa and continuous with rectal involvement. With extensive proximal involvement, signs of ileitis may be present (7).

### DIFFERENTIAL DIAGNOSIS

- GI (2,4): Functional abdominal pain, constipation, gastroesophageal reflux, peptic ulcer disease, cholelithiasis, appendicitis, mesenteric adenitis, gastroenteritis, infectious or allergic colitis, intussusception, colonic polyposis, Meckel diverticulum, hemorrhoids
- Other (2,4): Ovarian cyst or torsion, urinary tract infection, hemolytic uremic syndrome, Fitz-Hugh-Curtis syndrome

## TREATMENT

Management of exacerbations and complications should ideally involve GI and surgery consultation.

### INITIAL STABILIZATION/THERAPY

Volume repletion, hemodynamic support, and broad-spectrum antibiotics may be necessary if the patient is critically ill with suspected obstruction, toxic megacolon, perforation, peritonitis, or sepsis.

### MEDICATION

Consultation with GI specialists is recommended to discuss optimal medications and dosing, which may differ according to disease type and severity.

#### First Line

- 5-aminosalicylates (5-ASA) medications (sulfasalazine, mesalamine, and balsalazide) are used as initial therapy in mild IBD (although use in CD is controversial) (2,4,11).
- Oral sulfasalazine is most commonly used:
  - Typical dose is 15 mg/kg PO 3 times per day

#### Second Line

- Systemic corticosteroids are often used in moderate to severe disease (4,11):
  - Typically, prednisone, prednisolone, or methylprednisolone (15)
  - Prednisone 1–2 mg/kg/day PO, max single dose 60 mg/day
  - Treatment for 4–6 wk may be necessary with dose tapering.
- Oral budesonide (Entocort ES) formulated to release distally may have fewer side effects (11):
  - 9 mg/day to achieve remission; maintenance dosing is 6 mg/day.
- Immunomodulators are considered for severe disease, refractory to other treatment (4,11,15):
  - Agents include azathioprine (2–3 mg/kg/day PO), 6-mercaptopurine (1–1.5 mg/kg/day PO), methotrexate (15–25 mg/wk IM), and cyclosporin (2–4 mg/kg/day IV)
- Biologic agents (eg, infliximab, a monoclonal anti-tumor necrosis factor antibody) are considered in severe disease (4,11,15).
- Metronidazole (10–15 mg/kg/dose PO 3 times/day) and ciprofloxacin (PO: 20–30 mg/kg/day in 2 divided doses; IV: 15–20 mg/kg/day in 2 divided doses) may be used in chronic therapy and acute treatment of fistulae, abscesses, and pouchitis (4,11).

### SURGERY/OTHER PROCEDURES

- Elective surgery may be necessary for disease that is uncontrolled with medical therapy (4).
- Proctocolectomy can be “curative” for UC; surgery is not curative in CD (4).
- Emergent surgery for perforation, massive hemorrhage, unresolving obstructions (16,17)
- Intra-abdominal abscesses may be drained using interventional radiology techniques (16,17).

### DISPOSITION

#### Admission Criteria

- Patients with undifferentiated GI disease, significant illness, and suspected IBD may require admission for diagnostic testing and GI consult.
- Most patients with worsening disease or acute complications require inpatient care.
- Critical care admission criteria:
  - Bowel perforation, toxic megacolon, sepsis, or other severe illness

### Discharge Criteria

After excluding acute complications, well-appearing patients with appropriate outpatient therapy may be discharged with close follow-up.

### Issues for Referral

- Management may require transfer to a center with pediatric surgical and GI expertise.
- Referral to a gastroenterologist for diagnostic procedures is recommended if IBD is suspected.

## FOLLOW-UP

- Optimal management involves a multidisciplinary team approach (9).
- Periodic cancer screening is recommended.

### DIET

- Calorie supplementation is frequently necessary to improve nutritional status (9).
- Many patients are deficient in iron and poorly absorb vitamins B<sub>12</sub> and D, folate, and calcium (9).

### PROGNOSIS

- While mortality is low, morbidity can be high.
- 1/3 of those with CD have chronically active steroid-refractory disease (8).
- Ultimately, 50% of CD patients require surgery, but the recurrence rate may exceed 75% (2).
- 10% of those with UC have continuous symptoms (8).
- 15–40% of UC patients will require surgery (2).

### COMPLICATIONS

- UC: Toxic megacolon, perforation, peritonitis, massive hemorrhage, colorectal cancer (4)
- CD: Stricture, obstruction, fistula, perforation, peritonitis, abscess (4)
- Other: Primary sclerosing cholangitis, pouchitis, thromboembolism, failure to thrive (4)

## CODES

### ICD9

- 555.9 Regional enteritis of unspecified site
- 556.8 Other ulcerative colitis
- 558.9 Other and unspecified noninfectious gastroenteritis and colitis

## PEARLS AND PITFALLS

- Acute complications of IBD include life-threatening medical and surgical emergencies.
- The chronicity of symptoms helps distinguish IBD from acute infectious enteritis.

# INFLUENZA

Magdy W. Attia

## BASICS

### DESCRIPTION

- Influenza (flu) is a contagious respiratory illness caused by influenza viruses.
- Outbreaks usually occur during winter months.
- Seasonal influenza is a disease caused by the each year's predominant circulating viral subtype.
- Transmission is by aerosols created by coughing and sneezing.
- Pandemics with massive mortality have occurred:
  - Worldwide outbreak of disease is caused by a novel viral subtype.
- 1% of children with influenza will be hospitalized as a result.

### EPIDEMIOLOGY

#### Incidence

- Influenza pandemics occur every few decades. The most recent H1N1 pandemic began in the spring of 2009.
- Seasonal influenza epidemics are responsible for 3–5 million cases of severe illness and 250,000–500,000 deaths worldwide annually (1).
- Each year in the U.S., >200,000 people are hospitalized from flu complications and 36,000 people die from it (1).
- In the 2007–2008 flu season, 83 deaths in children were reported to the CDC.

#### Prevalence

- Each year in the U.S., on average, 5–20% of the population gets infected with influenza virus (2,3).
- ~15–20% of children are infected with influenza during annual outbreaks.

### RISK FACTORS

- For contracting the disease:
  - Exposure
  - Poor hand hygiene
  - Lack of immunization
  - Novel viruses
- For severity and complications:
  - The very elderly and the very young
  - Smoking
  - Underlying high-risk medical conditions such as lung disease, cardiac history, renal insufficiency, metabolic disorders, neuromuscular disease, and immune deficiency.
  - Pregnancy

### GENERAL PREVENTION

- Hand washing is considered the most effective method of prevention.
- Covering coughs and sneezes is another important preventative strategy.
- Infected persons should maintain social distancing by not attending work or school.
- Isolation of index cases may help decrease the spread of the disease. Since infectivity begins a day before the onset of symptoms, the effectiveness of isolation is limited.
- Other public safety measures such as school closure could be warranted if disease is widespread or pandemic (4).
- Face mask use when sharing common spaces with other household members may help prevent spreading the virus to others. The CDC does not recommend the widespread use of face masks in public.
- Influenza vaccination on a yearly basis can protect against influenza A and B viruses. The flu vaccine does not protect against influenza C viruses.
- The CDC recommends annual flu vaccination for all children  $\geq 6$  mo of age.
- Influenza antiviral drugs can be used to prevent influenza in subjects who are exposed but not ill with 70–90% efficacy. Chemoprophylaxis is not approved for infants <3 mo of age.
- Waterfowl are a common reservoir for influenza virus. In some areas, particularly Southeast and East Asia, mass slaughter of waterfowl is undertaken to prevent spread of deadly influenza such as H5N1 (avian flu).

### PATHOPHYSIOLOGY

See Etiology.

### ETIOLOGY

- 2 main types of influenza viruses cause seasonal epidemics: A and B.
  - Influenza A viruses are divided into subtypes based on 2 surface proteins: the hemagglutinin (H) and the neuraminidase (N).
  - Influenza B viruses are not divided into subtypes. There are several different types of influenza B strains.
- Type C causes mild respiratory illness but is not implicated in epidemics.
- In the fall of 2009, the subtypes of influenza A viruses circulating in humans were H1N1 (pandemic influenza) and H3N2 (seasonal influenza).
- Epidemics occur every 1–3 yr as a result of antigenic drift (minor changes in surface protein).
- Pandemics occur every 20–30 yr as a result of antigenic shift (major changes in virus structure).

### COMMONLY ASSOCIATED CONDITIONS

- Otitis media
- Exacerbation of asthma or reactive airway disease
- Croup
- Bronchiolitis
- Pneumonia
- Pharyngitis
- Sinusitis
- Conjunctivitis

## DIAGNOSIS

### HISTORY

- Clinical symptoms are similar for upper respiratory illnesses but are typically more severe.
- The classic symptoms of abrupt onset of fever, cough, coryza, chills, sore throat, headache, anorexia, fatigue, and myalgias are seen mostly in adults.
- These symptoms may not be as easily identified in younger children.
- Young children may also complain of vomiting, diarrhea, abdominal pain, or present with wheezing or a vague febrile illness.

### PHYSICAL EXAM

- Vital signs may reveal fever, tachycardia, and tachypnea.
- Constellation of respiratory findings may be present: Coryza, dry cough, rhonchi, wheezing, rales, retractions, nasal flaring.
- Other findings may include conjunctival injection, pharyngeal erythema, cervical adenopathy, otitis media, and abdominal tenderness.
- Tender leg muscles indicate myositis.
- Signs of dehydration or respiratory distress
- In rare occasions, patients may appear septic or in shock.

**DIAGNOSTIC TESTS & INTERPRETATION****Lab****Initial Lab Tests**

- Rapid influenza test with viral isolation in case of a negative rapid test.
- Clinicians need to keep in mind that the sensitivity of the rapid test is poor.
- With widespread disease, a clinical diagnosis of influenza without testing is appropriate.
- Indication for testing should be guided by the need for treatment, isolation or prophylaxis.
- Serologic testing for influenza may be performed if it is important to know the viral subtype, as in a pandemic.
- Other lab studies are not specific for establishing the diagnosis but may be ordered in the context of evaluating the febrile patient who is acutely ill or dehydrated:
  - CBC
  - Blood culture
  - Basic metabolic panel
  - Urine specific gravity

**Imaging**

A CXR may be indicated for select patients with suspected pneumonia.

**DIFFERENTIAL DIAGNOSIS**

- Common cold
- Seasonal allergies
- Viral upper respiratory tract infection
- Asthma
- Bronchiolitis
- Pneumonia
- Infectious mononucleosis
- Gastroenteritis

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Airway, breathing, and circulation should be assessed and stabilized.
- Initial management is typically focused on ruling out serious illness or concomitant dehydration or pneumonia.
- The mainstay of treatment is supportive care including hydration, use of antipyretics, and pain relief.
- In case of seasonal flu, antiviral therapy with oseltamivir begun within 24–48 hr of the onset can shorten the course of illness.

**MEDICATION****First Line**

- Antipyretics/Analgesics:
  - Ibuprofen 10 mg/kg PO/IV q6h as needed
  - Acetaminophen 15 mg PO/PR q4h as needed.

**Second Line**

- The decision to treat a symptomatic child presumptively with oseltamivir is a complicated one based on the child's age, duration of illness, degree of illness, and presence of co-morbidities.
- Antiviral therapy protocol:
  - Oseltamivir is approved to treat influenza A and B virus infection in children. The dosing schedule is as follows:
    - <3 mo of age: 12 mg b.i.d.
    - 3–5 mo: 20 mg b.i.d.
    - 6–11 mo: 25 mg b.i.d.
    - ≤15 kg: 60 mg/day divided into 2 doses
    - 16–23 kg: 90 mg/day divided into 2 doses
    - 24–40 kg: 120 mg/day divided into 2 doses
    - >40 kg: 150 mg/day divided into 2 doses
  - Amantadine: <40 kg, 5 mg/kg/day PO divided per day–b.i.d.; >40 kg, 200 mg/day divided per day–b.i.d.
  - Zanamivir is approved to treat influenza A and B virus infection in those ≥7 yr of age. The dose is two 5-mg inhalations (max single dose 10 mg) b.i.d.

**DISPOSITION****Admission Criteria**

- Febrile infants <4 wk of age who have a fever
- Children who present with evidence of significant complication requiring admission such as respiratory distress, pneumonia, or dehydration
- Critical care admission criteria:
  - Severe respiratory distress, acute respiratory distress syndrome, or respiratory failure

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

A close follow-up should be arranged with the primary care provider within 1–3 days of the initial evaluation.

**PROGNOSIS**

- Influenza is usually a benign self-limited illness.
- The vast majority of patients recover without consequences.
- In children with high-risk medical conditions, the infection can be particularly severe and may lead to significant morbidity or mortality.
- The rate of death from influenza infection in children is far less than that in adults.

**COMPLICATIONS**

- Secondary bacterial infections:
  - Pneumonia
  - Sinusitis
  - Otitis media
  - Pharyngitis
- Bronchiolitis
- Exacerbation of asthma/reactive airway disease
- Respiratory distress
- Respiratory failure
- Meningoencephalitis
- Myocarditis/Pericarditis
- Guillain-Barré syndrome
- Reye syndrome

**REFERENCES**

1. <http://www.cdc.gov/washington/pdf/flu.pdf>
2. Glezen WP. Emerging infections: Pandemic influenza. *Epidemiol Rev.* 1996;18:64–76.
3. Neuzil KM, Zhu Y, Griffin MR, et al. Burden of inter-pandemic influenza in children younger than 5 years: A 25-year prospective study. *J Infect Dis.* 2002;185:147–152.

**ICD9**

- 487.0 Influenza with pneumonia
- 487.1 Influenza with other respiratory manifestations
- 487.8 Influenza with other manifestations

**PEARLS AND PITFALLS**

- Pearls:
  - When influenza is widespread in a community, a clinical diagnosis of influenza can be made for most children with an influenza-like illness without the need for specific viral testing.
  - For pandemic influenza, CDC guidelines and surveillance reports will provide information on prevalence, management, and prophylaxis guidelines.
- Pitfalls:
  - Failure to understand that influenza may cause lower respiratory infection
  - Failure to diagnose respiratory distress or respiratory failure
  - Aspirin or salicylate-containing products (eg, bismuth subsalicylate [Pepto Bismol]) should not be administered to any confirmed or suspected case of influenza to avoid the potential development of Reye syndrome.

# INHALANT ABUSE/POISONING

David J. Story  
Sari Soghoian

## BASICS

### DESCRIPTION

- Inhalant poisoning is caused by the intentional inhalation of chemical vapors with the intent to alter consciousness:
  - Inexpensive, legally obtainable volatile hydrocarbons are most commonly used.
  - Nitrous oxide is also commonly used.
  - Rarely, other substances such as ethyl chloride, ether, or volatile anesthetics may be used.
- Abuse by:
  - Sniffing (directly from container)
  - Huffing or ragging (covering the mouth and nose with contaminated fabric or cloth)
  - Bagging (rebreathing from a bag containing the solvent)
- Such abuse is most common in teenagers and adolescents.

### EPIDEMIOLOGY

#### Incidence

4.5% of 12–17 yr olds have used inhalants in the past year.

#### Prevalence

- Lifetime prevalence is 10.5%.
- Peak at 14–15 yr of age

### RISK FACTORS

- Low socioeconomic status
- Immigrant
- History of depression (2–3 times more likely to use inhalants)

### GENERAL PREVENTION

- General education about risks associated with use
- Keep all solvents out of reach of children.
- Restrict sale of commonly abused home solvents and hydrocarbons (ie, keyboard cleaner) to minors.

### PATHOPHYSIOLOGY

- Lipophilic solvents quickly distribute to the CNS.
- Diffusion from alveoli into the blood is dependent on local concentration, partition coefficient, respiratory rate, pulmonary blood flow, and body fat.
- The cellular mechanism by which consciousness is altered is unclear, though it is thought to act through GABA activation.
- Eliminated unchanged via respiration or metabolized in liver

- Halogenated and aromatic hydrocarbons may hypersensitize the myocardium to produce an exaggerated response to endogenous or exogenous catecholamines:
  - This may result in “sudden sniffing death”:  
Sudden cardiovascular collapse if the patient is startled or has a sudden release of epinephrine
- Mechanism of permanent injury, including cardiomyopathy, neurocognitive impairment, cerebellar dysfunction, and peripheral neuropathy, is unclear for most substances.
- Nitrous oxide may cause megaloblastic anemia and peripheral neuropathy.
- Renal injury and renal tubular acidosis may result from toluene and other hydrocarbons.

### ETIOLOGY

- Acetone (nail polish remover)
- n-Butane
- 1,4-Butanediol
- Carbon tetrachloride
- Ether
- Gasoline
- n-Hexane (rubber cement)
- Isobutyl nitrite
- Methylene chloride
- Nitrous oxide
- Polycyclic aromatic hydrocarbons
- Toluene
- 1,1,1-Trichloroethane
- Trichloroethylene
- Ethyl chloride
- Volatile anesthetics

### COMMONLY ASSOCIATED CONDITIONS

- Dysrhythmias
- Type 4 renal tubular acidosis
- Methemoglobinemia (nitrites)

## DIAGNOSIS

### HISTORY

- Direct history from patient
- Discovery of solvents and/or inhaling paraphernalia (bags, rags)
- Dyspnea
- Palpitations
- Nausea/Vomiting, diarrhea
- Headaches
- Dizziness
- Patients may present after inadvertently drinking liquid intended for inhalation.

### PHYSICAL EXAM

- Assess vital signs and pulse oximetry:
  - Cardiac dysrhythmia may result from many types of hydrocarbons, particularly those that are halogenated or aromatic.
  - Methemoglobinemia may result from nitrates.
- Neurologic findings are most prominent:
  - Altered level of consciousness
  - Slurred speech
  - Transient cranial nerve palsies
  - Nystagmus
  - Tremor
  - Ataxia
  - Neuropathy, both cranial nerve and peripheral
- Rash around the mouth and nose may be present due to chronic irritation by solvent use.
- Distinct breath odor corresponding to solvent

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Serum electrolytes:
  - Chronic use, particularly of toluene, may result in renal tubular acidosis.
- Creatine phosphokinase may be elevated, especially with toluene.
- Myoglobin may be elevated, especially with toluene.
- Hepatic function panel
- CBC may reveal megaloblastic anemia from nitrous oxide, aplastic anemia, or leukemia from benzene.
- Blood gas analysis
- Methemoglobin level may be elevated with nitrite use.
- Blood lead level may be elevated with exposure to leaded gasoline (sale prohibited in U.S. in 2008).
- Confirmatory testing for positive identification is not generally available or required for acute management:
  - Gas chromatography can identify most inhalants in serum.
  - Hippuric acid is present in the urine of toluene users.

#### Imaging

- CXR if chemical pneumonitis is suspected (shortness of breath, hypoxia):
  - Pneumothorax or pneumomediastinum may be present if the agent was inhaled directly from a pressurized bottle or tank.
- CT brain for undifferentiated altered mental status
- MRI brain for chronic use associated with the development of leukoencephalopathy (follow-up testing, not in initial phase)

**Diagnostic Procedures/Other**

- ECG
- Electromyography for peripheral neuropathy (follow-up testing, not in initial phase)

**Pathological Findings**

- Frequent premature ventricular contractions (PVCs)
- Dysrhythmia

**DIFFERENTIAL DIAGNOSIS**

- Effects from other drugs of abuse
- Alcohol intoxication (ethanol, methanol, isopropanol, or ethylene glycol)
- Metabolic derangement (acidosis, electrolyte abnormalities, hyperglycemic coma)
- Meningitis, encephalitis
- Migraine headache
- Sedative hypnotic ingestion
- Trauma with intracerebral injury

**TREATMENT**

**PRE HOSPITAL**

Assess and stabilize airway, breathing, and circulation.

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Administer supplemental oxygen if any symptoms are present.
- Supportive care
- Keep patient calm, quiet
- Minimize environmental disturbances

**MEDICATION**

**First Line**

- Benzodiazepines for agitation or seizure
- Diazepam 0.05–0.1 mg/kg IV over 2–3 min (max single dose 10 mg), may repeat q5–10min PRN
- Midazolam 0.1 mg/kg IV, may be repeated q5–10min PRN
- Lorazepam 0.05 mg/kg IV over 2–5 min (max single dose 4 mg), may be repeated q10min PRN
- Hyperbaric oxygen for carbon monoxide (direct or related to methylene chloride inhalation)
- Beta-blockers may be useful if dysrhythmias present from sensitized myocardium.
- Propranolol 0.01 mg/kg slow IV push over 10 min, may be repeated in 6 hr to max single dose dose of 0.15 mg/kg/dose
- Methylene blue, indicated for methemoglobinemia; 1–2 mg/kg IV over 5 min
- Refer to the Methemoglobinemia topic for treatment indications.

**DISPOSITION**

**Admission Criteria**

- Persistent neurologic findings
- Renal injury
- Suicidality
- Critical care admission criteria:
  - Dysrhythmia
  - Hypoxia, acute lung injury

**Discharge Criteria**

- Effects generally last <2 hr, and a return to the patient’s neurologic baseline without any evidence of cardiotoxicity allows for safe discharge.
- Patient should be evaluated for depression and/or suicidality prior to discharge
- Social work consultation may be helpful

**Issues for Referral**

Although admission is sometimes necessary, referral to another hospital is required only if the necessary level of care (ie, ICU) is unavailable.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Do not use inhalants.

**Patient Monitoring**

Patients with persistent palpitations, dysrhythmia, frequent PVCs, or other cardiac findings require observation on a telemetry unit.

**PROGNOSIS**

- In the acute setting of intoxication, the prognosis for recovery is excellent.
- If chronic use has resulted in neuropathy, neurocognitive changes, or cardiac changes, these may be permanent.

**COMPLICATIONS**

- Cardiotoxicity (sudden sniffing death): Myocardial sensitization by the inhalant can trigger a fatal dysrhythmia if the patient is startled, causing a catecholamine surge.
- Other dysrhythmia
- Megaloblastic anemia
- Aplastic anemia
- Leukemia
- Peripheral neuropathy
- Dilated cardiomyopathy
- Type 4 renal tubular acidosis
- Metabolic acidosis
- Methemoglobinemia

**See Also (Topic, Algorithm, Electronic Media Element)**

- Hydrocarbon Poisoning
- Methemoglobinemia

**CODES**

**ICD9**

- 968.2 Poisoning by other gaseous anesthetics
- 987.9 Toxic effect of unspecified gas, fume, or vapor

**PEARLS AND PITFALLS**

- Inhalants are commonly abused by children and adolescents, primarily due to accessibility.
- Various adverse effects such as cardiac dysrhythmia, methemoglobinemia, and renal tubular acidosis are possible.
- Cardiac dysrhythmia secondary to halogenated or aromatic hydrocarbons may result in sudden sniffing death or other cardiac morbidity or mortality. Administer beta-blockers for multiple PVCs or ventricular tachycardia in this setting.

# INTESTINAL MALROTATION

Jeffrey A. Seiden

## BASICS

### DESCRIPTION

- *Intestinal malrotation* is a general term used to describe anomalies in typical intestinal rotation and fixation during fetal development.
- Midgut volvulus is a common complication of intestinal rotation, often presenting in the neonatal period.
- *Midgut volvulus* is defined as a twisting of the small bowel around the superior mesenteric artery with resultant bowel ischemia and necrosis.

### EPIDEMIOLOGY

#### Incidence

- Occurs in 1/500 live births, though many never become symptomatic
- Most patients present when the malrotation is complicated by midgut volvulus.
- Up to 40% present in the 1st week of life
- 50% diagnosed by 1 mo of age
- 75% diagnosed by 1 yr of age

### RISK FACTORS

- Male gender: In the neonatal period, the male to female ratio is 2:1.
- Other intestinal anomalies such as stenosis or atresia
- Other nonintestinal anomalies such as congenital heart disease

### PATHOPHYSIOLOGY

- During the 4th to 8th wk of embryonic development, the primary intestinal loop grows and rotates 90 degrees outside the abdominal cavity.
- During the 8th to 10th wk, the bowel returns to the abdomen and rotates another 180 degrees.
- Once normal rotation is completed, the proximal portion is fixed to the posterior abdomen at the ligament of Treitz.
- Abnormal or incomplete rotation results in the midgut being suspended on a narrow vascular pedicle rather than the normal wide base of mesentery.

### ETIOLOGY

Intestinal obstruction in patients with intestinal malrotation occurs in 2 ways:

- The narrow pedicle allows the mesentery to twist, resulting in midgut volvulus (intestinal torsion)
- Bands of peritoneum (Ladd bands) stretch across the duodenum to fixate abnormally located cecum. These can cause extrinsic compression and obstruction.

### COMMONLY ASSOCIATED CONDITIONS

- Vomiting
- Gastroschisis
- Omphalocele
- Congenital diaphragmatic hernia
- Duodenal or jejunoileal atresia
- Hirschsprung disease
- Gastroesophageal reflux
- Intussusception
- Anorectal malformations
- Persistent cloaca

## DIAGNOSIS

### HISTORY

- Acute midgut volvulus often presents in the neonatal period or early infancy with the sudden onset of bilious emesis.
- Acute duodenal obstruction (by Ladd bands) presents with forceful vomiting, which may or may not be bilious:
  - A high or proximal obstruction may not be associated with bilious emesis.
- Vomiting tends to be nonprojectile.
- Intolerance of feeds
- Decreased urine output
- Chronic volvulus or obstruction often presents later in childhood with recurrent abdominal pain, vomiting, and failure to thrive.

### PHYSICAL EXAM

- Bilious emesis
- Acute midgut volvulus presents with abdominal distention, pain, guarding, and bilious emesis.
- As the intestinal vasculature becomes further compromised, patients may have bright red blood per rectum and/or hematemesis secondary to bowel ischemia and necrosis.
- Patients may present with signs of dehydration or shock in advanced disease.
- Acute duodenal obstruction may present with abdominal distention and gastric peristaltic waves, similar to that seen in infants with pyloric stenosis.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC
- Basic metabolic panel
- Blood gas analysis and serum lactate
- Type and screen as per institutional protocol

#### Imaging

- Plain abdominal radiographs: May show signs of duodenal obstruction (double bubble sign) or a bowel gas pattern consistent with small bowel obstruction:
  - X-rays may be normal, thus limiting their utility.
- Upper GI series: Study of choice for stable patients. Failure of contrast to advance or seeing it taper in a corkscrew pattern is consistent with midgut volvulus.
- US: Requires an experienced pediatric radiologist for interpretation. May reveal inversion of the superior mesenteric artery and vein:
  - Can help to rule in or rule out other etiologies such as pyloric stenosis

#### Diagnostic Procedures/Other

NG tube insertion: Allows for proximal decompression

**DIFFERENTIAL DIAGNOSIS**

- Surgical causes of small bowel obstruction in early infancy:
  - Necrotizing enterocolitis
  - Intussusception
  - Pyloric stenosis
  - Duodenal or jejunoileal atresia
  - Anorectal malformations
- Nonsurgical etiologies of vomiting in early infancy:
  - Overfeeding
  - Ileus
  - Gastroenteritis
  - Gastroesophageal reflux
  - Raised intracranial pressure
  - Congenital adrenal hyperplasia
  - Metabolic disease

**TREATMENT**

**PRE HOSPITAL**

- Stabilize airway, breathing, and circulation, as indicated.
- Obtain vascular access and administer IV fluid if necessary.
- Keep patient NPO.

**INITIAL STABILIZATION/THERAPY**

- Stabilize airway, breathing, and circulation, as indicated
- Obtain vascular access and administer IV fluid if necessary.
- Keep patient NPO.
- Fluid resuscitation to correct hypovolemia, acidemia, and shock if present
- Correct electrolyte derangements.
- NG tube to low intermittent suction
- Administer appropriate analgesics, typically opioids.
- Immediate pediatric surgery consultation

**MEDICATION**

Broad gram-positive and gram-negative antibiotic coverage is needed:

- Ampicillin 50 mg/kg/dose IV t.i.d.–q.i.d.
- Gentamicin 5 mg/kg/dose IV as single daily dose or 2.5 mg/kg/dose IV t.i.d.
- Clindamycin 10 mg/kg/dose IV t.i.d.

**SURGERY/OTHER PROCEDURES**

- Ladd procedure: Reduction of volvulus (if present), division of Ladd bands, resection of necrotic bowel (with or without stoma creation), placement of small bowel on right and colon on left side of abdomen, appendectomy
- May consider laparoscopic technique if no volvulus is present

**DISPOSITION**

**Admission Criteria**

- All patients with symptomatic intestinal malrotation should be admitted for surgical treatment and postoperative care.
- Critical care admission criteria:
  - A pediatric ICU is warranted for immediate postoperative care.

**Discharge Criteria**

Patients with malrotation without volvulus may be discharged.

**Issues for Referral**

Patients diagnosed with malrotation without volvulus should be referred to a pediatric surgeon.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Patients will require continued care after hospitalization to ensure proper nutrition, growth, and development.

**PROGNOSIS**

- Overall mortality in patients with symptomatic intestinal malrotation is up to 9%, though patients without intestinal necrosis have a mortality rate of 1%.
- Recurrent volvulus occurs in ~3% of patients after successful surgery.

**COMPLICATIONS**

- Bowel obstruction
- Volvulus
- Dehydration
- Peritonitis
- Shock
- Sepsis
- Bowel necrosis

**ADDITIONAL READING**

**See Also (Topic, Algorithm, Electronic Media Element)**

- Pain, Abdomen
- Vomiting

**CODES**

**ICD9**

751.4 Congenital anomalies of intestinal fixation

**PEARLS AND PITFALLS**

- Any pediatric patient with the sudden onset of bilious emesis needs to be evaluated for intestinal malrotation with midgut volvulus.
- Volvulus involving proximal bowel may not be associated with abdominal distention or bilious emesis.
- In contrast to pyloric stenosis, infants with malrotation and volvulus tend to present sooner after birth and have bilious, nonprojectile emesis.

# INTRASOSEOUS INFUSIONS

Mark R. Zonfrillo

## BASICS

### DESCRIPTION

- Intraosseous (IO) placement is an emergent intravascular access technique used when attempts at peripheral access are unsuccessful.
- Use of IO infusions has gained acceptance in older children and adults.
- Placement of an IO needle is typically much more rapid than a central vascular line.
- The short length of an IO needle allows more rapid infusion of fluid than a central vascular line.

### EPIDEMIOLOGY

- IO infusions were 1st used in the 1920s and were the preferred vascular access technique for children in the 1930s.
- When plastic IV catheters were invented, the use of IO needles diminished.
- Although IO infusions were utilized in World War II, there was no subsequent increase in civilian use.
- In the late 1980s, the Pediatric Advanced Life Support (PALS) guidelines reintroduced the use of IO needles for children <6 yr old. The 2005 PALS guidelines expanded the use to all children.

### PATHOPHYSIOLOGY

- The bone marrow space serves as a “noncollapsible” vein that feeds into the central venous canal, nutrient vessels, and the central circulation.
- The short length of an IO needle allows more rapid infusion of fluid than a central vascular line.

### ETIOLOGY

See Description.

## COMMONLY ASSOCIATED CONDITIONS

Some conditions for which an IO may be placed emergently:

- Apnea
- Cardiopulmonary arrest
- Circulatory collapse
- Sepsis
- Shock
- Status epilepticus

## DIAGNOSIS

### HISTORY

- The patient requires rapid vascular access for an emergent reason.
- Peripheral vascular access is unavailable.

### PHYSICAL EXAM

Needle should firmly be located in extremity and not need stabilizing:

- Laxity of the needle within the extremity indicates improper placement or dislodgement.

## DIAGNOSTIC TESTS & INTERPRETATION

### Imaging

The needle should be located firmly in the extremity and not need stabilizing.

- This is without long-term sequelae.
- Routine x-ray is unnecessary to confirm needle position or assess for fracture.

## DIFFERENTIAL DIAGNOSIS

Not applicable

## TREATMENT

- There are multiple manual and mechanical models available:
  - Most manual IO devices have a trocar in the lumen of the needle and are inserted with a screwing or twisting motion.
  - Newer mechanical models use an injection gun or power drill for needle insertion. For the drill, the needle tip is placed at a 90-degree angle and is drilled into the bone at a preset length on the needle. The stylet is unscrewed, and the needle can then be used with traditional tubing or syringes.
- For children, IO placement is preferred in the proximal tibia, distal tibia, or distal femur:
  - Placement in the proximal tibia is 1–2 cm distal to the tibial tuberosity, along the medial border of the bone.
  - Placement in the distal tibia is 1–2 cm proximal to the medial malleolus. The distal tibia should not be used if the same bone was attempted proximally.
  - Placement in the distal femur is 1–2 cm proximal to the femoral plateau.
- Contraindications to placement include underlying bone disorders (eg, osteogenesis imperfecta), a fractured bone, an overlying skin infection, or a previous attempt at the identical site or distal site in the same bone.

**TECHNIQUE**

- Gather the following supplies prior to IO insertion:
  - Povidone iodine or chlorhexidine
  - IO needle device
  - 10-mL syringe
  - Saline
  - IV tubing
- Find the landmarks for the particular bone.
- Place a towel roll under the joint or extremity as necessary.
- Thoroughly cleanse the overlying skin with sterilizing solution.
- Injection of 1–2% lidocaine into the subcutaneous tissue to the periosteum can be used for awake patients, although this should not delay IO needle insertion.
- With either the manual or mechanical method, insert the needle perpendicular to the bone until it rests in the marrow space. In skeletally immature children, insertion should be angled slightly away from the growth plate. When properly inserted, the needle should remain in the bone without any support.
- Attach the syringe and attempt aspiration of bone marrow. If aspiration is successful, placement is confirmed. If it is unsuccessful, attempt infusion with saline. If the IO infuses without resistance or soft tissue fluid extravasation, placement is confirmed.
- Attach IV tubing and secure the IO needle to the skin with gauze and tape. Ensure that the site can be adequately observed for extravasation.
- Serum lab testing and IV infusions can be completed as with peripheral or central venous access.

**PRE HOSPITAL**

Placement in the prehospital setting is appropriate.

**INITIAL STABILIZATION/THERAPY**

After placement, the IO needle may be used to draw blood for lab assay as well as for fluid and medication infusion:

- No stabilization or securing of the IO needle is necessary. If the needle is loose or needs securing, it is dislodged and not placed within the bone.

**MEDICATION**

- Almost all types of medications and crystalloid solutions can be administered via an IO line at identical dosing to IV infusions.
- When peripheral access is unattainable, IO infusion is preferable to endotracheal tube administration.

**DISPOSITION**

**Admission Criteria**

Critical care admission criteria:

- IO needle placement may be used until peripheral or central venous access is obtained.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- The IO site should be constantly monitored for fluid extravasation or compartment syndrome.
- The IO needle should be removed after more permanent access is established to prevent potential complications.
- Activity:
  - The involved limb should be protected from needle dislodgement.

**COMPLICATIONS**

- Fluid extravasation is the most frequent minor complication.
- Severe complications are rare but include compartment syndrome, skin or muscle necrosis (particularly from extravasation of caustic medications), infection (including cellulitis and osteomyelitis), hematoma, fracture (including growth plate injury), and fat embolism.

**ADDITIONAL READING**

- Blumberg SM, Gorn M, Crain EF. Intraosseous infusion: A review of methods and novel devices. *Pediatr Emerg Care.* 2008;24:50–56.
- Hodge D. Intraosseous infusions. In King C, Henretig FM, King BR, et al., eds. *Textbook of Pediatric Emergency Procedures.* 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.

**PEARLS AND PITFALLS**

- With minimal instruction, IO placement is a straightforward and effective method of obtaining emergent vascular access.
- IO infusions should be used when initial attempts at peripheral or central venous access are unsuccessful.
- Do not execute multiple attempts on the same site.
- The IO needle and IV tubing should be properly secured to prevent dislodgement during resuscitation. However, the dressing should not obscure the insertion site or corresponding posterior extremity.
- Extravasation and compartment syndrome are complications that are preventable with close observation of the surrounding soft tissue.

# INTUSSUSCEPTION

Jeffrey A. Seiden

## BASICS

### DESCRIPTION

- Intussusception is the telescoping, or invagination, of 1 portion of the intestine (intussusceptum) into its more distal portion (intussusciens).
- It most commonly occurs at the junction of the terminal ileum and cecum, accounting for ~90% of cases (1).
- It is the most common abdominal emergency of early childhood.
- One of the most common causes of intestinal obstruction in the 1st 2 yr of life
- Strangulation of bowel typically occurs only after prolonged nonreduced intussusception.

### EPIDEMIOLOGY

#### Incidence

- Most commonly occurs in patients between 3 mo and 3 yr of age with peak during infancy
- 56 cases per 100,000 live births in 1st yr (2)
- 46 cases per 100,000 live births in 2nd yr (2)
- 38 cases per 100,000 live births in 3rd yr (2)

### RISK FACTORS

Males have 1.5–2 times greater risk.

### PATHOPHYSIOLOGY

- The intussusceptum, along with its mesentery, is drawn into the distal intussusciens by bowel peristalsis. This causes bowel obstruction, venous and lymphatic congestion, and edema.
- Ultimately, this can lead to arterial insufficiency, ischemia, necrosis, and bowel perforation.
- Hypertrophy of lymphoid tissue in Peyer patches at the terminal ileum is frequently responsible.

### ETIOLOGY

- Idiopathic in 90% of cases (1–4)
- Pathologic lead point is uncommon in patients between 3 mo and 3 yr of age.
- Up to 20% of patients >2 yr old may have a pathologic lead point (3,5). Meckel diverticulum is the most common lead point.

## COMMONLY ASSOCIATED CONDITIONS

- Meckel diverticulum
- Intestinal polyps
- Henoch-Schönlein purpura
- Duplication cysts
- Mesenteric adenopathy
- Gastroenteritis
- Parasitic infections
- Cystic fibrosis
- Celiac disease
- Abdominal trauma or surgery
- Nephrotic syndrome
- Inverted appendiceal stump
- Lymphoma

## DIAGNOSIS

### HISTORY

- Recurrent episodes of inconsolable crying often with drawing legs up to chest, lasting for a few minutes
- Between episodes, the child initially is described as normal, but as the disease progresses, the child may become more lethargic.
- Mental status changes may be present. Irritability or lethargy may be the chief complaint. Sometimes is confused with a postictal phase or other causes of altered mental status.
- Vomiting may be bilious but usually is not.
- Stool may have blood or mucus.
- The classic triad of paroxysmal abdominal pain, vomiting, and bloody “currant jelly” stool is uncommon; seen in ~1/3 of patients (3).
- In particular, most children have normal stools; bloody stool is a late finding.
- Symptoms are often preceded by a recent viral illness.

## PHYSICAL EXAM

- May be normal between episodes early in the course of the disease process
- Lethargy, disproportionate to dehydration if dehydration is present
- Diffuse or right-sided abdominal tenderness
- Palpable sausage-shaped mass in the right upper quadrant along with absence of bowel contents in right lower quadrant (Dance sign):
  - The absence of a palpable mass does not exclude the diagnosis.
- Digital rectal exam may reveal currant jelly stool.
- Decreased or absent bowel sounds
- Signs of peritonitis if perforation; diffuse tenderness, rigidity

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- No lab testing is routinely necessary.
- Consider serum electrolytes, glucose, and CBC with appropriate symptoms.
- Consider routine preoperative lab assays as per institutional protocol.

### Imaging

- Abdominal US has high sensitivity (98–100%) and specificity (88–100%) for intussusception (1).
- Doughnut sign: Hypoechoic outer rim with a central hyperechoic core on transverse view
- Pseudokidney sign: Kidney-like appearance on longitudinal view
- Plain abdominal radiographs are normal in 25% of cases (6):
  - May show signs of intestinal obstruction
  - Paucity of gas in right lower quadrant
  - Target sign: Soft tissue mass with 2 concentric radiolucent circles in the right abdomen
  - Meniscus sign: A crescent of gas in the colon outlining the apex of the intussusception
  - Free air representing bowel perforation
- CT is most useful in evaluating for a pathologic lead point.
- Air contrast or barium enema reduction is the standard nonoperative treatment for intussusception:
  - 70–85% success with barium enema (7)
  - Up to 90% success with air enema (7)
- Barium or air contrast enema exam is useful for both diagnosis and therapy.

**Diagnostic Procedures/Other**

- Barium or air contrast enema
- Consultation with a pediatric surgeon is strongly recommended prior to enema because surgery will be definitive intervention if enema fails or in rare cases of perforation resulting from enema.

**DIFFERENTIAL DIAGNOSIS**

- Gastroenteritis
- Bowel obstruction of other etiology:
  - Incarcerated hernia
  - Malrotation with volvulus
  - Adhesions
- Bowel perforation
- Ileus
- Foreign body
- Acute appendicitis
- Inflammatory bowel disease
- Other causes of crying or irritability colic, otalgia, hair-thread tourniquet, inflicted injury
- Other causes of lethargy:
  - Hypoglycemia
  - Meningitis
  - Encephalitis
  - Sepsis
  - Seizure
  - Infantile botulism
  - Toxic ingestion
  - Metabolic disorder

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Address issues of airway, breathing, and circulation as per Pediatric Advanced Life Support guidelines.
- Keep patient NPO.
- IV fluid resuscitation
- NG tube placement to decompress proximal bowel

**MEDICATION**

- Prior to attempts at reducing the intussusception, consider broad-spectrum antibiotics, analgesics, and procedural sedation.
- Broad-spectrum antibiotics:
  - Ampicillin
  - Clindamycin
  - Gentamicin
  - Metronidazole
- Analgesia:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
- Procedural sedation as per institutional protocol:
  - Ketamine is preferred due to its safety profile and preservation of protective airway reflexes and respiration.

**SURGERY/OTHER PROCEDURES**

- Consultation with a surgeon is mandatory prior to treatment, including enema reduction.
- The primary complication is bowel perforation with resultant peritonitis (barium) or pneumoperitoneum (air), though these are rare (1% of cases).
- Indications for operative surgical management include peritonitis, bowel perforation, shock, and failure of enema reduction.

**DISPOSITION****Admission Criteria**

Most sources recommend routine hospitalization for observation and continued fluid management.

**Discharge Criteria**

- Discharge of asymptomatic children with resolved intussusception may be considered if no comorbidities are present, very close observation is assured, and rapid return to the hospital for recurrence of symptoms is possible.
- Children suspected to have intussusception but who have a normal diagnostic evaluation (eg, US) may be considered for outpatient management.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Parents should monitor for signs of recurrence, such as increased pain, vomiting, or altered mental status.

**PROGNOSIS**

- The prognosis depends on the duration of intussusception; prolonged nonreduced intussusception may result in shock, loss of bowel, and death.
- The recurrence rate depends on the method of reduction:
  - ~10% after barium enema
  - 1% after manual surgical reduction
  - No recurrence after intestinal resection

**COMPLICATIONS**

- GI hemorrhage
- Bowel perforation
- Septic shock
- Dehydration

**CODES**

ICD9  
560.0 Intussusception

**PEARLS AND PITFALLS**

- Intussusception should be considered in infants and young children with altered mental status, even in the absence of the classic signs and symptoms of abdominal pain, vomiting, and bloody stool.
- Rapid diagnosis is key to reducing morbidity and mortality.
- Use of the 1st marketed rotavirus vaccine in the U.S. (RotaShield) resulted in a 22-fold increase in intussusception; this vaccine is no longer produced and was replaced by a safer rotavirus vaccine.

# IRON POISONING

Stephanie H. Hernandez

## BASICS

### DESCRIPTION

- Iron toxicity is a clinical disease in which GI symptoms precede systemic toxicity.
- Due to the widespread use of iron for prenatal supplementation and as a mineral supplement, iron toxicity is very common in children.
- Iron toxicity is classically described in phases where vomiting and GI symptoms are followed by a latent stage, systemic toxicity, hepatotoxicity, and ultimately delayed GI effects.
- Patients who have significant toxicity are not well during the latent phase and will have continued clinical or metabolic evidence of toxicity.

### EPIDEMIOLOGY

#### Prevalence

~30,000 calls for suspected and/or confirmed exposure reported per year to poison control centers in the U.S.

### RISK FACTORS

- Children in households of women who are pregnant or recently gave birth and may have prenatal vitamins still in the household
- Depression associated with pregnancy (during or postpartum) and access to prenatal vitamins
- Chewable iron supplements that may allow a child to have a large ingestion
- A large elemental iron load based on body mass and percentage of elemental iron of iron formulation ingested

### GENERAL PREVENTION

Iron-containing medications must be kept out of child's reach.

### PATHOPHYSIOLOGY

- The majority of the body's iron is incorporated into hemoglobin, and the remainder is stored as ferritin. Even while in transit in the body, it is bound to transferrin.
- Excess free unbound iron is toxic and does not exist within the body under normal conditions.
- Toxic doses vary:
  - Animal studies suggest that 150–200 mg/kg of elemental iron is lethal.
  - Ingestions <20 mg/kg of elemental iron are usually asymptomatic or minimally symptomatic.
  - 20–30 mg/kg of elemental iron typically causes limited GI symptoms.
  - Ingestion of >40 mg/kg of elemental iron is usually significantly symptomatic.
  - Ingestion of >60 mg/kg of elemental iron is potentially lethal.

- Death has been reported in a child with ingestion of 600 mg of elemental iron.
- Iron has a directly corrosive effect on tissue and may cause hemorrhagic necrosis and perforation of the stomach or other area of the GI tract.
- In overdose, free iron exceeds cellular defenses and causes widespread injury.
- Once absorbed, free iron has multiple toxic effects resulting in cellular dysfunction and cellular death with concomitant lactic acidemia, shock, and multisystem organ failure:
  - Iron is a catalyst for the production of oxidants such as free radicals, which cause damage to various organ systems.
  - Free iron causes metabolic acidosis by acting as a mitochondrial toxin, inhibiting oxidative phosphorylation, disrupting the electron transport chain, causing hypotension, and releasing hydrogen ions when it is absorbed from the GI tract.
  - Free iron is a potent negative inotrope and vasodilator leading to cardiovascular compromise.
  - Toxicity is classically described in 4 stages.
  - GI stage: Shortly after ingestion, corrosive effects cause abdominal pain, vomiting, and diarrhea. Significant GI hemorrhage may occur.
  - After this phase, a latent period may occur, usually lasting several hours.
  - This may be followed by hepatotoxic stage with abrupt coma, shock, metabolic acidosis, hepatic failure, coagulopathy, and death. Sepsis with *Yersinia enterocolitica* may occur.
  - If the patient survives, the convalescent stage follows, with potential GI scarring and obstruction from the initial caustic GI injury.

### ETIOLOGY

- Ferrous fumarate (33% elemental iron)
- Ferrous gluconate (12% elemental iron)
- Ferrous sulfate, regular (20% elemental iron)
- Ferrous sulfate, dried (30% elemental iron)
- A typical child's multivitamin tablet with iron contains 10–18 mg of elemental iron. Adult or prenatal vitamins contain up to 65 mg of elemental iron.

### COMMONLY ASSOCIATED CONDITIONS

- Pregnancy
- Iron-deficiency anemia

## DIAGNOSIS

### HISTORY

- Inquire about the total dose of elemental iron. It is necessary to know the total mg dose ingested and type of preparation to determine the elemental iron load.
- History of vomiting is key.
- A few episodes of vomiting in a well-appearing child may be indicative of only local GI toxicity.
- Systemic toxicity would not be expected unless multiple episodes of vomiting have occurred.
- Depending on how late after presentation, the patient may present with any of the initial 3 stages of toxicity. See Pathophysiology.

### PHYSICAL EXAM

- Assess vital signs with particular attention to cardiovascular status.
- GI findings predominate:
  - Nonspecific abdominal tenderness
  - Severe vomiting
  - GI hemorrhage by vomiting or diarrhea
- Cardiovascular: Hypotension and shock
- Altered mental status or seizures in severe cases
- Pallor
- Tachypnea may be present if systemic toxicity, and metabolic acidosis, or acute respiratory distress syndrome occurs.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Lab tests should not be used in isolation to guide management, but they are critically necessary.
- Immediately assess bedside capillary glucose in all patients.
- Serum iron concentration:
  - Check the total serum iron level 4–6 hr after ingestion, with a repeat measurement at 8–12 hr to rule out delayed absorption:
    - Generally, a 4–6-hr serum iron concentration <300 µg/dL is not associated with significant toxicity.
    - A serum iron concentration of 300–500 µg/dL is usually accompanied by GI symptoms and potential significant metabolic toxicity.
    - Severe toxicity is associated with serum iron concentration >500 µg/dL.
    - Serum iron concentrations may not be reflective of toxicity, especially if not drawn within 4–6 hr of ingestion.
    - A decreasing serum iron level does not necessarily correlate with clinical improvement.
- A basic chemistry, blood gas analysis, and lactate will assess for systemic toxicity, acidosis, and shock:
  - Low bicarbonate, significant anion gap, and elevation of lactate are all associated with significant toxicity.
- CBC to assess for possible blood loss
- LFTs may initially be mildly elevated with vomiting. Elevation of transaminases may occur within 48 hr of systemic toxicity.
- Total iron-binding capacity, serum glucose, and WBC count are not reliable markers for determining potential toxicity.
- Serum acetaminophen concentration should be sent on all patients with intentional ingestions.

#### Imaging

- Chest and abdominal x-ray to assess for radiodense tablets.
- Chewable and liquid formulations are rarely visualized.
- If whole-bowel irrigation is performed to remove iron tablets that were visible in the GI, perform repeat x-rays to assess result.

**Diagnostic Procedures/Other**

Vine rose test: No longer commonly used; administration of a “test” dose of deferoxamine IM with observation of urine to detect red/purple winelike appearance of urine. This was done to determine if chelatable free iron was present in the serum.

**DIFFERENTIAL DIAGNOSIS**

- Isopropyl alcohol ingestion
- Mushroom ingestion
- Heavy metal ingestion
- Caffeine or theophylline ingestion
- Caustic ingestion
- Nontoxicologic GI illnesses

**TREATMENT****PRE HOSPITAL**

Administer IV fluid.

**INITIAL STABILIZATION/THERAPY**

- Supportive care, GI decontamination, and antidotal therapy are the main treatment.
- Administration of IV fluid is necessary to replace losses from vomiting and to treat hypotension if present.
- GI decontamination may include NG aspiration or lavage for recent ingestion of liquid preparation or whole-bowel irrigation for large ingestions of tablets:
  - Activated charcoal will not bind iron and plays no role in therapy.
  - Severe vomiting will accompany significant iron ingestion. Use of ipecac syrup provides no additional benefit and may obscure the clinical picture by causing vomiting for which it is unclear whether iron is causal.
- Blood transfusion may occasionally be needed to replace GI blood loss.
- Exchange transfusion may rarely be necessary to lower serum free iron load in young children who are not clinically responding or deteriorating despite deferoxamine.

**MEDICATION**

Deferoxamine therapy is critical in the management of significant iron toxicity:

- IV deferoxamine starting at 15 mg/kg/hr and titrating up to 25 mg/kg/hr as tolerated
- Deferoxamine should be considered for metabolic acidosis, repetitive vomiting, toxic appearance, hypotension, shock, or serum iron concentration  $> 500 \mu\text{g/dL}$ .
- Deferoxamine treatment itself may cause hypotension in addition to hypotension from iron toxicity. Vasopressors may be needed to allow for treatment with deferoxamine in critically ill cases.

- Assure that the patient is adequately resuscitated with IV fluids, and obtain a baseline urine sample.
- Collect serial urine samples and compare them side by side, looking for an alteration in color termed *vine rose*, demonstrating chelated iron in urine.
- When the urine has cleared the vine rose color and the patient is clinically improved, chelation can be terminated.
- Antiemetic:
  - Ondansetron 0.15–0.2 mg/kg IV q6–8h PRN nausea or vomiting
- H2 blockers:
  - Ranitidine 5 mg/kg PO q12h, 1–2 mg/kg IV/IM q6h; adult 150 mg PO b.i.d., 50 mg/kg/dose IM/IV
  - Famotidine 0.6 mg/kg/day IV divided q8–12h, 1–2 mg/kg/day PO divided q12h; adult 20 mg PO/IV b.i.d.
  - Pantoprazole 1 mg/kg/dose PO/IV daily, max dose 80 mg.

**SURGERY/OTHER PROCEDURES**

- Rarely, gastrotomy to remove an accretion of iron in the stomach is necessary to remove a life-threatening depot of iron.
- This is done after confirmation of a large accretion in the stomach and expectation of severe morbidity or mortality.

**DISPOSITION****Admission Criteria**

- All patients with significant toxicity, such as severe vomiting, need for IV fluid or antiemetics should be admitted.
- Critical care admission criteria:
  - Chelation therapy indicated
  - GI hemorrhage
  - Metabolic acidosis
  - Hemodynamic instability
  - Suspicion of child abuse or neglect

**Discharge Criteria**

- $< 20$  mg/kg elemental iron ingested, child appears well, and has had  $\leq 2$  episodes of vomiting
- Child abuse or neglect should not be evident, and the child must be safe to discharge back to the home environment.
- Patients with limited mild GI symptoms who are asymptomatic or minimally symptomatic at 6 hr post-ingestion may be discharged.

**Issues for Referral**

- Consult with a poison control center, medical toxicologist, or other specialist experienced with chelation therapy for iron toxicity for decision making regarding chelation therapy.
- Refer intentional ingestions for psychiatric evaluation.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Follow up with a gastroenterologist to evaluate for sequelae as well as a psychiatrist as indicated.

**Patient Monitoring**

Follow up with a gastroenterologist to detect GI scarring resulting in pyloric stenosis or other obstructive sequelae.

**PROGNOSIS**

- The prognosis varies depending on the severity of ingestion and the success of treatment.
- In patients without shock or coma, mortality is  $< 1\%$ .
- If shock and coma are present, there is 50% mortality with supportive care and 10% mortality with supportive care and deferoxamine.

**COMPLICATIONS**

- GI hemorrhage
- Pyloric outlet obstruction 4–6 wk later
- Deferoxamine may foster the growth of *Y. enterocolitica*, and infection should be suspected if abdominal pain, fever, and diarrhea develop after resolution of iron toxicity.

**ADDITIONAL READING**

- Anderson BD, Turchen SG, Manoguerra AS, et al. Retrospective analysis of ingestions of iron containing products in the United States: Are there differences between chewable vitamins and adult preparations? *J Emerg Med.* 2000;19:255.
- Madiwale T, Liebelt E. Iron: Not a benign therapeutic drug. *Curr Opin Pediatr.* 2006;18:174.
- Manoguerra AS, Erdman AR, Booze LL, et al. Iron ingestion: An evidence-based consensus guideline for out-of-hospital management. *Clin Toxicol.* 2005;43:553.
- Siff JE, Meldon SW, Tomassoni AJ. Usefulness of the total iron binding capacity in the evaluation and treatment of acute iron overdose. *Ann Emerg Med.* 1999;33:73.

**CODES****ICD9**

964.0 Poisoning by iron and its compounds

**PEARLS AND PITFALLS**

- Iron ingestion must be evaluated with respect to elemental iron ingestion.
- An iron level drawn late ( $> 6$  hr) after ingestion may be misleadingly low because the iron has had a greater opportunity for cellular uptake.
- Indirect tests such as glucose and WBC count should not be used as a surrogate for serum iron concentration.

# IRRITABLE BOWEL SYNDROME

Yamini Durani

## BASICS

### DESCRIPTION

- Irritable bowel syndrome (IBS) is a chronic GI condition of unknown etiology.
- Its primary feature is an alteration of normal bowel habits, which is characterized by diarrhea or constipation, or both.
- Different subtypes are recognized based on the predominant stooling pattern:
  - IBS with constipation
  - IBS with diarrhea
  - Mixed IBS
  - Unsubtyped IBS
- The symptoms wax and wane over time, are often associated with other functional disorders, and can be severe enough to affect the quality of life (1).

### EPIDEMIOLOGY

#### Incidence

- IBS is one of the most common GI conditions.
- IBS accounts for 25–50% of all referrals to adult gastroenterologists (2).
- The exact incidence in children is not known.

#### Prevalence

- Studies have demonstrated a prevalence of 20–45% in pediatrics (3).
- IBS is thought to occur in all ages but is more frequent in adolescents.
- In childhood, it occurs equally in males and females.
- There is a 2 to 1 female predominance in adolescents (4).

### RISK FACTORS

- Anxiety, stress, and certain learned social behaviors can contribute to worsening the symptoms of IBS.
- Postinfectious IBS is a subtype of IBS that is preceded by an infectious diarrhea that leads to IBS characterized by diarrhea:
  - *Campylobacter* has been implicated as a pathogen in this setting (5).
- Other reported risk factors include female gender, food intolerance, the presence of other somatic symptoms, and depression (5–8).

### PATHOPHYSIOLOGY

- A combination of factors lead to abnormal motility and hypersensitivity of the colon.
- Genetics, psychosocial, environmental, and infectious factors have all been implicated in playing a role in the development of IBS.
- Studies have shown that the neurotransmitter serotonin has effects on the motility of the GI tract. It is hypothesized that there is either an abnormal release or response to serotonin in the colon resulting in an alteration from normal bowel habits.
- Some patients with IBS have been found to have abnormal motility studies and hypersensitivity of the rectum.
- Anxiety, stress, and certain learned social behaviors can contribute to worsening the symptoms of IBS.

### ETIOLOGY

No clear etiologies have been identified.

### COMMONLY ASSOCIATED CONDITIONS

- Patients with IBS are often more likely to have a comorbid rheumatologic diagnosis.
- Psychosocial stressors
- Anxiety and depression

## DIAGNOSIS

### HISTORY

- History and physical exam are at the cornerstone of diagnosis. Minimizing unnecessary testing can be accomplished by diagnosing IBS based on classic clinical symptoms.
- Rome III criteria helps to establish the diagnosis of IBS clinically, though there is limited data on its validity (3). Key features of the criteria are:
  - Recurrent abdominal pain or discomfort associated with at least 2 of the following symptoms for at least 25% of the time and for at least 2 mo: Pain that diminishes with defecation, alteration in stool frequency, and alteration in stool appearance. There must also be no presence of organic disease, such as inflammatory or metabolic, that could explain the symptoms (3).
- Abdominal pain is a key clinical feature. The quality and severity of pain is variable. Many describe crampy, intermittent pain generally in the lower abdomen that is relieved with defecation.
- Altered bowel habits are a prerequisite to diagnosis. Most complain of diarrhea, constipation, or alternating diarrhea and constipation.
- Constipation can last for months. Patients may complain of the sensation of incomplete defecation. Patients may strain excessively with stooling and overuse laxatives or enemas.
- Diarrhea often occurs in the morning or after meals and is preceded by abdominal pain. Some may experience incontinence.
- Mucus in the stool, bloating, and gas pain are commonly present.
- Other GI symptoms include gastroesophageal reflux, dysphagia, early satiety, and nausea.
- Extraintestinal symptoms that may occur include dysmenorrhea, polyuria, urgency, headache, and problems with sleep (5,9,10).

### PHYSICAL EXAM

- The physical exam is typically normal.
- A subset of patients may have abdominal distention or mild and generalized abdominal tenderness.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- No lab test is diagnostic of IBS.
- Tests may be needed to exclude other diseases: CBC/differential, liver enzymes, bilirubin, albumin, amylase, lipase, ESR, C-reactive protein, stool studies (culture, ova and parasite, occult blood test, and stool WBC test), lactose/fructose breath hydrogen test, and celiac disease testing.

#### Imaging

Indicated only for children with abdominal pain suspected to have a surgical etiology

#### Diagnostic Procedures/Other

Routine use of endoscopy and biopsy is not necessary to diagnose IBS:

- A gastroenterologist may choose to perform this procedure to evaluate for potential inflammatory bowel disease (IBD) (11).

### DIFFERENTIAL DIAGNOSIS

Anorexia, failure to thrive, weight loss, pain that awakens the patient from sleep, voluminous diarrhea, bloody stools, or greasy stools should prompt investigation for other etiologies. The differential diagnosis is broad: IBD, peptic ulcer disease, celiac disease, hepatobiliary disease, pancreatic disease, GI infections, urinary tract infection, kidney stones, thyroid disease, psychiatric disorders, and functional abdominal pain syndrome and constipation (12).

## TREATMENT

### MEDICATION

#### First Line

- There is no proven efficacious treatment.
- Pharmacologic agents may be prescribed if the symptoms are moderate to severe and not responding to nonpharmacologic therapy.
- An anticholinergic, antispasmodic agent may be prescribed:
  - Dicyclomine:
    - Children: 10 mg/dose PO t.i.d.–q.i.d.
    - Adolescents: 20–40 mg/dose t.i.d.–q.i.d.
    - Prescription from the emergency department are not recommended.
    - Side effects include dry mouth, constipation, and blurry vision.

#### Second Line

- In adults, selective serotonin reuptake inhibitors have been shown to improve symptoms:
  - In children, they may be considered in patients who have psychosocial factors that strongly contribute to their symptoms.
- Tricyclic antidepressants may be considered, but data in pediatrics is limited and their side effects may preclude use.

- Serotonin agonists and antagonists have been used in a small segment of adult patients with IBS not responding to other therapies:
  - Serotonin receptor antagonists have been associated with ischemic colitis.
- Tegaserod (Zelnorm) was the only medication with U.S. FDA approval as therapy for IBS:
  - The mechanism of action was selective agonism/antagonism at serotonin receptor subtypes.
  - It was withdrawn in 2007 in the 1st year of marketing due to increased risk of heart attack or stroke.
  - Generic tegaserod is available outside the U.S.

### COMPLEMENTARY & ALTERNATIVE THERAPIES

- Eliminate foods that may trigger or exacerbate symptoms: Spicy or fatty foods, dairy products, caffeine, and sweeteners.
- Fiber, in the form of dietary modification or supplements, is often helpful with constipation and improving stool consistency in diarrhea.
- In adults, the use of alternative therapies for IBS have been reported, but there is no evidence to support their routine use in pediatrics:
  - Dairy products containing lactobacilli and *Bifidus* species
  - Herbal medicines and ayurvedic treatments and acupuncture (5,13,14)

### DISPOSITION

#### Admission Criteria

- The need for admission is rare.
- Dehydration, intractable pain, or uncertain diagnosis may all be indications for admission.

#### Issues for Referral

Patients may be referred to a gastroenterologist if the diagnosis of IBS is uncertain, if an organic cause is suspected, or if symptoms are moderate to severe and not responding to nonpharmacologic therapy.

### FOLLOW-UP

#### FOLLOW-UP RECOMMENDATIONS

Activity:

- The primary goal is for patients to return to normal activity.
- Families and clinicians should help patients recognize triggers and discourage behaviors that result in avoidance of normal activity.

#### Patient Monitoring

Clinicians should monitor the severity of symptoms over time and should also be aware if any new signs or symptoms develop, which may be suggestive of an organic cause.

#### DIET

See Complementary & Alternative Therapies.

#### PROGNOSIS

- Long-term studies are limited, particularly in pediatrics. The development of organic disease is uncommon.

- In a study of 112 adults followed for a median of 29 yr, 9% developed an organic disease at a median of 15 yr after being diagnosed with IBS (15).
- In another study of 75 adults followed for up to 13 yr, 92% still had symptoms of IBS (16).
- For most patients with IBS, the symptoms wax and wane over time; in only a small proportion do they spontaneously improve.

### COMPLICATIONS

- Weight loss
- Impaired quality of life

ICD9

564.1 Irritable bowel syndrome

### PEARLS AND PITFALLS

- IBS is a chronic and relapsing condition for which there is no cure, but there are a variety of treatments to minimize symptoms.
- The diagnosis of IBS can be made clinically without excessive testing if the patient has a normal physical exam and meets the criteria of IBS based on symptoms.
- The primary features of IBS are chronic abdominal pain and an alteration of stooling habits.
- The presence of certain concerning factors in the history should prompt the clinician to exclude organic disease. These include but are not limited to pain awakening the patient from sleep, hematochezia, anemia, vomiting, weight loss, fever, persistent diarrhea, severe constipation, potential exposure to infectious agents (ie, travel to areas endemic to parasites), and family history of chronic GI diseases. Concerning physical exam findings include blood on rectal exam, anemia, abdominal mass, signs of malabsorption, and signs of thyroid dysfunction (5).

# JAUNDICE, CONJUGATED HYPERBILIRUBINEMIA

John T. Kanegaye

## BASICS

### DESCRIPTION

- Jaundice is yellow discoloration of skin and sclerae caused by bilirubin deposition.
- In the neonate, hyperbilirubinemia is most commonly unconjugated (see Jaundice, Unconjugated Hyperbilirubinemia topic).
- However, cholestatic jaundice, manifested by conjugated hyperbilirubinemia implies a wider differential diagnosis and a greater frequency of pathologic conditions requiring early treatment:
  - The various causes include infection, paucity of bile ducts, abnormal transport and metabolism of bile acids, and mechanical obstruction.
  - As a result of congenital disease and malformation, inborn errors of metabolism, perinatal infection, and hepatic immaturity, cholestatic jaundice occurs most commonly in the neonatal period.
- Young infants with cholestasis benefit from prompt referral to a pediatric tertiary center to ensure the appropriate choice of diagnostic tests and the skilled interpretation of imaging studies and biopsies.
- Diagnostic approach varies according to the initial presentation and screening tests (1). However, common modalities include tests of liver function, coagulation, and infection; US; and liver biopsy.
- In older children, acute viral infections predominate over other causes (hepatotoxins, metabolic, and biliary disease).
- Emergency department priorities are stabilization of life-threatening conditions and liver dysfunction, differentiation of conjugated from unconjugated hyperbilirubinemia, and identification of conditions that require prompt medical and surgical intervention (infectious and metabolic disorders, biliary obstruction).

### EPIDEMIOLOGY

#### Incidence

- At 2 wk of life, up to 15% of newborns are still jaundiced. Jaundice may persist in 9% of breast-fed infants at 4 wk:
  - This jaundice is overwhelmingly by unconjugated bilirubin.
- Cholestasis occurs in 1 in 2,500 births.
- The most common causes are neonatal hepatitis (1 in 5,000 live births) and biliary atresia (1 in 8,000–19,000 live births), which together account for 50–70% of cases.  $\alpha$ 1-antitrypsin deficiency accounts for an additional 5–15%.

### GENERAL PREVENTION

- Vaccination (hepatitis A and B, rubella)
- Prevention or early treatment of maternal diseases (syphilis, toxoplasmosis)
- Avoidance of hepatotoxic exposures

- Prompt diagnosis of cholestasis prevents or slows hepatic injury. Well-child exams may occur too soon (2 wk) or too late (2 mo) for timely recognition, but delays can be prevented by:
  - Measuring fractionated bilirubin levels if jaundice persists at 2 wk (or 3 wk for breast-fed infants) or if dark urine or pale stools occur
  - Stool color screening, which facilitates earlier identification of biliary atresia and other cholestatic diseases and improves short-term surgical outcomes (2)

### PATHOPHYSIOLOGY

- Bilirubin is the breakdown product of heme, primarily derived from hemoglobin.
- Bilirubin undergoes hepatic conjugation by UDP glucuronosyltransferase before excretion through the biliary tract into the intestine.
- Biliary obstruction results in a primarily conjugated hyperbilirubinemia, whereas hepatocellular disease causes a mixed (conjugated and unconjugated) hyperbilirubinemia. However, hepatocellular disease and biliary obstruction have considerable clinical and biochemical overlap.

### ETIOLOGY

- Infectious:
  - Bacterial infection: Gram-negative infection may accompany galactosemia.
  - Perinatal/congenital infection: Viral, spirochetal, protozoan, TB
- Genetic/Metabolic:  $\alpha$ 1-antitrypsin deficiency, galactosemia, tyrosinemia, cystic fibrosis, hereditary fructose intolerance, bile acid synthetic defects, hypothyroidism/hypopituitarism
- Mitochondrial and peroxisomal disorders: Zellweger syndrome
- Storage disease: Glycogen storage disease, neonatal iron storage disease
- Obstructive:
  - Biliary atresia: Obliteration/obstruction of part or all of the extrahepatic biliary tree with intrahepatic biliary fibrosis
  - Choledochal cyst
  - Alagille syndrome
  - Inspissated bile syndrome
  - Neonatal sclerosing cholangitis
  - Bile duct perforation
  - Gallstones
  - Caroli disease
  - Congenital hepatic fibrosis
- Other: Parenteral nutrition, progressive familial intrahepatic cholestasis
- Idiopathic neonatal hepatitis is the most common cause of neonatal cholestasis. As a diagnosis of exclusion, its incidence has decreased with the discovery of previously unknown diseases.
- Older children:
  - Acute hepatitis: A, B, C, Epstein-Barr, adenovirus
  - Dubin-Johnson and Rotor syndromes: Benign mixed hyperbilirubinemia due to decreased excretion
  - Hydrops of gallbladder: Cholestasis and fever rarely may be a presentation of Kawasaki disease (3).
  - Hepatotoxins

- Cholelithiasis, cholecystitis
- Inflammatory bowel disease
- Wilson disease

### COMMONLY ASSOCIATED CONDITIONS

- In the acutely ill patient, cholestatic jaundice is more often the result of underlying disease than primary hepatobiliary disease.
- Associated anomalies (cardiovascular defects, polysplenia, situs inversus, malrotation) occur in ~10% of cases of biliary atresia.

## DIAGNOSIS

### HISTORY

- Constitutional symptoms (irritability, feeding difficulty, lethargy with infection, galactosemia and tyrosinemia)
- Presence of dark urine or light stool
- GI symptoms
- Extraintestinal symptoms of liver (pruritis, fatigue) or systemic disease (rash, eye changes, joint complaints)
- Hepatotoxic exposures (ethanol, acetaminophen, isoniazid, Amanita mushrooms)
- Infectious exposures (perinatal, parenteral, sexual)
- Family history of jaundice, liver disease, or cholestatic conditions; unexplained childhood deaths

### PHYSICAL EXAM

- Growth parameters: Often deceptively normal in biliary atresia; low birth weight, failure to thrive in hepatocellular disease
- General appearance and hemodynamic status (ill appearing in sepsis, galactosemia)
- Facial features (eg, Alagille syndrome)
- Abdominal exam:
  - Hepatomegaly (biliary atresia), midline liver (polysplenia syndromes)
  - Splenomegaly (infection, advanced liver disease of any etiology)
  - Right upper quadrant mass (choledochal cyst)
  - Collateral circulation
- Neurologic (abnormalities in mitochondrial disease, Zellweger syndrome, Wilson disease)
- Stools (acholic in biliary atresia)
- Skin (rash, edema, angiomas)

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Total and conjugated (or direct-reacting) serum bilirubin levels determine the type of jaundice and the initial diagnostic evaluation. Direct bilirubin level is abnormal above 1 mg/dL if the total is <5 mg/dL. Direct bilirubin >20% of total is abnormal when the total is >5 mg/dL (1).
- Other tests may be performed as clinically indicated:
  - Evaluation for bacterial infection: Fever or temperature instability, behavior changes, feeding intolerance warrant evaluation for sepsis. Urinary infection may occur in afebrile, asymptomatic jaundiced infants.
  - Tests of hepatocellular integrity and function (transaminases, glucose, ammonia, PT)

- Biliary enzymes (alkaline phosphatase,  $\gamma$  glutamyl transpeptidase); may fail to distinguish hepatocellular from biliary disease
- Acute hepatitis serology
- More specialized testing, guided by the pediatric subspecialist, may include:
  - Evaluation for perinatal and viral infection (viral hepatitis, TORCH titers)
  - Metabolic (urine reducing substances, amino and organic acid analyses, RBC galactose-1-phosphate uridyl transferase activity)
  - Thyroid function tests
  - $\alpha$  1-antitrypsin levels and phenotyping
  - Serum bile acid analysis
  - Sweat electrolyte analysis

**Imaging**

- US: May identify biliary atresia (absent gallbladder, “triangular cord” sign [4]), choledochal cyst, and polysplenia.
- Other imaging tests have little role in the emergency department and are deferred to the specialist.

**Diagnostic Procedures/Other**

- Liver biopsy: Experienced centers have high diagnostic accuracy for biliary atresia, neonatal hepatitis, and other specific diseases.
- Bilirubin analysis of duodenal fluid
- Hepatobiliary scintigraphy: Sensitive for biliary obstruction but nonspecific and time-consuming
- Surgical exploration and intraoperative cholangiography

**Pathological Findings**

- Biliary atresia: Bile duct proliferation, portal fibrosis, bile stasis
- Neonatal hepatitis: Giant cell transformation

**DIFFERENTIAL DIAGNOSIS**

See Etiology.

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

- Correction of respiratory and hemodynamic disturbances and coagulopathy
- Identification and treatment of serious underlying conditions (infection, galactosemia)

**MEDICATION**

**First Line**

As determined by the initial presentation and diagnostic evaluation, first-line therapy may range from empiric antibiotic coverage to highly specific therapy (bile acid replacement).

**Second Line**

Supportive treatment for chronic cholestasis may include:

- Cholagogues, such as ursodeoxycholic acid
- Corticosteroids
- Bile acid-binding agents
- Prophylactic antibiotics (postoperative)

**SURGERY/OTHER PROCEDURES**

- In biliary atresia, the Kasai portoenterostomy re-establishes biliary flow and prolongs survival of the native liver.
- Liver transplantation: Biliary atresia is the most common reason for pediatric liver transplantation. Transplantation may also cure selected genetic/metabolic disorders.

**DISPOSITION**

**Admission Criteria**

- Initial evaluation of neonatal cholestasis, especially if biliary atresia and time-sensitive causes are possible
- Suspected serious bacterial infection, including postoperative cholangitis
- Hepatic dysfunction
- Critical care admission criteria:
  - Cardiorespiratory instability
  - Hepatic encephalopathy
  - Severe hemorrhage or coagulopathy

**Discharge Criteria**

- Adequate hydration and mental status
- Normal, or stable, hepatic function
- Diagnosis secure or disease highly likely to be self-limited

**Issues for Referral**

- Gastroenterology: Young infants with cholestasis often require pediatric subspecialty direction of the complex diagnostic evaluation and treatment regimens.
- Nutritional counseling (see Diet)

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- If not referred to a specialist for diagnostic evaluation, the patient requires close medical follow-up to ensure resolution of clinical findings.

**DIET**

- Chronic cholestasis causes malabsorption and nutritional deficiencies.
- Common supplements include medium-chain triglycerides, essential fatty acids, fat-soluble vitamins, and trace elements.

**PROGNOSIS**

- Surgical treatment of biliary atresia has better short-term (bile drainage) and long-term (survival with native liver) results if performed at <45–60 days of age and at more experienced centers.
- Transplantation is ultimately required in 80% of cases of biliary atresia even after portoenterostomy.
- Progressive hepatic disease occurs in 15–20% of patients with idiopathic neonatal hepatitis.

**COMPLICATIONS**

- All forms of cholestatic liver disease: Hepatic fibrosis, portal HTN, GI hemorrhage, cirrhosis, malabsorption, ascites, hepatic failure, pruritis, hyperlipidemia, xanthomata
- Biliary atresia: Above complications plus cholangitis, cessation of bile flow

Suchy FJ. Approach to the infant with cholestasis. In Suchy FJ, Sokol RJ, Balistreri WF, eds. *Liver Disease in Children.* 3rd ed. New York, NY: Cambridge University Press; 2007:179–189.

**CODES**

**ICD9**

- 277.4 Disorders of bilirubin excretion
- 774.6 Unspecified fetal and neonatal jaundice
- 782.4 Jaundice, unspecified, not of newborn

**PEARLS AND PITFALLS**

- Delayed recognition and treatment of biliary atresia is associated with decreased surgical success rates.
- Patients with biliary atresia may be deceptively well appearing, and the degree of jaundice and bilirubin elevation may be mild or fluctuate.
- Jaundice beyond 2 wk of age (or up to 3 wk in the breast-fed infant) warrants screening for conjugated hyperbilirubinemia, especially in the presence of pale stools or dark urine.
- The absence of acholic stool does not exclude early biliary atresia or other important causes of cholestasis.
- If the cause cannot be rapidly identified and treated, the young infant with cholestatic jaundice will benefit from prompt referral to a tertiary center.
- Hepatitis may be anicteric in childhood.

# JAUNDICE, UNCONJUGATED HYPERBILIRUBINEMIA

John T. Kanegaye

## BASICS

### DESCRIPTION

- Jaundice is a yellowish discoloration of skin, mucous membranes, and sclerae due to bilirubin deposition.
- The majority of pediatric patients with unconjugated hyperbilirubinemia are newborns with physiologic or breast-feeding jaundice due to immaturity of hepatic function.
- In older children, hemolysis and Gilbert syndrome are common.
- Emergency department priorities are assessment of risk for severe hyperbilirubinemia, treatment to prevent neurotoxicity, and the identification and treatment of pathologic causes.

### EPIDEMIOLOGY

#### Incidence

- Jaundice is visible during the 1st wk of life in 60% of term and 80% of preterm infants.
- Up to 85% of neonatal readmissions are for hyperbilirubinemia.
- ~0.1% of term and near-term infants develop total serum bilirubin (TSB) levels  $\geq 25$  mg/dL (1).

### RISK FACTORS

- Increased erythrocyte (RBC) mass
- Breast-feeding: Poor caloric intake may occur with unsuccessful lactation. Factors in breast milk also raise TSB levels and prolong the duration of jaundice. Breast-feeding is the most commonly reported mode of feeding in kernicterus (2).
- Excessive weight loss
- Male sex
- Maternal diabetes mellitus (DM)
- Hemolysis (ABO or Rh incompatibility with positive Coombs test; G6PD deficiency)
- Gestational age  $< 38$  wk
- Prior sibling with jaundice, especially if phototherapy was required
- Asian ethnicity
- Coexisting illness: Sepsis, hemolysis, and other illnesses (2)

### GENERAL PREVENTION

- Prophylactic administration of anti-D globulin (RhoGAM) to Rh-negative mothers
- Risk assessment and monitoring for jaundice, weight loss, and feeding difficulties
- Avoidance of oxidant stresses in patients with G6PD deficiency
- Avoidance of bilirubin-displacing drugs (sulfonamide antibiotics, ceftriaxone) in neonates or in jaundiced infants

### PATHOPHYSIOLOGY

- Bilirubin is the breakdown product of heme, primarily derived from hemoglobin.
- Bilirubin undergoes hepatic conjugation by UDP glucuronosyltransferase before excretion through the biliary tract into the intestine.
- Bilirubin levels increase under various conditions: Increased bilirubin load, increased enterohepatic circulation, reduced hepatic perfusion or uptake, and reduced conjugation.

- Hypoalbuminemia or displacement from blood increases tissue levels.
- Prematurity, asphyxia, and infection increase the neurotoxicity of bilirubin.

### ETIOLOGY

Multiple causes and contributing factors are listed in the Differential Diagnosis section.

## DIAGNOSIS

### HISTORY

- Method and adequacy of feeding: If breast-feeding, breast engorgement, milk output, success in latching, and duration of nursing
- Weight gain or loss
- Urine and stool output
- Maternal history: Blood type, DM, intrauterine infection, oxytocin induction
- Ethnicity
- Family history:
  - Disorders predisposing to hemolysis (G6PD deficiency, thalassemia, sickle cell disease)
  - Prior sibling with blood group incompatibility, hemolysis, phototherapy, or exchange transfusion

### PHYSICAL EXAM

- Assessment of respiratory and hemodynamic status, hydration, and level of activity and responsiveness
- Weight ( $> 10\%$  loss from birth weight is concerning in the newborn)
- Inspection (with dermal pressure) for presence of jaundice. The cephalocaudal progression of jaundice corresponds roughly to TSB (5 mg/dL at the face, 15 mg/dL at mid-abdomen). In older children, jaundice may appear with TSB  $> 2$  mg/dL.
- Abdominal exam for organomegaly or signs of intestinal obstruction
- Neurologic exam for signs of kernicterus (high-pitched cry, opisthotonos, loss of Moro reflex, weak suck)

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- TSB and direct (conjugated) bilirubin levels, together with the presenting history, presence of risk factors, and clinical evaluation, determine the need for additional lab tests (3). Hyperbilirubinemia is more likely to be nonphysiologic with:
  - Jaundice appearing in the 1st day of life or persisting beyond 10–14 days of life
  - Direct (conjugated) bilirubin  $> 2$  mg/dL
  - Rate of rise of TSB level  $> 5$  mg/dL/day
- Hemoglobin or hematocrit reveals polycythemia or suggests blood loss or hemolysis.
- Reticulocyte count: Elevated in hemolysis or significant blood loss
- Peripheral blood smear reveals RBC fragmentation or an underlying RBC abnormality in hemolytic anemias.
- Patient and maternal blood types: Newborn Rh or A and B antigens can give rise to an isoimmune hemolytic process if the mother's blood is Rh-negative or type O, respectively.

- In the presence of hemolysis:
  - Direct Coombs (direct antiglobulin) test: Positive in isoimmune hemolytic disease (Rh or blood group incompatibility)
  - RBC G6PD activity: Testing based on ethnicity or lack of response to phototherapy; may be falsely normal in the presence of hemolysis
- Evaluation for infection: Fever or temperature instability, behavior changes, and feeding intolerance warrant evaluation for sepsis. Urinary infection occurs in asymptomatic jaundiced infants, especially with onset  $> 8$  days of age (4).
- Albumin: In severe hyperbilirubinemia, hypoalbuminemia increases the fraction of unbound bilirubin and may impact treatment decisions.

### Imaging

Not necessary unless intracranial hemorrhage is suspected

### Diagnostic Procedures/Other

Transcutaneous bilirubin measurement is useful for screening if TSB is  $< 15$  mg/dL (2).

### DIFFERENTIAL DIAGNOSIS

- Physiologic neonatal jaundice<sup>a</sup>: Typically peaks at 3–5 days, resolving by 7 days of age in bottle-fed infants and lasting up to 3 wk in breast-fed infants
- Breast-feeding jaundice<sup>a</sup>
- Increased heme burden:
  - Hemolysis and ineffective hematopoiesis:
    - Isoimmune (ABO or Rh incompatibility),<sup>a</sup> autoimmune, or microangiopathic hemolysis
    - RBC membrane defects (spherocytosis)
    - Enzyme defects (G6PD deficiency)
    - Hemoglobinopathies (sickle cell disease,<sup>b</sup> thalassemia)
  - Contained blood (bruising, cephalohematoma, intracranial, swallowed blood)<sup>a</sup>
  - Polycythemia<sup>a</sup>
  - Hypersplenism, splenic crisis (sickle cell disease)<sup>b</sup>
- Infection:
  - Bacterial infection
  - Malaria<sup>b</sup>
- Disorders of bilirubin metabolism:
  - Gilbert syndrome<sup>b</sup>: This partial deficiency of glucuronyl transferase manifests with mild hyperbilirubinemia during other illnesses. No treatment is needed.
  - Crigler-Najjar syndrome, type I<sup>a</sup>: Absence of glucuronosyl transferase activity results in severe hyperbilirubinemia with high risk for progression to kernicterus.
  - Crigler-Najjar syndrome, type II<sup>a</sup>: Less severe, phenobarbital-responsive partial deficiency of glucuronosyl transferase with lower risk of kernicterus
  - Lucey-Driscoll syndrome: Inhibition of glucuronosyl transferase by hormones
  - Galactosemia, early stage<sup>a</sup>
- Endocrine-related disorders (hypothyroidism,<sup>a</sup> maternal DM<sup>a</sup>)
- Increased enterohepatic circulation (duodenal atresia, meconium ileus)<sup>a</sup>

<sup>a</sup> Exclusively or nearly always presenting in the neonatal period.

<sup>b</sup> Presenting outside of the neonatal period.

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

- Correction of respiratory and hemodynamic disturbances
- Identification and treatment of serious underlying or coexisting conditions (infection, hemorrhage, hemolysis, acute bilirubin encephalopathy)
- Phototherapy is the primary treatment modality for newborn jaundice and reduces the risk of severe hyperbilirubinemia and exchange transfusion (2). Nomograms incorporating TSB, postnatal and gestational age, and additional risk factors guide the use of phototherapy or exchange transfusion (3). Phototherapy thresholds for term infants range from 12 mg/dL at 24 hr of life to 21 mg/dL at 120 hr of life (3).
- Home phototherapy is an option for low-risk infants who can be monitored closely.
- The primary benefit of phototherapy is to prevent rise of bilirubin level to avoid exchange transfusion and/or kernicterus risk.
- There is no need or benefit for the use of phototherapy for children with bilirubin levels below those recommended for phototherapy.
- Exchange transfusion is appropriate in severe hyperbilirubinemia unresponsive to phototherapy when bilirubin levels are approaching the threshold for kernicterus.
- Exchange transfusion entails significant risks.
- Exchange transfusion thresholds for term infants range from 19 mg/dL at 24 hr of life to 25 mg/dL at 96 hr of life (3).
- Lower gestational age (35–37 6/7 wk) and the presence of other risk factors (hemolysis, G6PD deficiency, asphyxia, lethargy, temperature instability, sepsis, acidosis, albumin <3 g/dL) lower the phototherapy and exchange thresholds.
- Other considerations for exchange transfusion include a high TSB to albumin ratio, inability of phototherapy to lower TSB levels below the exchange threshold, and acute bilirubin encephalopathy (3).

**MEDICATION**

- IV immune globulin, 0.5–1 g/kg, in isoimmune hemolytic anemia when TSB values rise despite phototherapy
- Phenobarbital in Crigler-Najjar syndrome, type II

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Exposure to sunlight does not prevent progression to severe hyperbilirubinemia.
- Metalloporphyrins inhibit the production of bilirubin by heme oxygenase but are not yet approved for use in the U.S.

**DISPOSITION**

**Admission Criteria**

- Need for inpatient phototherapy or exchange transfusion
- Inability to ensure adequate follow-up or safety of patient
- Fever or other concern for serious bacterial illness in a neonate
- Critical care admission criteria:
  - Need for exchange transfusion
  - Cardiorespiratory instability

**Discharge Criteria**

Jaundiced newborns seen in the emergency department should undergo the same risk assessment for hyperbilirubinemia as performed at hospital discharge (3). Considerations include:

- Clinical risk factors
- Adequacy of feeding and hydration
- TSB level interpreted according to gestational and postnatal age

**Issues for Referral**

- Endocrinology: In hypothyroidism
- Metabolic: For galactosemia
- Gastroenterology: For inherited disorders of bile metabolism and excretion

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Newborns evaluated in the emergency department before 24–72 hr of life require follow-up by 72–120 hr of life. The timing may be modified by the TSB level or other risk factors (3,5).

**Patient Monitoring**

Parents should monitor adequacy of oral intake, urine and stool output, and skin color.

**DIET**

- Breast-fed infants should nurse regularly even if jaundiced or receiving phototherapy.
- Supplementation or temporary substitution with formula decreases breast-feeding jaundice but increases the risk of lactation failure.
- Glucose water supplements may increase TSB levels in breast-fed infants.
- Infants with suspected galactosemia require a lactose-free diet.

**PROGNOSIS**

When treated with phototherapy or exchange transfusion, otherwise-healthy term and near-term infants with TSB levels  $\geq 25$  mg/dL do not suffer adverse long-term neurodevelopmental sequelae (1).

**COMPLICATIONS**

- Acute bilirubin encephalopathy is characterized by hyperpyrexia, poor feeding, lethargy, high-pitched cry, opisthotonos, and seizures.
- Kernicterus is neurotoxic staining of brain tissue with bilirubin. The term also describes chronic bilirubin encephalopathy (motor delay, hearing loss, dental enamel dysplasia, cerebral palsy, and mental retardation).

**REFERENCES**

1. Newman TB, Liljestrand P, Jeremy RJ, et al. Outcomes among newborns with total serum bilirubin levels of 25 mg per deciliter or more. *N Engl J Med.* 2006;354(18):1889–1900.
2. Ip S, Chung M, Kulig J, et al. An evidence-based review of important issues concerning neonatal hyperbilirubinemia. *Pediatrics.* 2004;114(1):e130–e153.
3. American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics.* 2004;114(1):297–316.
4. Garcia FJ, Nager AL. Jaundice as an early diagnostic sign of urinary tract infection in infancy. *Pediatrics.* 2002;109(5):846–851.
5. Maisels MJ, Bhutani VK, Bogen D, et al. Hyperbilirubinemia in the newborn infant  $\geq 35$  weeks' gestation: An update with clarifications. *Pediatrics.* 2009;124(4):1193–1198.

**CODES**

**ICD9**

- 774.6 Unspecified fetal and neonatal jaundice
- 774.39 Other neonatal jaundice due to delayed conjugation from other causes
- 782.4 Jaundice, unspecified, not of newborn

**PEARLS AND PITFALLS**

- Visual estimation of jaundice may result in underestimation of TSB levels.
- Newborn TSB levels must be interpreted according to the postnatal and gestational age as well as risk factors.
- The TSB of infants examined before 36–72 hr of life is likely to continue to rise.

# KAWASAKI DISEASE

Esther M. Sampayo

## BASICS

### DESCRIPTION

- Kawasaki disease (KD) is an acute self-limited febrile vasculitic syndrome (1).
- The diagnosis is made clinically in children with prolonged fever.
- Coronary artery aneurysms (CAAs) occur in 15–25% of untreated children (2).

### EPIDEMIOLOGY

#### Incidence

- KD is the 2nd most common systemic pediatric vasculitis after Henoch-Schönlein purpura (3).
- In the U.S., KD affects ~10–15/100,000 children <5 yr of age (1):
  - 80–85% are <5 yr of age, with 50% of patients <2 yr of age (3).
  - Incidence is highest among those of Japanese ancestry; 50–200/100,000 children <5 yr of age.
- KD has surpassed rheumatic fever as the leading cause of acquired heart disease in children in developed countries (4).

### RISK FACTORS

- Factors possibly associated with KD include preceding respiratory illness, eczema, exposure to carpet cleaners, humidifiers, or residence near a standing body of water (3,5).
- Worldwide, KD is most common in all Asian populations and Pacific islanders followed by blacks, Hispanics, and whites.
- Male to female ratio of 1.5–1.7:1
- There may be a genetic component; familial incidence is ~2% (4,6).

### PATHOPHYSIOLOGY

An acute panvasculitis that affects small- and medium-sized blood vessels. KD is considered an immune-mediated disorder with cytokine cascade activation and endothelial cell activation resulting in the vasculitic process (1).

### ETIOLOGY

- The etiology remains unknown.
- The age distribution and seasonal outbreaks (primarily late winter and spring) suggest an infectious etiology (3).
- A specific viral or bacterial agent may result in an exaggerated immune response in a genetically susceptible individual (1).

## DIAGNOSIS

- Classic KD:
  - Diagnosis based on clinical criteria, which include fever for at least 5 days and 4 out of the 5 major clinical features with exclusion of other diseases with similar findings (1):
    - Bulbar nonexudative conjunctivitis
    - Oral mucosal changes
    - Polymorphous exanthem
    - Hand and feet swelling, skin peeling
    - Cervical lymphadenopathy
  - In the presence of  $\geq 4$  clinical criteria, KD diagnosis can be made on day 4 of fever.
- Patients with fever for at least 5 days and fewer than 4 criteria can be diagnosed with KD when CAAs are detected by echo or angiography.
- Incomplete KD:
  - Patients who do not fulfill the classic criteria of at least 4 of the 5 clinical findings
  - Incomplete KD and echo should be considered in children <6 mo of age with fever of >7 days duration with elevated C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) levels and no other explanation for febrile illness.
  - More common in children <1 yr of age
  - Higher rate of CAA
- The American Heart Association (AHA) proposed the following algorithm for the diagnosis of suspected incomplete KD (1):
  - If fever is  $\geq 5$  days and there are 2 or 3 of the typical features of KD, obtain a CRP and ESR.
  - If the CRP level is  $\geq 3$  mg/dL and ESR is  $\leq 40$  mm/hr, the child is monitored and followed daily.
  - If fever resolves but typical skin peeling occurs, an echo should be performed.
  - If the CRP is  $\geq 3$  mg/dL and ESR is  $\geq 40$  mm/hr, obtain albumin, ALT, platelets, WBC count, and urine studies.
  - If  $\geq 3$  supplemental lab criteria are abnormal, a diagnosis of KD is made. The child should have an echo and be treated.
  - If <3 lab criteria are abnormal, cardiac echo should be performed.
  - If the echo is positive, the child is treated for KD.
  - KD is unlikely with a normal echo.

### HISTORY

- Acute phase (up to weeks after onset):
  - Fever usually  $>39^{\circ}\text{C}$  for  $>5$  days
  - Irritability: Aseptic meningitis is reported in 25% of cases (7).
  - Nonexudative conjunctivitis
  - Mucosal changes in the mouth
  - Rash with accentuation in the perineal area
  - Edema and erythema of the extremities
  - Cervical lymph nodes
  - Shortness of breath or chest pain may reflect pericardial effusions or CHF (8).
  - Dysuria from urethritis or testicular swelling
  - Diarrhea, vomiting, and abdominal pain
  - Joint pain and/or swelling

- Subacute phase (2–8 wk from onset):
  - Desquamation of the perineal area, palms, and soles, especially the periungual area on the distal fingertips
  - Persistent arthralgia, arthritis

### PHYSICAL EXAM

- High fever,  $>39^{\circ}\text{C}$
- Nonexudative, painless bilateral bulbar conjunctivitis that is limbus sparing. Anterior uveitis may be present in 80% (9).
- Erythema, fissures, crusting of the lips, nonexudative oropharyngeal erythema, and/or strawberry tongue
- Adenopathy: Usually in the anterior cervical triangle, unilateral, nontender, nonsuppurative, nonerythematous adenopathy  $>1.5$  cm; least common of the 5 clinical criteria
- Carditis: Tachycardia, hyperdynamic precordium, gallop, murmur, signs of CHF:
  - Rarely, cardiogenic shock
- Right upper quadrant tenderness with palpable mass consistent with hydrops of the gallbladder, hepatomegaly, jaundice
- Extremity changes:
  - Acute phase: Erythema of palms and soles and/or induration edema of hands and/or feet
  - Subacute phase: Periungual desquamation
  - Convalescent phase: Beau lines—transverse grooves across the fingernails
  - Arthritis in 1/3 of cases
- Skin: Morbilliform rash that is polymorphous, usually not vesicular, and commonly in perineal area. Erythema and induration at the site of previous bacillus Calmette-Guérin vaccination (10).

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC:
  - Leukocytosis (50%  $>12,000/\text{mm}^3$ )
  - Thrombocytosis, after 7 days
- Basic metabolic panel, ESR, CRP, liver enzymes (elevated in up to 40% [7]), LDH, albumin, urinalysis (70% have sterile pyuria)
- CSF:
  - Lumbar puncture is not routinely indicated, but if CSF is sampled, it may reveal pleocytosis, normal glucose, and protein.

#### Imaging

- Chest radiograph may demonstrate cardiomegaly, increased pulmonary vasculature, or pneumonia (8).
- Consider US of the liver/gallbladder if GI symptoms are present.

#### Diagnostic Procedures/Other

- ECG:
  - Acute phase: Prolonged PR interval, decreased QRS voltage, flat T waves, and/or ST changes
  - Later phases: May show signs of MI secondary to CAA

- Echo:
  - Although CAAs generally are not present during the 1st 10 days of illness, any patient in whom KD is strongly suspected should receive echo because abnormalities that aid in the diagnosis may appear within the 1st 10 days of fever.
  - If there is no initial CAA, echo should be repeated at 2 and 6–8 wk.

**DIFFERENTIAL DIAGNOSIS**

- Clinical characteristics that would help exclude KD include exudative conjunctivitis or pharyngitis, discrete intraoral lesions, bullous or vesicular rash, and generalized lymphadenopathy as may be seen in the following conditions:
  - Adenovirus, Epstein-Barr virus, Measles
  - Streptococcal infection: Scarlet fever
  - Staphylococcal scalded skin syndrome
  - Toxic shock syndrome
  - Rocky Mountain spotted fever
  - Stevens-Johnson syndrome
  - Bacterial cervical adenitis
  - Systemic-onset juvenile idiopathic arthritis

 **TREATMENT**

**MEDICATION**

**First Line**

- Intravenous immune globulin (IVIG):
  - 1 dose of IVIG (2 g/kg) reduces the aneurysm rate from 25% to 3–5% if administered within the 1st 10 days after the onset of fever (1).
  - Not typically administered in the emergency department. Recommended duration of infusion is 10–12 hr.
  - Therapy should be initiated within 10 days of fever onset; however, other children who present later should still be treated if fever or other signs of persistent inflammation are present.
- Aspirin (1):
  - 80–100 mg/kg/day PO for 1st week
  - 3–5 mg/kg/day once fever is controlled
  - Discontinued when platelets and echo normalize, usually within 6 wk

**Second Line**

- Although the combination of IVIG and aspirin therapy is highly effective, 10–20% of patients will be refractory to this treatment regimen and may require a 2nd dose of IVIG.
- The role of corticosteroids in the treatment of KD is controversial and not well established.

**DISPOSITION**

**Admission Criteria**

- Admission is required for specialty consultation, echo, and IVIG therapy.
- Critical care admission criteria:
  - Critical care admission if there are signs of CHF or shock

**Discharge Criteria**

Children with prolonged fever who do not meet criteria for KD or incomplete KD may be discharged home with close follow-up.

**Issues for Referral**

Cardiology, rheumatology, and infectious disease experts may be involved in the care of patients with KD.

 **FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- In the current AHA guidelines, a stratification system has been developed to categorize patients by their risk of MI and to provide guidelines for long-term management (11).
- Risk levels I–V define the need for serial imaging and stress tests, physical activity, follow-up, diagnostic testing, and long-term antiplatelet and anticoagulant medication therapy.
- Discharge instructions and medications:
  - Stable patients with prolonged fever without a source and normal inflammatory markers should be discharged home with close follow-up with their primary care provider.

**PROGNOSIS**

- The mortality rate is reported to be 0.1–2%.
- In Japan, the recurrence rate of KD has been reported to be ~3% (1).

**COMPLICATIONS**

- 15–25% of untreated patients develop cardiac complications, including CAAs, acute MI secondary to true coronary artery obstruction, myocarditis, CHF, pericarditis with pericardial effusion that can lead to cardiac tamponade, mitral or aortic insufficiency, and dysrhythmias.
- The long-term sequelae of CAAs include ischemic heart disease, sudden death, and MI (2).
- If MI occurs, it typically occurs in the 1st yr of diagnosis; 40% occur in the 1st 3 mo.

 **CODES**

**ICD9**  
446.1 Acute febrile mucocutaneous lymph node syndrome (mcls)

**PEARLS AND PITFALLS**

- KD is the leading cause of acquired heart disease in children.
- The classic diagnosis of KD is based on at least 5 days of fever and 4 out of 5 clinical features including conjunctivitis, rash, cracked red lips or strawberry tongue, extremity swelling or redness of palms or soles, and cervical lymphadenopathy.
- Incomplete KD should be considered in any child with unexplained fever for ≥5 days in association with ≥2 of the principal features of this illness with supportive lab data such as ESR ≥40 mm/hr or CRP ≥3.0 mg/dL.
- Have a high index of suspicion for KD in children with prolonged fever without a source:
  - Infants <6 mo old
  - Lab evidence of systemic inflammation, such as elevated CRP and ESR
  - Thrombocytosis after 1st week
- The long-term prognosis and natural history of KD remain uncertain. In adult life, premature atherosclerosis may develop in these patients, with a risk for MI.

# LABIAL ADHESIONS

Cynthia J. Mollen

## BASICS

### DESCRIPTION

- Labial adhesions can occur when the labia minora are fused over the vestibule.
- The adhesions are an acquired condition.

### EPIDEMIOLOGY

#### Incidence

- 0.6–3.0% of prepubertal girls (1):
  - Likely much higher rate of asymptomatic adhesions
- Most common at 3 mo to 6 yr of age (1)
- Peak incidence 13–23 mo of age (1)
- Rare after puberty (1)

### RISK FACTORS

- Local irritation (contact dermatitis)
- Vulvovaginitis
- Recurrent diarrhea
- Sexual abuse
- Surgical procedures with vulvar trauma

### GENERAL PREVENTION

After the labia separate, some steps may help to prevent recurrence:

- Avoiding irritants
- Daily bathing in a tub of plain water
- Application of petroleum jelly

### PATHOPHYSIOLOGY

- The thin skin covering the labia becomes denuded.
- Labia adhere to the midline.
- Low levels of estrogen may contribute.

### ETIOLOGY

Unknown

## DIAGNOSIS

### HISTORY

- May be asymptomatic
- Parents may report urinary symptoms, such as retention, urinary tract infection, dysuria, or an altered urinary stream.
- There may be a history of dribbling of urine upon standing after urination.
- May have history of sexual abuse
- History of diaper rash, vulvovaginitis, diarrhea, dermatologic disorders, and use of creams.

### PHYSICAL EXAM

- Visual inspection of the vulva reveals a thin, midline, avascular line of fusion:
  - May be partial or complete
  - With partial, the fusion is located posteriorly closest to the anus, allowing unobstructed urinary flow.
- Full physical exam to assess for findings consistent with abuse or trauma:
  - Several studies have found that labial adhesions as a sole physical finding, and without a disclosure of sexual abuse, are not indicative of abuse (2,3).

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

No specific lab tests are needed to establish the clinical diagnosis.

### DIFFERENTIAL DIAGNOSIS

- Imperforate hymen:
  - An imperforate hymen presents as a midline bulging mass between the labia, reflecting trapped mucoid material.
- Lichen sclerosis et atrophicus:
  - Manifests as white, atrophic papules that can coalesce into plaques
  - Areas of small hemorrhage, purpura, bullae, or ulcers can appear within the atrophic area as well as areas of erosion. The whitening generally involves the labia minor and labia majora but can extend over the perineum and around the anus.
- Vulvovaginitis

## TREATMENT

### MEDICATION

#### First Line

- Topical estrogen (Premarin) cream b.i.d.
- Topical antibiotic therapy is not indicated.
- Topical corticosteroid therapy is not indicated as first-line therapy.

#### Second Line

Topical 0.05% betamethasone cream b.i.d.:

- May be more successful than estrogen (4)

### COMPLEMENTARY & ALTERNATIVE THERAPIES

- Watchful waiting:
  - For asymptomatic patients or those with partial adhesions not affecting the urinary stream, consider no treatment.
- Eliminate inciting factors (ie, irritation)

**SURGERY/OTHER PROCEDURES**

- Surgery is the preferred treatment for postpubertal patients.
- Manual separation with topical anesthesia (eg, lidocaine 2%, lidocaine 5%, or lidocaine 2.5%/prilocaine 2.5% creams)
- Surgical separation with anesthesia:
  - Failure or refusal of medical therapy or manual separation in symptomatic girls
  - Scarred or thick adhesions

**DISPOSITION****Discharge Criteria**

- No evidence of abuse on history or physical exam
- No additional diagnosis requiring hospitalization (eg, pyelonephritis, trauma)

**Issues for Referral**

Refer to a pediatric urologist, pediatric gynecologist, or pediatric surgeon for failed medical management.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Estrogen or betamethasone cream b.i.d. for 1–2 wk, followed by daily application of white petroleum jelly for 6–12 mo

**PROGNOSIS**

- Recurrences are common (15–35%), particularly if the inciting factor is still present (eg, diaper irritation, frequent vulvovaginitis).
- Spontaneous resolution will occur at puberty.

**COMPLICATIONS**

- If untreated, labial adhesions can predispose to urinary tract infection or lead to urinary retention:
  - In young children with labial adhesions, urine sampling may require suprapubic bladder aspiration due to the inability to catheterize.
- Hormonal creams may result in breast budding:
  - Will resolve after treatment completion
- Other rare side effects of topical therapy include vaginal bleeding and local irritation.

**REFERENCES**

4. Mayoglou L, Dulabon L, Martin-Alguacil N, et al. Success of treatment modalities for labial fusion: A retrospective evaluation of topical and surgical treatments. *J Pediatr Adolesc Gynecol.* 2009;22: 247–250.

**CODES****ICD9**

- 624.8 Other specified noninflammatory disorders of vulva and perineum
- 752.49 Other congenital anomalies of cervix, vagina, and external female genitalia

**PEARLS AND PITFALLS**

- Labial adhesions are common and only very rarely are a result of sexual abuse.
- Labial adhesion may be distinguished clinically from imperforate hymen; labia are not fused together when the hymen is imperforate.
- Considerable variation in recommended management exists. Consider the age of the patient, symptoms, and family preference.

# LACERATION REPAIR

Faiz Ahmad

Abu N.G.A. Khan

## BASICS

### DESCRIPTION

- For the purposes of this topic, a *laceration* is defined as a traumatic disruption through the epidermis due to a physical force rather than a chemical, thermal, or other force.
- Laceration repair is done to approximate wound edges neatly, control bleeding, preserve tissue function, prevent infection, expedite healing, and restore cosmetic appearance.
- Primary closure: Wound repair up to 24 hr (up to 48 hr for facial laceration) after the injury
- Wound that is allowed to heal by itself with granulation tissue is referred to as healing by secondary intention.

### EPIDEMIOLOGY

#### Incidence

- ~12 million wounds are treated in emergency departments each year in the U.S.
- Lacerations account for 30–40% of all injuries seen in the emergency department.

### RISK FACTORS

Immunocompromised patients:

- Patients on long-term steroids or chemotherapy
- Diabetes or vasculitis

### GENERAL PREVENTION

- Prevention of pediatric trauma: Use of helmets and other protective equipment are crucial in preventing a laceration.
- Educating the parents and children to avoid risky behavior

### PATHOPHYSIOLOGY

- Skin is highly elastic due to its high content of elastin fibers. Strength of the skin comes from a large number of collagen fibers.
- Laceration mechanisms:
  - Shearing: Laceration caused by an object with sharp edges (eg, knife or glass)
  - Tension: Laceration sustained by a blunt object striking skin at <90 degrees; surrounding tissues may be devitalized (eg, avulsion and flap lacerations)
  - Compression: Laceration caused by a blunt object striking the skin at 90 degrees (eg, stellate laceration)
- Wound-healing factors:
  - Lacerations with edge retraction >5 mm are under a large amount of tension and tend to heal with an unattractive scar.
  - Lacerations across the joints or perpendicular to wrinkle lines tend to heal with an undesirable scar.
  - Wounds most prone to infection are:
    - Those over the moist areas of the body (eg, axillae, web spaces, perineum, and intertriginous areas)
    - Those caused by bites
    - Those that come in contact with vaginal secretions and feces

- Those with large area of devitalized tissue due to extremely high bacterial concentrations
- Those contaminated with dirt or from swamp, marshes, or farms
- Certain host factors also may affect the laceration or wound outcome (eg, malnutrition, severe anemia, chronic steroid use, and conditions like Ehlers-Danlos syndrome that have potential for delayed healing or poor outcome).

### ETIOLOGY

Direct trauma or shearing force secondary to a fall or hit with a sharp object is the common cause of laceration in children.

### COMMONLY ASSOCIATED CONDITIONS

- Fracture of the long bone
- Injury to the blood vessels and nerves
- Head injury
- Internal organ injury

## DIAGNOSIS

### HISTORY

- Time since injury
- Mechanism of injury: May give a clue as to the extent of injury; possibility of foreign body in the wound; or involvement of nerves, tendon, major vessels, bones, or joints
- Environment in which the laceration was sustained
- Inquire about the patient's general health, past medical history, medication use, allergies, and immunization status.

### PHYSICAL EXAM

- Distal motor and nerve function should be assessed 1st:
  - Neurovascular integrity and tendon function should be tested before anesthetic use.
  - Assess motor strength, range of motion with and without resistance, sensation, and vascular supply.
- Hemostasis for good physical exam of the extremity can be achieved by using a tourniquet or sphygmomanometer cuff:
  - Deprivation of blood supply to the peripheral tissue does not generally cause damage if <2 hr in duration.
- Bone or joint underlying laceration should be assessed for fracture or joint disruption.
- Assess extent and type of injury: Avulsion vs. laceration.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

Usually no lab testing is required:

- Assessment of hematocrit if significant hemorrhage may have occurred

#### Imaging

X-ray if foreign body or fracture is suspected. At least 2 views should be obtained, as the object or fracture may not be visible depending on the axis of view. Refer to related topics.

### Diagnostic Procedures/Other

Injection of sterile methylene blue into the adjacent joint to rule out joint violation

### DIFFERENTIAL DIAGNOSIS

- Abrasion
- Burn: Chemical or thermal

## TREATMENT

### PRE HOSPITAL/INITIAL STABILIZATION

- Attention to airway, breathing, and circulation in case of a major injury
- Hemostasis, using direct pressure:
  - Intravascular access in case of a major laceration
  - IV fluid bolus as needed for fluid resuscitation
  - Splinting of extremity for any deformity

### MEDICATION

- Local infiltration with anesthetic or regional anesthesia is preferred:
  - LET (lidocaine, epinephrine, tetracaine) applied topically is a noninvasive method of anesthesia.
  - Injected anesthetic, such as lidocaine with or without epinephrine or longer-acting agents such as bupivacaine (max single dose without epinephrine 2.5 mg/kg) or ropivacaine (max single dose 5 mg/kg) may be used.
  - Use of regional nerve block may be preferable if the lesion is in an appropriate nerve distribution
- Though not usually necessary, pain control with NSAIDs or a parenteral narcotic agent (eg, morphine sulfate 0.1 mg/kg IV/SC/IM repeated as needed)
- Tetanus prophylaxis (see Tetanus topic)
- Antibiotic prophylaxis for dirty wound or in patients prone to infective endocarditis
- Consider antibiotic prophylaxis for animal bites and rabies prophylaxis if laceration was sustained by raccoons, skunks, foxes, bats, and possibly other animal bites (see Bite, Animal topic).

### COMPLEMENTARY & ALTERNATIVE THERAPIES

Conservative treatment or suturing of small uncomplicated lacerations without suturing may have a similar outcome.

### SURGERY/OTHER PROCEDURES

- The following injuries may require consultation with a surgical specialist:
  - Open fracture, tendon, nerve, or major blood vessel injury
  - Wounds involving specialized structures (eg, lacrimal duct, parotid duct, tarsal plate/eyelid laceration)
  - Tissue loss or neurovascular compromise
- Wound irrigation:
  - Normal saline for wound irrigation:
    - Use 20- or 30-cc syringe with splash guard or 18-gauge angiocatheter for irrigation.
    - ~100 cc for each centimeter of wound
    - Consider using less if skin glue will be used, since irrigation will cause swelling of skin and tissue around laceration.
    - Distention of the skin may make skin approximation by glue difficult.

- Wound closure by primary intention:
  - Most wounds <8 hr old may be closed without any increased risk of infection.
  - Most wounds up to 24 hr may be closed by primary intention in the emergency department.
  - Facial and scalp wounds may be closed up to 48 hr after injury.
- Primary closure using tissue glue:
  - Superficial skin lacerations may be closed using tissue glue such as octylcyanoacrylate (Dermabond, or similar product).
  - Advantages are that tissue glue is painless and no anesthetic injection is required.
  - This is best used in superficial lacerations with well-approximated edges.
  - Contraindicated for wounds over the eyelid or close to the eye, flexor or extensor surfaces of joints, wounds with extension into mucous membranes, or genital area wounds
  - Glue will drip or run toward the direction of gravity. If used on the face in a manner that might result in glue running toward eye, cover the eye with gauze and tape.
- Primary closure using sutures:
  - Sutures are appropriate for wounds extending into deeper subcutaneous tissues that are inappropriate for closure by skin glue.
  - Suturing is appropriate for the closure of lacerations of skin, fascia, muscle, tendons, and subcutaneous tissues.
  - There are 2 broad categories of sutures: Absorbable and nonabsorbable.
  - Absorbable sutures include plain gut, chromic gut, braided polyglactin (Vicryl and Dexon), and the absorbable monofilaments polydioxanone (PDS) and polyglyconate (Maxon).
  - Absorbable sutures on tapered needles are suitable for closure of deeper tissue layers and mucous membranes.
  - Gut sutures or rapid-absorbing Vicryl Rapide will retain their strength for 5–10 days, Vicryl and Dexon for 30–60 days, and the absorbable monofilaments for up to 90 days.
  - Nonabsorbable sutures include braided silk and the synthetic monofilaments Ethilon and Prolene:
    - On a cutting needle, these sutures are generally used to close the external skin surfaces.
    - Nonabsorbable sutures will need to be removed after 5–14 days to prevent scarring, depending on the site of the laceration.
  - A single-layer closure refers to simply suturing the skin surface, whereas a layered closure involves deeper layers as well as the skin.
  - By closing the deeper layers, the skin edges “fall” together with reduced tension, allowing for a superior cosmetic result.
  - Closure of the deeper layers also prevents “dead space” from forming. This dead space may allow pockets of blood or serum to accumulate, which will impair wound healing and can lead to a wound infection.

- Primary closure using staples:
  - Skin closure using surgical steel staples is a rapid and effective wound management technique.
  - A specialized stapler prefilled with staples is required for the procedure.
  - The steel staple is in the form of a wide, inverted U; as the staple is inserted, the cross arm is bent. This elevates, everts, and approximates the skin enclosed by the staple.
  - Skin stapling is appropriate for wounds on the scalp, trunk, or extremities. Having an assistant hold the wound edges together with forceps often aids in the procedure.
- Primary closure using the Steri-Strip:
  - Appropriate for wounds that do not require deeper layer closure with sutures and require little tension to maintain wound edge approximation.
  - Benzoin is typically used to permit the Steri-Strip to adhere to the skin more firmly.
  - An additional technique is the use of cyanoacrylate or other skin glue to attach the Steri-Strip to either side of the wound edge without actually using the skin glue to approximate the wound.
- Primary closure using hair apposition:
  - For small scalp wounds, hair braiding or the hair apposition technique to approximate the wound edges may be appropriate.

## DISPOSITION

### Admission Criteria

Large wounds that may require extensive reconstruction or for suspected internal injury

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Follow-up in 24–48 hr may be considered to inspect for infection and healing:
  - It is unclear if this is necessary or provides benefit over instructing the caregiver to return if the wound appears infected.
  - Remove facial sutures in 3–5 days.
  - Remove most other sutures in 10 days.
  - Sutures on the palms, soles, or around joints should be removed at 14 days.
- Activity: Avoid stress on the wound.

### COMPLICATIONS

- Scar
- Wound dehiscence
- Infection
- Keloid
- Bleeding

## ADDITIONAL READING

- Hock MO, Ooi SB, Saw SM, et al. A randomized controlled trial comparing the hair apposition technique with tissue glue to standard suturing in scalp lacerations (HAT study). *Ann Emerg Med.* 2002;40:19–26.
- Khan AN, Dayan PS, Miller S, et al. Cosmetic outcome of scalp wound closure with staples in the pediatric emergency department: A prospective, randomized trial. *Pediatr Emerg Care.* 2002;18:171–173.
- Quinn J, Cummings S, Callahan M, et al. Suturing versus conservative management of lacerations of the hand: Randomised controlled trial. *BMJ.* 2002;325(7359):299.

## CODES

### ICD9

- 873.40 Open wound of face, unspecified site, uncomplicated
- 879.8 Open wound(s) (multiple) of unspecified site(s), without mention of complication
- 879.9 Open wound(s) (multiple) of unspecified site(s), complicated

## PEARLS AND PITFALLS

- All wounds, particularly on the scalp and face, should be examined with distracting pressure applied to the wound edges. Wounds may initially appear to be only superficial lacerations or abrasions but are in fact full-thickness lacerations that are approximated by clotted blood.
- Always check neurovascular integrity and tendon function before anesthetic use.
- Look for a foreign body in any laceration caused by objects (including glass).
- Relative contraindications to laceration repair: Signs and symptoms of bacterial wound infection, evidence of primary closure, and lack of cosmetic or functional need for laceration repair
- Moist dressing may enhance healing.
- Lacerations in cosmetically sensitive areas should be covered with sunblock (SPF  $\geq$  15) for at least 6 mo to help prevent hyperpigmentation of the scar.

# LARYNGITIS

Frances M. Nadel

## BASICS

### DESCRIPTION

- Laryngitis is mucosal inflammation of the laryngeal upper airway, the area between the pharynx and the trachea that includes the cords. Acute laryngitis refers to symptoms of <3 wk.
- Patients usually present with hoarseness without airway obstruction.
- Cases are typically benign and self-limited.

### EPIDEMIOLOGY

Acute laryngitis is predominately seen in older children and teenagers.

### RISK FACTORS

- Viral infections
- Vocal cord overuse
- Desiccation from dehydration, decongestants
- Irritant exposure (smoke, pollution)
- Gastroesophageal reflux (GER)
- Allergies

### GENERAL PREVENTION

- Avoid upper respiratory infections.
- Avoid voice strain and irritant exposure.

### PATHOPHYSIOLOGY

- Infectious or irritant agents cause inflammation and edema of the laryngeal mucosa and vocal cords.
- Vocal cord edema disrupts normal cord function, resulting in a hoarse voice/cry.
- Chronic inflammation can lead to fibrosis and decreased mucus clearance.
- In GER, reflux of stomach contents into the airway causes inflammation and edema; this is referred to as laryngopharyngeal reflux (LPR).

### ETIOLOGY

- Acute laryngitis:
  - Upper respiratory viruses predominate.
  - Parainfluenza, adenovirus, human metapneumovirus, respiratory syncytial virus, rhinovirus, influenza
  - Pertussis, measles, mumps, and herpes simplex infections may be associated with acute laryngitis; additional clinical findings would aid in the diagnosis.
  - Consider diphtheria in an underimmunized child.
  - Consider fungal laryngitis in those who are immunocompromised or using inhaled steroids.
  - Vocal cord overuse

- Chronic or recurrent laryngitis:
  - GER
  - Allergens
  - Environmental irritants: Pollution, smoke
  - Medications: Inhaled corticosteroids, decongestants
- Rare causes: Secondary syphilis, TB, Wegener's granulomatosis, amyloidosis, lymphoma, sarcoidosis

## DIAGNOSIS

### HISTORY

- Pain with phonation, odynophagia
- Hoarseness:
  - May progress to aphonia
  - May be out of proportion to the rest of the symptoms
  - Duration >3 wk is usually considered chronic laryngitis.
- Fever, often low grade
- Malaise
- Myalgia
- Nasal congestion
- Cough
- Rhinitis
- Decreased oral intake due to pain
- Habitual or acute voice overuse
- Heartburn symptoms
- In LPR, chronic cough, throat clearing, wheezing, choking, and globus sensation may occur.
- Environmental tobacco exposure or smoking
- HIV status
- Constitutional symptoms are more concerning for systemic infectious or inflammatory disorders.

### PHYSICAL EXAM

- Physical exam is frequently normal except for a hoarse voice.
- Fever
- Pharyngeal erythema may be present.
- Stridor or increased work of breathing should not be present.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Acute laryngitis is usually caused by a viral infection and rarely requires further evaluation after a thorough history and physical exam.
- Consider a rapid streptococcal antigen test and culture if the patient has an associated pharyngitis.
- The evaluation of chronic laryngitis is highly variable and depends on the suspected etiology.
- If infectious diseases are being considered, a CBC, C-reactive protein, and applicable viral and bacterial cultures may be done.
- For suspicion of other inflammatory disorders, additional evaluation should be guided by the history and physical exam.

### Imaging

A lateral neck radiograph may be considered if there is stridor or dyspnea.

### Diagnostic Procedures/Other

- For chronic laryngitis, a skilled operator, usually an otolaryngologist, should undertake direct exam of the larynx.
- Visualization may be done in the emergency department using a flexible nasopharyngeal endoscope or under general anesthesia with a rigid laryngoscope.
- For patients without concerning constitutional symptoms, airway obstruction, or difficulties accessing medical care, an urgent outpatient referral for such an exam may be considered.
- Disease-specific testing, such as a pH probe to assess for GER, may be considered.

### DIFFERENTIAL DIAGNOSIS

- Croup
- Foreign body aspiration
- Epiglottitis
- Peritonsillar abscess
- Vocal nodules
- Vocal cord paralysis
- Laryngeal malignancy
- Laryngeal papillomatosis
- Asthma
- Psychogenic dysphonia
- Cranial nerve dysfunction

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Isolated laryngitis is rarely associated with airway obstruction or toxic appearance.
- Patients who appear toxic most probably have an alternate diagnosis and may require airway support and fluid resuscitation.

### MEDICATION

- Ibuprofen 10 mg/kg PO q6h PRN for fever or pain
- Chronic laryngitis therapy depends on the etiology.

### COMPLEMENTARY & ALTERNATIVE THERAPIES

- Zinc lozenges and vitamins A and C have been used to treat symptoms.
- Propolis, a bee-derived product that may be used to treat a sore throat, has been associated with allergic reactions in susceptible patients.

**SURGERY/OTHER PROCEDURES**

- In acute laryngitis, laryngoscopy will usually show mucosal and vocal cord erythema and edema.
- In chronic laryngitis, findings on laryngoscopy will depend on the etiology.
- In addition to inflammatory changes, vocal cord nodules, polyps, or granulomas may be seen with irritant or infectious etiologies.
- In GER, inflammation of the arytenoids and the posterior glottis may be seen.

**DISPOSITION****Admission Criteria**

- Dehydrated or unable to take oral hydration
- Toxic appearance, suggesting bacterial process or systemic disease
- Respiratory distress
- Airway obstruction

**Discharge Criteria**

Most children with uncomplicated acute laryngitis may be discharged from the emergency department.

**Issues for Referral**

Patients who have  $\geq 3$  wk of laryngitis despite adequate therapy should be referred to an otolaryngologist:

- Often, the otolaryngologist begins the evaluation.
- A gastroenterologist may be appropriate if GER is suspected.
- An allergist/pulmonologist may be appropriate if an allergic etiology is suspected.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Maintain adequate hydration.
  - Avoid irritants such as cigarette smoke.
- Activity:
  - Rest, including voice rest

**Patient Monitoring**

Symptoms from acute viral laryngitis usually resolve by 7–10 days:

- The hoarse voice may persist after the other viral symptoms.

**PROGNOSIS**

- Acute: Excellent—return to normal in 7–10 days
- Chronic: Variable—depends on the etiology

**COMPLICATIONS**

- Secondary bacterial infection
- Chronic: May have progressive and permanent loss of vocal cord function. Complications are also related to the primary etiology.
- Rare: Acute motor deficit from spinal epidermal cyst enlargement following laryngitis

**ICD9**

- 464.00 Acute laryngitis without mention of obstruction
- 476.0 Chronic laryngitis

**PEARLS AND PITFALLS**

- A complete history and physical exam is usually a sufficient evaluation for acute laryngitis.
- Warn patients to avoid whispering, as it causes more voice strain.
- Prolonged, progressive, recurrent, or systemic symptoms should prompt a more thorough evaluation.

# LARYNGOMALACIA/TRACHEOMALACIA

Jennifer R. Marin

## BASICS

### DESCRIPTION

- Malacia refers to softening:
  - In this context, it is an unusually collapsible airway and may occur at any level of the airway, including the larynx, trachea, and bronchi.
- Laryngomalacia:
  - Most common congenital laryngeal anomaly
  - Most common noninfectious cause of stridor in children (1)
- Tracheomalacia:
  - Most common congenital tracheal anomaly; may occur in either the intrathoracic or extrathoracic trachea
  - Common cause of chronic wheezing in infants
  - May occur as a congenital or primary developmental problem, or secondary or acquired, usually as a result of prolonged endotracheal intubation

### EPIDEMIOLOGY

- If primary, congenital malacia begins to manifest after the 1st weeks to months of life but also may be present at birth (2).
- 1 study estimated the incidence of the congenital form of tracheomalacia to be 1 per 1,445 infants (3).

### PATHOPHYSIOLOGY

- Malacia results from the weakness or deficiency of the cartilage that lines the airway.
- Laryngomalacia:
  - Immaturity of cartilage may result in weakness and collapse during inspiration.
  - Immaturity of neuromuscular control results in hypotonia of pharyngeal muscles.
- Tracheomalacia:
  - Immaturity of cartilage may result in weakness and collapse during inspiration or expiration.

### ETIOLOGY

- Primary or congenital malacia does not have a specific etiology and can be subdivided into:
  - Isolated (idiopathic)
  - Part of a recognized condition (syndromic)
- Secondary or acquired malacia is more common than primary and can be due to extrinsic compression of the airway or from any process causing chronic inflammation of the airway.

### COMMONLY ASSOCIATED CONDITIONS

- Several syndromes/conditions are associated with primary airway malacia (2,4):
  - Trisomy 21
  - DiGeorge syndrome
  - Larsen syndrome
  - Mounier-Kuhn syndrome
  - Williams-Campbell syndrome
- Secondary airway malacia can be seen with (2,4):
  - Compression:
    - Vascular malformations
    - Intra- and extrathoracic malignancies or lymphadenopathy
    - Congenital cysts
    - Tracheoesophageal fistula
    - Prolonged intubation or tracheostomy
  - Chronic inflammation:
    - Aspiration
    - Reflux
    - Bronchopulmonary dysplasia

## DIAGNOSIS

### HISTORY

- The following may be elicited from the history of a child with malacia (2,4):
  - Reflux symptoms
  - Persistent or recurrent respiratory symptoms
  - Chronic noisy breathing, especially when supine
  - Hoarseness
  - Feeding difficulties
  - The child may be asymptomatic during sleep or quiet breathing and worse with crying, agitation, feeding, upper respiratory infections, or supine positioning.
  - Apparent life-threatening event
- Other questions to consider that might indicate another diagnosis include:
  - Presence of fever (croup)
  - History of choking on an object or food (foreign body)
  - Birth history, including gestational age as well as intubation (vocal cord paralysis)

### PHYSICAL EXAM

- Assess vital signs, with attention to respiratory rate and pulse oximetry.
- Evaluate for increased work of breathing (tachypnea, dyspnea, retractions, stridor/wheezing) that is worse when the child is supine and improved when the child is prone (1).
- Symptoms worse when the patient is supine, crying, agitated, or feeding

- Laryngomalacia causes inspiratory stridor that characteristically improves with prone positioning.
- Tracheomalacia causes inspiratory stridor (extrathoracic) and/or expiratory wheezing or stridor (intrathoracic) depending on the location of airway involvement.
- Note cyanosis or drooling on exam, which may indicate an alternative diagnosis such as epiglottitis.

### DIAGNOSTIC TESTS & INTERPRETATION

- The diagnosis of primary malacia is usually made clinically based on the history and physical exam, and adjunct testing is often not necessary.
- If the diagnosis of laryngomalacia is in question, a trial of racemic epinephrine may be helpful, as this should produce minimal, if any, improvement.
- Similarly, if the diagnosis of tracheomalacia is unclear, inhaled beta-agonist therapy may be given in an effort to help distinguish malacia from other causes of wheezing:
  - Beta-agonists will not significantly improve the wheezing caused by malacia, and symptoms may be worsened (5).

### Imaging

- PA and lateral neck and chest radiographs may demonstrate an airway defect if the malacia is secondary to extrinsic compression.
- CXR may be useful to assess for other causes of cough or airway compression.
- Upper GI tract radiography is more sensitive for demonstrating airway narrowing secondary to extrinsic or intrinsic pathology.
- A CT scan or MRI of the neck and/or chest with contrast or CT angiography may detail the airway and the extrathoracic anatomy of compressive structures.

### Diagnostic Procedures/Other

- Bronchoscopy has been the gold standard for direct visualization of airway malacia (6).
- Videofluoroscopy with or without contrast
- Spirometry and flow-volume loops can examine function and airway flow.

### DIFFERENTIAL DIAGNOSIS

- Laryngomalacia is marked by stridor. Other conditions associated with stridor:
  - Croup
  - Airway foreign body
  - Subglottic stenosis
  - Epiglottitis
  - Respiratory papillomatosis
  - Hypocalcemia
  - Vocal cord paralysis
  - Vascular ring
  - Laryngeal hemangioma

- Tracheomalacia may be associated with stridor (proximal tracheomalacia) or wheezing (distal tracheomalacia). Other conditions associated with wheezing:
  - Reactive airway disease (asthma)
  - Bronchiolitis
  - Foreign body aspiration
  - Vascular ring
  - Mediastinal mass/tumor
  - CHF

## TREATMENT

- Initiating therapy depends on the degree of respiratory distress, including the presence of hypoxemia, and the growth and development of the child.
- It is always important to treat diseases that may exacerbate symptoms or delay resolution, such as reflux and upper respiratory infections.

### INITIAL STABILIZATION/THERAPY

- Although rare, if there is severe respiratory compromise, including hypoxemia or other signs of impending respiratory failure, the child should be managed by the principles of Pediatric Advanced Life Support.
- Positive pressure ventilation may be a means to overcome the collapsibility of the airway.

### MEDICATION

- Humidified air may be helpful to liquefy secretions, particularly during times of respiratory infections (2).
- Anticholinergics such as ipratropium bromide may assist with increasing airway tone in patients with moderate to severe tracheomalacia (5).

### SURGERY/OTHER PROCEDURES

- For severe cases, patients should be referred to a pulmonologist and/or an otolaryngologist.
- Long-term ventilation/continuous positive airway pressure with or without a tracheotomy may be needed in severe cases (7).
- Operative repair is reserved for those with severe malacia and includes resection of the affected segment; external splinting of the cartilage; pexy procedures in which airway structures or adjacent vessels are tacked down away from the area, causing compression; and stenting (8).

## DISPOSITION

### Admission Criteria

- Admission is required for patients with severe malacia who have significant respiratory distress or who are failing to demonstrate appropriate weight gain.
- Admission may be required for the child with malacia and a concomitant respiratory infection, making the degree of distress worse.

### Discharge Criteria

Candidates for emergency department discharge are those with normal work of breathing, normal pulse oximetry, and ability to tolerate oral feeding.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Most patients with malacia can be followed by the primary care physician.
- Patients should come to the emergency department for worsening respiratory symptoms or poor oral intake.

### PROGNOSIS

- In most cases, malacia self-resolves by about 2 yr of age (2).
- Symptoms typically improve between 6 and 12 mo of age for those with primary malacia.
- The cause of secondary malacia should be evaluated and treated in patients with extrinsic compression, even following relief of the compression; patients typically have evidence of ongoing collapsibility and/or compromise.

## CODES

### ICD9

- 519.19 Other diseases of trachea and bronchus
- 748.3 Other congenital anomalies of larynx, trachea, and bronchus

## PEARLS AND PITFALLS

- Laryngomalacia and tracheomalacia are self-resolving processes that usually do not require treatment.
- Symptoms of malacia may be exacerbated when patients are supine and improved when they are prone.
- It is critical to consider the differential diagnoses in cases of stridor or wheezing.
- Laryngomalacia and tracheomalacia are usually diagnosed clinically.

# LEAD POISONING

Harry C. Karydes

## BASICS

### DESCRIPTION

- Lead is a soft metal present in numerous places in the environment:
  - Vehicle exhaust
  - Paint
  - Pottery glaze
  - As a contaminant or deliberate additive to cosmetics and folk remedies
- Lead toxicity is the leading poisoning resulting in permanent neurologic injury in children.
- Lead toxicity is the most common environmental poisoning in children.
  - For this reason, leaded gasoline is no longer sold for use in on-road vehicles in the US.

### EPIDEMIOLOGY

An estimated 300,000 children 1–5 yr of age have a blood lead level > 10  $\mu\text{g}/\text{dL}$ .

### RISK FACTORS

- Pica
- Poverty
- Inner-city children
- Black, Mexican, and Central American children
- Some risk factors for lead toxicity are confounding factors also associated with impaired scholastic achievement, making causal association difficult to discern.

### GENERAL PREVENTION

- Screening blood lead levels in populations with housing stock that contains lead paint:
  - If > 27% of the housing stock was built prior to 1950
- Lead abatement in housing with lead paint

### PATHOPHYSIOLOGY

- Lead causes many cellular and molecular effects, resulting in alterations in:
  - Heme synthesis
  - Mitochondrial function
  - Neurotransmitter synthesis
  - Nucleotide metabolism
- Lead has multiple mechanisms:
  - Binds sulfhydryl groups and affects multiple enzymatic processes
  - Resembles  $\text{Ca}^{++}$  and therefore can interfere with  $\text{Ca}^{++}$ -dependent processes, including cell signaling
- Distribution:
  - Up to 99% of lead is bound to erythrocytes after initial absorption.
  - Ultimately redistributed into bone:
    - 99% of total body lead in adults
    - 70% of total body lead in children
  - High lead levels in the serum will compromise the blood–brain barrier and result in lead entry into the CNS and neurotoxicity.

- Often coexists with iron deficiency; this allows for increased lead absorption in the gut.
- Impairs heme synthesis, leading to elevated erythrocyte protoporphyrin; these complexes with zinc, causing elevated zinc protoporphyrin (ZPP).
- Lead is 99% bound to erythrocytes after ingestion; thereafter it distributes to soft tissue and bone.
- Compartment half-life in blood and soft tissues is months.
- Compartment half-life in bone is years to decades.
- Symptomatic illness after a single acute exposure is rare.

### ETIOLOGY

- Lead is most commonly ingested, but inhalation of fumes or fine particles is possible.
- Acute toxicity:
  - Most often owing to environmental exposure or ingestion of substance containing high amounts of lead
  - Pottery glaze
  - Certain folk remedies
  - Jewelry
  - Weights
  - Home-distilled alcoholic beverages
- Chronic toxicity:
  - Occupational exposures:
    - Most common via inhalation route
    - Smelting
    - De-leadings
    - Bridge painting
  - Nonoccupational:
    - Lead paint ingestion by children
    - Inhalational exposure when lead paint is stripped by heating or by sanding
    - Contamination of drinking water or food
    - Use of folk remedies containing high lead concentrations
    - A swallowed lead object, such as a curtain weight or fishing sinker weight, may result in a rapid, dangerous rise in lead levels and severe toxicity.
    - May also be seen when a retained bullet enters the synovium or other body cavity where it is systemically absorbed
    - Intentional inhalation of leaded gasoline

### COMMONLY ASSOCIATED CONDITIONS

- Anemia
- Developmental delay
- Poor school performance
- Peripheral neuropathy

## DIAGNOSIS

### HISTORY

- Many patients are discovered by screening blood lead level assays.
- Patients and caregivers may have myriad symptoms.
- Constitutional: Fatigue, malaise, cognitive changes, anorexia, weight loss
- GI: Crampy abdominal pain, nausea, constipation
- CNS manifestations may be prominent: Headache, diminished coordination, ataxia, impaired neuropsychiatric function, poor scholastic activity, encephalopathy, peripheral neuropathy/wrist drop.

### PHYSICAL EXAM

- Neurologic:
  - Seizures (may be prolonged and refractory)
  - Encephalopathy
  - Cerebral edema
  - Peripheral neuropathy (wrist drop); classic (but rarely seen) finding with chronic toxicity
- GI:
  - Ileus
  - Nausea, vomiting
  - Lead lines in gums (Burton lines) appear as a bluish tint to the gingival line.
  - Hepatitis, pancreatitis
- Cardiovascular:
  - HTN (generally secondary to renal failure)
  - Myocarditis and conduction defects
- Renal:
  - Chronic renal insufficiency with long-term exposure
  - Saturnine gout
- Hematologic:
  - Anemia (owing to interference with globin chain synthesis)
  - Elevated zinc protoporphyrin (ZPP)
  - Increases RBC fragility, so decreased RBC life span
- Musculoskeletal:
  - Lead lines from increased  $\text{Ca}^{++}$  deposition (not actually lead itself)
  - May lead to decreased bone strength and growth

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Whole blood lead level:
  - Normal < 10  $\mu\text{g}/\text{dL}$
  - 100  $\mu\text{g}/\text{dL}$ —severe encephalopathy. Cognitive effects increase with rising levels.
  - Expect that lead levels may rise again after chelation treatment is completed as lead redistributes into the serum again.
  - Levels correlate poorly with symptoms:
    - Acute exposures may be symptomatic with levels of 40–50  $\mu\text{g}/\text{dL}$ .
    - Chronic exposures may have minimal findings at levels of 70  $\mu\text{g}/\text{dL}$ .
- CBC:
  - For presence of anemia
  - RBC indices
- Electrolytes, BUN, creatinine, glucose:
  - For renal insufficiency
- Transaminases, LFTs
- Iron studies
- ZPP

#### Imaging

- Plain abdominal radiographs to look for radiopaque foreign body
- Long bone series to look for lead lines
- Cranial CT/other studies as indicated by patient's condition

**DIFFERENTIAL DIAGNOSIS**

- Heavy metal intoxications
- Cyclic antidepressants, other seizure-inducing toxins
- Encephalopathy, meningitis, encephalitis
- Causes of increased intracranial pressure
- Reye syndrome
- Status epilepticus
- Bowel obstruction
- Guillain-Barré syndrome
- Addison disease
- Cholera
- Peripheral neuropathies

**TREATMENT****PRE HOSPITAL**

- Assess and stabilize airway, breathing, and circulation.
- Cardiac monitoring
- Seizure management
- If possible to do so safely, bring containers in suspected overdose/poisoning.
- Decontaminate skin for obvious dermal exposures.

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation:
  - Cardiac monitor
  - Isotonic crystalloids as needed for hypotension; vasopressors for refractory hypotension
- Cardiovascular:
  - Isotonic crystalloids to support BP
  - Vasopressors for refractory hypotension (rare)
- Neurologic:
  - Treat seizures with benzodiazepines.
  - Assist ventilation as needed for respiratory insufficiency owing to neuromuscular weakness.
- Renal:
  - Hemodialysis for renal failure
- Decontamination:
  - If opacities are seen on upright abdominal film, consider whole bowel irrigation with 0.25–1 L/hr of polyethylene glycol until abdominal films are clear.
  - Activated charcoal is not effective.
- Evaluate if patient may potentially be a candidate for chelation therapy; based on:
  - Levels
  - Acuity of exposure
  - Symptoms
  - Consultation with a medical toxicologist (advised)
- Symptomatic patients commonly undergo chelation:
  - Generally, children with blood lead level  $>45 \mu\text{g/dL}$  are candidates for chelation.
  - Asymptomatic patients with lead levels  $>70 \mu\text{g/dL}$  should be chelated in a fashion similar to symptomatic patients.
  - Asymptomatic patients with levels  $<70 \mu\text{g/dL}$  may be treated with an oral chelating agent (dimercaptosuccinic acid [DMSA]).
  - Some experts recommend using  $\text{CaNa}_2\text{EDTA}$  for chelation if levels are  $>50 \mu\text{g/dL}$ .
  - There is some controversy as to when to begin chelation if levels are  $<45 \mu\text{g/dL}$  and asymptomatic.

**Pregnancy Considerations**

- There is much controversy about fetal lead toxicity.
- Consultation with maternal-fetal medicine and medical toxicology is recommended in pregnant patients with elevated lead levels:
  - DMSA is pregnancy category C.
  - Dimercaprol/British antilewisite (BAL) is pregnancy category C.
  - Calcium EDTA is pregnancy category B.

**MEDICATION**

- Calcium disodium EDTA:
  - Multiple regimens; for acute encephalopathy, 50 mg/kg/d as continuous IV infusion or 1 g/m<sup>2</sup> q12h
  - Treat for 5 days.
- Dimercaprol/BAL:
  - 3 mg/kg IM q4h for 3–5 days if mild to moderate symptoms; 4 mg/kg IM q4h for 5 days for severe symptoms (seizure, encephalopathy)
  - Caution: Cannot use if patient has peanut allergy
- DMSA (succimer): 10 mg/kg PO q8h for 5 days, then q12h for 14 days

**SURGERY/OTHER PROCEDURES**

Whole bowel irrigation with polyethylene glycol may be used if visible radiopaque paint chips or other material are present in the GI tract:

- By NG tube 0.25 L/hr for toddler and younger school-aged children; 0.5 L/hr school aged to teen; 0.5–1 L/hr in teenage patients

**DISPOSITION****Admission Criteria**

- Symptomatic lead intoxications
- Children at high risk for re-exposure in their current environment
- Pregnant patients with elevated lead levels—consult obstetrics and toxicology
- Critical care admission criteria:
  - Unstable vital signs
  - Seizure or encephalopathy

**Discharge Criteria**

- Asymptomatic patients not requiring IV chelation therapy (generally  $<50 \mu\text{g/dL}$ )
- Patients with suspected chronic intoxications who do not require admission should be referred for outpatient evaluation.
- Ensure that the home environment is safe for the patient prior to discharge.

**Issues for Referral**

Consult with a medical toxicologist, poison control center, or other clinician with specific expertise in management of lead toxicity may be useful:

- For ongoing care and follow-up in addition to initial care

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- It is critical to discharge to a leadfree home environment.

**Patient Monitoring**

Follow up, ongoing repeated lead testing, and possibly neuropsychiatric testing may be needed.

**PROGNOSIS**

- Other than decreasing major symptomatology such as encephalopathy or seizures to a functional mental status, it is unclear if therapy results in neuropsychiatric recovery.
- Recovery from anemia and peripheral neuropathy are typical.

**COMPLICATIONS**

- Anemia
- Developmental delay
- Mental retardation
- Cognitive dysfunction

**ADDITIONAL READING**

- Henretig F. Lead. In Goldfrank LR, Flomenbaum NE, Lewin NA, et al., eds. *Goldfrank's Toxicologic Emergencies*. 8th ed. Stamford, CT: Appleton & Lange; 2006.
- Needleman H. Lead poisoning. *Ann Rev Med*. 2004;55:209–222.
- Shannon M. Severe lead poisoning in pregnancy. *Ambul Pediatr*. 2003;3(1):37–39.

**See Also (Topic, Algorithm, Electronic Media Element)**

Anemia

**CODES****ICD9**

984.9 Toxic effect of unspecified lead compound

**PEARLS AND PITFALLS**

- It is critical to ensure a safe living environment prior to discharge.
- Inquire and test siblings family members in a patient with lead toxicity.
- Use of chelation therapy varies greatly: The lead level at which to begin chelation and whether chelation provides any benefit is greatly debated.
- Do not give BAL if the patient has a peanut allergy.

# LEUKEMIA

Lauren Daly

## BASICS

### DESCRIPTION

- Acute leukemia is a malignant proliferation of immature lymphohematopoietic cells.
- Leukemia is classified into acute vs. chronic, based on time from diagnosis to death and classified based on cell of origin (lymphoid vs. myeloid).
- Types of leukemia discussed here include the 2 most common subtypes in children: Acute lymphoid leukemia (ALL) and acute myeloid leukemia (AML).
- ALL is most common in childhood, whereas AML is more prominent in the adult population.
- The clinical presentation of ALL and AML shares considerable overlap; however, with AML, the splenomegaly is typically mild, lymph node swelling is rare, and the skin is involved more often in the form of leukemia cutis or chloromas.

### EPIDEMIOLOGY

- Leukemia is the most common malignancy among patients <15 yr of age.
- ALL is 5 times more common than AML, accounting for 75–80% of childhood leukemia.
- There are 2,500–3,500 new cases of ALL diagnosed in children each year.
- The incidence of ALL is 2.8 cases per 100,000:
  - Peak occurs between 2 and 5 yr of age
  - More common in boys than girls
- In the U.S., leukemia is twice as common in white children relative to blacks.

### RISK FACTORS

- Certain genetic syndromes place children at increased risk of leukemia:
  - Children with trisomy 21 have a 10–20-fold greater risk of ALL and AML.
  - Neurofibromatosis, Bloom syndrome, Fanconi syndrome, Diamond-Blackfan anemia, Kostmann disease, and Wiskott-Aldrich syndrome all increase a child's risk of leukemia.
- Twins and siblings of affected children are at increased risk.
- Exposure to chemotherapy or radiation, such as from x-rays
- Benzene exposure may result in leukemia.

### PATHOPHYSIOLOGY

- Acquired genetic changes that affect the structure and number of chromosomes in a single lymphoblast or myeloblast play a prominent role in the development of leukemia:
  - This blast undergoes clonal proliferation leading to overgrowth or normal bone marrow precursors, invasion of nonhematopoietic tissues, and suppression or differentiation of normal cells causing ineffective hematopoiesis.
- Genes that encode transcription factors controlling hematopoietic cell homeostasis, apoptosis, and growth factors are affected by mutations resulting in unchecked cell growth.

### ETIOLOGY

- Acquired genetic changes play a determining role in the development of leukemia.
- Although most cases of leukemia lack an identifiable etiology, ionizing radiation and chemical mutagens are thought to play a role.

## DIAGNOSIS

### HISTORY

- Signs and symptoms may be rather common, such as fever, fatigue, lymphadenopathy, bleeding, bone pain, or limp. However, if these symptoms are prolonged or unexplained, the practitioner should have a heightened concern for malignancy.
- The following signs are concerning:
  - Fever, if recurrent and not caused by infection:
    - ~2/3 of children with leukemia have fever at the time of presentation.
  - Lymphadenopathy, especially if accompanied by constitutional symptoms such as fever, night sweats, and weight loss, or in unusual locations such as supraclavicular or lower cervical areas
  - Weight loss, if nonintentional and prolonged
  - Bone/Joint pain, pathologic fracture: Sometimes accompanied by a limp; is a presenting symptom in 40% of cases of acute leukemia
  - Bleeding or bruising, petechiae, epistaxis with low platelet count or coagulopathy:
    - Bruising or bleeding: Excessive and sudden, not explained by common types of childhood activity or in irregular locations such as the back or abdomen
    - Fatigue, malaise, pallor, anemia
    - Headache, vomiting, new-onset seizure
    - Visual changes, blurred vision, diplopia
    - Dyspnea, wheezing, coughing stridor

### PHYSICAL EXAM

- The physician may detect pallor, ecchymoses, petechiae, mucosal bleeding, lymphadenopathy, or hepatosplenomegaly.
- There may be fever; if the patient is neutropenic, there may be signs of sepsis.
- Leukemic cell infiltration of extramedullary sites such as the lymph nodes, liver, spleen, or thymus may lead to enlargement of these organs or a mediastinal mass may be present.
- In AML specifically, there may be gingival hypertrophy and chloromas.
- Painless testicular swelling may be a rare presenting feature in ALL.
- Life-threatening situations such as superior vena cava (SVC) syndrome, heart failure, stroke, and spinal cord compression are also possible.
- SVC syndrome can be caused by an anterior mediastinal mass obstructing the SVC and may present with swelling of the face, neck, and upper limbs or with pain, dysphagia, or dyspnea.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC with manual differential
- Blood type and screen
- Electrolytes with calcium, magnesium, and phosphorous; lactate dehydrogenase (LDH); uric acid; liver and renal function tests
- Coagulation parameters (PT/PTT, INR)
- Blood culture:
  - The CBC is typically diagnostic, and findings may include lymphocytosis with leukemic blasts, neutropenia, anemia, and thrombocytopenia.
  - A minority of patients will present with lymphopenia.
  - In ~15% of patients with ALL and AML, there will be hyperleukocytosis, defined as WBCs > 100 × 10<sup>9</sup>/L.
- Elevations in serum LDH, uric acid, and phosphorous are common.

#### Imaging

A chest radiograph should be obtained to evaluate for a mediastinal mass.

#### Diagnostic Procedures/Other

Other procedures, usually not performed in the emergency department, include bone marrow aspiration for morphologic and cytochemical analysis and a lumbar puncture to evaluate for CNS involvement.

#### Pathological Findings

- Bone marrow aspiration/biopsy is the gold standard for histologic diagnosis:
  - The diagnosis of AML is established by demonstrating involvement of >20% of the blood and/or bone marrow by leukemic myeloblasts.
  - Though blast cells are seen on blood smear in 90% of cases of ALL, a bone marrow biopsy demonstrating infiltration of the marrow with leukemic cells is conclusive proof of ALL.
- Leukemic blasts can be found in the CSF of 33% of ALL patients and 5% of AML patients.

**DIFFERENTIAL DIAGNOSIS**

- Idiopathic thrombocytopenic purpura
- Aplastic anemia
- Infectious mononucleosis or other viral infections
- Juvenile rheumatoid arthritis
- Osteomyelitis
- Leukemoid reaction
- Chronic myeloid leukemia
- Other malignant processes involving the bone marrow such as neuroblastoma, rhabdomyosarcoma, retinoblastoma, or Ewing sarcoma

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Life-threatening conditions in the leukemic patient and the medical state that predisposes a patient to that condition include:
  - Symptomatic anemia
  - Sepsis: Neutropenia
  - CHF or shock: Anemia
  - Hemorrhage or disseminated intravascular coagulation (DIC)
  - Intracranial hemorrhage secondary to bleed or stroke secondary to hyperleukocytosis or DIC
  - Severe electrolyte derangements such as hyperkalemia or renal failure: Tumor lysis syndrome
- Patients also may require transfusions of blood products, broad-spectrum antibiotics, and therapy directed to control anemia, infection, or electrolyte derangements of tumor lysis syndrome.

**MEDICATION**

- Emergency department medications may include:
  - Ibuprofen 10 mg/kg PO/IV q6h PRN
  - Acetaminophen 15 mg/kg PO/PR q4h PRN
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
- Broad-spectrum antibiotics depending on neutrophil count and presumed or documented infection:
  - Ceftriaxone 50 mg/kg/day IV
  - Vancomycin 10 mg/kg/dose IV q6h

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- In cases of hyperleukocytosis, leukapheresis or exchange transfusion may be necessary.
- Allogenic bone marrow transplant is indicated for ALL with the presence of the Philadelphia chromosome or early hematologic relapse and T-cell ALL with poor early response or hematologic relapse.

**DISPOSITION****Admission Criteria**

- All children with suspected new-onset leukemia should be referred to a pediatric center and admitted to the hospital for further evaluation.
- Early consultation with a pediatric oncologist is mandatory.
- Critical care admission criteria:
  - Patients with any of the aforementioned life-threatening conditions, or who may be candidates for pheresis, should be admitted to the ICU. These conditions include sepsis, severe anemia, intracranial hemorrhage, and stroke.

**Issues for Referral**

All patients should be referred to pediatric oncologist for continued care.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- After chemotherapy is complete, frequent follow-up visits with the oncologist and the primary care provider are necessary to screen for disease recurrence and long-term side effects.

**PROGNOSIS**

- The 5-yr event-free survival rate for childhood ALL is >80%.
- There are subsets of patients with a worse prognosis, including those with the Philadelphia chromosome, hypodiploid karyotype, slow response to induction chemotherapy, and infantile ALL.
- An especially poor prognosis in ALL occurs in those who relapse <18 mo after the end of therapy and those with treatment-related AML.

**COMPLICATIONS**

- Symptomatic anemia
- Sepsis
- CHF
- Shock
- Hemorrhage or DIC
- Intracranial hemorrhage or stroke
- Severe electrolyte derangements
- Renal failure

**See Also (Topic, Algorithm, Electronic Media Element)**

Idiopathic Thrombocytopenic Purpura

**CODES****ICD9**

- 204.00 Lymphoid leukemia, acute, without mention of having achieved remission
- 204.10 Lymphoid leukemia, chronic, without mention of having achieved remission
- 205.00 Myeloid leukemia, acute, without mention of having achieved remission

**PEARLS AND PITFALLS**

- Leukemia is the most common malignancy among patients <15 yr of age, with 2,500–3,500 new cases of ALL each year.
- To diagnose leukemia, it is important to have a manual differential performed by hematology since leukemic blasts may be misinterpreted as monocytes or atypical lymphocytes on automated differentials.
- Emergency department physicians must carefully assess patients for potentially life-threatening complications such as hyperleukocytosis, tumor lysis syndrome, or sepsis.

# LICE (PEDICULOSIS)

Brenda J. Bender

## BASICS

### DESCRIPTION

- Lice are 6-legged insects.
- There are 3 louse subspecies that affect 3 anatomic regions: the head and scalp, the body, and the pubic area.
- The major infestation in children involves the scalp.
- Lice are transmitted via casual direct contact with infected people; fomites such as baseball caps, helmets, or bedding; and sexual contact.

### EPIDEMIOLOGY

- 10 million cases annually in the U.S.
- Head lice:
  - Infestation in schools and day care centers are common.
  - All socioeconomic groups are affected.
  - In the U.S., head lice infestations are less common in black children (1).
- Body lice:
  - Found in persons with poor hygiene
  - Typically only occur in populations without access to hygiene, such as homeless persons, refugees, or prisoners
- Pubic lice (crabs):
  - Only occur in sexually active persons

### PATHOPHYSIOLOGY

- Head lice:
  - The female attaches her eggs to the hair shaft.
  - The eggs (nits) then hatch, leaving behind numerous nits.
  - Eggs cannot hatch at a lower ambient temperature than that close to the scalp.
  - The incubation period from laying the eggs to the hatching of the 1st nymph is 10–14 days but can be shorter in hot climates and longer in cold climates (1).
  - Mature adult lice, capable of reproducing, do not appear until 2 wk later.
  - Both nymphs and adult lice feed on human blood.
  - Head lice can survive up to 2 days away from the scalp.
  - Head lice are not a health hazard, as they are not responsible for the spread of any disease.

- Body lice:
  - Larger than head lice
  - Live on clothing and stay on the human only to feed
  - Lay eggs on clothing, which incubate and hatch when warmed by the body
  - Body lice can survive off the human body for over a week.
  - Body lice can be a vector for disease (typhus, trench fever, relapsing fever) (2).
- Pubic lice:
  - Pubic lice infestations are common among young adults and adolescents and are transmitted via sexual contact or contaminated items.
  - For both body lice and pubic lice, the incubation period from laying eggs to hatching of the 1st nymph is 6–10 days.

### ETIOLOGY

- Head lice are *Pediculus humanus capitis*.
- Body lice are *Pediculus humanus corporis*.
- Pubic lice (crab lice) are *Phthirus pubis*.

### COMMONLY ASSOCIATED CONDITIONS

- Pubic lice: 50% of patients have another STI.
- Body lice: Typhoid

## DIAGNOSIS

### HISTORY

- Head lice:
  - Often a history of close contact (school outbreak) with someone infected
  - The most common complaint is pruritus, especially of the scalp, neck, and behind the ears.
  - Many children with head lice are asymptomatic, and a parent discovers the nits or mature lice in the scalp and hair.
- Pubic lice:
  - Severe groin pruritus in a sexually active patient
  - The patient may report seeing a crab louse in the pubic hair.

### PHYSICAL EXAM

- Head lice:
  - Characteristic nits in hair
  - May have secondary findings such as folliculitis, furunculosis, and impetigo
- Body lice may have erythematous macules, pruritic papules, or urticarial wheals.
- Pubic lice bites may cause maculae caeruleae (nonblanching gray-blue macules) on the lower abdomen and thighs; may also affect eyelashes.

### DIAGNOSTIC TESTS & INTERPRETATION

- No specific diagnostic tests are indicated; rather, the diagnosis is established by visual inspection.
- Visual inspection:
  - Nits (eggs) are very firmly attached to the scalp. They are oval and yellow-white and measure 0.3–0.8 mm in size (3).
  - Nits are usually found 1–3 cm from the scalp and are most commonly seen above and behind the ears. Those seen far from the root indicate months of infection (3).
- Adult head lice are seen less commonly than nits.
- Eggs (nits), nymphs, and lice can be seen with the naked eye.
- Nits fluoresce under a Wood lamp exam.
- Microscopic identification of a nit confirms the diagnosis.
- Pubic lice appear as brownish crawling “flecks.”

### DIFFERENTIAL DIAGNOSIS

- Scabies
- Eczema
- Contact dermatitis
- Seborrheic dermatitis

## TREATMENT

### MEDICATION

#### First Line

- For head lice, treat with one 10-min application of 1% permethrin (Nix) or two 10-min applications of a pyrethrin-based shampoo 1 wk apart.
- Some experts recommend a 2nd treatment with permethrin 7–10 days after the 1st (1).
- Resistance to permethrin is common.
- For pubic lice, apply a pyrethrin-based product for 10 min and repeat in 1 wk.
- For body lice, if bathing and laundering is not enough, treat with a pyrethrin or lindane lotion: Apply to entire body, leave on overnight, then wash off in the morning.

#### Second Line

- Benzyl alcohol 5% was FDA approved in 2009 as a pediculicide, and it appears to be very effective with minimal toxicity.
- Lindane (1%) shampoo (Kwell) can be used in children >2 yr of age for head and pubic lice.
- Malathion (0.5%) can be used for treatment failures in children >6 yr of age.
- Permethrin (5%) is not approved by the FDA. It is applied for several hours or overnight and then rinsed off.
- When lice are resistant to all topical agents, ivermectin or trimethoprim/sulfamethoxazole orally may be used. Neither is FDA approved for this purpose.

### SURGERY/OTHER PROCEDURES

- Head lice:
  - Treat all household contacts at the same time.
  - Remove hair nits with a fine-toothed comb.
  - Wash all clothing and bedding in very hot water (>52°C) for 10 min.
  - Place all hats, headgear, and combs in a plastic bag for 2 wk.
  - Since lice attach close to the scalp, there is no role to cut hair short, but completely shaving the head is completely curative.

- Pubic lice:
  - May also use medications mentioned, but shaving pubic hair is curative
- For body lice, frequent bathing and laundering of clothing and bedding for at least 10 min is all that is usually needed.
- Treat eyelash lice with petrolatum twice a day for 8 days. The lice stick to the petrolatum, cannot feed, and die (4).
- Can treat generalized pruritus with hydroxyzine or diphenhydramine

### DISPOSITION

Patients can be discharged from the hospital and have outpatient follow-up.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Follow-up with the primary care provider in 1 wk.

### COMPLICATIONS

- Treatment failure
- Toxic side effects of medications:
  - Malathion is an organophosphate and if ingested can cause significant respiratory distress. It is also flammable (4).
  - Lindane can cause CNS toxicity, including seizures and death (1).

## CODES

### ICD9

- 132.0 *Pediculus capitis* (head louse)
- 132.1 *Pediculus corporis* (body louse)
- 132.9 *Pediculosis, unspecified*

## PEARLS AND PITFALLS

- Treatment failures are common.
- Head lice are not the result of poor hygiene.
- Patients may experience itching or mild burning of the scalp lasting many days after lice are killed, caused by inflammation of the skin in response to the topical treatment.

# LIMP

Seema Bhatt

Lynn Babcock Cimpello

## BASICS

### DESCRIPTION

- Limp may be characterized by any alteration of the normal age-appropriate gait pattern.
- Can be painful or painless and the result of a range of conditions from the benign to the life and limb threatening
- Differential diagnosis of limp is extensive and can be classified by disease category, age of child, or by location of pathology.

### EPIDEMIOLOGY

- 1 study reported that 1.8/1,000 children presenting to their pediatric emergency department had a chief complaint of limp (1).
- Trauma is the most common cause of limp in all ages, followed by transient (toxic) synovitis, infection, and rheumatic disease.

### RISK FACTORS

- Varies according to etiology of limp
- History of antecedent viral illness is commonly associated with toxic synovitis.
- Obesity associated with slipped capital femoral epiphysis (SCFE)
- Sickle cell anemia associated with osteonecrosis and avascular necrosis of the femoral head
- History of trauma is commonly associated with osteomyelitis and musculoskeletal injuries.

### PATHOPHYSIOLOGY

3 major factors cause limp:

- Pain
- Weakness
- Structural or mechanical abnormalities of the spine, pelvis, or lower extremity

### ETIOLOGY

- Infection: Osteomyelitis, septic arthritis, viral arthritis, gonococcal arthritis, Lyme disease, abscess, cellulitis, myositis, meningitis, pelvic inflammatory disease (PID)
- Trauma: Fracture, sprain/strain, contusion, foreign body, child abuse, overuse injury (Osgood Schlatter disease, Sever disease)
- Rheumatologic/Inflammatory: Transient/Toxic synovitis, acute rheumatic fever, juvenile idiopathic arthritis, reactive arthritis, systemic lupus erythematosus (SLE), Henoch-Schönlein purpura, discitis, appendicitis
- Neurologic: Cerebral palsy, muscular dystrophy, myelomeningocele, stroke, peripheral neuropathy, complex regional pain syndrome
- Neoplasm:
  - Benign: Osteoblastoma, osteoid osteoma
  - Malignant: Ewing sarcoma, osteosarcoma, leukemia, neuroblastoma, spinal cord tumors
- Congenital: Vertical talus, tarsal coalition, spinal dysraphism, clubfoot
- Hematologic: Osteonecrosis (sickle cell disease), hemarthrosis (bleeding disorders)
- Metabolic: Rickets, hyperparathyroidism

- Acquired/Developmental: Developmental dysplasia of the hip, Blount disease, limb length discrepancy, Legg-Calvé-Perthes disease (avascular necrosis of the femoral head), SCFE, osteochondritis dissecans, chondromalacia patellae
- Psychiatric: Conversion disorder

## DIAGNOSIS

### HISTORY

- Onset, duration, and progression of limp: Acute vs. chronic
- Recent trauma and mechanism
- Exercise history: Suggests trauma as etiology
- Associated pain: Intermittent vs. continuous, localized vs. generalized, sharp vs. dull vs. burning, referred
- Preceding/Intercurrent illness: Diarrhea (reactive arthritis), pharyngitis (acute rheumatic fever), upper respiratory infection (transient/toxic synovitis)
- Weakness: Suggests neurologic etiology
- Ability to walk/bear weight
- Family history
- Associated signs and symptoms:
  - Abdominal pain: Neuroblastoma, psoas abscess, appendicitis, PID
  - Back pain: Discitis, spinal cord tumor, vertebral osteomyelitis
  - Fever, anorexia, weight loss, night sweats: Consider malignancy, osteomyelitis, rheumatologic disorder, septic arthritis.
  - Joint/Limb swelling: Suggests infectious, traumatic, rheumatologic, or hematologic etiologies
  - Neck pain and photophobia: Meningitis
  - Migratory joint pain: Acute rheumatic fever, gonococcal arthritis, Lyme disease
  - Morning stiffness: Rheumatologic disorder

### PHYSICAL EXAM

- General:
  - Vital signs: Fever may indicate an underlying infectious or inflammatory process.
  - Body habitus: In obese adolescents, consider SCFE.
  - Height and weight: Poor growth is an indicator of a chronic disorder.
- Musculoskeletal:
  - Resting limb position: A flexed, externally rotated hip suggests fluid in the hip joint space.
  - Gait: Ability to bear weight, type of gait
  - Swelling: Suggests trauma, infection, rheumatologic/inflammatory causes
  - Deformity
  - Laxity
  - Tenderness to palpation:
    - Inspect and palpate the sole of foot to rule out foreign body.
    - Isolate areas of the leg and apply force through the areas to determine if pain is in the bone to which force is applied: Apply force through the foot/ankle in isolation, through the tibia/fibula, and then through the femur/hip.

- Range of motion: Resistance to extension and internal rotation of hip suggests increased fluid in hip joint, as can be seen with septic arthritis or toxic synovitis.
- Symmetry of limbs
- Trendelenburg sign: When standing on 1 leg, the pelvis on that side drops, indicating weak hip abductor muscles and suggestive of a neuromuscular abnormality
- Galeazzi sign: Asymmetric flexion of infants' knees to buttocks indicates a possible congenital hip abnormality.
- Patrick/FABER test: Flexion, ABduction, and External Rotation of the hip causes pain, indicating a traumatic, infectious, or inflammatory hip or sacroiliac joint abnormality
- Pelvic compression test: If pain or instability is elicited with direct pressure on the iliac crests, pelvic trauma should be considered.
- Spine exam for scoliosis or dimpling
- Neurologic:
  - Sensation and strength
  - Deep tendon reflexes and spasticity
  - Meningeal signs
- Skin:
  - Warmth, color, rashes, bruising, or petechiae
- Abdomen:
  - Tenderness, rebound, guarding, masses: If present, suggests abdominal (appendicitis, abscess) or pelvic pathology
  - Hepatomegaly or splenomegaly: If present, may suggest malignancy

### DIAGNOSTIC TESTS & INTERPRETATION

- Tailored to history and physical exam findings
- The goal in the emergency setting is to rule out life- and limb-threatening conditions that include bacterial infections of the bone or joint, malignancy, and disorders threatening the blood supply to the bone (avascular necrosis, SCFE).

### Lab

- Infection, inflammatory process, or malignancy:
  - CBC with differential
  - C-reactive protein (CRP)
  - ESR
  - If synovial aspiration is indicated, send fluid for a cell count, Gram stain, and culture.
    - Septic joint fluid:
      - Turbid
      - WBCs  $>50,000/\text{mm}^3$
      - Polymorphonuclear (PMN) cells  $>75\%$
    - Toxic synovitis joint fluid:
      - Clear, yellow
      - WBCs  $5,000\text{--}15,000/\text{mm}^3$
      - PMN cells  $<25\%$
    - Blood culture
  - SLE: Antinuclear antibody
  - Acute rheumatic fever: Antistreptolysin O titer, throat culture
  - Bleeding disorder: Coagulation studies
  - Reactive arthritis: Stool cultures
  - Gonococcal arthritis: Cervical, pharyngeal, rectal cultures

## Imaging

- Plain radiographs:
  - Minimum of 2 views
  - Effective screening for fracture or other bony abnormality, joint effusion, lytic lesion, periosteal reaction, and avascular necrosis
  - Consider comparative views of other extremity, pelvis/Lauenstein (frog-leg) views, and/or imaging of the joint above and below the area of concern.
- US:
  - Abscess or effusion
  - Highly sensitive for detecting effusion but cannot differentiate between sterile, purulent, or hemorrhagic fluid
- CT:
  - Indicated when cortical bone needs to be visualized or when there is concern for intra-abdominal/pelvic pathology
- MRI:
  - High sensitivity and specificity in detecting soft tissue, cartilage, medullary bone, and spinal cord abnormalities
- Bone scintigraphy (bone scan):
  - Useful for detecting occult or stress fractures, osteomyelitis, discitis, bone infarcts, tumors, and metastatic lesions
  - High sensitivity but lacks specificity

## Diagnostic Procedures/Other

Joint aspiration: US guided vs. fluoroscopic guidance vs. blind:

- Depends on the joint and is center dependent

## DIFFERENTIAL DIAGNOSIS

- All age groups: Trauma, infection
- Toddler (age 1–3 yr): Septic arthritis, osteomyelitis, developmental dysplasia of the hip, occult fractures, leg length discrepancy
- Child (age 4–10 yr): Septic arthritis, osteomyelitis, Legg-Calvé-Perthes disease, transient/toxic synovitis, juvenile idiopathic arthritis, fractures, leukemia
- Adolescent (age 11–18 yr): Osteomyelitis, SCFE, Osgood-Schlatter disease, tumors, sprains, fractures, overuse injury, gonococcal arthritis

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation.
- Immobilize the limb.
- Provide analgesia.

### MEDICATION

- Analgesics:
  - Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
  - NSAIDs:
    - Consider NSAID medication in anticipation of prolonged pain and inflammation:
      - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
      - Ketorolac 0.5 mg/kg IV/IM q6h PRN
      - Naproxen 5 mg/kg PO q8h PRN

- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine/Acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone/Acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- Antibiotics:
  - Indicated as soon as possible for infection
  - Coverage for MSSA:
    - Nafcillin 25–50 mg/kg/dose IV q6h, max single dose 12 g/24 hr, OR
    - Oxacillin 25–50 mg/kg/dose IV q6h, max single dose 12 g/24 hr
  - MRSA treatment:
    - Clindamycin 10 mg/kg/dose IV q6h, max single dose 1.2 g
    - Vancomycin 15 mg/kg/dose IV q6h, max single dose 1 g
  - Consider coverage for *Streptococcus* species, *Salmonella* (sickle cell), and *Neisseria* (sexually active teens):
    - 2nd- or 3rd-generation cephalosporin
    - Ceftriaxone 100 mg/kg IV per day, max single dose 2 g/day
    - Cefuroxime 50 mg/kg/dose IV q8h, max single dose 3 g

## SURGERY/OTHER PROCEDURES

- As indicated based on etiology of limp
- Infection:
  - Incision, drainage, debridement, or washout
  - Direct antibiotic instillation into joint
- Trauma/Fractures:
  - Splinting, casting
  - Internal or external fixation with screws, pins, rods, or plates

## DISPOSITION

### Admission Criteria

- Indicated in those patients with life- or limb-threatening causes of limp, specifically septic arthritis, osteomyelitis, tumor, and SCFE
- Need for IV antibiotics, surgical management, or parenteral analgesics

### Discharge Criteria

- Benign condition diagnosed
- If the initial workup including screening radiographs and labs (CBC, ESR, CRP) is nondiagnostic, the child may be discharged from the emergency department if non-toxic appearing with close follow-up.

### Issues for Referral

If limp persists or there are abnormalities on labs or radiographs, admission or appropriate referrals should be made.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- A definitive diagnosis is not often obtained in ED. Close follow up with primary care physician or specialist is mandatory until the limp is resolved or the cause identified.
- Discharge instructions and medications:
  - Pain control
  - Follow up within 48 hr.

- Activity:
  - Determined by the etiology of the limp. Allow weight bearing as tolerated except for certain types of fractures.

## PROGNOSIS

- Dependent on underlying etiology
- With correct treatment of the underlying cause and rehabilitation, the persistence of limp in children is very low.

## COMPLICATIONS

- Dependent on cause
- The most common complications are associated with missing or inadequate management of an infectious or malignant etiology:
  - Loss of limb
  - Permanent limb injury/disability

### ICD9

781.2 Abnormality of gait

## PEARLS AND PITFALLS

- The most common causes of limp in the pediatric age group are trauma and toxic synovitis.
- Critical action in emergency department is to rule out life- and limb-threatening causes of limp.
- Workup in the emergency department often will include CBC, ESR, CRP, and plain radiographs.
- Treatments involve alleviating pain and tending to the underlying etiology of the limp.

# LYME DISEASE

Christopher J. Russo

## BASICS

### DESCRIPTION

Lyme disease is a systemic illness caused by the tickborne spirochete *Borrelia burgdorferi*. Clinical manifestations are divided into 3 stages:

- Early localized disease: Characterized by the classic erythema migrans (EM) rash at the site of a recent tick bite. Constitutional symptoms (fatigue, headache, arthralgia, myalgia) may be present. Onset is 3–30 days after a tick bite.
- Early disseminated disease: Affected patients may demonstrate multiple EM rashes, cranial nerve palsies (most commonly facial nerve VII), lymphocytic meningitis, conjunctivitis, or carditis. Constitutional symptoms may also occur. Onset is 3–12 wk after tick bite.
- Late disease: Manifests as recurrent arthritis, (pauciarticular, with a proclivity for large joints, especially the knee). Rarely, peripheral neuropathy or CNS involvement at this stage. Onset is >2 mo after tick bite.

### EPIDEMIOLOGY

- ~20,000 new cases of Lyme disease are reported each year; overall rate of 7–8 per 100,000 U.S. population.
- The most common tickborne disease in the U.S.
- Peak incidence is in summer months in the U.S.
- Most common in the Northeast, Midwest, and California

### RISK FACTORS

- Affects people of all ages, but is most common in those age 5–14 yr and 45–54 yr.
- Endemic areas in northeastern, mid-Atlantic, North-Central, and Pacific Coast states

### GENERAL PREVENTION

- Tick exposure:
  - Removal of leaf litter (larval deer ticks attach to leaves) may reduce the risk of acquiring the disease at home.
  - Treat exposed skin with 30% DEET (can be applied safely to skin in infants  $\geq 2$  mo of age).
  - Wear long sleeves and long pants tucked into socks when outside in deer tick-infested areas.
- Tick bites:
  - Daily tick checks and prompt tick removal before the tick is engorged
  - If a deer tick is found attached to the skin, grasp the tick close to the mouth parts with forceps or tweezers and pull directly outward.

- Antibiotic prophylaxis is not routinely recommended for tick bites alone in the absence of clinical disease; however, prophylaxis (single 200-mg oral dose of doxycycline) may be justified in communities with the highest risk.
- A Lyme vaccine was approved by the FDA in 1998 but was withdrawn in 2002:
  - Numerous patients developed chronic arthritis and neurologic symptoms very similar to the sequelae of Lyme disease.

### PATHOPHYSIOLOGY

- The deer tick *Ixodes scapularis* (previously referred to as *Ixodes dammini*) acquires the spirochete *B. burgdorferi* by feeding on mice.
- The spirochete is inoculated into the skin, where migration occurs, producing the typical EM rash in the majority of patients.
- The organism may disseminate by lymphohematogenous routes, producing infection in the skin, nervous system, heart, joints, and eyes.

### ETIOLOGY

- *B. burgdorferi*, a tickborne spirochete
- In Europe, may be caused by *Borrelia garinii* and *Borrelia afzelii*.

### COMMONLY ASSOCIATED CONDITIONS

*Ixodes* ticks may also transmit *Ehrlichia* and *Babesia*; coinfection with these organisms may occur.

## DIAGNOSIS

### HISTORY

- Tick bite: History of tick bite only elicited in 1/3 of patients with Lyme disease; the vast majority of patients with tick bites do not develop Lyme disease:
  - Inquire about the size of the tick: Unengorged deer ticks are smaller (about the size of a pencil point) than dog ticks, although the size of the tick varies greatly depending on attachment time.
- Rash: Most patients will have or can recall having the classic EM rash:
  - The rash is not typically painful but may be pruritic.
  - Most rashes occur on the head, neck, arms, legs, and back.
  - Begins as a red macule and expands to a single annular lesion
  - Most EM lesions are larger than a half-dollar coin.
  - The lesion may have central clearing or be confluent erythema.
  - In later phases, there may be multiple EM lesions.
- Influenza-like illness: Many patients will complain of fever (usually low grade), fatigue, myalgias, headaches, and arthralgias.
- Joint pain: Arthralgia typically presents early in the course; true arthritis occurs later. Chronic arthritis may also occur.

- Meningoencephalitis symptoms: Severe headache, neck pain, photophobia, and neurocognitive changes may be present.
- Chronic neurologic symptoms may be present, including memory, mood, and sleep disturbances.

### PHYSICAL EXAM

- The EM rash, when identified, is pathognomonic of Lyme disease.
- Patients may have arthritis in later phases, usually involving the knee (90%).
- Patients may have peripheral facial nerve palsy, 6th nerve palsy, or lymphocytic meningitis:
  - Bilateral facial nerve palsy in children is considered pathognomonic for Lyme disease.
- Meningitis, encephalitis, or meningoencephalitis may cause nuchal rigidity, neurocognitive changes, or altered mental status.
- Conjunctivitis may be present.
- Irregular heartbeat may be present.
- Physical exam may be completely normal early in the course of disease.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Lyme disease is diagnosed clinically in early stages. Early testing may be falsely negative because of insufficient time to mount an antibody response.
- ELISA or immunofluorescent assay (IFA) both detect IgG and IgM antibodies. These assays are sensitive but not specific and can lead to false-positive results. May remain positive for years after treatment:
  - Testing patients with nonspecific complaints such as chronic fatigue should be strongly discouraged. A low disease prevalence among this tested population will yield a very low positive predictive value (many false positives).
- Western blot analysis confirms diagnosis; Positive ELISA or IFA and positive Western blot indicates the patient has been infected.
- ELISA and IFA may cross react with other spirochetal infections, autoimmune diseases, and some viral infections (Epstein-Barr virus and parvovirus B9).
- Polymerase chain reaction testing is not as reliable.

##### Diagnostic Procedures/Other

- ECG may reveal heart block.
- Lumbar puncture should be considered for children with nuchal signs (positive Kerning or Brudzinski signs) or headaches:
  - Lumbar puncture need not be performed for those with peripheral 7th nerve palsy without headaches or nuchal rigidity.
  - CSF findings in Lyme meningitis reveal an increased leukocyte count with a predominance of lymphocytes and monocytes, elevated protein concentration, and normal or slightly decreased glucose concentration.

**DIFFERENTIAL DIAGNOSIS**

- Influenza or other viral illness
- Rash: Erythema annulare, erythema marginatum, nummular eczema, pityriasis rosea, subacute cutaneous lupus, juvenile idiopathic arthritis, erysipelas, tinea corporis, cellulitis, urticaria
- Arthritis: Viral, septic, postinfectious, juvenile rheumatoid arthritis, rheumatic fever, Reiter syndrome
- Peripheral facial nerve palsy: Herpes simplex virus, varicella zoster virus, otitis media, HIV
- Ehrlichiosis
- Babesiosis
- Tularemia
- Southern tick-associated rash illness (STARI)

**TREATMENT**

**MEDICATION**

**First Line**

Early localized disease:

- Oral antibiotics remain the initial therapy for early Lyme disease.
  - Doxycycline 1–2 mg/kg/dose PO b.i.d. for 14–21 days; drug of choice for those >8 yr of age
  - Amoxicillin 50 mg/kg/day divided b.i.d.–t.i.d. 14–21 days; preferred for younger children or for doxycycline intolerance
- Treat EM rash for 14–21 days. This treatment will not alter the course of the rash but will prevent chronic sequelae.

**Second Line**

- Early disseminated disease:
  - Treatment of multiple EM lesions is as outlined above, for 21 days
  - Treatment of peripheral facial nerve palsy is as outlined above, for 28 days.
    - Such treatment will not hasten resolution of palsy but prevents chronic sequelae.
    - Use of eye lubricant is helpful to avoid ophthalmic complications from peripheral facial nerve palsy.
    - Corticosteroid therapy to treat Lyme-associated facial nerve palsy is not well-established.
  - Ceftriaxone 75–100 mg/kg IV/IM daily for 14–28 days to treat meningitis or carditis.
- Late disease:
  - Ceftriaxone 75–100 mg/kg IV/IM daily for 14–28 days for persistent arthritis

**DISPOSITION**

**Admission Criteria**

- Consider admission for patients with severe disease that requires IV fluid resuscitation or parenteral analgesics.
- Critical care admission criteria:
  - Severe neurologic symptoms including meningoencephalitis; cardiac symptoms including carditis or heart block

**Discharge Criteria**

Patients with isolated EM rash or with peripheral facial nerve palsy may be safely discharged home with oral antibiotic therapy.

**Issues for Referral**

Referral may be helpful for patients with chronic symptoms (eg, rheumatology for chronic arthritis).

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

**Discharge Instructions**

- Follow-up with the primary physician for results of testing may be necessary. ELISA/IFA results may need to be confirmed with Western blot.
- No activity restrictions are necessary.

**PROGNOSIS**

- Prognosis is much better for children than for adults. ~10% of adults (<5% of children) have chronic inflammatory joint disease.
- Most of the cardiac manifestations will resolve in a short time with or without treatment; however, they may later recur.
- EM rash will resolve with or without treatment.
- Peripheral facial nerve palsy will generally resolve with or without treatment.

**COMPLICATIONS**

- Chronic arthritis occurs in <5% of children.
- Much controversy exists regarding whether or not Lyme disease may be complicated by chronic symptoms such as fatigue, headaches, and weakness.
- Heart block
- Complications may arise from parenteral therapy, such as infections from indwelling catheters or cholecystitis from ceftriaxone.

**CODES**

**ICD9**

- 088.81 Lyme disease
- 711.80 Arthropathy, site unspecified, associated with other infectious and parasitic diseases

**PEARLS AND PITFALLS**

- Lyme disease can be diagnosed clinically by identifying the classic EM rash; no testing is indicated in this early localized stage.
- As initial test results may dictate that confirmatory tests may need to be performed, the lab diagnosis of Lyme disease is not immediate. Proper follow-up with primary care providers remains essential.
- Perform lumbar puncture in patients with Lyme disease and CNS changes.
- Early antibiotic therapy may not hasten symptom resolution but can help prevent neurologic or cardiac sequelae.
- Patients presenting with monoarthritis of the knee, in the absence of trauma or fever, should be suspected to have late persistent Lyme disease.
- Lyme disease is often implicated as a cause of vague chronic symptoms such as fatigue, headache, arthralgias, and myalgias. In such cases, most “positive” serologic tests will represent false positives.

# LYMPHADENOPATHY

Caroline Altergott

## BASICS

### DESCRIPTION

- *Lymphadenopathy* is defined as abnormality in size, consistency, or number of lymph nodes.
- Most normal palpable lymph nodes are <1 cm, mobile, soft, and often found in the cervical and inguinal areas.
- Lymph node mass increases from birth to late childhood.
- Atrophy of nodes begins in adolescence and continues throughout life.
- Lymphadenopathy can be generalized (enlargement of >2 noncontiguous lymph node regions) or localized.

### EPIDEMIOLOGY

#### Incidence

Unknown precise incidence. 38–45% of well children have palpable lymph nodes (1).

### RISK FACTORS

- Exposure to animals (dogs, rabbits, rats, and kittens)
- Unpasteurized milk consumption
- Fish tank exposure
- IV drug use
- Unprotected sexual activity

### PATHOPHYSIOLOGY

- Causes of enlargement of lymph nodes:
  - Proliferation of intrinsic cells (lymphocytes, plasma cells, monocytes, and histiocytes) or infiltration of extrinsic cells (neutrophils) in response to a local infection
  - Secondarily may be caused by nodal accumulation of inflammatory cells in response to infection in the node, invasion of neoplastic lymphocytes or macrophages, or presence of metabolite laden macrophages
- Areas of drainage:
  - Cervical: Drains the tongue, external ear, parotid, deeper structures of neck
  - Submaxillary/Submental: Drains the mouth
  - Occipital: Drains the posterior scalp
  - Preauricular: Drains the conjunctivae, cheek, eyelids, temporal region of scalp
  - Postauricular: Drains the temporal/parietal scalp
  - Mediastinal: Drains the thorax (often associated with supraclavicular nodes)
  - Supraclavicular: Drains the head, neck, arms, superficial thorax, lungs, mediastinum, and abdomen
  - Axillary: Drains the arm, lateral chest, abdominal wall, and lateral breasts
  - Epitrochlear: Drains the hand and forearm
  - Abdominal: Drains the legs, pelvis, and abdominal organs
  - Iliac/Inguinal: Drains the leg, perineum, buttocks, and lower abdominal wall

### ETIOLOGY

- Acute regional: Enlarged nodes in 1 region:
  - Infectious:
    - Upper respiratory infection (most common cause of acute cervical adenopathy): Reactive adenopathy may persist 2–3 wk beyond resolution of symptoms
    - Adenovirus: Conjunctivitis, pharyngitis, rash with cervical adenopathy
    - Beta-hemolytic *Streptococcus* or *Staphylococcus aureus*: Unilateral, firm, tender, warm cervical, submaxillary, inguinal, and axillary node
    - Epstein-Barr virus (EBV): Posterior cervical adenopathy, malaise, fever, exudative tonsillitis, hepatosplenomegaly (HSM). (See Infectious Mononucleosis topic.)
    - STI: Inguinal adenopathy associated with genital lesions; herpes, chancroid, lymphogranuloma venereum, syphilis
  - Kawasaki disease (KD): Cervical adenopathy in 50–70%; node > 1.5 cm; fever > 5 days, bilateral conjunctival erythema, mucous membrane involvement, peripheral edema/erythema and rash; usually <4 yr of age. (See Kawasaki Disease topic.)
- Chronic regional:
  - Infectious:
    - *Bartonella henselae*: Axillary, cervical, epitrochlear nodes; exposure to cats, primary lesion at site with a 2-wk delay in regional adenopathy proximal to site. (See Cat Scratch Disease topic.)
    - *Mycobacterium tuberculosis*: Most common adult mycobacterial disease; urban; history of exposure; systemic symptoms often present; bilateral/fixed/matted cervical nodes/scrofula. (See Tuberculosis topic.)
    - Atypical mycobacteria (*Mycobacterium scrofulaceum*, *Mycobacterium avium-intracellulare*): Most common type of mycobacterial disease in children; <5 yr of age; rural predominance; unilateral; <3 cm; fluctuance with ulceration common; no systemic signs; contact or ingestion of soil, dust, unpasteurized dairy, or eggs; exposure to fish tanks rare
    - Cytomegalovirus (CMV): Cervical adenopathy, pharyngitis, and atypical lymphocytosis (similar to EBV)
    - *Toxoplasmosis gondii*: Asymptomatic single nontender posterior cervical node; exposure to cats, cat litter, uncooked meat, or unpasteurized milk
    - Brucellosis: Axillary, cervical adenopathy associated with fever, malaise, and HSM; ingestion of unpasteurized milk/milk products
  - Malignancy: Painless, firm, slowly growing node:
    - Hodgkin disease: Insidious, painless, unilateral enlargement; most frequently cervical; consider in those > 10 yr of age with cervical or supraclavicular nodes
    - Non-Hodgkin: Rapidly enlarging peripheral or mediastinal adenopathy; associated with superior vena cava (SVC) syndrome

- Lymphosarcoma: Cervical and mediastinal nodes either unilateral or bilateral; initially firm, rubbery, and painless and then matted
- Neuroblastoma, rhabdomyosarcoma. (See Neoplasm, Brain; Neoplasm, Lymphoma; and Neoplasm, Neuroblastoma topics.)
- Other: Sarcoidosis—bilateral chronic cervical adenopathy, more commonly in black children; 80% involve scalene nodes
- Generalized: ≥2 noncontiguous regions secondary to systemic process:
  - Systemic infection:
    - EBV and CMV: Fever, exudative pharyngitis, fatigue, malaise, HSM with enlarged cervical nodes
    - HIV: Large soft nodes in the posterior triangle of the neck with mild generalized adenopathy; weight loss, failure to thrive, malaise
    - Histoplasmosis: Most common fungal cause; central U.S.; inhalation of infected spores (bat/bird feces); primary pulmonary infection
  - Autoimmune disease: Juvenile rheumatoid arthritis, serum sickness
  - Malignancy: Primary lymphoid neoplasm, metastatic neoplasm, histiocytosis
  - Storage disease: Gaucher, Niemann-Pick; associated with HSM
  - Drugs: Phenytoin, isoniazide, pyrimethamine, allopurinol; generalized adenopathy 1–2 wk after drug initiation, disappears 3–4 wk after drug discontinued
  - Other: PFAPA syndrome (periodic fever, aphthous stomatitis, pharyngitis, cervical adenitis)

## DIAGNOSIS

### HISTORY

- Time of onset: Acute (<3 wk) or chronic (>6 wk)
- Rate of growth
- Number of nodes
- Associated symptoms: Fever, rash, pruritus, cough, weight loss, anorexia, nausea, night sweats, recent illness
- Medications (especially phenytoin, isoniazide)
- Prior history
- Illicit IV drug use
- Animal exposure
- Unprotected sexual activity

### PHYSICAL EXAM

- Size is considered abnormal if:
  - Cervical > 2 cm
  - Axillary > 1 cm
  - Inguinal > 1.5 cm
  - Malignancy is usually associated with nodes > 3 cm.
- Location: It is normal to have cervical, inguinal, and axillary nodes <1 cm. Any supraclavicular and epitrochlear nodes raise suspicion for malignancy.
- Character of adenopathy:
  - Freely mobile, easily compressible, soft, small nodes are benign causes of adenopathy.
  - Fixed, matted, cold: Invasion from cancer or inflammation in tissue near node (TB)

- Hard, cold: Malignant
- Firm, rubbery, cold: Lymphoma
- Erythema, tenderness, warmth, fluctuance: Infectious causes/abscess
- Associated systemic findings:
  - Fever, sore throat, rash: Streptococcal infection
  - Fever, sore throat, HSM, posterior cervical nodes: EBV
  - Conjunctivitis, pharyngitis, preauricular node: Ocularglandular syndrome
  - Irritation in scalp
  - Failure to thrive
  - Splenomegaly
  - Hepatomegaly
  - Rash

**DIAGNOSTIC TESTS & INTERPRETATION**

**Lab**

**Initial Lab Tests**

- Lab tests are not needed in most cases. Consider selectively:
- CBC:
  - Elevated WBC suggests infection.
  - Blasts on smear suggest leukemia.
  - Atypical lymphocytes suggest infectious mononucleosis.
- Blood culture if child appears toxic
- Monospot for suspicion of EBV infection:
  - False negatives are more common in children <7 yr of age.
- Streptococcal screen and culture
- Hepatic and renal function, lactate dehydrogenase, uric acid, calcium, and phosphorous for malignancy
- Titers for specific microorganisms: EBV, CMV, *B. henselae*, toxoplasmosis, syphilis, and HIV

**Imaging**

- Imaging is not needed in most cases.
- CXR findings:
  - Widened mediastinum with lymphoma
  - Nodular infiltrate with TB
- US:
  - Helpful to determine solid vs. cystic mass
  - Extent and/or presence of suppuration or infiltration
  - Can be used to facilitate needle-guided biopsy
- CT scan:
  - Helpful to determine solid vs. cystic mass
  - Extent and/or presence of suppuration or infiltration
  - Chest CT for suspicion of lymphoma

**Diagnostic Procedures/Other**

- PPD for TB
- ECG/Echo for suspicion of KD
- Lymph node biopsy: Excisional biopsy is generally preferred over fine-needle aspiration.
- Aspiration of node for culture

**DIFFERENTIAL DIAGNOSIS**

See Etiology.

**TREATMENT**

**MEDICATION**

Antibiotic treatment should be 7–14 days but varies on the type of infection and degree of infection.

**First Line**

Oral antibiotics are based on suspected pathogen; most frequently, *Staphylococci* or *Streptococci*.

Consider MRSA:

- Cephalexin 50 mg/kg/day divided t.i.d. or q.i.d., max single dose 4 g/day
- Clindamycin 10–30 mg/kg/day divided t.i.d., max single dose 1.8 g/day
- Amoxicillin/Clavulanic acid 40 mg/kg/day divided t.i.d.
- Sulfamethoxazole/Trimethoprim (TMX) (200/40 mg) 6–12 TMX mg/kg/day divided b.i.d.

**Second Line**

- Resistant bacteria: Persistent fever, increasing node size/tenderness, developing fluctuance. Parenteral antibiotics:
  - Nafcillin 100 mg/kg/day divided q.i.d.
  - Vancomycin 40 mg/kg/day divided q.i.d.
  - Clindamycin 25–40 mg/kg/day divided q.i.d., max single dose 4.8 g/day
  - Piperacillin/Tazobactam 240–400 mg/kg/day divided q.i.d., max single dose 18 g/day
  - Ampicillin/Sulbactam 100–200 mg/kg/day divided q.i.d., max single dose 8 g/day
- *M. tuberculosis* (see Tuberculosis topic):
  - Isoniazide 10–15 mg/kg/day per day or divided b.i.d.
  - Rifampin 10–20 mg/kg/day per day or divided b.i.d.
  - Pyrazinamide 20–40 mg/kg/day per day or divided b.i.d., max single dose 2 g/day

**SURGERY/OTHER PROCEDURES**

- Excisional biopsy for diagnosis and treatment
- Excision for atypical mycobacterium (non-TB) disease for treatment

**DISPOSITION**

**Admission Criteria**

- Illness requiring parenteral antibiotics, immunocompromise, toxic appearance
- Critical care admission criteria:
  - SVC syndrome with airway compromise

**Discharge Criteria**

- Mild infection, treatable with oral antibiotics
- Able to take oral antibiotics/fluids
- Adequate follow-up within 24–48 hr

**Issues for Referral**

- Fixed, hard mass
- Cervical node size >3 cm
- Unusual location (supraclavicular, deeper cervical)
- Enlarging mass despite adequate therapy
- No improvement over a 4-wk period
- Generalized adenopathy with systemic symptoms not explained by EBV

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Follow up within 24–48 hr
- HSM secondary to EBV requires ceasing contact sports and strenuous activities until the patient is fully recovered and the spleen no longer is palpable.

**PROGNOSIS**

- Prognosis is based on underlying etiology.
- Most acute regional adenopathy resolves without complication.

**COMPLICATIONS**

- Mortality and morbidity are rare secondary to primarily infectious origin.
- Complications are specific to the underlying disease process (eg, mediastinal adenopathy leading to SVC syndrome, with obstruction of blood flow, bronchial/tracheal obstruction, and dysphagia)
- Infectious: Lymphadenitis, cellulitis, abscess

**REFERENCE**

**CODES**

ICD9

785.6 Enlargement of lymph nodes

**PEARLS AND PITFALLS**

- Lymphadenopathy in patients unresponsive to treatment should be referred for potential malignancy.
- Watch the location of nodes: There is a high risk of malignancy with supraclavicular nodes.

# LYMPHOGRANULOMA VENEREUM

Raquel Mora

## BASICS

### DESCRIPTION

Lymphogranuloma venereum (LGV) is an STI caused by serotypes of *Chlamydia trachomatis*.

### EPIDEMIOLOGY

#### Incidence

- Endemic to underdeveloped countries in Africa and developing countries in Asian subcontinent
- In recent years, a significant number of cases have been reported in 9 European countries and the U.S. (1).
- Since it is not a reportable disease in all locales, the true incidence is unknown.
- Most common among homosexual males:
  - Very few cases reported in children (2)

### RISK FACTORS

- HIV, particularly for homosexual males (1)
- Unprotected intercourse
- Multiple partners
- Sexual intercourse with prostitutes
- Sharing sexual toys

### GENERAL PREVENTION

- Barrier protection devices (ie, condom use)
- Avoidance of risky sexual behaviors

### PATHOPHYSIOLOGY

- The agent causing LGV, *C. trachomatis*, is an obligate intracellular parasite with a number of different serotypes.
- Unlike other chlamydial infections that result in local inflammation, LGV is a disease of lymphoid tissue and results in dramatic lymphoproliferative inflammation.
- Transmitted through breaks in the skin via any type of unprotected intercourse (oral, vaginal, or anal), sharing of sexual toys/enema tips, or behaviors (ie, fisting) (1,2)
- Incubation period: 1–3 wk

- Primary stage:
  - Males: Nontender penile papule or ulcer
  - Males can transmit disease until the primary lesion heals.
  - Females can be asymptomatic carriers or have an ulcer on the external genitalia.
- Secondary stage:
  - Unilateral tender lymphadenitis (Bubo):
    - Most common clinical manifestation
    - 40% are bilateral.
  - “Groove sign”:
    - Scarred or coalescent large inguinal and/or femoral nodes for depression parallel to inguinal ligament
  - Constitutional symptoms (chills, fever, malaise)
  - Proctitis
  - Arthropathy (rare)
  - Erythema nodosum
- Tertiary stage:
  - Occurs in chronic untreated patients
  - Anorectal strictures
  - Perirectal abscesses
  - Genital elephantiasis
  - Penile deformities

### ETIOLOGY

*Chlamydia trachomatis* serotype L1, L2, L3

### COMMONLY ASSOCIATED CONDITIONS

- HIV
- Gonorrhea
- Other STIs

## DIAGNOSIS

### HISTORY

- Genital papule or ulcer
- Dysuria from urethritis
- Female: Ulcer on external genitalia
- Anorectal pain
- Bloody rectal discharge
- Diarrhea or constipation
- Abdominal pain

### PHYSICAL EXAM

- Nontender papule that progresses to a painless ulcer:
  - Often spontaneously heals before presentation for medical evaluation
- Proctitis
- Female: Ulcer on external genitalia
- Rectovaginal fistula
- Inguinal adenopathy, often bilateral
- Cervical adenopathy (rare):
  - Occurs after primary oropharyngeal infection

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Clinical symptoms + positive serology = presumptive LGV diagnosis
- The standard *Chlamydia* DNA probe does not detect serotypes that cause LGV.
- Serologic testing to detect evidence of infection with *Chlamydia* (1):
  - Complement fixation:
    - Diagnosed with *Chlamydia* if titer > 1:64
  - ELISA:
    - Microimmunofluorescence
    - Not reliable due to false positive from cross reactivity of the antigens used in serology testing
    - Does not distinguish the *C. trachomatis* serotypes
    - Does not distinguish current from previous infection

- Nucleic acid amplification testing (NAAT):
  - Polymerase chain reaction (1):
    - Can identify serotypes resulting in LGV
    - Results within 2 hr
    - Requires confirmatory testing
- Cultures:
  - Cell cultures
  - Rectal biopsy
- When testing for other STIs, false-positive VDRL in 20%

**Imaging**

Endoscopy:

- Bleeding mucosal aphthous ulcerations
- Rectal mucosa can be edematous and swollen.

**Diagnostic Procedures/Other**

- Frei test:
  - Intradermal test for delayed hypersensitivity reaction
  - Positive if >0.5-cm reaction on day 4
  - Low sensitivity and limited specificity
  - Has largely been replaced by serology and NAAT
- Bubo aspiration and culture
- Biopsy of granulation tissue

**DIFFERENTIAL DIAGNOSIS**

- Ulcerative lesion:
  - Herpes simplex
  - Syphilis
  - Chancroid
  - Granuloma inguinale
- Lymphadenitis:
  - Bacterial infections: *Staphylococcus aureus*, group A streptococcus
  - Viral: HIV, Epstein-Barr
  - Mycobacterial
  - Fungal
  - Sarcoidosis
  - Histoplasmosis
- *C. trachomatis* (non-LGV type)
- Pelvic inflammatory disease
- Proctitis:
  - *Neisseria gonorrhoeae*, *C. trachomatis*, herpes, mycoplasma, entamoeba, shigella, campylobacter
  - Inflammatory bowel disease

**TREATMENT**

**MEDICATION**

**First Line**

- Doxycycline 100 mg PO b.i.d. × 3 wk
- Pregnant patients:
  - Erythromycin (nonestolate form) 500 mg PO q.i.d. × 3 wk
  - Azithromycin 1 g PO qd × 3 wk
- Asymptomatic contact with infected person:
  - Azithromycin 1 g single dose OR
  - Doxycycline 100 mg b.i.d. × 1 wk

**Second Line**

Tetracycline 2 g/day PO divided q.i.d. × 3 wk

**SURGERY/OTHER PROCEDURES**

- Aspiration of buboes:
  - Prevents fistula/sinus formation
- Surgical therapies for anorectal stricture/fistula formation

**DISPOSITION**

**Admission Criteria**

- Presence of surgical complications such as perirectal abscess, fissure, stricture
- Systemic manifestations with potential complications (fever, sepsis, etc.)
- Uncertain diagnosis

**Discharge Criteria**

- No urgent surgical interventions are needed.
- No systemic medical conditions present requiring urgent interventions.

**Issues for Referral**

- Evaluation for other STIs, including HIV in both the patient and partners
- Determine if LGV is reportable to local health authorities, and respond accordingly.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Need testing for other STIs
  - Treatment of sexual partners
- Activity:
  - Safe sex practice counseling

**COMPLICATIONS**

- Ruptured buboes may lead to sinus formation
- Anorectal strictures or fistulas
- Penile/vulvar elephantiasis
- Hepatitis
- Meningitis
- Increased risk of acquiring HIV

**REFERENCES**

1. Kapoor S. Re-emergence of lymphogranuloma venereum. *J Eur Acad Dermatol Venereol.* 2008;22:409–416.
2. Goh BT, Forster GE. Sexually transmitted diseases in children: Chlamydial oculo-genital infection. *Genitourin Med.* 1993;69:213–221.

**ADDITIONAL READING**

**See Also (Topic, Algorithm, Electronic Media Element)**

U.S. CDC: <http://www.cdc.gov/std/lgv/default.htm>

**CODES**

**ICD9**

099.1 Lymphogranuloma venereum

**PEARLS AND PITFALLS**

- Due to relative rarity in the U.S., LGV is often overlooked as a potential diagnosis.
- The diagnosis of LGV typically must include serologic testing, as clinical findings are nonspecific and may be result of other STIs.
- LGV is strongly associated with high-risk sexual behaviors and other STIs.
- Once the diagnosis is suggested, presumed, or confirmed, the patient should be evaluated for other types of STIs—especially HIV.

## BASICS

### DESCRIPTION

- Malaria is a febrile illness due to the *Plasmodium* species of protozoan parasites.
- *Plasmodium falciparum* and *Plasmodium vivax* most commonly infect humans, though *Plasmodium malariae* and *Plasmodium ovale* also produce infection.
- The *Anopheles* mosquito serves as the vector for *Plasmodium* transmission.
- Malaria is among the most common vector-borne illnesses worldwide.

### EPIDEMIOLOGY

#### Incidence

- ~300 million to 500 million cases of malaria occur throughout the world annually.
- Between 1,200 and 1,400 cases of malaria are diagnosed in the U.S. each year, with the majority imported from endemic areas.
- Children account for ~20% of imported cases of malaria.

### RISK FACTORS

- The primary risk factor for acquisition of malaria is recent travel to a malaria-endemic area (eg, Asia, Africa, South America).
- Cerebral malaria is more common in children than in adolescents and adults.

### GENERAL PREVENTION

- Personal protective measures against mosquito bites are extremely important:
  - Remain in well-screened areas.
  - Protective clothing covering exposed skin surfaces is advised.
  - Insect repellents such as DEET are recommended. However, for children <2 yr of age, concentrations <10% are recommended; concentrations <35% may be used in the older child.
- Chemoprophylaxis is strongly advised prior to travel to a malaria-endemic area:
  - Chloroquine is the drug of choice, except in resistant areas. Chloroquine resistance is widespread. Dosing is 500 mg once a week or 5 mg/kg once a week.
- In chloroquine-resistant areas, the following may be used:
  - Mefloquine: 250 mg once a week
    - <15 kg: 5 mg/kg
    - 15–19 kg: 1/4 tablet
    - 20–30 kg: 1/2 tablet
    - 31–45 kg: 3/4 tablet

- Atovaquone/proguanil is equally effective, with fewer side effects than mefloquine:
  - 11–20 kg: 1 Malarone pediatric tablet PO qd (62.5 mg of atovaquone and 25 mg of proguanil hydrochloride)
  - 21–30 kg: 2 Malarone pediatric tablets PO qd
  - 31–40 kg: 3 Malarone pediatric tablets PO qd
  - >40 kg: 4 Malarone adult tablets PO qd (250 mg of atovaquone and 100 mg of proguanil hydrochloride)
- Doxycycline (age >8 yr, 2 mg/kg/day PO qd, max 100 mg PO/day) or chloroquine (5 mg/kg/dose PO weekly) plus proguanil are additional alternatives to mefloquine.
- Chloroquine and mefloquine chemoprophylaxis should be initiated 1 wk prior to travel and continued during the period of exposure and for an additional 4 wk after leaving the endemic region.
- Atovaquone/proguanil is started 2 days prior to travel and continued 1 wk after return.
- Travelers should use pyrimethamine/sulfadoxine if a febrile illness occurs while on chloroquine and access to medical care is not readily available.

### PATHOPHYSIOLOGY

- There are 2 discrete stages of the *Plasmodium* life cycle—the sexual stage and the asexual stage:
  - Sexual stage: Develops in the female *Anopheles* mosquito, which provides sporozoites to the host
  - Asexual stage: Occurs in the human, 1st in the liver producing merozoites and then in the erythrocytes as trophozoites. Trophozoites cause red cell hemolysis, which releases more merozoites to infect other erythrocytes.
  - Fever correlates with hemolysis.
- The life cycle is characteristically synchronous and periodic, giving the typical tertian periodicity seen in *P. falciparum*, *P. vivax*, and *P. ovale* and the quartan periodicity seen in *P. malariae*.

### ETIOLOGY

- Infection is primarily acquired via transmission through the bite of the female *Anopheles* mosquito.
- Rarely, malaria can be acquired via contaminated blood transfusions or needles or through congenital transmission.
- The most common infecting species are *P. falciparum* and *P. vivax*:
  - *P. falciparum* tends to cause more severe disease, and morbidity is significantly increased due to multiorgan system involvement.
- *P. vivax* and *P. ovale* are associated with relapsing disease because of the persistent hepatic stage of the infection.

## DIAGNOSIS

### HISTORY

- Recent travel to a malaria-endemic region and prescription/compliance with malaria prophylaxis
- Symptoms typically develop within the 1st month after return from an endemic zone, though presentation up to 12 mo later may occur.
- Malaise, high fevers, headache, chills, sweating, rigors, and myalgia/arthritis are common presenting complaints.
- Classic malarial paroxysm is 15–60 min of chills followed by 2–6 hr of nondiaphoretic fever:
  - Profuse sweating occurs with defervescence.
  - Pattern of fever can be helpful; with *P. falciparum* typically recurs every 72, but with other *Plasmodium* infections, fever occurs at 48-hr intervals.
- Cough, irritability, anorexia, vomiting, abdominal pain, back pain, and arthralgias may also be reported.
- Dark urine

### PHYSICAL EXAM

- Ill-appearance during fever, with relatively well appearance in between
- Jaundice
- Pallor
- Hepatosplenomegaly may be present.
- Rash is not a typical feature of malaria; the presence of rash should elicit consideration of alternative diagnoses.
- GI symptoms of vomiting, diarrhea, and fever may occur.
- Pulmonary findings including dyspnea, rales, and pulmonary edema may occur.
- Cerebral malaria, the most severe complication of malaria, may manifest with signs of increased intracranial pressure, encephalopathy, focal neurologic findings, and seizures.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC:
  - Hemoglobin: Hemolytic anemias present initially as mild but may be more severe depending on the *Plasmodium* species.
  - Leukocyte counts are usually normal or low; eosinophilia is not present.
  - Thrombocytopenia may occur in severe cases due to liver and splenic sequestration.
- Peripheral blood smear:
  - Microscopic identification is essential for the diagnosis of malaria.
  - Thick and thin peripheral blood smears are both required (thick smears enable better sensitivity level if parasitemia is low; thin smears allow for species identification).
  - If initial smears are negative, repeat specimens should be obtained q8–12h during a 72-hr period to confirm a truly negative result.

- The percent of infected red cells (parasitemia) is an important risk factor for illness severity.
  - Parasitemia >5%, CNS involvement (eg, mental status changes), or other organ involvement are indications for more aggressive, intensive therapy.
- Quantitative buffy coat (QBC) analysis is available for rapid screening, but confirmation by blood smears is necessary.
- Serologic tests and indirect immunofluorescent assays have low sensitivity in early phases of acute infection.
- Other tests, including rapid detection kits and polymerase chain reaction techniques have demonstrated variable sensitivity and specificity, but may be of use in the future

### DIFFERENTIAL DIAGNOSIS

- Other common endemic diseases in high-malaria zones also producing fever in travelers include:
  - Typhoid fever
  - Dengue fever
  - Yellow fever
  - Hepatitis
  - Hemolytic-uremic syndrome
  - Leptospirosis
- Common etiologies of fever
- Other causes of altered mental status
- Other cause of diarrheal illness

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Airway protection and circulatory stabilization are frequently indicated.
- Hypoglycemia is a common complication of severe malaria; early detection and treatment is necessary.
- Using blood gas measurement, treat tissue hypoxia using IV fluid and supplemental oxygen.
- Seizures may result from cerebral malaria and should be treated promptly with benzodiazepines.
- Aggressive antimalarial treatment should be promptly administered.

### MEDICATION

#### First Line

- For all *Plasmodium* species except chloroquine-resistant *P. falciparum* and *P. vivax*: Chloroquine phosphate is recommended at a dose of 10 mg/kg PO (max 600 mg), then 5 mg/kg PO in 6 hr (max 300 mg), then 5 mg/kg PO at 24 and 48 hr (max 300 mg).
- For chloroquine-resistant *P. falciparum* or *P. vivax*: Quinine sulfate, 25 mg/kg/day orally in 3 doses a day for 3–7 days, plus doxycycline, 2 mg/kg/day PO b.i.d. for 7 days (max 1 g/day) is recommended:
  - Instead of doxycycline, clindamycin 20–40 mg/kg/day orally in 3 doses for 5 days may be used.
- Alternatives include:
  - Mefloquine 15 mg/kg PO followed by 10 mg/kg PO 8–12 hr later
  - Pyrimethamine (25 mg)/sulfadoxine (500 mg):
    - 5–10 kg: 1/2 tablet PO single dose
    - 11–20 kg: 1 tablet PO single dose
    - 21–30 kg: 1.5 tablet PO single dose
    - 31–45 kg: 2 tablets PO single dose
    - >45 kg: 3 tablets PO single dose

- Quinine sulfate plus doxycycline
- Atovaquone plus proguanil:
  - 5–8 kg: 2 Malarone pediatric tablets PO daily for 3 days
  - 9–10 kg: 3 Malarone pediatric tablets PO daily for 3 days
  - 11–20 kg: 1 Malarone adult tablet PO daily for 3 days
  - 21–30 kg: 2 Malarone adult tablet PO daily for 3 days
  - 31–40 kg: 3 Malarone adult tablet PO daily for 3 days
  - >40 kg: 4 Malarone adult tablets PO daily for 3 days
- Artesunate 2.4 mg/kg IV or IM
- Artemether 3.2 mg/kg IM for patients in high- or low-endemic zones

### DISPOSITION

#### Admission Criteria

- Most patients should be admitted and managed as inpatients.
- Even if initial peripheral blood smears are normal but there is still a high clinical suspicion for malaria, the patient should be admitted.
- Critical care admission criteria:
  - Severe or complicated malaria (eg, cerebritis, severe anemia, shock, acidosis, disseminated intravascular coagulation) should be managed in the an intensive care setting.

#### Discharge Criteria

- Children without severe symptoms who are considered partially immune (>6 yr of age, history of malaria infection, recent residence in endemic zone) may have serial thick and thin smears as outpatients.
- If the patient has traveled to a non-falciparum malaria-endemic area, serial peripheral blood smears may be conducted as an outpatient.

## FOLLOW-UP

### PROGNOSIS

- Poor prognosis is associated with presentations of severe malaria, specifically cerebral infection, severe hemolysis, hypoglycemia, acidosis, shock, and renal involvement.
- Prognosis is worse in younger children and with *P. falciparum* infection; infants account for substantial mortality, with case fatality rates between 0.6% and 3.8%.

### COMPLICATIONS

- Severe malaria is defined as the presence  $\geq 1$  of the following:
  - Prostration
  - Impaired consciousness
  - Respiratory distress
  - Multiple convulsions
  - Circulatory collapse
  - Pulmonary edema
  - Abnormal bleeding
  - Jaundice
  - Hemoglobinuria
  - Severe anemia
  - Hypoglycemia
  - Acidosis
  - Renal impairment
  - Hyperlactatemia
  - Hyperparasitemia

- Splenic rupture may occur.
- Cerebral malaria
- Black water fever: Severe hemolysis, hemoglobinuria, and renal failure
- Chronic relapses may occur from *P. vivax* and *P. ovale* infection, in periods ranging from every few weeks to months.
- Congenital malaria in infants

## CODES

### ICD9

- 084.0 Falciparum malaria (malignant tertian)
- 084.1 Vivax malaria (benign tertian)
- 084.6 Malaria, unspecified

### PEARLS AND PITFALLS

- Delay in diagnosis increases morbidity and mortality up to 20-fold compared to diagnosis within 24 hr of presentation.
- Even with optimal therapy, severe malaria has high morbidity and mortality.
- Periodicity of fever is less commonly seen in young children and travelers.
- Malaria must be ruled out in any febrile traveler returning from an endemic zone.
- If treated promptly, even *P. falciparum* malaria responds well to current treatment options if severe parasitemia is not present.

# MALLET FINGER

Ruby F. Rivera

## BASICS

### DESCRIPTION

Mallet finger is digit deformity that commonly occurs in individuals involved in contact or ball-handling sports:

- Also called drop or baseball finger
- It results from disruption of the extensor mechanism of the distal interphalangeal (DIP) joint.

### EPIDEMIOLOGY

Most commonly occurs in young to middle-aged men who are involved in contact or ball handling sports such as basketball or baseball.

### PATHOPHYSIOLOGY

- Mallet finger typically occurs after a direct force to the tip of the finger resulting in a sudden forceful flexion (or hyperflexion) of the distal phalanx:
  - During this injury process, the extensor tendon may become partially or completely (ruptured) torn.
  - This can be associated with an avulsion fracture of the distal phalanx.
- Less common mechanisms include distal fingertip lacerations, partial and complete finger amputations, and crush injuries.
- The 3rd and 4th digits of the hand are the most commonly injured (1).

### ETIOLOGY

See Pathophysiology.

## DIAGNOSIS

### HISTORY

- Direct force that forcibly flexes an extended finger (eg, jammed finger on ball)
- Finger strikes a fixed, hard surface

### PHYSICAL EXAM

- Bruising, pain, and swelling over the dorsum of the DIP joint of the involved finger and sometimes even the neighboring digits
- Deformity may be noted if there is an associated phalangeal avulsion fracture.
- Flexion of the DIP joint most commonly is seen since there is unopposed flexion with no working extension mechanism in place.
- Inability to extend the DIP joint, though passive extension is possible:
  - It is important to isolate the flexion and extension of the DIP joint by holding the proximal interphalangeal (PIP) joint in complete extension.
- “Swan neck” deformity can be a late finding in undiagnosed individuals:
  - Hyperextension at the PIP joint because of extensor mechanism dysfunction and imbalance
  - Not specific to traumatic mallet finger since it is also seen with rheumatoid arthritis

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

Radiographs should be obtained to evaluate the presence of fractures and joint subluxation:

- Obtain AP, lateral, and oblique views:
  - Avulsion fractures and subluxation are best noted on the lateral views.

### DIFFERENTIAL DIAGNOSIS

- Finger contusion or “jammed finger”
- Rheumatoid arthritis can also cause swan neck deformity.
- Subluxation of phalanges without disruption of extensor mechanism
- Felon
- Phalanx fracture

## TREATMENT

### PRE HOSPITAL

Ice and standard splinting as necessary

### INITIAL STABILIZATION/THERAPY

- Immobilize the DIP joint in full extension or slight hyperextension (5–15 degrees) while permitting full range of motion of the PIP joint.
- Closed mallet finger injuries are treated with continuous splinting of the DIP joint in extension for  $\geq 6$  wks:
  - Splinting must be maintained in complete extension even during sleep.
  - If splint needs to be temporarily removed, the DIP joint needs to be maintained in full extension.
  - If this regimen is not adhered to and there is a lapse in compliance and the DIP joint is not kept in full extension, then the full extension of the DIP joint needs to be maintained for another 6 wk.

### MEDICATION

#### First Line

- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Ibuprofen 10 mg/kg/dose PO q6h PRN
    - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

#### Second Line

Opioids:

- Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
- Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN

**SURGERY/OTHER PROCEDURES**

- There is insufficient evidence to determine when surgery is indicated for closed mallet finger (2).
- Usual indications for surgical referral include:
  - Open or severe mallet finger injuries
  - Inability to achieve full passive extension of DIP joint
  - Palmar subluxation of a distal phalanx
  - Presence of fracture that will not permit passive healing to occur without deformity or limitation of range of motion

**DISPOSITION****Admission Criteria**

No need to admit isolated mallet finger injuries unless an overlying wound is present, thus requiring operative debridement.

**Discharge Criteria**

All patients with mallet finger injuries should be able to be discharged unless they require immediate surgical intervention or have concerning concomitant injuries.

**Issues for Referral**

Consider referral to a hand specialist, orthopedist, or plastic surgeon, especially for:

- Fractures involving > 1/3 of the articular surface
- Nonoperative treatment failure

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - See Treatment.
- Activity:
  - Palmar and dorsal splints can be used in contact sports athletes who want to return to play.

**Patient Monitoring**

- Patients should be evaluated q2wk to check for skin breakdown and compliance.
- If active extension is present after 6 wk, splinting can be limited to nighttime for 2 wk and during athletic activities for another 4 wk.
- The most important reason for treatment failure of the conservative splinting approach is noncompliance to the 6-wk treatment regimen.

**PROGNOSIS**

- Closed mallet finger injuries heal with minimal functional deficits with conservative treatment.
- Patients should be advised to expect a slight extension lag (5–10 degrees) and prominent bump on the dorsum of the finger after treatment.
- Splinting is successful up to 3 mo after the injury.

**COMPLICATIONS**

- Skin breakdown from continuous splinting
- Chronic stiffness or deformity:
  - Swan neck deformity of the finger can result if mallet finger is left untreated.

**See Also (Topic, Algorithm, Electronic Media Element)**

- Fracture, Hand
- Tendon Laceration

**ICD9**  
736.1 Mallet finger

**PEARLS AND PITFALLS**

- Pearls:
  - It is important to isolate tendons on physical exam.
  - A splint should be applied over DIP joint only; the PIP joint should be allowed to move to prevent stiffness of the PIP joint.
  - Patient compliance is key to success of splinting.
- Pitfalls:
  - The splint can be removed to clean finger for a few minutes; however, the finger should be kept in extension (place on a flat surface). Otherwise, the time of immobilization needs to be prolonged further.
  - Slight flexion of the finger during treatment may disrupt healing and requires restarting the splinting duration from time zero.

# MASTITIS

Robert A. Belfer

## BASICS

### DESCRIPTION

- Mastitis is an infection of the breast tissue.
- Signs and symptoms of mastitis include swelling, redness, warmth, tenderness, and induration of the affected breast.
- Children may present with fever, but other systemic symptoms are uncommon.

### EPIDEMIOLOGY

#### Incidence

The precise incidence is unknown.

#### RISK FACTORS

- Age: Mastitis typically occurs in 2 age groups:
  - Neonates: It occurs most commonly in term infants <5 wk of age, with a peak incidence at age 3 wk.
  - Less commonly, it may affect children 8–17 yr of age.
- Gender: This infection affects females more often than males in a 2:1 ratio. In the majority of cases, only 1 breast is involved. There is no predilection for the right or left breast.
- Maternal skin or soft tissue infection
- Local skin infection
- Trauma
- Obesity
- Mammary duct ectasia
- Epidermal cysts
- Nursery outbreaks of streptococcal infections

#### GENERAL PREVENTION

- Proper skin hygiene
- Avoidance of risk factors

#### PATHOPHYSIOLOGY

- Maternal hormonal stimulation predisposes the neonatal breast to infection with skin and mucous membrane pathogens via the nipple and mammary ducts.
- Hematogenous spread, especially with gram-negative infections
- Trauma can introduce bacteria from the skin into the ductal system.

### ETIOLOGY

- The majority of cases are caused by *Staphylococcus aureus*, including methicillin-resistant strains.
- Less common causes include:
  - *Streptococcus pyogenes*
  - *Escherichia coli*
  - *Salmonella* species
  - *Shigella* species
  - *Pseudomonas aeruginosa*
  - *Klebsiella pneumoniae*

### COMMONLY ASSOCIATED CONDITIONS

- Breast abscess (40–70% of cases)
- Cellulitis
- Fasciitis
- Osteomyelitis
- Sepsis

## DIAGNOSIS

### HISTORY

- Breast swelling
- Breast erythema
- Breast discharge
- Fever (25–40%)
- Irritability
- Poor feeding
- Lethargy
- Inquire about maternal history:
  - Breast-feeding
  - Maternal infections

### PHYSICAL EXAM

- In addition to breast swelling and erythema, the affected region may be warm, tender, indurated, or fluctuant.
- Fluctuance may be indicative of an abscess.
- Nipple discharge may be present:
  - It is critical to differentiate nipple discharge that is purulent from neonatal milk production that may result from maternal hormones.
- Axillary lymph nodes may be enlarged.
- Assess for signs of sepsis-like syndrome:
  - Ill appearance
  - Lethargy
  - Tachycardia
  - Tachypnea
  - Hypotension
  - Delayed capillary refill

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC: Elevation of WBC count, with neutrophil predominance in 50–70%
- C-reactive protein elevation
- Blood culture
- Nipple or breast drainage: Gram stain and culture
- If it is unclear whether drainage from nipple is pus or milk, microscopy can differentiate.
- Consider evaluation of CSF for meningitis in ill-appearing or febrile neonates and young infants.

#### Imaging

- US is helpful in identifying and defining neonatal mastitis and detecting a breast abscess.
- US can also be used to differentiate between cystic or solid lesions if a breast mass is palpated on exam.

**Diagnostic Procedures/Other**

- If an abscess is identified, treatment consists of either aspiration or incision and drainage of the abscess.
- Incision should be conducted by clinician experienced with the procedure, as permanent damage to underlying breast tissue and deformity are possible.

**DIFFERENTIAL DIAGNOSIS**

- Physiologic breast hypertrophy:
  - Common in the immediate newborn period
  - Marked by breast swelling and milk discharge that may appear similar to pus. After vaccine in 1963, the U.S. incidence decreased by 99% and is no longer considered endemic in the U.S.
  - Erythema, warmth of tissue, and fever should not be present with physiologic breast hypertrophy.
- Mammary duct ectasia
- Trauma
- Carcinoma

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

Assess and stabilize airway, breathing, and circulation.

**MEDICATION**

**First Line**

- In general, broad-spectrum antibiotics to treat both gram-positive and gram-negative infections should be used.
- Gram-positive therapy with either clindamycin or vancomycin:
  - Clindamycin:
    - Neonates: 15–30 mg/kg/day divided q6–8h
    - Children: 25–40 mg/kg/day divided q6–8h
  - Vancomycin:
    - Neonates: 15–20 mg/kg/dose q8h
    - Children: 40 mg/kg/day divided q6–8h

- Gram-negative therapy with either cefotaxime or gentamicin:
  - Cefotaxime:
    - Neonates: 150–200 mg/kg/day divided q6–8h
    - Children: 100–200 mg/kg/day divided q6–8h
  - Gentamicin:
    - Neonates: 2.5 mg/kg/dose q8h or single daily dosing 3.5–5 mg/kg q24h
    - Children: 2.5 mg/kg/dose q8h or single daily dosing 5–7.5 mg/kg q24h
- Initial antibiotic therapy may be chosen based on Gram stain results.

**Second Line**

If there is good response to parenteral antibiotic therapy, transition to oral antibiotics can be considered after 3–5 days.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

Warm compresses to affected breast

**SURGERY/OTHER PROCEDURES**

- If there is no response to antibiotic therapy, a breast abscess should be considered.
- If an abscess is identified, definitive therapy is drainage by aspiration or incision.

**DISPOSITION**

**Admission Criteria**

- All neonates with mastitis should be hospitalized for parenteral antibiotic therapy.
- Critical care admission criteria:
  - Ill appearance, poor responsiveness, unstable vital signs, or coagulopathy

**Discharge Criteria**

If a good response to parenteral antibiotic therapy is noted, transition to oral antibiotics and discharge from the hospital may be considered after 3–5 days.

**Issues for Referral**

Surgical evaluation for possible incision and drainage of any abscess

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Most children will be discharged on oral antibiotics, guided by Gram stain or culture results.

**Patient Monitoring**

Parents must monitor for signs that the infection is recurring or worsening: Swelling, induration, fluctuance, tenderness, warmth, or redness of the breast; fever.

**PROGNOSIS**

- Is universally favorable with a full recovery expected
- Recurrence is rare.

**COMPLICATIONS**

- Abscess development
- Surgical drainage may lead to breast asymmetry.

**ADDITIONAL READING**

- Borders H, Mychaliska G, Gebarski KS. Sonographic features of neonatal mastitis and breast abscess. *Pediatr Radiol.* 2009;39:955–958.
- Stauffer WM, Kamat D. Neonatal mastitis. *Pediatr Emerg Care.* 2003;19:165–166.

**CODES**

**ICD9**

- 611.0 Inflammatory disease of breast
- 778.7 Breast engorgement in newborn

**PEARLS AND PITFALLS**

- The absence of fever does not rule out the diagnosis of mastitis.
- Consider abscess formation in cases of mastitis that do not respond to parenteral antibiotic therapy.
- In the majority of children with mastitis, the infection is localized to the breast without systemic spread.
- Physiologic breast hypertrophy is distinguished from mastitis by the absence of tenderness, warmth, or intense erythema.
- Discharge from the nipple may be milk due to breast hypertrophy resulting from maternal hormonal influence.

# MASTOIDITIS

Jeffrey A. Seiden

## BASICS

### DESCRIPTION

- Acute mastoiditis is infection of the mastoid air cells.
- This is usually a complication of acute otitis media (AOM), in which the bacterial infection spreads beyond the mucosa of the middle ear cleft and causes osteitis or periosteitis of the mastoid air cells.
- Up to 50% of patients with mastoiditis present without a known pre-existing diagnosis of AOM.

### EPIDEMIOLOGY

#### Incidence

- Most common in children <2 yr of age
- Prior to the advent of antibiotics, acute mastoiditis developed in 20% of cases of AOM.
- In countries with lower rates of antibiotic prescriptions for AOM (eg, the Netherlands), the incidence of acute mastoiditis is ~4 cases per 100,000 person-years for children <15 yr of age (1).
- In countries with higher rates of antibiotic usage for AOM (eg, the United States), the incidence is 1.2–2 cases per 100,000 person-years (1).

### RISK FACTORS

- Age <2 yr
- AOM

### GENERAL PREVENTION

Treatment of AOM with antibiotics may prevent mastoiditis.

### PATHOPHYSIOLOGY

- AOM causes inflammation of the mucosa within the mastoid air cells.
- When inflamed mucosa prevents drainage of the air cells, infection becomes trapped.
- Persistent infection in the mastoid cavity leads to osteitis in the mastoid air cells or periosteitis of the mastoid process.
- The infection can then erode through the bone into contiguous structures, leading to CNS infections such as intracranial abscess.

### ETIOLOGY

- *Streptococcus pneumoniae* is the most common etiologic organism in acute mastoiditis (2). *Streptococcus pyogenes* (group A streptococcus) and *Haemophilus influenzae* are also commonly implicated (3).
- Chronic mastoiditis is usually polymicrobial and may involve *Staphylococcus aureus*, anaerobic bacteria, enteric bacteria, and *Pseudomonas aeruginosa*.
- Unusual agents of chronic mastoiditis include mycobacteria, *Nocardia* species and *Histoplasma* species.

### COMMONLY ASSOCIATED CONDITIONS

- AOM
- Cellulitis
- Intracranial abscess

## DIAGNOSIS

### HISTORY

- Acute mastoiditis occurs with or shortly after an episode of AOM.
- Fever is often present and persistent despite appropriate oral antibiotic treatment for AOM.
- Pain, often deep inside or behind the ear, is nearly universal.
- Parents often describe asymmetry in the appearance of the ears, with the affected ear “sticking out” more than the other ear.
- Hearing loss and otorrhea may also be reported.

### PHYSICAL EXAM

- Fever is often present.
- Otitis media is present on otoscopic exam of the affected ear.
- The affected auricle often protrudes out and can be displaced downward.
- The mastoid process is tender and often has overlying soft tissue swelling, warmth, and erythema.
- The ear canal is typically normal in appearance.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC, C-reactive protein, and ESR may be helpful in monitoring the effectiveness of therapy, though none of these tests is necessary for diagnosis.
- Blood culture may be obtained prior to antibiotic administration.
- If the tympanic membrane has perforated, otorrhea can be obtained for culture and Gram stain. Otherwise, fluid can be obtained during surgery or myringotomy by the otorhinolaryngologist.
- Lumbar puncture should be performed in all children with symptoms of meningitis.

##### Imaging

- Temporal bone CT scan is the standard study for evaluating suspected cases of acute mastoiditis.
- Plain radiographs lack sensitivity but may demonstrate clouding of the mastoid air cells with bone destruction.
- Intracranial extension of infection is best evaluated by MRI and can be helpful for surgical planning.

##### Diagnostic Procedures/Other

In patients with concomitant AOM, myringotomy with tympanocentesis for relief of symptoms and to obtain specimens for culture

### DIFFERENTIAL DIAGNOSIS

- Infection:
  - Otitis media
  - Otitis externa
  - Cat scratch disease
  - Atypical mycobacteria
  - Parotitis
- Postauricular lymphadenopathy
- Auricular or mastoid trauma
- Branchial cleft cysts
- Tumor

## TREATMENT

### MEDICATION

- Parenteral antibiotics are directed against the most common organisms, with consideration for regional resistance patterns.
- Consider:
  - Ampicillin/Sulbactam 40 mg/kg IV q8h
  - Ticarcillin/Clavulanate 75 mg/kg IV q6h
  - Ceftriaxone 50 mg/kg IV per day
  - Consider vancomycin 10 mg/kg IV q8h for coverage of resistant *S. pneumoniae*.
- Analgesics including NSAIDs or opioids as needed
- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2 μg/kg IV q2h PRN:
    - Initial dose of 1 μg/kg IV may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation:
    - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
    - Ketorolac 0.5 mg/kg IV/IM q6h PRN
    - Naproxen 5 mg/kg PO q8h PRN
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- Tailor coverage based on results of culture and/or Gram stain.

### SURGERY/OTHER PROCEDURES

- Tympanostomy tube placement encourages drainage and administration of topical medications directly to the middle ear and mastoid system.
- Surgical mastoidectomy (simple vs. radical) may be required depending on severity and stage of disease.

## DISPOSITION

### Admission Criteria

- Critical care admission criteria:
  - Those with intracranial spread of infection or sepsis should be admitted to a critical care unit.
- All patients with suspected or confirmed acute mastoiditis should be treated as inpatients with parenteral antibiotic therapy initially.

### Discharge Criteria

Patients with clinical response to inpatient therapy may be discharged, typically to complete oral antibiotic therapy on an outpatient basis.

### Issues for Referral

Patients may require transfer to a facility with the appropriate subspecialists available, such as pediatric otolaryngologists, pediatric neurosurgeons, and/or pediatric intensivists.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- Patients should continue the prescribed antibiotics upon discharge.
- Patients should be monitored for signs of worsening or extending infection, such as fevers, altered mental status, hearing loss, or ill appearance.

### Patient Monitoring

Patients should be followed up by a pediatric otolaryngologist, and audiography should be performed.

### PROGNOSIS

Patients with acute mastoiditis without intracranial extension or facial nerve involvement should recover completely.

### COMPLICATIONS

- Conductive and sensorineural hearing loss
- Facial nerve palsy
- Labyrinthitis
- Extension may lead to intracranial infections, cranial osteomyelitis, subperiosteal abscess, or dural sinus thrombosis.

Otitis Media

## CODES

### ICD9

- 383.00 Acute mastoiditis without complications
- 383.1 Chronic mastoiditis
- 383.9 Unspecified mastoiditis

## PEARLS AND PITFALLS

- Evaluation of any child with otalgia or AOM should routinely include evaluation of the pinna and postauricular area to detect mastoiditis.
- Patients with chronic otitis media should be referred to an otolaryngologist in order to prevent progression to mastoiditis.
- Both mastoiditis and otitis externa may be associated with posterior auricular tenderness; with mastoiditis, the external ear canal is typically normal.
- The significant reduction of mastoiditis and its complications in the last century has resulted from antimicrobial therapy for AOM.

# MEASLES

Sujit Iyer

## BASICS

### DESCRIPTION

- Measles is an exanthematous, highly contagious paramyxovirus infection.
- Clinical syndrome includes:
  - Classic measles in immunocompetent patients marked by high fever, rash, conjunctivitis, and cough
  - Modified measles in patients with partial immunity:
    - Longer incubation period (17–21 days)
    - Milder symptoms than classic disease
  - Atypical measles in patients immunized with killed virus vaccine:
    - Killed virus vaccine was used between 1963 and 1967 in the U.S., so atypical measles is a disease of adults in the U.S.
  - Severe, progressive measles in patients with defects in cell-mediated immunity (AIDS, lymphoma, malignancies)

### EPIDEMIOLOGY

#### Incidence

- The World Health Organization (WHO) estimates that >20 million individuals are affected annually.
- In the U.S., >90% of children <15 yr old were infected with the measles virus prior to vaccine availability.
- After vaccine in 1963, the U.S. incidence decreased by 99% and is no longer considered endemic.
- Last outbreak of 131 cases in the U.S. from January to July 2008, largest since 1996:
  - Not due to greater number of imported cases, but due to greater transmission of disease once imported into the U.S.
  - 91% of cases occurred in unimmunized or patients with unknown immunization status.
  - Decreased herd immunity in communities with large clusters of unvaccinated people

#### Prevalence

In 2000, an estimated 197,000 children died from measles worldwide (mostly children <5 yr of age).

### RISK FACTORS

- There is a high attack rate in those exposed and susceptible (75%), so unvaccinated status is the primary risk factor.
- Children <1 yr old, not eligible for vaccine
- Defects in cell-mediated immunity (AIDS, malignancies, etc.)
- Exposure to infected people from developing parts of the world
- Overcrowding in endemic, poorly vaccinated communities. 95% of measles deaths worldwide occur in low-income countries.

### GENERAL PREVENTION

- In the U.S., current recommendation is use of a live attenuated 2-dose vaccine strategy, with the 1st dose given no sooner than age 12 mo. When administered properly, >99% of recipients develop antimeasles antibody, leading to long-term immunity.
- Transmission is thought to occur mainly by aerosolized respiratory secretions. Young children can also spread the virus by direct inoculation of infectious droplets into their nose. Infected patients should wear a surgical mask and be separated from other patients in waiting rooms.
- Patient is contagious from 4 days before rash appears to 5 days after rash abates, with maximum contagiousness when febrile with respiratory symptoms (late prodromal phase).
- The CDC defines an outbreak as a single confirmed case. All suspected cases should be reported to the local health department for investigation:
  - Once outbreak occurs, the 1st step is immunization of all susceptible (nonimmune) individuals.

### PATHOPHYSIOLOGY

4 phases—incubation, prodrome, exanthem, and recovery:

- Incubation phase: Virus migrates to regional lymph nodes
- Prodromal phase: Viremia with spread of virus to body surfaces. Epithelial necrosis and giant cell formation in many tissues. Viral shedding begins in this phase.
- Exanthem phase: Rash results from a small cell vasculitis and formation of epidermal syncytial giant cells. With onset of rash, antibody production begins and symptoms begin to wane.
- Recovery phase: May cause transient suppression of T-cell response for weeks after infection and has thus been associated with reactivation of TB

### ETIOLOGY

Single-stranded RNA virus in the Paramyxoviridae family. Humans serve as the natural host for measles.

## DIAGNOSIS

### HISTORY

- Prodromal phase (lasts 2–4 days):
  - Characterized by malaise, fever, coryza, conjunctivitis, and cough
  - Fever is an early sign, often before the start of respiratory symptoms.
  - Early respiratory symptoms mimic the common cold.
  - Photophobia, increased lacrimation from conjunctivitis

- Exanthem phase (appears on the 14th day after exposure):
  - Spread of rash is centrifugal—from head to feet. Starts behind the ear and on the forehead at the hairline.
  - Fever peaks on the 2nd day of rash. Fever persistent beyond the 4th day of rash is often a sign of a complication.
  - Vomiting, diarrhea and abdominal pain may be seen in young children.
- Atypical measles (usually in those who received kill virus vaccines—adults):
  - Sudden onset of high fever and headache 1–2 wk after exposure
  - Dry cough and pleuritic chest pain
  - Maculopapular rash starts on the extremities and spreads to the trunk
  - Severe respiratory distress with pneumonia/pneumonitis and sometimes pleural effusion
  - Peripheral edema and paresthesias

### PHYSICAL EXAM

- Prodromal phase:
  - May have transitory macular rash early in the prodrome phase
  - Slit lamp reveals corneal and conjunctival lesions.
  - Cough is described as having a “brassy” quality and becomes worse through the prodromal phase.
  - On day 10 after exposure, Koplik spots will be seen:
    - Pathognomonic of measles
    - White to blue lesions on a bright red mucosal base start on the buccal mucosa opposite lower molars and within 12 hr will become numerous and coalesce along the mucosa.
- Exanthem phase—lasts 6–7 days:
  - Appears after Koplik spots have peaked
  - Starts as erythematous and maculopapular, spreading from head to feet
  - Rash then confluent in the same centrifugal pattern, always worse on the face.
  - After rash fades (by 4th day of rash), skin may look coppery and then desquamate.
  - Cough may still be persistent in this phase for 10 more days.
  - Pharyngitis, lymphadenopathy, and splenomegaly also are seen in this phase.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC: During the prodrome and exanthem phases, patients may have leukopenia.
- In low prevalence countries (U.S.), paired acute and convalescent IgM and IgG titers can aid in diagnosis. A 4-fold increase is diagnostic.
- Diagnosis may be made clinically, and any suspected case should be reported to local health authorities while diagnostic workup is in progress.

#### Imaging

CXR to visualize either primary viral pneumonia or subsequent bacterial pneumonia. Giant cell pneumonia can occur in immunocompromised hosts.

**DIFFERENTIAL DIAGNOSIS**

- Viral exanthem
- Meningococemia
- Toxic shock syndrome
- Influenza
- Adenovirus
- Respiratory syncytial virus
- Mycoplasma pneumoniae
- Drug eruption
- Human herpesvirus 6
- Rubella
- Rocky Mountain spotted fever
- Scarlet fever
- Kawasaki disease
- Infectious mononucleosis

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing and circulation.
- Primary therapy for measles is supportive care in normal hosts and prevention of subsequent complications.
- Antitussives when indicated for persistent cough

**MEDICATION**

- Antipyretic:
  - Acetaminophen 15 mg/kg PO/PR q4h PRN
  - Ibuprofen 10 mg/kg PO/IV q6h PRN
- Antitussive:
  - Dextromethorphan:
    - 2–6 yr of age: 2.5–7.5 mg PO q6h PRN
    - 7–12 yr: 5–10 mg PO q4h PRN
    - >12 yr: 10–30 mg q4–8h PRN
  - Codeine:
    - >2 yr: 1.5 mg/kg/day divided q4–6h PRN
- Immune globulin 0.25–0.5 mL/kg IV, max 15 mL:
  - Given to susceptible persons (immunocompromised, children <1 yr of age, pregnancy) within 6 days of exposure to modify disease course
- Vitamin A:
  - 6–12 mo of age: 100,000 IU PO per day × 2 days
  - 1–2 yr: 200,000 IU PO per day × 2 days
  - Although the mechanism of action of vitamin A is not known, it is thought that it may help treat a viral-induced state of hypoproteinemia.
  - The American Academy of Pediatrics recommends vitamin A therapy for the following children in developed countries:
    - Children 6–12 mo hospitalized with measles or its complications
    - Children >6 mo with immunodeficiency and eye findings of vitamin A deficiency
    - Malnutrition or impaired GI motility
    - Recent immigrant from a high measles mortality area
  - The WHO recommends vitamin A therapy in these circumstances:
    - All areas where vitamin A deficiency is prevalent or mortality for measles is >1%

**DISPOSITION****Admission Criteria**

- Severely ill patients with dehydration, altered mental status, seizures, immunocompromise, or respiratory distress should be hospitalized.
- Critical care admission criteria:
  - Severe respiratory compromise

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Notify nonimmune contacts to receive vaccination or avoid contact with any measles case until 3 wk after rash disappears.
- Activity: Restrict when still having cough and pulmonary symptoms, as measles causes extensive ciliary damage to respiratory tract and exposure may put patient at risk for secondary bacterial infections.

**PROGNOSIS**

Morbidity and mortality are greatest in children <5 yr of age (especially <1 yr) and those >20 yr of age.

**COMPLICATIONS**

- Otitis media: Most frequent complication of measles
- Laryngotracheitis (croup)
- Pneumonia
- Encephalitis:
  - Acute disseminated encephalomyelitis: A postinfectious encephalomyelitis that occurs 2 wk after the rash; 10–20% mortality
  - Subacute sclerosing panencephalitis: Progressive, fatal degenerative neurologic disease developing 7–10 yr after primary measles infection; progresses from behavioral changes to myoclonus and eventual decorticate posturing and death
- Corneal ulceration
- Myocarditis
- Pericarditis
- Hepatitis
- Mesenteric lymphadenitis

**ICD-9**

055.9 Measles without mention of complication

**PEARLS AND PITFALLS**

- The characteristic spread of the measles rash from head to feet helps to distinguish it from other viral exanthems.
- In the emergency department waiting and exam areas, children suspected to have measles must be separated from others.
- Children with risk factors for lower vitamin A levels due to virus (and thus at increased risk for morbidity from the illness) should receive vitamin A therapy.

# MECKEL'S DIVERTICULUM

Denise G. Karasic

## BASICS

### DESCRIPTION

- Meckel diverticulum occurs when a congenital blind pouch of the intestine results from an incomplete closure of the vitelline (omphalomesenteric) duct during the 5th week of embryonic development.
- It is the most common congenital anomaly of the digestive tract.
- It is the most common cause of painless GI bleeding in children.
- Most children are asymptomatic and typically come to attention as a result of painless rectal bleeding.

### EPIDEMIOLOGY

#### Incidence

- The rule of 2's is an easy way to remember basic information about Meckel diverticulum:
  - The diverticulum is within 2 feet of the end of the ileocecal valve.
  - The diverticulum is 2 inches in length.
  - It occurs in 2% of the population (male to female ratio is 2:1).
  - Complications occur in 2% of the population.
  - Children <2 yr of age are most likely to have complications.
- It is the most prevalent congenital abnormality of the GI tract.

### RISK FACTORS

Children <2 yr of age account for 50–60% of patients who will develop symptoms.

### PATHOPHYSIOLOGY

- The diverticulum contains all the normal layers of the intestinal wall and resembles the adjacent ileum.
- 55% of the diverticulum can contain ectopic gastric tissue; smaller proportions of pancreatic tissue may be seen.
- Colonic tissue in Meckel diverticula has been found in pediatric patients.
- Colonic, carcinoid, duodenal, lipoma, and leiomyosarcoma tissues may also be found in adults.
- Meckel diverticulum usually is found 2 feet or proximal to the ileocecal junction on the antimesenteric side of the ileum.
- Initial sentinel bleed can be small and may spontaneously resolve, and it may be followed by more significant bleeding.

### ETIOLOGY

A congenital blind pouch of the intestine resulting from incomplete closure of the vitelline (omphalomesenteric) duct

### COMMONLY ASSOCIATED CONDITIONS

- Omphalic-ileal fistula
- Enterocystoma
- Umbilical sinuses
- Anal atresia
- Esophageal atresia
- Omphalocele
- Cleft palate
- Small bowel obstruction
- Intussusception

## DIAGNOSIS

### HISTORY

- Painless rectal bleeding is the typical presentation:
  - This may range in volume from occult blood to severe, bright red hemorrhage.
  - Bleeding is usually acute but may be episodic over a longer period of time.
  - Blood is passed per rectum, commonly without stool.
  - Iron-deficiency anemia that is refractory to iron therapy may be the presenting complaint in patients with intermittent occult bleeding.
- Abdominal pain may be the presenting complaint:
  - Partial or complete bowel obstruction may result from volvulus or internal herniation. This is accompanied by typical obstructive findings: Severe emesis, pain, abdominal distention.
  - Inguinal pain may be the presenting complaint of a Littre hernia, an indirect inguinal hernia involving the diverticulum.
  - Intermittent abdominal pain or lethargy may be the presenting symptoms of intussusception, with the diverticulum acting as the lead point.
- Diverticulitis may cause right lower quadrant pain and can mimic appendicitis:
  - The diverticula may ulcerate and perforate, causing bleeding and fecal contamination with peritonitis.
  - Signs and symptoms are extremely similar to appendicitis.

### PHYSICAL EXAM

- General: The child is usually well appearing without abnormal physical findings. However, on occasion, the following abnormalities may be detected:
  - Pallor or lethargy secondary to acute blood loss and/or intussusception
  - Tachycardia or hypotension may be associated with acute blood loss.
  - Skin: Pallor, prolonged capillary refill
  - Abdomen: Often nontender, but there may be focal right lower quadrant tenderness or diffuse abdominal tenderness with peritoneal signs and guarding associated with diverticulitis and rupture of the diverticulum or obstruction.

- A sausage-shaped loop of bowel may be palpated on abdominal exam in patients with intussusception.
- Inguinal swelling and tenderness may be associated with herniation of the diverticulum.
- Rectal exam: Bright red rectal bleeding is a common presentation.

### DIAGNOSTIC TESTS & INTERPRETATION

- The diagnostic evaluation will vary depending on the severity of symptoms. Lab assay and plain radiography may be suggestive but are not diagnostic.
- Diagnosis is made by surgical exploration or Technetium-99m (Tc99; Meckel) scan.

### Lab

#### Initial Lab Tests

- CBC: Anemia secondary to hemorrhage, leukocytosis secondary to peritonitis. Assess platelet count.
- Electrolytes: Acidemia from hypovolemia
- Venous blood gas: Acidemia from hypovolemia
- Lactate level: May be elevated if hypovolemia
- Coagulation screening
- Blood type and cross-match

### Imaging

- Imaging modality of choice is a Tc99-perchnetate scan. This will detect a Meckel diverticulum that has ectopic gastric mucosa:
  - This is most helpful in stable patients with rectal bleeding.
  - Scan has ~90% sensitivity and specificity in children.
  - False-negative scan results when the Meckel diverticula has no gastric mucosal cells
  - False-positive scans are common and occur in other abdominal pathology with bleeding: Intussusception, hemangioma, arteriovenous malformation, inflammatory bowel disease.
- Abdominal x-ray in patients with suspicion of intestinal obstruction or perforation
- Meckel diverticula may be found on CT of the abdomen.

### Pathological Findings

- In 1 study of 58 resected specimens, 59% contained ectopic tissue and 41% were normal histologically.
- The most common ectopic tissue found in most patients is gastric mucosa.

### DIFFERENTIAL DIAGNOSIS

- Rectal bleeding:
  - Anal/Rectal fissures
  - Hemorrhoids
  - Intussusception
  - Meckel diverticulum
  - Juvenile polyyps
  - Familial polyposis
  - Henoch-Schönlein purpura

- Peritoneal irritation:
  - Acute nonperforated or perforated appendix
  - Primary peritonitis
  - Pancreatitis
- Acute intestinal obstruction:
  - Intussusception
  - Incarcerated inguinal, umbilical and femoral hernias
  - Malrotation of the bowel with volvulus

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation.
- Fluid resuscitation may be necessary as a result of hemorrhage:
  - Vascular access with large-bore IVs for crystalloid fluid resuscitation and support
- Oral intake should be stopped.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Fluid resuscitation may be necessary as a result of hemorrhage:
  - Vascular access with large-bore IVs for crystalloid fluid resuscitation and support
  - Severe acute blood loss in a patient with a marked decrease in the hemoglobin will require transfusion with packed RBCs.
- An NG tube should be inserted if the patient has symptoms suspicious for intestinal obstruction.
- Patients should be monitored closely for changes in heart rate and BP.
- Surgical consult
- Patients with a tender abdomen and suspicion of a ruptured viscus should be treated with antibiotics.

### MEDICATION

- Fluid resuscitation:
  - Crystalloid: Normal saline or lactated Ringer solution 20 mL/kg boluses rapidly
  - Blood transfusion for severe acute blood loss
- Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
  - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
- Ampicillin/Sulbactam 75 mg/kg IV q8h
- Cefoxitin 50 mg/kg IV q8h
- Clindamycin 10 mg/kg IV q6h
- Gentamicin 7.5 mg/kg IV per day; may also be given in divided dose 2.5 mg/kg IV q8h
- Metronidazole 8 mg/kg IV q6h

### SURGERY/OTHER PROCEDURES

- The appropriate surgical procedure will be dictated by the presentation of the patient.
- Severe bleeding needs surgical intervention.
- Surgery should not be delayed in patients with severe bleeding.
- Diverticulectomy may be sufficient.
- Bowel resection may also be necessary.
- Intussusception may be reduced radiologically, followed by a Meckel scan.

## DISPOSITION

### Admission Criteria

- Admit patients with nontrivial rectal bleeding suspected to be due to Meckel diverticula.
- Critical care admission criteria:
  - Admit to the ICU all patients with severe hemorrhage, unstable vital signs, shock, peritonitis, bowel obstruction, or those requiring blood transfusion.

### Discharge Criteria

Well-appearing patients with a few episodes of painless bloody stools may be discharged with a plan for close follow-up and a Meckel scan as an outpatient.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

#### Patient Monitoring

- For inpatients: Cardiac monitoring including pulse and BP and urine output are indicated.
- Outpatients should follow up with general surgery as appropriate.

### DIET

- Patients should have no oral intake if there is significant rectal bleeding, suspicion of a Meckel diverticulum, or incarcerated inguinal hernia, volvulus, peritonitis, or bowel obstruction.
- Following surgery and at discharge, dietary instructions are as per general surgery.

### PROGNOSIS

The prognosis is dependent on the presentation to the emergency department. Simple diverticulectomy may be an appropriate treatment. The findings at laparotomy will dictate which procedure is appropriate.

### COMPLICATIONS

- Diverticulitis
- Peritonitis
- Bowel ulceration
- Bowel perforation
- Bowel necrosis
- Littre hernia
- Intussusception
- Volvulus
- Small bowel obstruction

- Rectal Bleeding

## ICD-9 CODES

### ICD9

751.0 Meckel's diverticulum

## PEARLS AND PITFALLS

- Meckel diverticulum occurs in ~1% of the population.
- Symptomatic Meckel is seen most commonly in patients  $\leq 2$  yr of age.
- Meckel may be associated with symptoms other than painless rectal bleeding.
- Severe abdominal pain and vomiting may be seen with associated intussusception, bowel obstruction, or hernia.
- Bleeding associated with Meckel diverticulum may be severe, resulting in hypotension, shock, or death.

# MEDIASTINAL MASS

Raemma Paredes Luck

## BASICS

### DESCRIPTION

Mediastinal masses are a heterogeneous group of congenital, neoplastic, or infectious lesions that arise from the mediastinal structures.

### EPIDEMIOLOGY

- Mediastinal masses are uncommon among adults and children.
- The prevalence of malignancy among pediatric patients with mediastinal masses is lower than in adults (37% vs. 47%).
- The most common pediatric mediastinal tumors include:
  - Neurogenic tumors (46%)
  - Germ cell tumors (19%)
  - Lymphomas (13%)
  - Congenital cysts (8%)
  - Thymomas (4%)

### RISK FACTORS

- Risk factors in the development of lymphomas include:
  - Presence of congenital or acquired immunodeficiency syndromes
  - Infection with certain viruses such as Epstein-Barr virus, human herpesvirus 8 and human T-cell leukemia/lymphoma 1
  - Exposure to agricultural or wood chemicals
- There is an association between germ cell tumors and the presence of 47XXY chromosomal abnormality (Klinefelter syndrome).
- The presence of specific abnormalities on chromosomes 1 and 17 increases risk of developing neuroblastoma.

### PATHOPHYSIOLOGY

- Mediastinal masses arise from structures within the mediastinum:
  - The anterior compartment contains the thymus, the extrapericardial great vessels and its branches, and some lymphatic tissue.
  - The middle compartment contains the pericardium, the heart and its intrapericardial great vessels, and the trachea.
  - The posterior compartment contains the esophagus, thoracic duct, vagus nerves, sympathetic chain, and azygous venous system.
- Enlargement of the mass into surrounding areas produces symptoms such as respiratory distress.
- Mediastinal masses may also produce systemic effects due to the release of hormones, antibodies, or cytokines to the circulation.

### ETIOLOGY

- Mediastinal masses can have congenital, infectious, or neoplastic causes.
- The majority of mediastinal masses originate from the posterior compartment (52%), followed by the anterior compartment (32%), and least likely from the middle compartment (12%).
  - Neurogenic tumors are the most common masses arising from the posterior compartment.
  - Lymphomas and germ cell tumors are the most common masses arising from the anterior compartment.

### COMMONLY ASSOCIATED CONDITIONS

Systemic diseases such as myasthenia gravis, immune deficiencies, carcinoid syndromes, and thyroid disorders have been associated with mediastinal masses.

## DIAGNOSIS

### HISTORY

- Most mediastinal masses are asymptomatic and detected on plain radiography performed for other reasons.
- The most common symptoms are respiratory distress, cyanosis, cough, and chest pain.
- Orthopnea suggests severe tracheal narrowing.
- Other symptoms include recurrent pulmonary infections, hemoptysis, dysphagia, hoarseness, and stridor.
- Systemic symptoms such as fever, night sweats, diarrhea, weight loss, and other autonomic or endocrine effects may also be elicited.

### PHYSICAL EXAM

- Physical findings may include respiratory distress, cyanosis, stridor, or hoarseness.
- Patients may present with the superior vena cava syndrome consisting of neck or facial swelling and plethora.
- Depending on the etiology of the mass, systemic manifestations may include pallor, hepatosplenomegaly or generalized lymphadenopathy, opsoclonus/myoclonus, or HTN.
- Rarely, new-onset wheezing may be the 1st manifestation of a mediastinal mass.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Lab tests are directed on the likely diagnosis and usually include a CBC and electrolytes.
- Other studies may include a 24-hr urinary catecholamine and metanephrine level in suspected cases of pheochromocytoma.
- A 24-hr urinary homovanillic acid and vanillylmandelic acid level is obtained to assess for neuroblastoma.
- Alpha-fetoprotein or beta-hCG levels may be elevated in certain germ cell tumors.

##### Imaging

- The chest radiograph, often the 1st imaging study used, is highly sensitive in detecting mediastinal masses but has low diagnostic specificity.
- With its high spatial and temporal resolution, CT of the chest with contrast is the modality of choice in delineating the nature, size, location, and extension of the mass.
- MRI is valuable in the evaluation of neurogenic tumors or in a patient with a contraindication to the contrast material used in CT scanning.
- Young children may need procedural sedation prior to an imaging study. Consider placement of an artificial airway prior to procedural sedation if airway compromise is a concern.

##### Diagnostic Procedures/Other

Biopsy of mass may be indicated.

### DIFFERENTIAL DIAGNOSIS

- The differential diagnosis depends on the anatomic location of the mass and age of the child.
- Anterior mediastinum:
  - Lymphomas
  - Teratomas
  - Thymic tumors
  - Hemangiomas
  - Lymphangiomas
  - In infants and children, the normally enlarged thymus may be mistaken for an underlying neoplasm.
- Middle mediastinal masses are developmental malformations of the foregut:
  - Bronchogenic cysts
  - Enteric cysts
  - Neurenteric cysts
  - Enlarged lymphadenopathy can also result from inflammatory or infectious conditions such as TB, sarcoidosis, or histoplasmosis.
- Posterior mediastinal masses are neurogenic in origin:
  - Neuroblastomas
  - Ganglioneuroblastomas
  - Ganglioneuromas
  - Nerve sheath tumors such as schwannoma and neurofibroma are less common.

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Patients in respiratory distress or cyanosis should be expeditiously assessed and managed:
  - Sudden airway obstruction and cardiovascular collapse have occurred when the patient is in the supine position.
  - Predictors of increased risk of anesthetic complications and difficult intubation include the presence of orthopnea, upper body edema, great vessel compression, and main stem bronchus compression.

### SURGERY/OTHER PROCEDURES

- Malignant-appearing masses usually require a biopsy using the least invasive route to determine the exact cause.
- Benign primary mediastinal masses should be removed by surgical resection:
  - Minimally invasive video-assisted thoracic surgery has been used successfully to resect most benign tumors.

### DISPOSITION

#### Admission Criteria

- All patients with a mediastinal mass need to be admitted for emergent evaluation.
- Critical care admission criteria:
  - Any patient with a mediastinal mass and respiratory distress, cyanosis, facial or neck swelling, or hemodynamic instability needs to be monitored closely in the ICU.

#### Discharge Criteria

A patient with a mediastinal mass should not be discharged home until fully evaluated.

#### Issues for Referral

Transfer to a tertiary center with multidisciplinary capabilities is recommended.

## FOLLOW-UP

### PROGNOSIS

- The prognosis depends on the cause, extent of the mass, and age of the patient. Benign lesions can be fully resected with minimum morbidity.
- Mortality and morbidity depends on the type, stage, and complications of the neoplastic lesion.

### COMPLICATIONS

- Mediastinal masses can enlarge and compress nearby structures and cause hemorrhage, infection, or rupture:
  - Airway obstruction is the most serious complication.
- Rare complications of mediastinal masses include superior vena cava syndrome, superior mediastinal syndrome, spinal cord compression syndrome, and vertebral erosion.

Neoplasm, Lymphoma

## CODES

### ICD9

- 164.9 Malignant neoplasm of mediastinum, part unspecified
- 212.5 Benign neoplasm of mediastinum
- 786.6 Swelling, mass, or lump in chest

## PEARLS AND PITFALLS

- A patient with a mediastinal mass needs to be admitted in a tertiary hospital for further evaluation.
- Symptomatic patients are more likely to have malignant tumors.
- Do not force a child with a mediastinal mass to lie supine. Doing so may precipitate sudden airway and cardiovascular collapse.
- Young children may need procedural sedation prior to a CT study. Consider placement of an artificial airway prior to procedural sedation if airway compromise is a concern.

# MENINGITIS

Jose Ramirez

## BASICS

### DESCRIPTION

- Meningitis is an inflammatory process involving the CNS, specifically involving the meninges.
- Significant morbidity and mortality
- Typically an acute infectious process:
  - Infectious agents include bacterial, viral, fungal, and atypical organisms.
- May be noninfectious:
  - Chemical
  - Malignancy

### EPIDEMIOLOGY

- Bacterial meningitis usually occurs in children <24 mo of age.
- Aseptic meningitis occurs commonly in summer and fall seasons.
- Fungal meningitis occurs almost exclusively in immunocompromised persons.

### RISK FACTORS

- Lack of immunization
- Immunocompromise: HIV, asplenia, immunoglobulin deficiency
- Living in closed quarters, such as dormitories used by college students or military personnel

### GENERAL PREVENTION

- Childhood immunizations including *Haemophilus influenzae* type b (HIB), pneumococcal, and meningococcal vaccines
- Minimize respiratory contact with ill persons.
- Postexposure chemoprophylaxis for HIB, *Neisseria meningitidis*

### PATHOPHYSIOLOGY

The offending agent typically crosses the blood–brain barrier by hematogenous spread or direct spread from adjacent structures such as the nasopharynx, sinuses, or middle ear.

### ETIOLOGY

- Varies by age
- Neonates:
  - Group B streptococcus
  - *Escherichia coli*
  - Gram-negative enteric organisms
  - *Listeria monocytogenes*
- Infants/Children:
  - Aseptic meningitis: Enterovirus is most common; 80% are coxsackievirus; and echovirus also is common.
  - Aseptic meningitis is more common than bacterial meningitis.
  - Typically summer/fall
  - Caused by viruses as well as fastidious bacteria such as *Borrelia burgdorferi*, ehrlichiosis, babesiosis, and other zoonotic diseases
  - Consider herpes simplex virus (HSV) in early infancy.
  - Bacterial: Particularly in unimmunized patients:
    - *N. meningitidis*
    - *Streptococcus pneumoniae*
    - HIB
  - IVIG use is often associated with development of aseptic meningitis.

## COMMONLY ASSOCIATED CONDITIONS

- Cochlear implants
- Vaccination refusal
- Miliary TB
- Immunocompromised patient

## DIAGNOSIS

### HISTORY

- History will depend on age.
- Typical presentation includes:
  - Fever
  - Neck pain
  - Irritability in infants and young children
  - Headache reported by in older children/adolescents who can verbalize pain
- Other suggestive findings:
  - Somnolence or lethargy
  - Altered mental status
  - Photophobia
  - Vomiting

### PHYSICAL EXAM

- Assess vital signs with attention to fever and the Cushing triad (bradycardia, HTN with widened pulse pressure, and irregular respirations).
- Evaluate for altered mental status, lethargy, and coma.
- Neurologic exam with attention to note focal findings
- Nuchal rigidity
- Kernig sign (with hips flexed 90 degrees, extension of the legs cannot be completed without pain)
- Brudzinski sign (flexion of neck elicits involuntary flexion of hips)
- Skin evaluation to note perfusion as well as presence of petechiae or purpura

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- CSF analysis:
  - Normal opening pressure in lateral position is <200 mm H<sub>2</sub>O
  - Culture and Gram stain
  - Cell count and differential
  - Chemistry: Glucose, protein
  - Consider latex agglutination assay for CSF bacterial antigens, particularly if the patient is already being treated with antibiotics.
  - Consider polymerase chain reaction for HSV, *B. burgdorferi* (Lyme), ehrlichiosis, Epstein-Barr virus, enterovirus, syphilis, or other uncommon organisms when appropriate.
- Blood culture
- CBC to assess for leukocytosis and platelet count
- C-reactive protein
- In sepsis or shock, obtain blood gas to assess for acidemia, base excess, and lactate.
- Serum electrolytes and blood glucose
- PT/PTT should be obtained if petechiae or purpura are present.

## Imaging

Consider cranial CT scan to evaluate for signs of elevated intracranial pressure prior to lumbar puncture (LP) as well as intracranial pathology such as hemorrhage or abscess:

- Obtaining a CT prior to LP in patients with closed fontanelle is not universally practiced.
- The purpose of this imaging is to avert LP in patients with elevated intracranial pressure so as to prevent cerebral herniation through the foramen magnum.
- If focal neurologic findings are present, LP should only be performed after CT is obtained.

### Diagnostic Procedures/Other

- LP in lateral decubitus or sitting position
- Contraindications:
  - Respiratory distress that will be exacerbated by body flexion
  - Potential cerebral herniation
  - Bleeding disorder or severe thrombocytopenia

## DIFFERENTIAL DIAGNOSIS

- Encephalitis
- Meningoencephalitis
- Cervical adenitis
- Brain abscess
- Toxin-induced encephalopathy
- Tumor
- Intracranial hemorrhage

## TREATMENT

### PRE HOSPITAL

Stabilization and treatment of ABCs

### INITIAL STABILIZATION/THERAPY

- Stabilization and treatment of ABCs
- Rapid assessment and therapy is critical.
- Secure IV access.
- Continuous hemodynamic monitoring is important, as both under- and overhydration may be complications.

### MEDICATION

- Routine antibiotic therapy in those <1 mo of age:
  - Ampicillin 150–200 mg/kg/day IV divided q6–8h
  - Cefotaxime 150–200 mg/kg/day divided q8h
- Routine antibiotic therapy in those >1 mo of age:
  - Ceftriaxone 100 mg/kg/day IV/IM divided q12–24h
- Additional/Alternative antibiotic therapy:
  - Vancomycin should be added based on local susceptibility patterns of *S. pneumoniae*:
    - <7 days of age: 20 mg/kg/day divided q12h
    - 1–4 wk: 30 mg/kg/day divided q8h
    - >1 mo: 40–60 mg/kg/day divided q6h
  - Vancomycin should be used in patients who have ventriculoperitoneal shunts:
    - May be used as a single antibiotic agent
  - Gentamicin, as alternative to 3rd-generation cephalosporin:
    - <7 days of age: 5 mg/kg/day divided q12h
    - 1–4 wk: 7.5 mg/kg/day divided q8h
    - >1 mo: 7.5 mg/kg/day divided q8h

- Other agents:
  - Acyclovir 60 mg/kg/day divided q8h for concern of HSV meningitis
  - Amphotericin B, liposomal: 6 mg/kg/24 hr IV per day for concern for fungal meningitis
  - For antitubercular treatment, see the Tuberculosis topic.
  - Dexamethasone 0.15 mg/kg q6h for 4 days:
    - Administer with or just prior to IV antibiotic.
    - Data supports great benefit in HIB meningitis and TB.
    - Efficacy in other types of bacterial meningitis is not proven.
  - Acetaminophen 15 mg/kg PO/PR q4h PRN for fever or pain
  - Ibuprofen 10 mg/kg PO/IV q6h PRN for fever or pain

**DISPOSITION**

**Admission Criteria**

- CSF pleocytosis
- Toxic patient
- Suspected bacterial meningitis
- Lack of follow-up
- Critical care admission criteria:
  - Patients with unstable vital signs
  - Focal neurologic deficit or evidence of elevated intracranial pressure

**Discharge Criteria**

- Well-appearing child with adequate pain control
- CSF with normal CSF analysis consistent with viral meningitis
- Able to maintain hydration
- Reliable caregiver

 **FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Close contacts of patients with meningitis should receive prophylactic antibiotics.
- Close contacts include household members, roommates, intimate contacts, individuals at a child care center, young adults in dormitories, military recruits in training centers, and sitting next to an index patient for >8 hr on an airplane or individuals who have been exposed to oral secretions (eg, intimate kissing, mouth-to-mouth resuscitation, endotracheal intubation, or endotracheal tube management).
- For *N. meningitidis*:
  - Rifampin:
    - 0–1 mo of age: 5 mg/kg PO q12h × 2 days
    - >1 mo: 10 mg/kg PO q12h × 2 days
    - Adolescent/Adult 600 mg PO q12h × 2 days
  - Ciprofloxacin:
    - Adolescent/Adult 500 mg PO × 1 dose
  - Ceftriaxone:
    - <15 yr of age: 125 mg IM × 1 dose
    - >15 yr: 250 mg IM × 1 dose
  - Azithromycin:
    - <15 yr of age: 10 mg/kg PO × 1 dose
    - >15 yr: 500 mg PO × 1 dose

- Discharge instructions and medications:
  - Worsening symptoms
  - Inability to maintain hydration
  - Follow up with the primary care provider within 1 day.
- Activity:
  - Avoid school or work attendance until asymptomatic to prevent transmission of infection to others.

**PROGNOSIS**

- A low Glasgow Coma Score on presentation is predictive of severe morbidity and mortality.
- Bacterial meningitis:
  - Potentially devastating
  - Mortality 5% in developed countries, 10% in developing countries
  - Delay in treatment may result in neurocognitive impairment or death.
- Aseptic meningitis:
  - Fairly good prognosis except for HSV
  - HSV meningitis in neonates and young infants has severe morbidity, and surviving patients often have permanent neurologic deficits, including permanent cognitive impairment and mental retardation.

**COMPLICATIONS**

- SIADH
- Subdural effusion/empyema
- Severe to catastrophic neurologic injury:
  - Mild to severe speech/cognitive impairment
  - Hearing impairment/deafness
  - Death

**See Also (Topic, Algorithm, Electronic Media Element)**

- Encephalitis
- Fever in Children Older than 3 Months
- Fever in Infants 0–3 Months of Age
- Ventriculoperitoneal Shunt Malfunctions

**ICD9**

- 047.9 Unspecified viral meningitis
- 320.9 Meningitis due to unspecified bacterium
- 322.9 Meningitis, unspecified

**PEARLS AND PITFALLS**

- Rapid diagnosis and therapy is required to minimize morbidity and mortality.
- Know the most common organisms by age group.
- Note focal neurologic deficits or other evidence of elevated intracranial pressure prior to LP to prevent cerebral herniation.
- Do not wait for radiologic/lab studies to initiate antimicrobial therapy:
  - Prompt diagnosis and antimicrobial therapy is essential for optimal outcome.
  - CSF analysis may still be useful 24–48 hr after initiation of treatment.

# MENINGOCOCCEMIA

John M. Loisel

## BASICS

### DESCRIPTION

- Meningococemia is the presence of *Neisseria meningitidis* (meningococcus) bacteria within the bloodstream.
- This is usually associated with clinical disease, often sepsis or meningitis.
- Meningococcal disease is the presence of *N. meningitidis* in a normally sterile site—blood, CSF, or joint fluid.

### EPIDEMIOLOGY

#### Incidence

- There are 2 main peaks of meningococemia:
  - 9.2/100,000 in infants <1 yr of age
  - 1.2/100,000 in children 11–19 yr of age
- 25% of disease occurs in children <1 yr of age

### RISK FACTORS

- Anatomic or functional asplenia
- Terminal complement component deficiency C3, C5-9
- Crowding: Living in dormitories, refugee camps, etc.
- Chronic underlying illness, especially those associated with immunodeficiency:
  - HIV disease
  - Oncologic condition
- Active and passive smoking
- Chronic immunosuppression due to medical therapy: Methotrexate, corticosteroids, cyclosporine, tacrolimus, chemotherapy

### GENERAL PREVENTION

- Prophylactic antibiotics for those at high risk:
  - Sickle cell anemia
  - Asplenia
- Meningococcal vaccination:
  - Tetravalent conjugate vaccine
  - Covers serotypes A, C, Y, W-135
  - No effective vaccines for serogroup B
  - Recommended at age 11–12 yr checkup with a booster at 16 yr, or 1 dose to college freshmen living in dormitories if previously unvaccinated.
- Chemoprophylaxis is indicated for those with close contact to a case of meningococemia:
  - Includes those with direct exposure to oral secretions, child care and nursery school contacts, and those living in the same household
  - Rifampin is recommended for those <18 yr of age.
- Immunoprophylaxis is recommended in an unimmunized contact exposed to infection caused by a serogroup covered by the vaccine.
  - MPSV4 in children 2–10 yr of age
  - MCV4 in children ≥11 yr

### PATHOPHYSIOLOGY

- *N. meningitidis* is a gram-negative diplococcus that colonizes the mucosa of the nasopharynx.
- The bacteria are transmitted through respiratory droplets from patients or carriers.
- Nasopharyngeal carriage occurs in 2–20%.
- Colonization may stimulate an immune response leading to immunization.
- In rare cases, bacteria will invade the bloodstream from the nasopharynx.
- Bacteremia may progress to septicemia or meningitis.
- Meningococcus produces endotoxin (LPS) that is responsible for shock and circulatory collapse:
  - Trigger activation of the inflammatory cascade that leads to shock and disseminated intravascular coagulation (DIC)
- Adolescents without prior exposure may be at greater risk for invasive disease.

### ETIOLOGY

- Serogroups B, C, and Y are the most common causes of meningococcal disease in the U.S.
- Serogroup B causes >50% of disease in children <1 yr of age.
- 75% of cases in patients >11 yr of age are caused by serogroups C, Y, and W-135.

### COMMONLY ASSOCIATED CONDITIONS

- Meningitis
- Septic shock

## DIAGNOSIS

### HISTORY

- Initial symptoms are often nonspecific and similar to influenza:
  - Fever
  - Headache
  - Vomiting
  - Irritability
  - Myalgia
  - Rash
  - Poor feeding
  - Lethargy
  - Leg pain
- Classic findings of meningococemia in children will include leg pain, cold hands/feet, and mottled skin.

### PHYSICAL EXAM

- Variable initial presentation from well appearing to toxic
- Clinical signs of shock:
  - Tachycardia
  - Tachypnea
  - Hypotension
  - Altered mental status
  - Abnormal skin color and perfusion of extremities
- Petechiae or purpura:
  - Large petechiae and purpura (hemorrhagic lesions >3 mm in diameter) predominate in meningococemia.
  - Diffuse distribution
  - Located below the nipple line
  - The greater the number of petechiae, the higher the likelihood of meningococemia.

- Purpura
- Fever
- Limb tenderness
- Arthritis: Multiple joint involvement, severe pain, highly limited range of motion
- Nuchal rigidity, Kernig/Brudzinski positive

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- Consider brain CT prior to lumbar puncture.
- CXR to rule out pneumonia or acute respiratory distress syndrome (ARDS)

#### Lab

##### Initial Lab Tests

- C-reactive protein is typically elevated.
- WBC count may be abnormal (<5,000 or >15,000) with high band count:
  - This finding is not reliably or invariably present.
- Venous or arterial blood gas with lactate: Elevated lactate level, acidemia, base deficit
- Fibrinogen levels, fibrin degradation products, PT/PTT if DIC suspected
- Blood culture
- CSF studies when indicated
- Culture of synovial fluid when indicated
- Bacteria may be isolated from petechial or purpuric lesions, but testing is not routine.

#### Diagnostic Procedures/Other

Appropriate culture from sterile sites: Blood, CSF, synovial fluid

#### Pathological Findings

Presence of *N. meningitidis* in a normally sterile site: Blood, CSF, or joint fluid

### DIFFERENTIAL DIAGNOSIS

- Petechiae:
  - Traumatic petechiae from forceful vomiting or cough
  - Rocky Mountain spotted fever
  - Other viral or bacterial causes
- Vasculitis, Henoch-Schönlein purpura
- Thrombocytopenia: Idiopathic thrombocytopenic purpura, leukemia

## TREATMENT

### PRE HOSPITAL

- Assess and stabilize airway, breathing, and circulation.
- Administer fluid resuscitation with 20 mL/kg of normal saline as necessary.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Obtain vascular access for blood sampling and for fluid and medication administration.
- Correct hypotension or shock by fluid resuscitation or vasopressors if necessary.
- Patients should be managed with droplet isolation precautions.
- For septic or severely ill patients, hemodynamic monitoring as well as fluid input and output

**MEDICATION**

**First Line**

- Antibiotic therapy should not be delayed while waiting to perform lumbar puncture:
  - CSF may sterilize as soon as 15 min after administration of ceftriaxone
- Consider initial treatment with a 3rd-generation cephalosporin until an organism has been identified and antimicrobial sensitivity is known:
  - IV ceftriaxone 100 mg/kg/dose per day for meningitis
  - IV cefotaxime:
    - Children < 12 yr of age: 45 mg/kg/dose q.i.d.
    - Children > 12 yr: 1–2 g/dose t.i.d.
- If penicillin susceptible, may switch to it rather than a 3rd-generation cephalosporin:
  - IV penicillin G, 100,000 units/kg/dose
  - Nearly all meningococcus is penicillin susceptible.
- Vasopressors as needed:
  - See Septic Shock for specific medications.

**Second Line**

- IV chloramphenicol (25 mg/kg/dose) is recommended for penicillin allergy.
- Give specific dose, frequency

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Dexamethasone is recommended for Hib meningitis in children and pneumococcal meningitis in adolescents/adults:
  - Benefit in setting of *N. meningitidis* meningitis is unproven.
  - Once diagnosis of meningococemia is definitive, corticosteroid treatment should be immediately discontinued.
- Anticytokine, protein C, recombinant activated protein C, monoclonal antibodies against antitoxins, hemofiltration, and immunomodulators are not shown to be effective.

**DISPOSITION**

**Admission Criteria**

- Any patient suspected of having meningococemia should be admitted and treated with parenteral antibiotics with close monitoring pending results of cultures.
- Isolation with droplet precautions is recommended until 24 hr after initiation of antimicrobial therapy.
- Critical care admission criteria:
  - Overwhelming sepsis, meningitis, presence of cardiovascular instability, or evidence of DIC, ARDS, or other serious sequelae

**Discharge Criteria**

- Well-appearing children > 12 mo of age with fever and petechiae but normal WBC, PT/PTT, and inflammatory markers are at low risk of meningococemia and may be safely discharged from the emergency department.
- These recommendations are independent of where on the body the petechiae are located.

**Issues for Referral**

Meningococemia is a reportable disease. Referral to the state or regional health department is indicated.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- After hospital therapy, oral antibiotic therapy should be continued and patients should follow up with their primary care providers.

**ALERT**

Consider chemoprophylaxis of close contacts of patients with meningococcal disease:

- Close contacts include household members, roommates, intimate contacts, individuals at a child care center, young adults in dormitories, military recruits in training centers, and sitting next to an index patient for > 8 hr on an airplane or individuals who have been exposed to oral secretions (eg, intimate kissing, mouth-to-mouth resuscitation, endotracheal intubation, or endotracheal tube management):
  - Oral rifampin:
    - 0–1 mo of age: 5 mg/kg q12h × 2 days
    - > 1 mo: 10 mg/kg q12h × 2 days
    - Adolescents: 600 mg q12h × 2 days
  - Oral ciprofloxacin:
    - Adolescents: 500 mg × 1 dose
  - IM ceftriaxone:
    - < 15 yr of age: 125 mg × 1 dose
    - > 15 yr: 250 mg × 1 dose
  - Oral azithromycin:
    - < 15 yr of age: 10 mg/kg × 1 dose
    - > 15 yr: 500 mg × 1 dose

**PROGNOSIS**

- Prognosis is grave; even with treatment, morbidity and mortality are high.
- Overall mortality is 8%.
- Mortality rate is highest among adolescents and approaches 20%.

**COMPLICATIONS**

- 11–19% of survivors have sequelae:
  - Hearing loss
  - Neurodevelopmental disorder
  - Extremity ischemia and amputation
- Purulent meningitis
- Cranial nerve deficits
- CHF
- Pneumonia
- Pulmonary edema
- Arthritis
- Vasculitis
- Pericarditis
- Urethritis
- Waterhouse-Friderichsen syndrome

- Disseminated Intravascular Coagulation
- Meningitis
- Sepsis
- Shock, Cardiogenic
- Shock, Hypovolemic
- Shock, Neurogenic

ICD9  
036.2 Meningococemia

**PEARLS AND PITFALLS**

- Initial symptoms often mimic viral illnesses.
- Lab findings do not reliably predict meningococemia.
- Leg pain is an early sign of meningococemia and presents prior to classic symptoms.
- Classic findings include petechiae or purpura, fever, and ill appearance, but these are not typically present early in the course of illness.
- Close contacts should have chemoprophylaxis.
- Classmates of school-aged children with meningococemia do not routinely require chemoprophylaxis

# MENSES, DYSMENORRHEA

Hanan Sedik

## BASICS

### DESCRIPTION

- Dysmenorrhea is uterine pain during menstruation that either limits daily activities or requires medication.
- Primary dysmenorrhea occurs in the absence of any pelvic disease.
- Secondary dysmenorrhea occurs in the presence of an underlying pelvic disease.

### EPIDEMIOLOGY

#### Prevalence

- ~40% of postmenstrual girls
- The prevalence of dysmenorrhea increases in women of early reproductive years and reaches a peak during early adulthood.
- There is a 36% incidence of symptoms during the 1st gynecologic years compared to 65% in the 5th gynecologic year after menarche.

### RISK FACTORS

- Family history of dysmenorrhea
- Early menarche
- Menorrhagia
- Smoking
- Alcohol use
- Depression

### GENERAL PREVENTION

Avoidance of risk factors such as smoking and alcohol use

### PATHOPHYSIOLOGY

- Dysmenorrhea appears to be caused by excess production of endometrial prostaglandin (PG) F<sub>2</sub> alpha or an elevated PGF<sub>2</sub> alpha/PGE<sub>2</sub> ratio:
  - Excessive levels of endometrial but not plasma PGE<sub>2</sub> and PGF<sub>2</sub> alpha have been detected in women with primary dysmenorrhea. These compounds can cause dysrhythmic uterine contractions, hypercontractility, and increased uterine muscle tone leading to uterine ischemia.
  - They also can account for nausea, vomiting, and diarrhea via stimulation of the GI tract.
- The role of PGs in the pathogenesis of primary dysmenorrhea is supported by the observation that NSAIDs (ie, PG synthetase inhibitors) often alleviate the symptoms of primary dysmenorrhea.

### ETIOLOGY

- Primary dysmenorrhea: Unknown
- Secondary dysmenorrhea:
  - Endometriosis
  - Leiomyoma
  - Adenomyosis
  - Ovarian cysts
  - Presence of a copper intrauterine device
  - Hematocolpos

### COMMONLY ASSOCIATED CONDITIONS

- Depression
- Sedentary lifestyle
- Alcoholism

## DIAGNOSIS

### HISTORY

- Crampy or dull pain, localized to the lower quadrants of the abdomen that either limits daily activity or requires medication
- Associated symptoms of nausea, vomiting, diarrhea, fatigue, back pain, headache, or dizziness
- Pain at the onset of or a few days prior to the onset of menstruation that persists for 1–3 days

### PHYSICAL EXAM

Abdominal exam: Lower abdominal and/or suprapubic tenderness:

- Pelvic exam: Normal external genitalia
- Diffuse uterine tenderness
- Cervical motion or adnexal tenderness suggests endometriosis.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

Consider pregnancy testing, and gonorrhea and chlamydia testing for STIs. Also, consider testing for ESR and fecal occult blood test for inflammatory bowel disease as indicated by history and physical exam. See the Inflammatory Bowel Disease topic for more information.

### Imaging

Consider pelvic US to rule out ovarian pathology such as ovarian cyst or ovarian torsion, genital tract abnormalities, or obstructive lesions.

### Diagnostic Procedures/Other

Consider outpatient referral for laparoscopy in patients with adnexal or cul-de-sac pelvic tenderness, family history of endometriosis, or persistent pain despite treatment.

### DIFFERENTIAL DIAGNOSIS

- GI: Constipation and inflammatory bowel disease
- Neurologic: Fibromyalgia and herniated disc
- Urologic: Kidney stones and urinary tract infection
- Gynecologic: Pregnancy, pelvic inflammatory disease, endometriosis, imperforate hymen

## TREATMENT

### INITIAL STABILIZATION/THERAPY

Grading dysmenorrhea according to the severity of pain and limitation of daily activities will help guide treatment decisions. General measures for therapy include patient reassurance and education.

### MEDICATION

#### First Line

NSAIDs block production and decrease the effects of PGs:

- Should be started at the onset of menses and continued for the 1st 1–2 days of the menstrual cycle or for the usual duration of crampy pain
- Ibuprofen 400–600 mg PO q6h PRN
- Naproxen: Depending on tablet dosage, either 500 mg once PO followed by 250 mg q6h PRN or 550 mg once PO followed by 275 mg q6h PRN
- Mefenamic acid 500 mg once PO followed by 250 mg q6h PRN

#### Second Line

- Hormonal therapy using combination oral contraceptive pills (OCPs) is indicated in patients when NSAIDs have shown no improvement, only a suboptimal response, or the patient did not tolerate NSAIDs.

- OCPs prevent menstrual pain by suppressing ovulation, thereby decreasing uterine PG levels. An additional mechanism may result from the reduction of menstrual flow after several months of use. In a sexually active female, OCPs may be considered a 1st line of therapy because they serve a dual purpose—prevention of both pregnancy and dysmenorrhea:
  - Monophasic regimen (eg, Lo/Ovral, Ortho-Cyclen, Ortho-Novum): A 21-day pack uses tablets that are 1 strength and 1 color for 21 days.
  - Biphasic regimen (eg, Mircette, Necon, Nelova, Ortho-Novum): A 21-day pack consists of tablets of 1 strength and color taken for 7 or 10 days, then a 2nd tablet with a different strength and color for the next 11 or 14 days.
  - Triphasic regimen (eg, Ortho-Novum 7/7/7, Ortho Tri-Cyclen, Tri-Norinyl, Triphasil): This pack consists of tablets with 3 different colors and strengths. For the 1st phase, there are tablets of 1 color for 5–7 days; for the 2nd phase, a 2nd color and strength tablet is taken for 5–7 days; and for the 3rd phase, a 3rd color and strength tablet is taken for 5–10 days.
  - OCPs should be prescribed for at least 3 mo for optimal results.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- There is limited evidence from controlled trials to support the use of complementary and alternative medicine like acupuncture and yoga for the treatment of dysmenorrhea.
- Transcutaneous electrical nerve stimulation appears to be a useful alternative in patients who cannot or prefer not to take oral analgesics.
- Surgical interruption of pelvic nerve pathways has been exercised for relief of pelvic pain.
- The use of heat therapy has been suggested.
- Behavioral therapy and stress reduction may be beneficial.

**SURGERY/OTHER PROCEDURES**

As indicated for the underlying cause of secondary dysmenorrhea

**DISPOSITION**

**Admission Criteria**

Admission is rarely warranted but may be necessary for intractable pain or if concerning diagnoses have not been ruled out.

**Discharge Criteria**

Nearly all cases can be treated on outpatient basis.

**Issues for Referral**

Consider referral to an adolescent gynecologist for consideration of laparoscopy and management of endometriosis.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- NSAIDs should be taken with food to minimize side effects such as GI irritation or bleeding.

**Patient Monitoring**

Patients should be followed by their primary care provider for the 1st few months after initiating therapy to evaluate the response of medication and to re-evaluate for possible secondary dysmenorrhea.

**PROGNOSIS**

- The prognosis for primary dysmenorrhea is excellent with the use of NSAIDs.
- The prognosis for secondary dysmenorrhea varies depending on the underlying disease process.

**COMPLICATIONS**

Limitation of activities secondary to pain

ICD9  
625.3 Dysmenorrhea

**PEARLS AND PITFALLS**

- Pelvic exams can be deferred in patients who were never sexually active, as a clinical diagnosis of primary dysmenorrhea can be made if the characteristic clinical features of primary dysmenorrhea develop in ovulatory adolescents.
- Dysmenorrhea’s effect on the patient’s physical and emotional health can be significant, especially if underlying disorders are untreated.
- Adequate treatment should be pursued to avoid missed school or work, decreased academic performance, sports participation, and peer socialization.
- To maximize treatment options, it is critical that the clinician not assume that dysmenorrhea is “only a normal part of menses.”
- The primary care physician is in an ideal position to identify patients with dysmenorrhea and effectively evaluate and treat them.

# MENSES, OLIGOMENORRHEA

Janet Semple-Hess

## BASICS

### DESCRIPTION

- In early adolescence, menstrual cycles are usually every 21–42 days, with an average 2–8 days of menstrual flow (1).
- In older teens and adults, cycles are on average every 21–35 days, with an average 7 days of menstrual flow (1).
- Oligomenorrhea or anovulatory cycles may be a normal variant, especially in young teens.
- Oligomenorrhea is defined as a menstrual cycle occurring less frequently than every 35 days.
- Greater concern arises when a menstrual cycle is longer than 90 days.
- Normal blood loss with menses is 30–80 mL/day. With oligomenorrhea, flow is usually lighter as well.
- The most common cause of oligomenorrhea is an anovulatory cycle.
- Ectopic pregnancy is the most dangerous etiology.

### EPIDEMIOLOGY

#### Incidence

5% of women will have an episode of oligomenorrhea each year.

#### Prevalence

- 50% of all adolescents have some menstrual dysfunction (2).
- 11% of marathon runners have oligomenorrhea/amenorrhea (3).
- Anovulatory cycles:
  - Menarche begins < 12 yr of age: 50% of cycles are anovulatory at 1 yr.
  - Menarche that begins between 12 and 13 yr of age: 50% of cycles are anovulatory at 3 yr.
  - Menarche > 13 yr of age: 50% are anovulatory at 4.5 years.
- 5 years after menarche, 20% of all cycles are anovulatory (4).

### RISK FACTORS

- Obesity
- Abnormal body mass index (BMI):
  - Anorexia and other eating disorders
  - Female athlete triad syndrome (amenorrhea, osteoporosis, and disordered eating)
- Hyperthyroidism
- Hyperprolactinemia

### GENERAL PREVENTION

- Weight loss for obese children
- Normalization of BMI
- Management of underlying endocrine condition

### PATHOPHYSIOLOGY

- The most common cause of oligomenorrhea is an anovulatory cycle.
- Impairment of the hypothalamic-pituitary-ovarian axis at any level can cause oligomenorrhea.
- Most commonly, a lack of rise in follicle-stimulating hormone during the mid-cycle fails to stimulate a dominant follicle, which in turn causes anovulation.
  - Therefore, estrogen and progesterone levels fail to rise.
- Without a robust endometrium and lack of progesterone fail to induce menses, the menses is then delayed and “light.”
- Immaturity of the hypothalamic-pituitary-ovarian axis during the 1st 2 yr of menses is normal.
- In athletes, a loss of the luteinizing hormone (LH) surge or a luteal phase deficiency tends to be present. The resultant inadequate progesterone production may be coexistent with high, low, or normal estrogen levels in these athletes.

### ETIOLOGY

- Normal variant (anovulatory cycle)
- Pregnancy, ectopic pregnancy
- Endocrine disorders:
  - Hyperthyroidism
  - Hypothyroidism (less commonly)
  - Hyperprolactinemia
  - Premature ovarian failure (rare in adolescents)
- Polycystic ovarian syndrome (PCOS)
- Anorexia, bulimia, or other eating disorders

### COMMONLY ASSOCIATED CONDITIONS

Abnormal BMI (obese or underweight)

## DIAGNOSIS

### HISTORY

- General:
  - Nausea
  - Vomiting
  - Abdominal pain
- Menstrual history:
  - Infrequent menses, occurring >35 days apart
  - Light menstrual flow with infrequent menses
  - Last menstrual cycle
- Sexual history:
  - Pregnancy
  - Sexual activity
  - History of prior pregnancy
- History of PCOS

### PHYSICAL EXAM

- Abnormal BMI:
  - Galactorrhea
  - Acne
  - Hirsutism
- Other evidence of androgen excess:
  - Voice
  - Prominent thyroid cartilage
  - Male patterned hair loss
- Pregnancy:
  - Increase in abdominal girth (may not be present initially)

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Urine or serum pregnancy test
- If concern for endocrine disorder, check:
  - FSH
  - LH
  - Thyroid studies
  - Prolactin level
- Electrolytes, calcium and phosphate if concerns about eating disorder

#### Imaging

- Pelvic US if pregnant to rule out ectopic pregnancy
- Head CT or MRI if prolactin levels are high to rule out pituitary adenoma

#### Diagnostic Procedures/Other

- If concerns about anorexia/bulimia, obtain an ECG.
- No further procedures are recommended in the absence of pregnancy.

### DIFFERENTIAL DIAGNOSIS

See Etiology.

## TREATMENT

### PRE HOSPITAL

Address ABCs.

### INITIAL STABILIZATION/THERAPY

If ruptured ectopic pregnancy is suspected:

- IV access
- Hematocrit
- Type and screen/cross
- Confirm pregnancy.
- Consult obstetric or surgical service.

**MEDICATION**

- Medical treatment depends on the etiology of oligomenorrhea. Most cases do not require therapy since most cases are the result of an anovulatory cycle.
- See respective topics, or other references for treatment that are beyond the scope of this topic:
  - PCOS: Oral contraceptives (See Polycystic Ovary Syndrome.)
  - Hyperthyroidism:
    - Methimazole (Tapazole) 20–40 mg PO per day or b.i.d.
    - Second line: Propylthiouracil (PTU) 100–150 mg PO t.i.d.
    - For cardiac symptoms (tachycardia, HTN related to thyrotoxicosis):
      - Propranolol 20–80 mg PO q4–8h
      - Atenolol 50–100 mg PO per day
  - Hypothyroidism:
    - Levothyroxine: Usual adult dose 100–200 µg/day
    - May start at 50 µg/day and increase over 2–4-wk intervals until euthyroid
  - Hyperprolactinemia: Bromocriptine 1.25–1.5 mg PO initially, to be increased every few days to 5–10 mg PO divided b.i.d.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

Nutritional support for adolescents with low BMI

**SURGERY/OTHER PROCEDURES**

Surgery for unstable ectopic pregnancy

**DISPOSITION**

**Admission Criteria**

- Oligomenorrhea associated with anorexia or bulimia with symptoms of bradycardia or other ECG arrhythmias, electrolyte imbalance or hypoglycemia, altered mental status, suicidal thoughts, or extreme weight loss
- Critical care admission criteria:
  - Ectopic pregnancy with unstable vital signs or acute hemorrhage
  - Thyroid storm

**Discharge Criteria**

- Ectopic pregnancy ruled out
- If pregnant and delivery is not imminent, counseling regarding pregnancy has been given

**Issues for Referral**

- To endocrinology:
  - Hyperthyroidism
  - Hypothyroidism
  - Pituitary adenoma
  - PCOS (androgen excess)
- To adolescent medicine or psychiatry:
  - Severe anorexia/bulimia or other eating disorders
- To obstetrics/gynecology:
  - Pregnancy
  - Oligomenorrhea >90 days

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Follow up with the primary care provider:
    - Within 1–2 days if therapy was initiated
    - Within 1–2 weeks if no specific therapy was initiated
- Activity:
  - No limitations

**Patient Monitoring**

Continued outpatient care by endocrinology, adolescent medicine, psychiatry, or obstetrics/gynecology

**DIET**

- Weight loss if obese
- Nutritional support if anorexic/bulimic

**PROGNOSIS**

The prognosis depends on the cause.

- For most girls in whom PCOS or other endocrine disorders are not suspected, the prognosis is good.
- The prognosis for other endocrine disorders or eating disorders causing oligomenorrhea depends on the individual disorder.
- The greatest concern in young women is for future fertility.
- For pregnancy-related issues, see specific topics.

**COMPLICATIONS**

- Death from ruptured ectopic pregnancy
- Infertility (most commonly seen in women with PCOS)
- Complications from endocrine disorders (thyroid storm)
- Complications related to eating disorders (arrhythmias, shock, sudden death, electrolyte abnormalities)

- Pregnancy

**CODES**

ICD9  
626.1 Scanty or infrequent menstruation

**PEARLS AND PITFALLS**

- Obtain a urine pregnancy test in all adolescent patients with oligomenorrhea.
- Once pregnancy is ruled out and vital signs are stable, most causes of oligomenorrhea are not emergent.
- Oligomenorrhea should not be of great concern in the 1st 2 yr of menses.
- Oligomenorrhea may be accompanied by eating disorders and/or female athlete triad syndrome.

# MESENTERIC ADENITIS

Magdy W. Attia

## BASICS

### DESCRIPTION

- Mesenteric adenitis is a self-limited inflammation of the mesenteric lymph nodes typically causing abdominal pain:
  - This may be localized to the right lower quadrant mimicking acute appendicitis.
  - However, enlarged mesenteric nodes can be seen on various imaging modalities, such as US and CT scan, even in asymptomatic children.
- The diagnosis of mesenteric adenitis is not mutually exclusive of other more serious causes of abdominal pain, such as appendicitis or intussusception, until they have been excluded.

### EPIDEMIOLOGY

#### Incidence

In patients with abdominal pain who are preselected for imaging, the incidence of mesenteric adenitis is low:

- In 1 report, 8% of patients who underwent CT evaluation for acute abdominal pain met criteria for the diagnosis.

#### Prevalence

In asymptomatic children, the prevalence of enlarged mesenteric lymph nodes is reported to be as high as 29%.

### RISK FACTORS

- The condition is more common in children < 15 yr of age.
- More common in boys than girls
- Other risk factors include recent upper respiratory infection, viral gastroenteritis, and bacterial enteritis.

### PATHOPHYSIOLOGY

- Microbial agents in the GI tract drain to the regional mesenteric lymph nodes via the lymphatic system, causing inflammation.

- The lymph nodes can then become enlarged and painful.
- Macroscopically, the nodes are soft and the adjacent mesentery could become edematous. Occasionally, there is evidence of suppuration.
- Microscopically, the lymph nodes show nonspecific hyperplasia, but in cases of suppurative infection, necrosis and pus is seen.

### ETIOLOGY

- Mesenteric adenitis is most frequently caused by viral pathogens. Adenovirus, coxsackie group B, and enteric cytopathic human orphan (ECHO) viruses have been implicated.
- Enteric bacterial agents have also been implicated, most commonly *Yersinia species*.
- Mesenteric lymphadenopathy may also be secondary to a detectable or known intra-abdominal inflammatory process such as acute appendicitis, Crohn disease, or systemic lupus erythematosus.

## DIAGNOSIS

### HISTORY

- Abdominal pain, often in the right lower quadrant, but the pain can be generalized
- Other symptoms may include:
  - Fever and malaise
  - Diarrhea
  - Nausea and vomiting

### PHYSICAL EXAM

- The main finding is abdominal tenderness, often in the right lower quadrant:
  - The site of tenderness may shift when the patient's position changes, whereas the location of the tenderness tends to be fixed with appendicitis.
  - Although there is much overlap, the degree of tenderness on palpation tends to be less for those with mesenteric adenitis compared to those with peritoneal findings due to appendicitis.
- Typically, there are no signs of peritonitis in uncomplicated mesenteric adenitis
- Patients may show signs of dehydration such as dry mucous membranes or delayed capillary refill.

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- Pregnancy tests for all sexually mature females
- Lab studies are not specific for establishing the diagnosis but may be ordered in the context of evaluating the patient with acute abdominal pain. Consider:
  - CBC: May show leukocytosis
  - C-reactive protein
  - Hepatic enzymes
  - Amylase and lipase
  - Urinalysis

### Imaging

- US of the right lower quadrant is the study of choice to minimize radiation exposure:
  - US may also assist in the detection of other possible etiologies such as appendicitis, ovarian cyst, tubo-ovarian abscess, ectopic pregnancy, or ovarian torsion.
- For children with abdominal pain and tenderness of unclear etiology, abdominal and pelvic CT scans with IV contrast are recommended if US results are equivocal:
  - CT is especially useful for evaluation of possible appendicitis in children in whom visualization of the appendix may be compromised by their body habitus.

### DIFFERENTIAL DIAGNOSIS

- The diagnosis of mesenteric adenitis is one of exclusion. The clinician must eliminate the possibility of surgical conditions before establishing a diagnosis of inflammation of the mesenteric nodes.
- The main differential diagnosis is acute appendicitis.
- Although the clinician should consider all causes of undifferentiated acute abdominal pain in the differential, mesenteric adenitis is most often considered in the evaluation of the child with focal abdominal tenderness.
- Important alternative diagnoses to consider in the child with unilateral tenderness include appendicitis, ovarian cyst or torsion, tubo-ovarian abscess, ectopic pregnancy.

The differential diagnosis can be further classified as follows:

- Prepubertal:
  - Malrotation: Midgut volvulus
  - Intussusception
  - Hernia: Incarcerated/Strangulated
  - Appendicitis
  - Small bowel obstruction (adhesions)
  - Trauma (inflicted)
  - Foreign body ingestion
  - Meckel diverticulum
  - Peptic ulcer disease
  - Necrotizing enterocolitis
- Postpubertal:
  - Hemorrhagic/Ruptured ovarian cyst
  - Pelvic inflammatory disease
  - Ectopic pregnancy
  - Fallopian tube torsion
  - Appendicitis
  - Endometriosis
  - Hernia: Incarcerated/Strangulated
  - Small bowel obstruction (adhesions)
  - Trauma (inflicted)
  - Peptic ulcer disease
  - Functional pain
- Common/Medical:
  - Constipation
  - Gastroenteritis
  - Urinary tract infection
  - Lower lobe pneumonia
  - Henoch-Schönlein purpura
  - Sickle cell anemia with pain crisis
  - Pancreatitis
  - Hepatitis
  - Hemolytic uremic syndrome
  - Renal calculi

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- The airway, breathing, and circulation should be assessed, as in all patients.
- The patient should be kept without any oral intake in preparation for possible operative intervention.
- Mesenteric adenitis is a self-limited condition, and management is conservative.

## MEDICATION

- The initial management is typically focused on pain control and suppression of nausea and or vomiting:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
      - Typically, mesenteric adenitis does not cause severe pain, and the need for opioids warrants careful evaluation for other causes of pain.
- Ondansetron 0.15 mg/kg IV q6–8h for nausea or vomiting
- In very rare occasions, the presentation is that of sepsis:
  - This is typically associated with yersiniosis.

## DISPOSITION

### Admission Criteria

- Patients requiring parenteral analgesia or IV rehydration should be admitted.
- Admission for serial abdominal exams is warranted for patients when other surgical emergencies have not been completely ruled out.

## FOLLOW-UP

### PROGNOSIS

The prognosis is excellent. Most patients have complete resolution of their symptoms within 2 wk.

### COMPLICATIONS

Most associated with suppurative adenitis secondary to severe *Yersinia enterocolitica* infection in an immunocompromised host

## ADDITIONAL READING

ICD9  
289.2 Nonspecific mesenteric lymphadenitis

## PEARLS AND PITFALLS

- Mesenteric adenitis is not mutually exclusive of other serious diagnoses such as appendicitis or intussusception.
- Mesenteric adenitis commonly mimics appendicitis.
- All other surgical emergencies should be ruled out prior to fully attributing abdominal pain to mesenteric adenitis.
- Important alternative diagnoses to consider in the child with unilateral tenderness include appendicitis, ovarian cyst or torsion, tubo-ovarian abscess, ectopic pregnancy.
- Prior to the use of CT and sonography, up to 1/5 of children undergoing appendectomy based on clinical diagnosis had mesenteric adenitis.
- Management consists of supportive care.

# METABOLIC ACIDOSIS

Eileen C. Quintana

## BASICS

### DESCRIPTION

- Metabolic acidosis is an acid-base abnormality marked by a pH  $\leq 7.35$  due to a decrease of bicarbonate ( $\text{HCO}_3^-$ ) or an increase of hydrogen ( $\text{H}^+$ ).
- When obtaining a basic metabolic panel, the  $\text{CO}_2$  level indicates acid-base status. In children, the low-normal level is 20 mEq/L:
  - Metabolic acidosis is a nonspecific lab finding indicating an underlying disease process requiring treatment.
  - Primarily, it is due to an acquired process, inborn error of metabolism (early in life presentation), or poisonings.

### RISK FACTORS

- Dehydration
- Ingestions
- Renal failure
- Infection
- GI obstruction

### PATHOPHYSIOLOGY

- The 3 basic mechanisms for metabolic acidosis are increased  $\text{H}^+$  extracellularly, increased  $\text{HCO}_3^-$  loss, or decreased renal  $\text{H}^+$  excretion.
- In primary metabolic acidosis, the pH  $< 7.35$  in the absence of  $\text{PaCO}_2$  elevation:
  - The most immediate compensatory mechanism is hyperventilation (respiratory alkalosis). This is marked by a  $\text{PaCO}_2 < 40$  mm Hg when the pH is  $< 7.35$ :
    - Infants and young children may lack ability to increase minute ventilation adequately to respond in this manner.
  - The Winter formula predicts normal respiratory response to a metabolic acidosis:  $\text{PaCO}_2 = 1.5 \times (\text{HCO}_3^-) + 8 \pm 2$ . It is inaccurate with pH  $< 7.0$
  - If the calculated  $\text{PaCO}_2$  is not equal to serum  $\text{PaCO}_2$ , then a second acid-base disturbance is occurring along with the metabolic acidosis.
  - The delayed compensatory mechanism (days) is increased renal excretion of  $\text{H}^+$  with eventual full correction of the metabolic acidosis.

### ETIOLOGY

- The causes of metabolic acidosis are separated into 2 groups based on whether or not the anion gap (AG) is elevated:
  - AG formula:  $\text{Serum (Na)} - ([\text{Cl}] + [\text{HCO}_3])$
  - Normally, AG ranges from 12–20 mEq/L.
- Elevated AG metabolic acidosis:
  - Lactic acidosis (ie, hypoxia, infection, hypovolemia, circulatory failure, toxins)
  - Renal failure
  - Ketoacidosis (most commonly diabetic ketoacidosis [DKA], but starvation ketoacidosis is possible)
  - Diarrheal dehydration (most common cause of elevated anion gap metabolic acidosis)
  - Inborn errors of metabolism (ie, phenylketonuria [PKU], maple syrup urine disease)
  - Massive rhabdomyolysis (damaged muscle releases hydrogen and organic anions)
  - Poisons/Ingestion (ie, alcohols, ethylene glycol, salicylates, iron, isoniazid)
- Metabolic acidosis associated with increased osmolar gap (difference between calculated and measured osmolality) should increase suspicion of occult alcohol poisoning:
  - Calculated osmolality =  $2(\text{Na}) + (\text{BUN} \div 2.8) + (\text{glucose} \div 18)$
  - Normal osmolar gap  $\leq 10$  mOsm/L
- Metabolic acidosis with normal AG:
  - Dilution by rapid volume expansion
  - Carbonic anhydrase inhibitors and other similar drugs (ie, acetazolamide)
  - Hyperalimentation
  - Ureterostomy
  - Enteric fistulas
  - Early renal failure
  - Hypernatremic dehydration
  - Renal tubular acidosis (RTA): A syndrome with hyperchloremic non-AG metabolic acidosis. Renal regulation of bicarbonate is compromised (1,2).
    - RTA type 1 (distal RTA) is the mildest form presenting in preterm infants (formerly known as RTA type 3).
    - RTA type 2 (proximal RTA) is associated with Fanconi syndrome.
    - RTA type 4 (hyperkalemic distal RTA) is most commonly found in children.

### COMMONLY ASSOCIATED CONDITIONS

- Insulin-dependent diabetes mellitus
- RTA
- Gastroenteritis
- Shock/Sepsis
- Inborn errors of metabolism

## DIAGNOSIS

### HISTORY

- Symptoms are highly variable and dependent on the underlying process causing the metabolic acidosis.
- GI symptoms could include nausea, vomiting or diarrhea, abdominal pain, or polydipsia and polyuria.
- Renal symptoms could include anuria.
- Neurologic complaints might include altered mental status.
- Pulmonary symptoms could include dyspnea, hyperpnea, respiratory distress, or cough.
- Musculoskeletal symptoms could include muscle weakness.

### PHYSICAL EXAM

- Physical exam findings reflect the underlying disease.
- Tachycardia is commonly found initially even with mild metabolic acidosis.
- Myocardial depression can occur with significant acidosis, worsening hypotension and shock.
- Among the more common signs are tachypnea, delayed capillary refill, dry mucous membranes, and altered mental status.
- Kussmaul respirations (deep and rapid breathing) is a common finding in patients with significant metabolic acidosis.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Venous or arterial blood gas is an essential lab test in metabolic acidosis.
- Other lab studies should include electrolytes, including BUN/creatinine and glucose, lactate levels, serum osmolality, and urinalysis.
- Toxicology screen for specific poisons such as carbon monoxide, or toxic alcohols or medications such as salicylates that are the suspected cause of metabolic acidosis (see Differential Diagnosis):
  - Increased osmolar gap should increase suspicion of occult toxic alcohol (methanol, ethylene glycol) poisoning.
- CBC may show leukocytosis, a nonspecific finding, but could be suggestive of sepsis/infection. Anemia may also compromise oxygen delivery to tissues, worsening lactic acidosis.
- Urine pH  $\geq 5.5$  in metabolic acidosis suggests RTA or salicylates poisoning.
- ECG should be obtained early in the evaluation process to screen for dysrhythmias.
- Repeat blood gas every 1–2 hr based on disease severity and progression.

**DIFFERENTIAL DIAGNOSIS**

- Acute anemia
- Bacteremia/Sepsis
- Dehydration
- DKA
- Gastroenteritis, diarrhea
- Intestinal volvulus and malrotation
- Necrotizing enterocolitis
- Myocarditis
- RTA
- Poisoning, ingestion—**MUDPILES**:
  - Methanol, Uremia, DKA, Phenformin/metformin, Iron/isoniazid, Lactic acidemia (includes carbon monoxide, cyanide), Ethylene glycol, Salicylates
- Inborn errors of metabolism: PKU, amino acid and fatty acids metabolism

**TREATMENT**

**PRE HOSPITAL**

Assess and stabilize airway, breathing, and circulation.

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Treatment of the underlying causes of metabolic acidosis is paramount.
- Venous access is essential for fluid resuscitation and medication administration.
- Stabilization beyond airway, breathing, and circulation will be dependent on etiology:
  - RTA treatment in the emergency department should include the use of bicarbonate. Judicious correction is warranted because blood pH rise could exacerbate hypokalemia and worsen weakness and cardiac dysrhythmias.
  - Rehydration is usually the only treatment needed in diarrheal dehydration and ketoacidosis.
  - Shock needs to be recognized and treated promptly; depending on the cause, diuretics, antibiotics, fluids, and pressor agents may be indicated.

**MEDICATION**

**First Line**

- Normal saline or lactated Ringer solution is the fluid of choice for initial fluid resuscitation. An initial 20 cc/kg bolus is appropriate.
- Specific medications as appropriate for condition

**Second Line**

- Sodium bicarbonate (NaHCO<sub>3</sub>) administration is based on the following formulas:
- Mild to moderate acidosis (7.20–7.37): HCO<sub>3</sub> deficit = [20 mEq/L (normal serum level) – (measured serum level)] × 20% total body weight in kilograms:
  - For example: A 10-kg child with a pH of 7.25 and HCO<sub>3</sub> of 15 should receive 25 mEq HCO<sub>3</sub>.

- Severe acidosis (pH <7.2): HCO<sub>3</sub> deficit = [20 mEq/L (normal serum level) – (measured serum level)] × 50% total body weight in kilograms:
  - For example: A 10-kg child with a pH of 7.16 and HCO<sub>3</sub> of 10 should receive 50 mEq HCO<sub>3</sub>.
- Complete correction should not be attempted in the emergency department. A serum bicarbonate level of 15–18 mEq/L and/or pH ≥7.25 should be the goal:
  - Complications of bicarbonate treatment are hypokalemia, alkalosis, CSF acidosis, sodium overload (with the use of NaHCO<sub>3</sub>), and hypocalcemia.
  - The use of bicarbonate in DKA is controversial. Children with DKA treated with NaHCO<sub>3</sub> are at a higher risk for cerebral edema.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Tromethamine (THAM) is a sodium-free alkalinizing solution. It can be used to prevent and correct acidosis. It increases serum bicarbonate:
  - Dosing: 0.5–1 mEq/kg/dose IV (1.66–3.33 mL/kg/dose)
  - IV dosing based on base deficit (BD): mL of 0.3 mol/L THAM = body weight (kg) × BD (mEq/L) × 1.1. Titrate according to serum pH.
  - Close monitoring is warranted because it can cause respiratory depression and hypoglycemia.
- Alcohol ingestion (ethylene glycol, methanol, or isopropyl alcohol) is associated with elevated AG metabolic acidosis. Consider use of fomepizole, ethanol, or hemodialysis.

**DISPOSITION**

**Admission Criteria**

- Admission is recommended for all children with significant metabolic acidosis, especially if the underlying etiology is not apparent or if the acidosis is not corrected in the emergency department.
- Critical care admission criteria:
  - Unstable vital signs, shock or impending shock, significant electrolyte abnormalities, or pH <7.1

**Issues for Referral**

Consider early consultation with toxicology, endocrine, surgery, or nephrology depending on the suspected or confirmed cause of the metabolic acidosis.

**FOLLOW-UP**

**PROGNOSIS**

Prognosis is highly variable and dependent on the etiology and the speed with which interventions are made.

**COMPLICATIONS**

- Complications vary depending on the etiology. Most severe and concerning complications include:
  - Seizure
  - Permanent neurologic sequelae
  - Shock
  - Death
- Complications of bicarbonate treatment are hypokalemia, alkalosis, CSF acidosis, sodium overload (with the use of NaHCO<sub>3</sub>), and hypocalcemia.

**ADDITIONAL READING**

- Glaser N, Barnett P, McCaslin I, et al. Risk factors for cerebral edema in children with diabetic ketoacidosis. The Pediatric Emergency Medicine Collaborative Research Committee of the American Academy of Pediatrics. *N Engl J Med*. 2001;344(4):264–269.

**CODES**

**ICD9**

- 276.2 Acidosis
- 276.4 Mixed acid-base balance disorder
- 775.81 Other acidosis of newborn

**PEARLS AND PITFALLS**

- Metabolic acidosis is a nonspecific lab finding indicating an underlying disease process requiring treatment.
- Diarrheal dehydration is the most common cause of elevated AG metabolic acidosis.
- Early identification of the underlying cause for metabolic acidosis is key for appropriate management of these patients. Morbidity and mortality are directly related to the underlying disease process.
- Maintain a high index of suspicion for toxin exposure, including MUDPILES toxins.

# METHEMOGLOBINEMIA

Daniel M. Lugassy

## BASICS

### DESCRIPTION

- Methemoglobinemia (MetHb) is a potentially life-threatening condition characterized by elevated methemoglobin, causing cyanosis and functional hypoxia.
- MetHb exists when the iron-containing heme portion of hemoglobin is oxidized from the ferrous (Fe<sup>2+</sup>) to the ferric (Fe<sup>3+</sup>) state.
- In the ferric state, iron cannot bind oxygen and does not transport oxygen, causing cellular hypoxia.
- MetHb can occur via acquired (ie, oxidative stress from medications, chemicals, sepsis, etc.) and congenital causes.
- Patients with MetHb classically present with cyanosis, decreased pulse oximetry readings, and chocolate brown-colored arterial blood.
- The clinical effects depend on the magnitude of MetHb and comorbidities.
- In healthy patients MetHb levels <10% may produce little to no symptoms, and values >50% may cause systemic hypoxia that may be fatal.

### EPIDEMIOLOGY

- The congenital causes of MetHb are so rare that the true incidence and prevalence are unknown.
- Most of the acquired causes of MetHb are still believed to be idiosyncratic without predictable responses to repeated or increasing dosing to known oxidants.
- Benzocaine (ethyl aminobenzoate), a topical anesthetic used in adults and pediatrics is a well-known cause of MetHb that has been studied in several reviews, demonstrating a rate of 0.067–0.115% of patients developing MetHb.
- Most of the data regarding the incidence of each individual causative agent is unreliable due to underreporting.

### RISK FACTORS

- Any abnormalities that impair the normal ability to reduce MetHb back to its functional form increases the risk of clinically significant MetHb, such as methemoglobin reductase deficiency.
- Patients with cardiovascular/hematologic comorbidities such as chronic obstructive pulmonary disease (COPD), anemia, coronary artery disease, or recent surgery
- Increased metabolic demand such as sepsis, shock, and dehydration
- Specific pediatric risk factors:
  - Age <4 mo (lack of the functional enzyme that reduces MetHb)
  - Fetal hemoglobin more susceptible to oxidation
  - Low birth weight, prematurity, dehydration, acidosis, diarrhea, and hyperchloremia

### GENERAL PREVENTION

- Patients with known congenital defects that predispose to MetHb should avoid known oxidant exposures.
- Pediatricians should recognize that younger patients (especially those <4 mo of age) are at high risk and must be aware of the common acquired causes of MetHb and recognize the risk factors.
- Do not use benzocaine in children, particularly for teething.

### PATHOPHYSIOLOGY

- Hemoglobin is under constant oxidative stress; up to 3% MetHb is normal.
- MetHb is formed when the iron-containing heme portion of hemoglobin is oxidized from the ferrous (Fe<sup>2+</sup>) to the ferric (Fe<sup>3+</sup>) state.
- MetHb is a functional anemia resulting in impaired oxygen delivery to the tissues because:
  - MetHb is unable to bind oxygen.
  - MetHb induces detrimental conformational changes, impairing oxygen delivery.
  - MetHb impairs normal hemoglobin's ability to deliver oxygen by increasing oxygen affinity on the remaining oxygen binding sites.
- MetHb reducing mechanisms:
  - Significant elevated levels of MetHb occur when reducing mechanisms are exceeded.
  - Methemoglobin reductase (NADH-cytochrome b5 reductase) is the primary enzyme responsible for the reduction of MetHb; this enzyme requires ample amounts of NADH.
  - NADPH reductase: Minor responsibility in reducing MetHb; requires NADPH
  - Ascorbic acid and reduced glutathione are also minor pathways in the reduction of MetHb, probably only beneficial in congenital MetHb.
- The severity of clinical symptoms depends on the extent of MetHb production, rate of reduction, and underlying comorbidities.
- Patients with hereditary conditions have compensatory mechanisms allowing them to adapt better compared to acquired causes with similar MetHb levels.
- Cyanosis develops because of the color imparted on the skin by the oxidized state of iron in MetHb and not by deoxyhemoglobin, as occurs in a condition of peripheral hypoxia.
- MetHb concentrations are the signs and symptoms likely to present in the healthy patient with acquired MetHb:
  - 0–3% (normal): No symptoms
  - 3–15%: None to mild symptoms, slate gray cutaneous coloration, pulse oximeter may begin to read low
  - 15–20%: Cyanosis, chocolate brown blood
  - 20–50%: Dyspnea, headache, fatigue, dizziness, syncope, and weakness
  - 50–70%: Tachypnea, metabolic acidosis, seizures, CNS depression, and coma
  - >70%: Severe hypoxic symptoms; death

- Pediatric considerations:
  - Diminished MetHb reductase activity (<4 mo of age)
  - Fetal hemoglobin is easier to oxidize.
  - Higher gastric pH in infancy may allow bacterial growth and increased nitrate absorption.
  - Dietary exposure to nitrites/nitrates: Well water, home processed/pureed food
  - An association in infants exists among gastroenteritis and the development of MetHb, vomiting, diarrhea, acidosis, and leukocytosis.

### ETIOLOGY

- Acquired causes are the most common and include medication, chemical, and metabolic/systemic causes.
- Congenital causes such as methemoglobin reductase deficiency or hemoglobin M
- Medications:
  - Dapsone, benzocaine, phenazopyridine, and sodium nitrate are very common causes.
  - Development of MetHb is unpredictable and may occur after a single exposure to a medication or prolonged therapeutic use.
  - Other drugs known to cause oxidant stress leading to MetHb production: Amyl nitrite, local anesthetics (Cetacaine, lidocaine, prilocaine, procaine), nitric oxide, nitroglycerin, nitroprusside, phenacetin, quinones (chloroquine, primaquine), sulfonamides (sulfanilamide, sulfathiazole, sulfapyridine, sulfamethoxazole)
- Chemicals:
  - Aniline dye derivatives (shoe dyes, marking inks), butyl nitrite, chlorobenzene, fires (heat-induced denaturation), well water, or food adulterated or with high levels of nitrites, isobutyl nitrite (common drug of abuse often called “poppers”), naphthalene (mothballs), trinitrotoluene

### COMMONLY ASSOCIATED CONDITIONS

- Metabolic, cardiovascular, systemic, or infectious conditions often exist, overwhelming the normal reducing capabilities of MetHb.
- Congenital disorders of decreased methemoglobin reductase, and NADPH reductase activity

## DIAGNOSIS

### HISTORY

- Symptoms of cyanosis, breathlessness, and dyspnea
- It is critical to attempt to identify the possible etiology of acquired MetHb to remove the patient from further exposure:
  - Exposure to medications, food, or chemicals
- Family history of MetHb

### PHYSICAL EXAM

- Findings will be determined by the magnitude, rate of formation, and elimination of MetHb.
- Comorbidities, current illnesses, and anemia will determine the significance of the functional anemia caused by rising MetHb.

- Cyanosis:
  - Depends on the total content of MetHb
  - Requires 1.5 g/dL of MetHb to be present, (10% MetHb concentration in a healthy individual with a hemoglobin of 15 g/dL, while it would require a MetHb of 33% in an anemic patient who has hemoglobin of 7.5 g/dL)
  - Should not improve with oxygen
  - Central and peripheral skin change
  - Symptoms often out of proportion to what would be expected from degree of cyanosis
  - Tachycardia, tachypnea, altered mental status, seizures, and coma in severe cases

**DIAGNOSTIC TESTS & INTERPRETATION**

**ALERT**

- Bedside pulse oximetry uses only light absorbances at wavelengths for deoxy- and oxyhemoglobin to calculate measurements.
- MetHb is not accounted for and, in addition, alters the readings obtained,
- Measurements in patients with significant elevations in MetHb will often range between 75% and 85%, but this is not true of all cases.
- Normal readings do not rule out MetHb.
- MetHb is quantitatively diagnosed by co-oximetry using blood gas analysis.
- Co-oximetry measures light absorbances at multiple wavelengths, allowing accurate determination of all hemoglobin species. It will provide the true oxygen saturation value as well as the precise MetHb concentration.

**Lab**

**Initial Lab Tests**

- Measurement of MetHb concentration by co-oximetry using blood gas:
  - Venous blood gas is preferred, as it provides the same information and is less invasive to obtain.
- Blood gas analysis to assess oxygenation, ventilation, and tissue perfusion
- Consider serum electrolytes and lactate.

**DIFFERENTIAL DIAGNOSIS**

- Other cyanotic disorders: Cyanotic congenital heart disease, pulmonary disease
- Skin discoloration such as argyria (silver toxicity), chronic/massive blue dye ingestion, other drugs (amiodarone, antimalarials)
- Sulfhemoglobinemia:
  - Occurs from sulfur incorporated into heme
  - Similar to MetHb in that oxygen-carrying capacity is decreased, milder symptoms
  - Considered if patient does not respond to methylene blue therapy for MetHb

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Administer 100% oxygen.
- Provide supplemental dextrose, which is necessary for NADH and NADPH production.
- Discontinue the offending agent as soon as possible.
- MethB that is mild (<25% in healthy individuals who are cyanotic) but otherwise asymptomatic can be resolved by discontinuing the offending drug and observation.
- Patients with MetHb associated with dapsone use are at particular risk for recurrent symptoms due to the long half-life of dapsone:
  - Repeated treatment with methylene blue may be needed.

**MEDICATION**

- Methylene blue:
  - Dosing: 1–2 mg/kg (0.1–0.2 mL/kg of 1% methylene blue) IV over 5 min
  - Indications:
    - Elevated MetHb with symptoms of cardiopulmonary compromise or other end organ damage; tachycardia, tachypnea, myocardial ischemia, dysrhythmia, altered mental status, seizures, coma
    - Metabolic acidosis
    - MethB concentrations >25% even without symptoms
    - May use in lower MetHb concentrations in patients with baseline anemia or hypoxia
- Methylene blue is reduced by NADPH MetHb reductase to leukomethylene blue, which reduces MetHb back to normal hemoglobin.
- If cyanosis does not resolve in 1 hr, a repeat dose can be given. Consider the following: inadequate original dose, G6PD deficient, inadequate decontamination, NADPH reductase deficiency, sulfhemoglobinemia
- Relative contraindications:
  - G6PD deficiency: NADPH is required to reduce methylene blue to leukomethylene to function as a reducing agent of MetHb. It is not produced in ample amounts in G6PD.
  - The use of methylene blue may have no value in the G6PD-deficient patient.
- Hemolysis:
  - Methylene blue itself is an oxidizing agent and may cause hemolysis and MetHb if it is unable to be reduced to leukomethylene blue.
  - Potential reason to avoid using methylene blue in G6PD-deficient patients

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Cimetidine (a potent CYP450 inhibitor) is often given to patients with MetHb from dapsone because it prevents the conversion of dapsone to its MetHb-inducing metabolite.
- For patients who fail methylene blue therapy:
  - Hyperbaric oxygen
  - Exchange transfusion

**DISPOSITION**

**Admission Criteria**

- Admit all patients who are cyanotic, dyspneic patients with clinically significant MetHb, or any patients with a MetHb level >20%.
- Critical care admission criteria:
  - Unstable vital signs or severe illness

**Discharge Criteria**

Patient stable with no significant MetHb concentration and no perceived continued risk

**Issues for Referral**

Consider consultation with a poison control center or medical toxicologist.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Several months after resolution, it may be warranted to test the patient for hereditary causes of MetHb or G6PD deficiency in treatment failures.

**PROGNOSIS**

Patients usually make a full and complete recovery.

**COMPLICATIONS**

- Sequelae are related to the amount of hypoxic damage if any occurs systemically.
- Death is rare and is usually seen with MetHb >70% or in patients with significant comorbidities.

**See Also (Topic, Algorithm, Electronic Media Element)**

Cyanosis

ICD9  
289.7 Methemoglobinemia

**PEARLS AND PITFALLS**

- Suspect MetHb based on cyanosis unresponsive to oxygen therapy in the appropriate setting.
- Pulse oximetry readings are inaccurate due to inability to account for MetHb. Co-oximetry measurement of blood gas is required.
- Methylene blue is curative, but use with caution or avoid altogether in G6PD deficiency.

# MIGRAINE HEADACHES

Esther D. P. Ho  
Vincent J. Wang

## BASICS

### DESCRIPTION

- Migraine headaches (MHs) are a common primary cause of unilateral or bilateral headaches (HAs), often accompanied by nausea, vomiting, photophobia, phonophobia, and sensory aura:
  - MHs are more commonly bilateral and frontotemporal in young children as compared to those in adults.
  - An adult pattern of unilateral pain usually develops later in adolescence or adulthood.
- Among diseases causing disability, MHs are ranked 19th by the World Health Organization (1).
- According to the International Headache Society (IHS), pediatric migraines can be divided into 3 primary categories: (1) migraine without aura, (2) migraine with aura, and (3) childhood periodic syndromes that are common precursors of migraines:
  - The IHS has also categorized retinal migraines separately from these primary migraine types.
- Migraines without auras (previously known as common migraines) account for 80% of MHs. According to the IHS (1), diagnostic criteria are at least 5 attacks, accompanied by:
  - HA lasting 1–72 hr
  - HA with at least 2 of the following:
    - Unilateral location (can be bilateral in children <15 yr of age)
    - Pulsating quality
    - Moderate to severe pain intensity
    - Causing avoidance of or aggravation by routine physical activity
  - During the HA, at least 1 of the following must accompany the HA:
    - Photophobia or phonophobia
    - Nausea and/or vomiting
  - HA is not attributable to another disorder.
- Migraines with auras (previously known as classic migraines) account for 20% of MHs. According to the IHS (1), diagnostic criteria are at least 2 attacks of HAs with a migraine aura:
  - Migraine auras typically consist of reversible focal neurologic symptoms, developing gradually over 5–20 min, lasting <60 min, with the HA following the aura symptoms. The following subtypes exist:
    - Typical aura with MH
    - Typical aura with non-MH
    - Typical aura without HA
    - Familial hemiplegic migraine (FHM)
    - Sporadic hemiplegic migraine
    - Basilar-type migraine
  - HA not attributable to another disorder
- Periodic syndromes of childhood that are commonly precursors of migraine (which develop later in life) include the following:
  - Benign paroxysmal vertigo:
    - Occurs in young children with  $\geq 5$  abrupt episodes of unsteadiness or ataxia that resolve within minutes to hours
    - Episodes often are associated with nystagmus or vomiting; unilateral HAs can occur with some episodes.

- Cyclic vomiting syndrome:
  - Recurrent;  $\geq 5$  episodes are characterized by intense nausea and vomiting lasting 1 hr to 5 days with symptom-free periods.
- Abdominal migraine:
  - Recurrent;  $\geq 5$  episodes of vague, midline or periumbilical pain with anorexia, nausea, vomiting, or pallor with interval wellness
- Benign paroxysmal torticollis (not included by the IHS) may be a 4th childhood migraine precursor (2).
- Retinal migraines involve repeated attacks of monocular visual disturbance associated with a MH (1).
- Some patients also experience a premonitory phase occurring hours to days before the HA, including symptoms such as repetitive yawning, hypo- or hyperactivity, depression, craving for particular foods, and other symptoms.

### EPIDEMIOLOGY

#### Prevalence

- $\sim 10\%$  of the U.S. population suffers from migraines (3):
  - 1 in 6 (17%) women have MHs.
  - 6% of men have MHs.
- Migraines in children occur in (4):
  - 3% of children age 3–7 yr
  - 4–11% of children age 7–11 yr
  - 8–23% of children age 12–15+ yr

### RISK FACTORS

- The following conditions may be precursors to migraines: Benign paroxysmal vertigo, cyclic vomiting, abdominal migraine, paroxysmal torticollis, or acute confusional migraine.
- Family history of FHM

### GENERAL PREVENTION

Avoid precipitants if known.

### PATHOPHYSIOLOGY

The pathophysiology of MHs is unknown.

### ETIOLOGY

- Unknown for most migraine variants
- FHM mutations of specific genes (1,2)

## DIAGNOSIS

### HISTORY

- The aura should precede onset of the HA; the HA may begin after or during the aura.
- Reversible symptoms of aura (1):
  - Typical aura with MH:
    - Typical aura develops preceding the HA, lasting  $\leq 60$  min
    - No motor symptoms
    - Sensory symptoms are homonymous and/or unilateral
    - Mix of positive and negative features
    - Visual symptoms: Presence of flickering spots, lines, lights (positive features); loss of vision (negative feature)
    - Sensory symptoms: Presence of pins and needles sensation; numbness
    - Dysphasic speech disturbance
    - Different symptoms may occur in sequence.

- Typical aura with non-MH:
  - Similar aura but with a non-MH
- Typical aura without HA:
  - Similar aura but without HA
- Familial hemiplegic migraine:
  - 1st- or 2nd-degree relatives have migraine auras.
  - Reversible motor weakness
  - Visual, sensory, dysphasic speech symptoms (as with aura above)
  - Different symptoms may occur in sequence.
- Sporadic hemiplegic migraine:
  - Same as FHM except there are no 1st- or 2nd-degree relatives with migraine auras
- Basilar-type migraine:
  - Migraine with aura originating from the brainstem and/or both hemispheres are simultaneously affected
  - No motor weakness
  - At least 2 of the following symptoms: Dysarthria, diplopia, visual symptoms, vertigo, tinnitus, hypacusia, decreased level of consciousness, ataxia, paresthesias
  - Different aura symptoms may occur in sequence and may last 5–60 min.
- Retinal migraines:
  - Reversible monocular visual disturbance (scotomas, hemianopsia, scintillations, etc.)
  - Confirmed visual deficit by exam during the attack, with a normal exam between attacks
- Characterize the HA:
  - Frontotemporal in location:
    - Occipital HAs suggest another cause.
  - Pulsatile, throbbing pain
  - Unilateral or bilateral pain
  - Should be similar to previous episodes
  - Different symptoms suggest other causes
- Associated symptoms:
  - Nausea and/or vomiting
  - Photophobia or phonophobia
- Past medical history of MH:
  - Current medications
  - Previous success/failure of MH medications
- Family history of MHs (70–80%)
- Pertinent negative elements of history:
  - No history of head trauma
  - No fever or meningismus
  - No systemic illness, weight loss, malaise

### PHYSICAL EXAM

- During the aura, the following may exist:
  - Visual field defects
  - Sensory defects
  - Motor weakness
- The physical exam should be normal after the aura.
- Presence of physical exam abnormalities after the aura has resolved suggests other causes but may still be associated with the migraine.

**DIAGNOSTIC TESTS & INTERPRETATION**

The diagnosis of MHs is clinical, especially with a past history or family history of MHs.

**Imaging**

- Imaging is typically not necessary with known diagnosis of MH.
- Consider intracranial CT scan for atypical symptoms if concern for other processes exists:
  - Imaging may be necessary for the 1st episode of migraine symptoms.

**DIFFERENTIAL DIAGNOSIS**

- Common HA: Cluster, tension, withdrawal
- Meningitis and encephalitis
- Intracranial masses
- Intracranial/Subarachnoid hemorrhage
- Pseudotumor cerebri
- Temporal arteritis
- Sinusitis
- Carbon monoxide poisoning
- Temporal mandibular joint syndrome
- Stroke: Hemorrhagic and ischemic
- Epilepsy
- Retinal detachment, ocular foreign bodies (for retinal migraines)
- Gastroenteritis, appendicitis, bowel obstruction (for abdominal migraines)
- HTN

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Assess ABCs.
- IV rehydration as needed for dehydration

**MEDICATION**

- Adult studies have shown migraine relief from multiple triptans, NSAIDs, aspirin, combinations of acetaminophen/aspirin/caffeine, and opiates (5).
- Pediatric studies: In 2 systematic reviews of pharmacotherapy for migraines, both concluded that acetaminophen, ibuprofen, and sumatriptan (intranasal) showed moderate efficacy in the acute treatment of migraines in children (4,6,7).

**First Line**

- Acetaminophen 15 mg/kg/dose PO/PR q4h
- Ibuprofen 10 mg/kg/dose PO/IV q6h
- Triptans: While generally safe, triptans are not FDA approved for children:
  - Sumatriptan (Imitrex) intranasal: 5, 10, or 20 mg spray in 1 nostril for adolescents; may repeat in 2 hr. Max dose is 40 mg/day.

**Second Line**

- Triptans: The following triptans have been shown to be helpful in adult studies but may not be effective in children:
  - Sumatriptan (Imitrex):
    - SC: 0.06 mg/kg/dose in children, 6 mg in adults; may repeat in 1 hr. Max single dose is 12 mg/day.
    - Oral: Adult dose is 25–100 mg; may repeat in 2 hr.
  - Rizatriptan (Maxalt): 5–10 mg oral dissolving tablets; may repeat in 2 hr. Max single dose is 30 mg/day.
  - Zolmitriptan (Zomig): 2.5 mg PO in adolescents
- Dihydroergotamine (DHE):
  - IV: 0.5–2 mg/dose, repeat q1h to 2 mg
  - IM: 1 mg/dose

- Adjuncts may help nausea and vomiting and have effects on aborting MHs as monotherapy:
  - Prochlorperazine (Compazine):
    - Adolescents: 5 mg IV q12h
  - Metoclopramide (Reglan):
    - Children 6–14 yr of age: 2.5–5 mg IV/IM q8h
    - Adolescents and adults: 10 mg IV/IM q8h
- For nausea and vomiting alone:
  - Ondansetron (Zofran):
    - 0.15 mg/kg/dose IV/PO q8h. Max single dose is 8 mg.

**Third Line**

- Acetaminophen with codeine PO
- Morphine sulfate IV, IM

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Minimize environmental stimulation.
- Relaxation techniques
- Stress management and biofeedback
- Acupuncture

**DISPOSITION****Admission Criteria**

- Severe unremitting HAs requiring frequent narcotic pain relief
- Protracted vomiting requiring IV hydration

**Discharge Criteria**

Adequate hydration and pain control

**Issues for Referral**

Neurology for persistent HAs refractory to maximal medical therapy

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Follow up with the primary care provider PRN.
- Medications as noted:
  - Take the appropriate recommended dose as soon as the HA begins.
  - Avoid using analgesics >3 doses per week.
- A HA diary and a plan for abortive, rescue medications may be discussed with the patient but should be supervised by the primary care provider:
  - Migraine prophylaxis should be considered.
- Activity as tolerated:
  - Minimize sounds, lights, and identified triggers.

**PROGNOSIS**

- Generally good
- In adult studies, recent evidence has linked migraine to a broader range of ischemic vascular disorders including angina, claudication, coronary revascularization, and MI (8).

**COMPLICATIONS**

- Dehydration
- Absence from school or work activities

**ICD-9 CODES****ICD9**

- 346.00 Migraine with aura, without mention of intractable migraine without mention of status migrainosus
- 346.10 Migraine without aura, without mention of intractable migraine without mention of status migrainosus
- 346.20 Variants of migraine, not elsewhere classified, without mention of intractable migraine without mention of status migrainosus

**PEARLS AND PITFALLS**

- Early treatment of MHs may attenuate symptoms and decrease the amount of overall therapy necessary:
  - Teach patients to start medications at the onset of symptoms.
- Atypical symptoms suggest causes of HA other than migraine.
- Avoid narcotics if possible.

# MOLLUSCUM CONTAGIOSUM

Kate Cronan

## BASICS

### DESCRIPTION

- Molluscum contagiosum (MC) is a common cutaneous viral illness caused by a pox virus.
- The rash is characterized by flesh-colored clusters of papules.
- It is spread by autoinoculation.
- There is bimodal distribution of disease:
  - School-age children contract MC by close physical contact with siblings and peers (1).
  - Adolescents and adults contract MC as an STI affecting genital areas, contracted skin trauma, and inoculation from sex partner.

### EPIDEMIOLOGY

- Humans are the only known source of the virus.
- Outbreaks are common in the tropics.

### Incidence

- There has been a dramatic increase in MC cases in recent years (2).
- Boys are affected 3 times as frequently as girls.
- Incidence is as high as 7–20% in the pediatric population (1).
- School-aged children have the highest incidence of new cases.

### RISK FACTORS

- Atopic dermatitis (2)
- Immunocompromised patients such as those with cancer, transplanted organs, or HIV (2)
- Swimming in a chlorinated pool (2)
- Sexual activity if 1 partner has MC lesions
- Participation in sports such as wrestling and track (1)

### GENERAL PREVENTION

- Avoiding shared baths and towels of patients with MC
- Covering lesions with clothes or watertight bandages when swimming aids in prevention of spread to others.

### PATHOPHYSIOLOGY

Infection is by direct contact with an infected child or from fomites.

### ETIOLOGY

MC is caused by a poxvirus, a large double-stranded DNA virus that replicates in the cytoplasm of host epithelial cells.

### COMMONLY ASSOCIATED CONDITIONS

- Atopic dermatitis
- In sexually active teens, other STIs may occur in association with MC.

## DIAGNOSIS

### HISTORY

- Flesh-colored papules, often in clusters
- A variable number of papules may be present—from 10–20 papules to overwhelming numbers in immunocompromised patients.
- Lesions are often present for weeks or months before medical attention is sought.
- No systemic complaints such as malaise or fever
- No inflammation reported
- Some patients have a history of pruritus associated with rash, especially when atopic dermatitis coexists.
- There may be a history of sexual contact with another person who has the infection.
- Genital lesions could indicate a history of child abuse, but many children have lesions in this area with no sexual exposure.

### PHYSICAL EXAM

- Multiple, discrete, flesh-colored pearly papules usually noted in clusters
- Classically, the lesion has an umbilicated central area.
- In contrast to vesicles associated with herpes, lesions are solid tissue/flesh and are not fluid filled.
- There may be linear configurations of the lesions.
- Lesions vary in size from 2–8 mm.
- Absence of swelling, erythema, or warmth
- Lesions are often located on the face, neck, eyelids, trunk, face, extremities, and axillae.
- Occasionally, lesions are noted on the genital mucosa and conjunctivae.
- Surrounding dermatitis is common.
- In HIV patients, lesions may be large and numerous.
- If genital or sexually transmitted MC, perform a bimanual pelvic exam to assess for pelvic inflammatory disease.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- MC is generally a clinical diagnosis; routine lab testing is not indicated or diagnostic.
- Testing for associated STIs, such as gonorrhea/chlamydia, syphilis, and HIV are appropriate if MC was contracted by sexual contact.

##### Pathological Findings

- The molluscum papule consists of a lobulated sticky mass of virus-infected epidermal cells.
- Dermatologic removal of the central plug of a lesion, when examined, reveals a cup-shaped mass of homogenous cells often with lobules; this is diagnostic.
- Henderson-Patterson or molluscum bodies become more prominent as the cells advance upward from the basal layer toward the stratum corneum.
- Wright or Giemsa staining of the cells from the central core of the lesion shows intracytoplasmic inclusions.
- Electron microscopy shows typical poxvirus particles.

### DIFFERENTIAL DIAGNOSIS

- Varicella
- Trichoepithelioma
- Basal cell carcinoma
- Ectopic sebaceous glands
- Warts, human papillomavirus
- Warty dyskeratoma
- In HIV patients: Cryptococcosis

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Treatment is supportive.
- Although therapies to enhance clearance of lesions exist, for immunocompetent patients the natural history will be clearance and resolution regardless of whether treatment is given or not.

**MEDICATION****First Line**

Topical corticosteroids and antipruritics may be used to treat patients with underlying atopic dermatitis or significant pruritus:

- 1% or 2.5% hydrocortisone ointment applied b.i.d.
- Diphenhydramine 1 mg/kg PO q4–6h PRN for pruritus
- Loratadine: 2–5 yr of age, 5 mg PO per day; >5 yr, 10 mg PO per day PRN for itching:
  - Less sedating than diphenhydramine but less effective

**Second Line**

- In many cases, treatment is not indicated and watchful waiting is recommended.
- Currently, there are no treatments for MC that are approved by the FDA (2).
- Definitive treatment is usually not initiated in the emergency department but rather under the guidance of a dermatologist.
- Use of chemical agents such as cantharidin, tretinoin, and podophyllin to initiate a local inflammatory response:
  - Cantharidin induces vesiculation of the skin.
  - Should be used by clinicians experienced with applications, as severe blistering results:
    - When skillfully used, it is the treatment of choice (1).
    - Do not give to parents/patients for home application; is highly toxic and sometimes fatal if ingested even in small amounts and causes severe skin blistering when applied topically.
    - Recommended concentration is 0.7% or 0.9%.
- Immunologic therapies include Imiquimod:
  - Assists the immune clearance of MC infection
  - Application 3 times a week or every other day for several weeks

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Candida antigen
- Cimetidine
- Antiviral therapies include cidofovir, which should be reserved for recalcitrant MC; other than immunocompromised adult patients, there is not much experience with the use of this medication for MC (3).
- Pulse dye laser may be considered in specific cases (2).

**SURGERY/OTHER PROCEDURES**

- Cryotherapy is a very commonly used method of treatment:
  - Eliminates lesions and may accelerate development of antibodies to virus
- Curettage

**DISPOSITION**

- Well-appearing immunocompetent patients may be discharged.
- Follow up with a dermatologist or general pediatrician if capable of providing ongoing care.

**Issues for Referral**

- Patients with MC who are immunocompromised should be referred to a dermatologist.
- Patients with recalcitrant lesions or significant pruritus should be referred for treatment by a dermatologist.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Advise patient that recurrence is common and of the expected course; recurrence does not usually denote treatment failure.
- Patients should be instructed to avoid scratching lesions.
- Parents should be reassured and encouraged to seek care if lesions become inflamed or appear to be infected.

**PROGNOSIS**

- Self-limited condition, with the average attack lasting 6–9 mo (2)
- In some patients, lesions persist for years (1).
- Scarring may occur.

**COMPLICATIONS**

- Secondary infection
- Scarring
- In patients with MC eyelid lesions, chronic conjunctivitis or superficial keratitis may occur.

**ICD9**  
078.0 Molluscum contagiosum

**PEARLS AND PITFALLS**

- In young children, lesions in the perineal area are usually not indicative of sexual abuse.
- Symptomatic treatment for MC may be initiated by emergency department physicians; however, more definitive therapy should be guided by a dermatologist.

# MUMPS

Mercedes M. Blackstone

## BASICS

### DESCRIPTION

- The CDC clinical case definition of mumps: “An illness with acute onset of unilateral or bilateral tender, self-limited swelling of the parotid or other salivary gland(s), lasting at least 2 days, and without other apparent cause”
- Only cause of epidemic parotitis

### EPIDEMIOLOGY

#### Incidence

- Occurs worldwide
- Cases in the U.S. have fallen dramatically since the introduction of the live attenuated mumps vaccine in 1967.
- Mumps is now a reportable disease in the U.S.
- There have been several outbreaks in susceptible individuals since vaccine licensure.
- Contracting mumps confers lifelong immunity.
- Since 2000, excluding epidemics, there were <350 reported cases per year in the U.S.
- In 2006, a large epidemic occurred in the midwestern U.S. with >6,000 reported cases, mostly among college students.
- Prior to widespread vaccination, mumps was mostly a disease of childhood with peak incidence in late winter and early spring:
  - Recent outbreaks, however, have mostly affected adolescents and adults and have no seasonality.

### RISK FACTORS

- Close living quarters
- Lack of or inadequate vaccination
- Waning immunity

### GENERAL PREVENTION

- The live mumps virus contained in the measles, mumps, rubella (MMR) vaccine is recommended for disease prevention:
  - Childhood immunization schedule is 0.5 mL at 12–15 mo and again at 4–6 yr.
  - Immunocompromised children should not be vaccinated.
  - College students should have evidence of 2 doses of vaccine.
  - 2-dose effectiveness is ~90%.
  - Outbreaks have occurred even in well-vaccinated populations due to close living conditions, waning immunity, and antigenic variation of viruses.
  - There is no proven link between the MMR vaccine and autism.
  - The MMR vaccine can cause a fever and rash 7–10 days after it is given.
- Natural infection with the mumps virus usually confers lifelong immunity, but mild or atypical reinfection can occur.

### PATHOPHYSIOLOGY

- Mumps is acquired through contact with respiratory droplets and saliva.
- The virus replicates in the nasopharynx and lymph nodes.
- After an incubation period of 12–25 days, viremia occurs, lasting 3–5 days:
  - During this time, the virus commonly spreads to the parotid glands as well as the meninges, testes, ovaries, and pancreas, causing inflammation of these tissues.
  - Mumps is highly contagious, with the peak infectious period lasting from 2 days prior to symptom onset to 5 days after.

### ETIOLOGY

- Mumps is a single-stranded RNA virus in the Paramyxovirus family.
- Humans are the only known reservoir for mumps.

### Pregnancy Considerations

- Mumps infection in the 1st trimester has been associated with an increased risk of spontaneous abortions.
- Pregnant women should not receive the MMR vaccine.

### COMMONLY ASSOCIATED CONDITIONS

- Parotitis
- Orchitis
- Aseptic meningitis
- Pancreatitis

## DIAGNOSIS

### HISTORY

- Often presents with nonspecific prodromal symptoms including fever, malaise, myalgias, anorexia, and headache
- Parotitis usually ensues within ~48 hr of symptom onset:
  - Can be unilateral, bilateral, or subclinical
  - Often begins as otalgia and pain over the angle of the jaw
  - Progresses to pain and swelling over the parotid gland, both pre- and postauricular
- 1/3 of patients present with respiratory symptoms, with no significant parotitis.
- Complaints of localized pain may point to specific complications such as meningitis, orchitis, or pancreatitis.

### PHYSICAL EXAM

- Patients with mumps may exhibit the following:
  - Nonerythematous unilateral or bilateral parotid swelling and tenderness
  - Swelling of other salivary glands
  - Swelling and erythema of Stensen’s duct, where the parotid gland inserts in the mouth (at level of upper 2nd molar)
  - Parotid pain worsens with salivation.
- Morbilliform rash may rarely be present.
- Mumps orchitis presents with testicular pain and swelling with associated systemic symptoms.
- Aseptic meningitis presents with fever and neck stiffness.
- Epigastric tenderness may result from pancreatitis.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Lab studies are not required in patients with a typical presentation.
- Leukopenia with lymphocytosis and elevated serum amylase support the diagnosis.
- Serum lipase may be used to detect pancreatic involvement.
- Gram stain and culture of pus from salivary gland
- Lumbar puncture if meningitis is suspected
- Infection can be diagnosed in several ways:
  - Serology:
    - Mumps IgM (positive 3 days after symptom onset, peaks after 1 wk)
    - Rise in IgG titers between acute and convalescent specimens (2–3 wk later)
    - May not be reliable in vaccinated individuals
  - Detection of viral RNA by polymerase chain reaction or viral culture from clinical specimen (eg, swab from parotid duct, saliva, urine, CSF)

#### Imaging

US or CT may rarely be indicated to rule out a pseudocyst in mumps pancreatitis.

**DIFFERENTIAL DIAGNOSIS**

- Dental abscess
- Other causes of parotitis or similar swelling:
  - Other viral infections: Epstein-Barr virus, cytomegalovirus, adenovirus, influenza A, parainfluenza, HIV, enterovirus
  - Bacterial infections: *Staphylococcus aureus*, rarely nontuberculous mycobacterium, cat scratch disease
  - Mechanical obstruction: Salivary calculi, tumors
  - Autoimmune diseases: Sjögren syndrome, sarcoidosis, Wegener's granulomatosis
  - Metabolic: Diabetes mellitus, malnutrition
  - Iatrogenic: Thiazide diuretics, iodide contrast media, other medications
  - Other: Juvenile recurrent parotitis, polycystic parotid disease, pneumoparotitis

**TREATMENT**

- Treatment of mumps is generally supportive and includes the following:
  - Analgesics and antipyretics
  - Warm or cold packs to the parotid gland
- Patients with mumps orchitis respond to bed rest, NSAIDs, ice packs, and scrotal support.

**MEDICATION**

- Ibuprofen 10 mg/kg PO/IV q6h PRN for fever or pain
- Acetaminophen 15 mg/kg PO/PR q4h PRN for fever or pain
- Naproxen 5 mg/kg PO q8–12h PRN for pain
- Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
  - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.

**DISPOSITION****Admission Criteria**

- Most children with mumps do not require hospitalization.
- Admission may be needed for administration of IV hydration or analgesics:
  - Sometimes necessary in cases of mumps orchitis or pancreatitis
- Meningitis with need for IV antibiotics pending CSF cultures

**Discharge Criteria**

Ability to tolerate oral fluids and analgesics

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Patients should stay out of school or work for 5 days after symptom onset to prevent transmission.
- Significantly elevated pancreatic enzymes should be followed until they normalize.

**DIET**

- Hydration is recommended.
- Acidic foods or other foods that cause significant salivation may cause pain.

**PROGNOSIS**

- Although complications may occur, mumps is usually self-limited with recovery 1–2 wk from symptom onset:
  - Parotid swelling typically resolves in 7–10 days.
  - Testicular pain improves in ~6 days.
- Mortality rates are exceedingly low, particularly in children (1 death per year from 1980–1999; no deaths during 2006 epidemic).

**COMPLICATIONS**

- Orchitis:
  - Most common complication of postpubertal males (occurs in up to 50%)
  - Typically occurs after parotitis but can occur at any time or without other symptoms
  - Often results in some testicular atrophy, but sterility is rare (higher with bilateral orchitis).
- Aseptic meningitis:
  - Often occurs without parotitis
  - CSF pleocytosis occurs in >50% of cases.
  - Symptomatic meningitis in ~10%
  - Male to female ratio of 3:1
  - Encephalitis is extremely rare.
- Oophoritis:
  - Occurs in 5% of postpubertal females; can mimic appendicitis
- Pancreatitis:
  - Usually brief and self-resolves
  - No causal relationship with diabetes mellitus
- Deafness:
  - Sensorineural hearing loss due to mumps; usually unilateral but severe
  - Very rare in postvaccine era
- Spontaneous abortion
- Cardiac involvement
  - ECG changes in up to 15% of patients
  - Symptomatic myocarditis very rare
- Other rare complications include arthritis, thyroiditis, mastitis, interstitial nephritis, and transverse myelitis.

**See Also (Topic, Algorithm, Electronic Media Element)**

<http://www.cdc.gov/vaccines/vpd-vac/mumps/outbreak/case-def.htm>

**CODES****ICD9**

- 072.0 Mumps orchitis
- 072.1 Mumps meningitis
- 072.9 Mumps without mention of complication

**PEARLS AND PITFALLS**

- A failure to recognize mumps infection can lead to local outbreaks.
- The MMR vaccine should not be deferred for children with mild febrile illnesses.
- Close contacts of immunocompromised children should be vaccinated with the MMR vaccine; they will not transmit the mumps virus.
- Expression of pus through Stensen's duct can help differentiate bacterial parotitis from viral parotitis.

# MUNCHAUSEN SYNDROME BY PROXY

Mark R. Zonfrillo

## BASICS

### DESCRIPTION

- Munchausen syndrome by proxy (MSBP) is a form of child maltreatment from caregiver fabrication or induction of illness for the purpose of secondary gain.
- The *DSM-IV* has replaced MSBP with the term *factitious illness by proxy*.
- The American Professional Society on the Abuse of Children has further classified MSBP into *pediatric condition falsification* (ie, the abuse component) and *factitious disorder by proxy* (ie, the motive component, as described in the *DSM-IV*) (1).
- Typically results in repeated interactions with the medical care system, often leading to multiple medical procedures

### EPIDEMIOLOGY

- The incidence is 0.4/100,000 in children <16 yr of age and 2/100,000 in those <1 yr of age (2).
- Males and females are affected equally (3).
- Average time from onset of symptoms to diagnosis is 22 mo.
- Mortality is estimated to be at least 6%, but may be higher when the mechanism is suffocation or poisoning.
- The majority of MSBP perpetrators are birth mothers of the child with unrevealed psychiatric illness, pleasant personalities, and health care knowledge or training.

### RISK FACTORS

The involved parent often has medical training, often as an allied health professional such as nurses aide, medical technician, or emergency medical technician.

### PATHOPHYSIOLOGY

See Etiology.

### ETIOLOGY

- The caregiver fabricates or induces the illness.
- Symptoms may be completely fabricated.

- Illness may be a real disease and can be induced by multiple means:
  - Suffocation
  - Administration of drugs (eg, sodium chloride, anticonvulsants, opiates, benzodiazepines, ipecac, warfarin)
  - Injection of bacteria-contaminated fluids (eg, saliva, urine, or feces in a patient's IV line) to produce infection

### COMMONLY ASSOCIATED CONDITIONS

The caregiver may have Munchausen disorder (fabrication of an individual's own illness for secondary gain), depression, a personality disorder, or other psychiatric illness.

## DIAGNOSIS

### HISTORY

- The caregiver will provide a history of symptoms that are either fictitious or intentionally induced. These most commonly include a history of:
  - Apnea
  - CNS depression
  - Seizures
  - Bleeding
  - Vomiting
  - Diarrhea
  - Fever
  - Rash
- Events tend to be recurrent and intermittent.
- The history may be dramatic or atypical for the presenting illness.
- The caregiver and child often have multiple visits to different health care settings without a specific diagnosis or with treatment failure.
- The caregiver may report that physicians have been puzzled by the child's disease.
- If the child is older, he or she may endorse or believe the presenting symptoms, making the presenting illness more convincing and the diagnosis of MSBP more difficult.
- Illness typically improves or resolves while in the hospital under medical care.

### PHYSICAL EXAM

- There may be inconsistencies between the history and physical exam.
- For fictitious symptoms, the physical exam may be normal.
- In contrast to physical abuse, victims do not typically have physical findings suggestive of the diagnosis.
- For induced illness, the patient may manifest symptoms similar to organic disease.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Caregivers may be eager to obtain diagnostic testing for the child, including unnecessary or invasive procedures.
- Lab testing should be directed by the presenting complaints in order to rule out organic causes.
- For MSBP from ingestions, standard serum or urine toxicologic testing may have limited benefit, as most of the reported agents used are not included on routine screens (2).
  - Likely due to caregiver background medical knowledge and understanding of lab assay limitations
- Caregivers should not be given the opportunity to tamper with any specimens such as blood or urine.

#### Imaging

Imaging studies will not establish the diagnosis but may be useful in ruling out other etiologies in the differential diagnosis.

### DIFFERENTIAL DIAGNOSIS

- Physical abuse
- Malingering
- Functional complaint
- Caregiver delusional disorder
- Organic disease consistent with presentation:
  - Apnea
  - Seizures
  - Bleeding disorders
  - GI disorders

## TREATMENT

- Treatment should be directed toward the presenting complaint to help exclude organic causes of disease (ie, if treatment is ineffective) and to minimize morbidity from induced disease.
- When standard therapy for the presenting symptoms is ineffective, MSBP must be suspected.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Signs, symptoms, and lab findings consistent with infection, metabolic abnormalities, or toxidrome should be appropriately treated.

### SURGERY/OTHER PROCEDURES

Covert video surveillance has proven valuable in confirming cases of MSBP and other abuse (eg, suffocation) of hospitalized patients, although such monitoring is controversial.

### DISPOSITION

- As with any form of child abuse, emergency medicine providers should have a low threshold to admit patients with MSBP:
  - This allows for further evaluation of potential organic etiologies and protection of the patient.
- Close monitoring of the patient and caregiver is essential to observe extinguishing of the illness; a hallmark of MSBP.
- In some cases, video monitoring has been employed to observe a caregiver inflict harm to a child; such use is controversial.
- Child protection services should be involved if MSBP is confirmed.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Emergency department providers should be cautious about discharging patients with suspected MSBP, as admission and observation is often necessary for equivocal cases.
- Caregivers may become inappropriately upset if told they will be discharged. This may be an additional clue for MSBP diagnosis.

### Patient Monitoring

- Child protective services, with input from physicians, must decide on a case-by-case basis which children may need to be separated from the caretaker.
- The caregiver will need to receive psychotherapy.
- The patient will need close ongoing monitoring by the primary care provider with particular attention to growth and developmental milestones.

### PROGNOSIS

The prognosis depends on duration of abuse and the means the caregiver has used on the patient.

### COMPLICATIONS

- Complications vary depending on the method the caregiver uses to induce illness.
- Complications may include infection, anemia, dehydration, or adverse drug affects.

## CODES

### ICD9

301.51 Chronic factitious illness with physical symptoms

## PEARLS AND PITFALLS

- MSBP can be very difficult to diagnose in the emergency department; a detailed history is paramount for the diagnosis.
- Providers may not suspect MSBP because the perpetrator is invested in the child's care.
- While mortality for MSBP is much lower than other forms of child abuse, morbidity is much higher.
- While it is important to rule out organic disease, providers should avoid excessive or unnecessary interventions in these patients to avoid contribution to disease perpetuation.
- Providers should have a high index of suspicion for MSBP, stabilize any life-threatening conditions, and admit for further evaluation and monitoring.

# MUSCULAR DYSTROPHY

Pradeep Padmanabhan

## BASICS

### DESCRIPTION

- Muscular dystrophy (MD) describes a heterogeneous group of genetic disorders that regulate muscle result in disease with variable distributions and clinical progressions.
- The proximal striated skeletal muscle is typically involved, but MD can also affect cardiac smooth muscle.
- Major MD types include:
  - Duchenne muscular dystrophy (DMD)
  - Becker muscular dystrophy (BMD)
  - Congenital muscular dystrophy (CMD)
  - Limb-girdle muscular dystrophy (LGMD)

### EPIDEMIOLOGY

#### Incidence

- DMD is the most common, occurring in 1/3,500 male births.
- The incidence of BMD is ~10 times less common than DMD, with the other types of dystrophy even less common.

#### Prevalence

The prevalence rate of DMD is 3 per 100,000.

### ETIOLOGY

Genetic; MDs can be classified on the basis of their inheritance pattern:

- X linked (eg, DMD, BMD, and Emery-Dreifuss)
- Autosomal recessive (eg, LGMD types 2A, 2B, 2C; CMD; distal dystrophies)
- Autosomal dominant (eg, myotonic dystrophies; LGMD types 1A, 1B, 1C)

### PATHOPHYSIOLOGY

- DMD and BMD are caused by a genetic defect on the short arm of the X chromosome, resulting in weakness of the structural muscle protein dystrophin.
- The destruction of sarcolemma or muscle membrane leads to wasting and destruction of muscle, resulting in the characteristic muscle weakness and associated clinical features.
- Respiratory muscle weakness results in poor clearance of secretions, atelectasis, and impaired ventilation and culminates in respiratory insufficiency and failure.

### COMMONLY ASSOCIATED CONDITIONS

- Scoliosis
- Cardiomyopathy
- Mental retardation

## DIAGNOSIS

### HISTORY

MD manifests at varying ages. The autosomal recessive types have earlier onset, rapid worsening, and higher creatine kinase (CK) values:

- DMD presents before 5 yr of age in males with waddling gait, falling, and difficulty in climbing stairs. Even though DMD and BMD are X-linked, some female carriers also manifest weakness, calf muscle hypertrophy, and dilated cardiomyopathy.
- Memory disturbances and learning disabilities are associated with DMD.
- BMD presents between 6 yr and adulthood with symptoms similar to DMD but milder. Cardiomyopathy may be the primary presenting finding.
- CMD presents with poor head control and decreased muscle mass. Cardiomyopathy and heart failure distinguish the Fukuyama variety, while other congenital types are associated with seizures and mental retardation.
- LGMD manifests as weakness in specific muscle groups indicated by the subtypes (scapulohumeral, pelvic girdle) with sparing of extraocular muscles.
- Intellect is more commonly affected in CMD and DMD, while cognitive abilities are often intact in LGMD types.

### PHYSICAL EXAM

- Proximal muscle weakness, muscle wasting, pseudohypertrophy
- The Gower maneuver is characteristic of DMD. Affected patients get up from a lying to standing posture by pushing down on thighs to extend the trunk and hip joints. A positive sign suggests weakness in the pelvic and lower back musculature.
- Calf hypertrophy (pseudohypertrophy) from fatty infiltration of muscles is more commonly observed in DMD and occasionally in BMD. The deep tendon reflexes are weak or absent.
- Lumbar lordosis and progressive scoliosis can be present with DMD.
- Cranial malformations such as holoprosencephaly or lissencephaly are sometimes noted in CMD.
- Myotonia (inability to relax a muscle after contracting) is the classical feature of CMD. It can manifest in a peculiar smile in infants.
- CMD presents at birth with contractures or arthrogryposis, hypotonia, and absent or decreased deep tendon reflexes.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CK, especially CK-MM isoenzyme, is moderately elevated. Earlier in the course of the disease, the values may be marginally elevated or normal, leading to erroneous exclusions of the diagnosis of MD.
- In DMD, serum CK values are high at or soon after birth.

### Imaging

- Cardiac screening including baseline echo must be performed in all infants suspected of CMD.
- Neuroimaging is recommended for CMD and if craniofacial abnormalities are present.

### Diagnostic Procedures/Other

- ECG may reveal conduction defects in DMD due to fibrosis of the left ventricle manifesting as tall “R” waves in the right precordium.
- Prolonged PR and QTc intervals in the ECG are predictive of the risk of sudden cardiac death and the need for pacemaker.
- Muscle biopsy is diagnostic in all MD and will demonstrate evidence of degeneration, regeneration, and fat deposition in muscle.
- Electromyography can demonstrate myopathic changes with polyphasic small potentials.
- Dystrophin immunoblotting can be used to predict severity of DMD and BMD.
- Pulmonary function testing should be done at baseline and at appropriate intervals based on the severity of progression. Decreased vital capacity may warrant assisted noninvasive ventilation.

### DIFFERENTIAL DIAGNOSIS

- Myasthenia gravis
- Myopathy
- Polyneuropathy
- Myositis and dermatomyositis are associated with pain, whereas dystrophies typically are painless.
- Electrolyte disturbances

## TREATMENT

### PRE HOSPITAL

Assess and stabilize airway, breathing, and circulation.

### INITIAL STABILIZATION/THERAPY

Assess and stabilize airway, breathing, and circulation:

- Respiratory compromise is a common issue.

### ALERT

- Procedural sedation and endotracheal intubation require special considerations in patients with MD.
- Perform pulmonary function assessment prior to sedation or intubation.
- Consider an anesthesiology consultation prior to sedation.
- Consider end-tidal carbon dioxide monitoring during procedural sedation and after intubation.
- Assisted ventilation should be considered for children with forced vital capacity (FVC) <50% during procedural sedation.
- Closely monitor cardiac, pulmonary, and fluid status after the procedure.
- Halogenated agents such as halothane in combination with depolarizing agents can cause rhabdomyolysis and malignant hyperthermia.
- The use of depolarizing agents (succinylcholine) during intubation could be fatal.

### MEDICATION

#### First Line

There are no specific medications that are routinely used in the treatment of MD in the emergency department setting.

**Second Line**

- All children with MD should receive the pneumococcal vaccine.
- Angiotensin-converting enzyme inhibitors and/or beta-blockers may slow worsening of the left ventricular ejection fraction in DMD:
  - Enalapril 0.05–0.1 mg/kg PO 1–2 times per day
  - Propranolol 0.025 mg/kg PO 3–4 times daily
- Glucocorticoids have been shown to improve muscle strength, ambulation, and pulmonary parameters such as FVC. The optimal specific drug, dose, time of initiation, and duration of therapy have not been firmly established.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Intermittent positive pressure ventilation has been utilized during respiratory infections and to treat hypoventilation during sleep.
- Nocturnal mechanical ventilation can reduce symptoms and improve survival in children with chronic hypoventilation from MD.

**SURGERY/OTHER PROCEDURES**

- Surgery is indicated for contractures and for scoliosis, which may improve the life span by maintaining pulmonary function.
- Elective tracheostomy may be useful in some patients.

 **FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Physical therapy and regular stretching may delay the onset of contractures.
- Pulmonary evaluations should be performed every 6 mo in children with DMD.
- Annual or biannual echo is recommended in children with DMD after 10 yr of age.

**DIET**

- Creatine supplementation can improve muscle strength in MD.
- Dietary calcium and vitamin D supplementation may prevent orthopedic complications of corticosteroids such as osteoporosis and fractures.

**PROGNOSIS**

- Even though CMD manifests early and often with severe manifestations at birth, the progression is slow and the course is benign.
- DMD: Most children become wheelchair bound by 12 yr of age.
- Children with BMD and LGMD typically survive into adulthood.

**COMPLICATIONS**

- Arrhythmias, especially supraventricular, can be present most commonly in the Emery-Dreifuss type.
- Cardiomyopathy
- Fractures
- Scoliosis
- Contractures and pressure ulcers may result from immobility.
- Pneumonia is the usual cause of death.

 **CODES**

- ICD9**
- 359.0 Congenital hereditary muscular dystrophy
  - 359.1 Hereditary progressive muscular dystrophy
  - 359.21 Myotonic muscular dystrophy

**PEARLS AND PITFALLS**

- MD should be considered when the CK is high in infancy or with unexplained muscle weakness.
- The lack of muscle weakness and normal CK levels in the initial phases does not exclude MD.
- Rarely, cardiomyopathy may be the presenting clinical feature of MD.
- Exercise immense caution in choosing drugs for procedural sedation and intubation.
- Supplemental oxygen in the management of DMD (eg, nocturnal hypoventilation or procedural sedation) can be detrimental, as it can suppress respiratory drive.
- While the dystrophies are not curable, medical management, assisted ventilation, and surgeries have contributed to an increasing life span and improvements in pulmonary and muscle function.

# MYASTHENIA GRAVIS

Christopher J. Russo

## BASICS

### DESCRIPTION

Myasthenia gravis is an autoimmune disorder characterized by weakness and fatigability of voluntary muscles. 4 types of myasthenia gravis are seen in infants and children:

- Juvenile myasthenia: Similar to adult onset; caused by autoantibodies against the nicotinic acetylcholine receptor on the postsynaptic membrane at the neuromuscular junction
- Transient neonatal: Caused by passive transmission of maternal antibodies
- Congenital: Infants born to healthy mothers without the disease; a genetic mutation resulting in neuromuscular transmission
- Drug/Toxin-induced: D-penicillamine is the prototype; also curare, aminoglycosides, quinine, procainamide, calcium channel blockers, phenytoin, organophosphate ingestion

### EPIDEMIOLOGY

#### Incidence

Wide range of incidence: 2–10 per million per year (Virginia, U.S.) to 20 per million per year (Barcelona, Spain):

- Juvenile: ~1 new diagnosis per 1,000,000 population per year
- Transient neonatal: Affects 1/5 of infants born to mothers with the disease
- Congenital: Rare—<10% of all childhood myasthenia

#### Prevalence

Overall prevalence approaches 20 per 100,000. Juvenile myasthenia accounts for 10–15% of all myasthenia (including adults).

### RISK FACTORS

- Juvenile: More frequent association among family members with disease (2–7%)
- Prepubertal female to male ratio is 1.8:1.
- Postpubertal female to male ratio is 14:1.
- Greater among black than Caucasian population
- Congenital types are generally autosomal recessive.
- Bimodal peak: 1st peak in 3rd decade of life and 2nd peak in 6th and 7th decades of life
- Myasthenia in a sibling is associated with increased risk of transient neonatal, congenital, and juvenile myasthenia.

### PATHOPHYSIOLOGY

Dysfunctional signal transmission at the neuromuscular junction; pure motor deficit (no sensory or cognitive symptoms occur):

- Acetylcholine synthesized in presynaptic nerve terminal, released into synaptic cleft on nerve impulse
- Acetylcholine binds with receptors on postsynaptic membrane, causing influx of sodium into muscle fiber, leading to contraction.

- Acetylcholinesterase hydrolyzes acetylcholine to terminate neuromuscular transmission so that muscle fiber can be stimulated again.
- In myasthenia syndromes, there are reduced numbers of acetylcholine receptors as well as autoantibodies to the receptors themselves, resulting in impaired ability to repetitively activate muscle fibers.

### ETIOLOGY

- Factors that initiate and maintain the autoantibody response are largely undiscovered.
- Though largely caused by B-cell antibodies against acetylcholine receptors, T cells may also play a role.
- Thymic abnormalities found in nearly 75% of patients with myasthenia (germinal hyperplasia noted in 85% and thymic tumors in 15%):
  - Children have a lower incidence of tumors than adults with myasthenia.

### COMMONLY ASSOCIATED CONDITIONS

Other than thymic disorders, autoimmune disorders are also associated:

- Rheumatoid arthritis, diabetes mellitus, pernicious anemia, systemic lupus erythematosus, sarcoidosis, Sjögren syndrome, polymyositis, ulcerative colitis, and pemphigus
- Increased incidence of nonthymic tumors in patients who have not undergone thymectomy; risk returns to baseline after thymectomy

## DIAGNOSIS

### HISTORY

- Transient neonatal myasthenia presents at birth or shortly after with weakness, poor muscle tone, and poor suckle. There may be a history of maternal myasthenia.
- Congenital myasthenia presents later in infancy with symptoms similar to transient neonatal myasthenia as well as failure to reach expected motor milestones appropriately.
- Juvenile myasthenia presents during early childhood with progressive weakness that worsens after exercise; ptosis, diplopia, and bulbar symptoms such as dysphonia, dysphagia, difficulty with coordinated swallowing.
- Progression of weakness may occur in a craniocaudal direction.
- May have antecedent viral infection

### PHYSICAL EXAM

- Ptosis and ophthalmoplegia are often the earliest findings. The face may appear expressionless.
- Weakness may be observed in extremities, may be asymmetric, and is more pronounced with repetitive tasks.
- Observe for shallow or rapid respirations suggesting impending respiratory failure (myasthenic crisis).
- Infants with neonatal myasthenia may be hypotonic with weak suck, weak cry, and ptosis.
- Tendon jerks are usually normal or exaggerated.
- No objective sensory or cognitive signs are present. Pupils are typically spared.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

Diagnosis is based mostly on the results of the test for the antibody against the acetylcholine receptor and neurophysiologic tests:

- Most (80–85%) will demonstrate antibody to acetylcholine receptor (diagnostic gold standard): These are considered “seropositive” patients (this is a highly specific test).
- 15–20% are thus “seronegative”; these patients may demonstrate antibodies to other receptors.

#### Imaging

- CT or MRI of the chest may be used to screen for thymic tumors.
- MRI of the brain may be indicated if a structural or inflammatory brainstem lesion is suspected.

#### Diagnostic Procedures/Other

Neurophysiologic tests:

- Edrophonium (Tensilon) test: An acetylcholinesterase inhibitor, edrophonium, works within 30 sec and lasts about 5 min. Demonstration of immediate, transient improvement in strength constitutes a positive test.
  - Placebo (saline) dose should be given 1st.
  - Low but serious risk of bradycardia and/or hypotension: Should only be carried out where diagnosis is urgently needed and there are facilities for full resuscitation. Have atropine and epinephrine readily available.
- Ice pack test: Rarely performed—application of ice to affected eyes in patients with ptosis results in improvement in ptosis.
- Electrophysiologic tests: Repetitive nerve stimulation test almost always is positive in generalized myasthenia; may be negative in nearly 50% of cases with only ocular myasthenia.
- Single fiber electromyography is the most sensitive test in myasthenia.

### DIFFERENTIAL DIAGNOSIS

- Botulism
- Guillain-Barré syndrome (especially the Miller-Fisher variant)
- Lambert-Eaton syndrome
- Hypermagnesemia
- Tick paralysis
- Brainstem tumors, or mass lesions near the orbit, cavernous sinus, or sella turcica
- Brainstem encephalitis
- MS
- Acute spinal cord compression with extremity weakness; facial muscles spared in this case
- Organophosphate toxicity
- Ingestion of other drugs known to cause myasthenia: Indicated above

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Identify respiratory failure immediately; myasthenic crisis is a serious complication:
  - Look for shallow, rapid breathing suggesting impending respiratory failure.
  - May require tracheal intubation and mechanical ventilation

**ALERT**

- If paralysis for endotracheal intubation or other purposes is needed, patients with myasthenia may have an exaggerated and prolonged response to nondepolarizing neuromuscular blocking agents such as pancuronium, vecuronium, atracurium, rocuronium, etc. Using the shortest-acting nondepolarizing neuromuscular blocker available is preferable.
- Myasthenic patients typically have resistance to succinylcholine, a depolarizing neuromuscular blocker. Thus, it is not recommended for use.

**MEDICATION**

**First Line**

Acetylcholinesterase inhibitors:

- Usually, the initial drugs used; they do not alter course of disease but only offer symptomatic benefit.
- Pyridostigmine 1 mg/kg/dose PO, 30–60 mg (max 240 mg), q4–6h
- Neostigmine 0.3 mg/kg/dose IV q4–6h as needed

**Second Line**

- Prednisone or prednisolone 2 mg/kg/day PO per day for 1 mo followed by a tapering dose:
  - Improves myasthenia in the majority of patients
  - May start at low dose (0.25–0.5 mg/kg/day); may gradually increase by 50% every 3rd day to a max of 60 mg/day
  - Improvement usually begins in 2–4 wk; max benefit at 6–12 mo or more.
- Immunosuppressants:
  - May be considered after consultation with neurology
  - Options include azathioprine, cyclophosphamide, cyclosporin, methotrexate, mycophenolate mofetil
  - Low-dose tacrolimus plus corticosteroids has been reportedly effective in intractable disease.
  - IV immunoglobulin: Dosing is institution dependent and ranges from 2 g/kg divided over 2–5 days.

**SURGERY/OTHER PROCEDURES**

- Plasmapheresis: Associated with rapid but temporary improvement:
  - Indicated in myasthenic crisis, preparation of patients before thymectomy, in the early postoperative period, and in cases of symptom worsening during tapering or initiation of immunosuppressive therapy

- Thymectomy: Controversial, especially for those without demonstrable thymic tumors:
  - For thymic tumors (10% of patients with myasthenia)
  - For treatment of myasthenia gravis: Nearly 80–85% eventually experience improvement in symptoms; benefits usually appear months to years after surgery.
  - Earlier surgery may improve outcome.

**DISPOSITION**

**Admission Criteria**

- Consider admission for newly diagnosed cases for workup and initial stabilization.
- Consider admission for known cases with airway or breathing compromise in the emergency department or with comorbidity, particularly myasthenic crisis or medication-induced weakness.
- Critical care admission criteria:
  - Respiratory compromise

**Discharge Criteria**

Patients can be safely discharged from the hospital if their symptoms are mild and they do not show signs of respiratory involvement.

**Issues for Referral**

Anticipate referral to a specialist (pediatric neurology) to optimize medication regimen and establish an ongoing relationship with the patient and family.

**FOLLOW-UP**

**PROGNOSIS**

- Untreated myasthenia had been associated with a 10-yr mortality of 10–20%. However, with current therapies, the prognosis remains excellent with virtually no mortality.
- Spontaneous remission rate: 2% per year
- Most patients are able to live normal lives; however, lifelong immunosuppressants are usually needed.
- Myasthenia gravis in older patients with thymoma carries a poor prognosis.
- Neonatal transient: Self-limited illness; however, infants may require ventilatory support during the 1st few months of life.
- Congenital: Prognosis varies depending on the specific defect:
  - Autosomal recessive disorders tend to be more severe. Immunosuppressants remain ineffective in congenital myasthenia.

**COMPLICATIONS**

- Respiratory failure
- Respiratory arrest
- Pneumonia
- Autoimmune diseases
- Adverse drug reaction to medication:
  - The following medications can exacerbate myasthenia gravis: Corticosteroids (may worsen symptoms), aminoglycosides, ciprofloxacin, lithium, quinidine, procainamide, phenytoin.

**Pregnancy Considerations**

- 1/3 of pregnant patients with myasthenia show improvement during pregnancy, 1/3 become worse, and 1/3 remain stable.
- Plasmapheresis may be safely carried out during pregnancy.
- As the uterus is smooth muscle, obstetric problems are uncommon until the 2nd stage of labor, when the abdominal striated muscle is used.

**See Also (Topic, Algorithm, Electronic Media Element)**

<http://www.myasthenia.org>

**CODES**

- **ICD9**
- 358.00 Myasthenia gravis without (acute) exacerbation
- 358.01 Myasthenia gravis with (acute) exacerbation
- 775.2 Neonatal myasthenia gravis

**PEARLS AND PITFALLS**

- Be cautious when starting new medications in patients with myasthenia gravis.
- Be aware of the potential for intermittent worsening of symptoms, and always assess respiratory status.
- Hypersalivation, lacrimation, and abrupt onset of symptoms help to distinguish an organophosphate exposure from myasthenia gravis.

# MYOCARDIAL CONTUSION

Katrina E. Iverson  
Curt Stankovic

## BASICS

### DESCRIPTION

- Myocardial contusion is a bruise of the myocardium.
- Cardiac contusions present as a spectrum of symptoms of varying severity.

### EPIDEMIOLOGY

#### Incidence

Cardiac injury occurs in <5% of children with blunt chest trauma (1):

- Up to 95% of these injuries are myocardial contusions.

#### Prevalence

The exact prevalence of pediatric blunt cardiac injury is unknown but is thought to be <1% (1).

### RISK FACTORS

- Severe trauma
- Multiple system traumas
- Participation in collision sports

### GENERAL PREVENTION

- Use of protective athletic equipment
- Use of seat belts and air bags
- Correct installation of an age/size-appropriate child car seat

### PATHOPHYSIOLOGY

Injury to the myocardium leads to hemorrhage, edema, and necrosis of myocardial muscle cells. This injury can lead to:

- Conduction abnormalities and precipitating arrhythmias
- Wall motion abnormalities or wall rupture resulting in decreased cardiac output and hypotension

### ETIOLOGY

Blunt cardiac trauma from a direct blow to the chest or from rapid deceleration:

- A direct blow or a sustained force to the thoracic wall compresses the heart between the sternum and spine.
- Rapid deceleration causes the heart to strike the internal sternum.
- The most common cause is a motor vehicle collision. However, sports injuries, falls, blast forces, and indirect compression on the abdomen can cause a myocardial contusion.

### COMMONLY ASSOCIATED CONDITIONS

- Commotio cordis
- Often accompanies multisystem trauma including CNS, abdominal, skeletal, and other intrathoracic injuries:
  - Great vessel injury
  - Valvular damage
  - Traumatic septal defect
  - Tamponade secondary to hemopericardium
  - Myocardial rupture
  - Cardiogenic shock
  - CHF
  - Sternal and rib fractures

## DIAGNOSIS

### HISTORY

- Mechanism of injury should raise suspicion.
- Patients may complain of retrosternal chest pain or shortness of breath.

### PHYSICAL EXAM

- Tachycardia out of proportion to the degree of injury is a concerning finding.
- Patients may have no symptoms or present with tachycardia, reproducible chest pain, dysrhythmias, hypotension, or shock.
- Evidence of thoracic wall trauma such as ecchymosis, crepitus, abrasions, flail chest segments, or contusions should also increase suspicion.
- Distended neck veins and muffled heart sounds may indicate the presence of pericardial tamponade or tension pneumothorax.
- Other associated injuries may mask signs and symptoms of myocardial contusion:
  - Most mildly injured patients with a cardiac contusion tolerate the injury and show no symptoms.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Troponin I/T (2,3)
- Creatine kinase–MB and creatine phosphokinase–MB have a low sensitivity and specificity and are not routinely utilized to evaluate blunt thoracic trauma patients (3).
- Consider AST, ALT, amylase, lipase, and urinalysis to evaluate for intra-abdominal injury.
- Consider a CBC as well as blood type and screen for severely injured patients.

### Imaging

- Transthoracic echo on all patients with hemodynamic instability, abnormal ECG, or abnormal troponin I (3):
  - Transthoracic echo may show wall motion abnormalities.
  - Also evaluate for associated valvar lesions, pericardial effusion, and ventricular dilatation.
  - Rarely, a transesophageal echo may be necessary in patients with a painful chest wall injury.
- CXR and CT scans offer little or no information in the diagnosis of a myocardial contusion.
- CXR and CT may be helpful evaluating traumatic injury.

### Diagnostic Procedures/Other

- ECG is the most utilized screening tool:
  - It may be normal or show nonspecific abnormalities.
  - The most common arrhythmias are sinus tachycardia and ventricular or atrial extrasystoles.
- Radionuclide imaging has limited role in the acute evaluation of a myocardial contusion.

### Pathological Findings

- Intramyocardial hemorrhage, edema, and necrosis of myocardial muscle cells
- Can eventually result in scar formation

### DIFFERENTIAL DIAGNOSIS

- Dysrhythmia
- Myocardial ischemia/infarction
- Angina
- Rib or sternal fracture
- Hemopericardium
- Pericarditis
- Myocarditis
- Other traumatic chest wall injury
- See Commonly Associated Conditions.

## TREATMENT

### PRE HOSPITAL

Assess and stabilize airway, breathing, and circulation:

- Administer supplemental oxygen, preferably by nonrebreather mask.

### INITIAL STABILIZATION/THERAPY

- Assess ABCs and follow Advanced Trauma Life Support (ATLS) and Pediatric Advanced Life Support (PALS) protocols to identify other life-threatening injuries:
  - Significant blunt trauma to the chest imparts risk for cardiac dysrhythmia.
  - Initial fluid resuscitation if presenting with shock:
    - Judicious IV fluid management since excessive IV fluids may worsen the symptoms of cardiogenic shock (4)
  - Inotropic support for persistent hypotension (3,4)

- Dysrhythmia recognition and appropriate treatment (4):
  - Dysrhythmias are treated the same as nontraumatic dysrhythmias:
    - Supraventricular tachycardia: Vagal maneuvers, adenosine, cardioversion
    - Ventricular tachycardia (VT): Cardioversion, amiodarone, procainamide, lidocaine
    - Pulseless arrest (VT/ventricular fibrillation [VF]): Defibrillation, epinephrine, amiodarone, lidocaine, magnesium
    - Pulseless arrest (not VT/VF, pulseless electrical activity, asystole): Epinephrine
- Immediate consultation with cardiology and cardiothoracic surgery

**MEDICATION**

**First Line**

- Analgesics for chest pain, but avoid NSAIDs, which may impair cardiac healing and worsen bleeding
- Inotrope for persistent hypotension:
  - Dobutamine 2–20 µg/kg/min IV
  - Dopamine 2–20 µg/kg/min IV
  - Epinephrine 0.1–1 µg/kg/min IV
  - Norepinephrine 0.1–2 µg/kg/min IV
- Antiarrhythmics as needed for persistent arrhythmia:
  - Adenosine 0.1 mg/kg rapid IVP/IO, may double and repeat if no response, max 12 mg
  - Amiodarone 5 mg/kg IV over 20–60 min for VT or 5 mg/kg IV/IO bolus for VF/VT pulseless arrest
  - Epinephrine 0.01 mg/kg IV/IO (1:10,000) or 0.1 mg/kg tracheal tube (1:1,000)
  - Lidocaine 1 mg/kg IV/IO/TT
  - Magnesium 25–50 mg/kg IV/IO
  - Procainamide 15 mg/kg IV over 30–60 min

**DISPOSITION**

**Admission Criteria**

- Patients with abnormal troponin I levels, abnormal cardiac function or injury noted on echo, or atypical ECG in the setting of blunt thoracic trauma should be admitted for close monitoring and observation.
- No single test will accurately predict which patients can safely go home. Consider admission for patients who have a significant mechanism of injury or a high index of clinical suspicion for injury.
- Critical care admission criteria:
  - Hemodynamically unstable, serious cardiac arrhythmia on presentation to the emergency department; patients requiring pressor or antidysrhythmic medications
  - Severe associated injury

**Discharge Criteria**

- Patients with myocardial contusion should be routinely admitted.
- Discharge from an emergency department short-stay unit may be done with caution.
- Asymptomatic patients with no ECG abnormalities or dysrhythmias and normal troponin I levels may be discharged after a 4–6 hr observation in the emergency department (2,3).
- Hospitalized patients may be discharged after normalization of troponin I levels and ECG.

**Issues for Referral**

All patients with myocardial contusion should receive follow-up with cardiology to assess for long-term complications.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Patients with myocardial injury should have a follow-up cardiology appointment within a week.
  - Patients discharged from the emergency department are presumed to have no myocardial injury; for these patients, no specific follow-up is routinely necessary.
  - Return of any respiratory distress, worsening chest pain, dizziness, palpitations, or change in activity
- Activity:
  - Bed rest until symptoms abate and return to normal level of activity endurance
  - If a myocardial injury has occurred, contact sports should be avoided until cardiology clearance is given at the follow-up appointment.
  - Patients without myocardial injury can resume normal activity as early as other injuries, such as rib fracture, closed head injury, etc., permit.

**Patient Monitoring**

Patients with abnormal initial ECG or troponin I/T should have serial ECGs and troponin I/T levels drawn for at least 24 hr.

**PROGNOSIS**

- The majority of all patients with a cardiac contusion have a favorable outcome with no long-term effects.
- Severe cardiac contusion with myocardial necrosis heals by scar formation and may lead to ventricular aneurysm formation or chronic heart failure:
  - Chronic heart failure may result from a ventricular septal defect, mitral or tricuspid valve insufficiency, or arrhythmias. Scar tissue may restrict function.

**COMPLICATIONS**

- 81–95% of life-threatening ventricular arrhythmias and acute cardiac failure occur within 24–48 hr of trauma (3).
- MI:
  - Coronary artery dissection
- Aortic dissection

**CODES**

**ICD9**

- 861.01 Contusion of heart without mention of open wound into thorax
- 861.11 Contusion of heart with open wound into thorax

**PEARLS AND PITFALLS**

- Pearls:
  - 81–95% of life-threatening ventricular arrhythmias and acute cardiac failure from myocardial contusion occur within 24–48 hr of injury.
  - Patients with normal troponin I and ECG can be safely sent home after 4–6 hours of observation.
- Pitfall:
  - Other associated injuries may mask or mimic symptoms from myocardial contusion.

# MYOCARDIAL INFARCTION

Raquel Mora

## BASICS

### DESCRIPTION

- Myocardial infarction (MI) in children is uncommon, though recent advances in diagnosis have shown greater prevalence than perceived in the past.
- While there are no definitive diagnostic criteria for pediatric MI, lab testing and imaging modalities can help to support the diagnosis.

### EPIDEMIOLOGY

- Unusual at a young age, especially among neonates
- The estimated incidence of acute MI in adolescents in the U.S. is about 150 per year.

### RISK FACTORS

- Congenital heart disease (CHD):
  - 1% of all live births have CHD
  - 7% mortality for those with CHD and thromboembolic disease
- Familial homozygous hypercholesterolemia
- Use of drugs or medications associated with myocardial ischemia
- Thrombogenic disorders
- Cardiac surgery/interventions
- Kawasaki disease
- Atherosclerosis
- Cardiomyopathy

### PATHOPHYSIOLOGY

Physiologic conditions leading to an MI include:

- Thrombosis/Embolism
- Coronary artery spasm
- Acquired or congenital cardiac anomaly resulting in hypoperfusion/hypoxia to cardiac structures

### ETIOLOGY

- MI results when cardiac muscle is deprived of oxygen.
- A large number of factors predispose to MI; these are discussed under Risk Factors and Commonly Associated Conditions

## COMMONLY ASSOCIATED CONDITIONS

- Anomalous left coronary artery:
  - Most common pediatric cardiac anomaly causing MI
  - Present in 1–2% of the population
- Valvular stenosis
- Pulmonary atresia with intact ventricular septum
- Hypoplastic left heart syndrome
- Transposition of great vessels
- Truncus arteriosus
- Endocardial fibroelastosis
- Medial calcinosis of coronary arteries
- Coagulopathy/Thrombosis:
  - Occult malignancy
  - Cardiac surgical patients
  - Cardiac catheterization
  - Sickle cell disease
  - Premature atherosclerosis
- Drug and medication induced:
  - Illicit:
    - Sympathomimetics (cocaine, amphetamine)
  - Therapeutic agents:
    - Chemotherapy: Adriamycin, cisplatin
    - Epinephrine
    - Pseudoephedrine, ephedrine, and other sympathomimetics
- Infection:
  - Sepsis
  - Myocarditis (toxic, infectious)
- Systemic:
  - Kawasaki disease
  - Collagen vascular disease:
    - Systemic lupus erythematosus
    - Takayasu arteritis
    - Polyarteritis nodosa
  - Valvular or intracardiac embolic source
  - Nephrotic syndrome
  - Chronic renal failure
- Genetic disorders:
  - Homocystinuria
  - Mucopolysaccharidoses
  - Fabry disease
  - Pompe disease

## DIAGNOSIS

### HISTORY

- A thorough review of systems and inquiries about comorbidities should be performed.
- Clinical presentation varies with age:
  - Nonverbal child:
    - Poor feeding, dyspnea, vomiting, colic, irritability, shock
  - Older children:
    - Shortness of breath
    - Chest pain: The location and radiation are often described reliably, but younger children invariably describe it as “sharp.”
  - Adolescents:
    - Ingestion/Medication history and events proximal to onset of symptoms

### PHYSICAL EXAM

- Tachycardia
- Hyper- or hypotension
- Tachypnea
- High sensitivity findings in children:
  - Friction rub, gallop, jugular venous distension (JVD), arrhythmia
  - Infants rarely manifest JVD, basilar rales, or peripheral edema.
  - Unknown sensitivity in children
  - Cyanosis, diaphoresis, poor perfusion, tachypnea, rales, anxiety
- Adolescent evaluation is similar to young adult:
  - Murmurs, gallop, rales, peripheral edema

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- Troponin and creatine kinase–MB:
  - Specific for myocardial injury
  - No prospective studies in pediatric population exist to date.
- Arterial blood gas:
  - When evaluating for neonatal congenital heart defects, use the right upper extremity for hyperoxia testing (PaO<sub>2</sub> response to 100% oxygen).
- Serum electrolytes
- CBC or C-reactive protein to assess for inflammation associated with infection
- Blood cultures
- Rheumatologic screening indices as indicated
- Natriuretic peptide (BNP):
  - Normal reference ranges may vary with age of the child and the degree of neonatal prematurity.

**EKG**

- No established definitive criteria for pediatric MI, but there are suggestive findings:
  - Q waves: New appearance of wide Q waves (>35 msec):
    - Most specific finding for childhood MI
    - Increased amplitude or duration (>35 msec)
    - New onset in serial tracings
  - Notching:
    - 2 forms noted: Wide stair stepped in a QSQ'S' pattern or subtle notched and slurred Q waves
  - ST segment elevation (> 2 mm) and prolonged QT interval corrected for heart rate (QTc >440 ms) when associated with any other criterion
  - Ventricular arrhythmias
- Non-Q wave MI criteria have not been established in children.

**Imaging**

- CXR:
  - Assess cardiac size, shape of cardiac silhouette, pulmonary vascular markings
- Echo:
  - Evaluate wall motion and rule out congenital anomaly.
- Myocardial perfusion imaging:
  - Evaluates myocardial ischemia, infarction, and damage associated with various congenital or acquired heart diseases
  - Estimates right heart pressures
  - Can be utilized in pharmacologic cardiac stress testing in children
  - Sensitivity for coronary stenosis up to 90%
  - Specificity varies 33–100%.

**Diagnostic Procedures/Other**

Cardiac catheterization:

- Identifies anatomy and function
- Usually not warranted in the majority of patients, because occlusive coronary disease is not likely in the child without risk factors.

**DIFFERENTIAL DIAGNOSIS**

- Myocarditis
- Endocarditis
- Vasculitis diseases
- Genetic disorders, inborn errors of metabolism
- Trauma and musculoskeletal
- Substance abuse
- Hypoxic events
- Pneumonia
- Reactive airway disease

**TREATMENT**

**INITIAL-STABILIZATION**

- Evaluation for airway, breathing, circulation
- Initiate supportive care, and consult with a pediatric cardiologist.

**MEDICATION**

Current therapies are extrapolated from adult therapy.

**First Line**

- Oxygen 100% by nonbreather mask
- Aspirin 60–100 mg/kg/day PO divided q6–8h
- Sodium nitrate continuous IV infusion:
  - 0.25–0.5  $\mu$ g/kg/min
  - Can increase by 0.5–1  $\mu$ g/kg/min q3–5min as needed to max dose of 20  $\mu$ g/kg/min
- Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
  - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.

**Second Line**

- Thrombotic occlusions resulting in MI may be treated with thrombolytic therapy.
- Limited role among children in the emergency department setting because occlusive coronary disease is not likely in the child without risk factors for such disease:
  - Tissue-type plasminogen activator: bolus 0.2 mg/kg (max 15 mg) followed by infusion 0.75 mg/kg over 30 min (max 50 mg)
  - Unfractionated heparin: Bolus 75 U/kg followed by infusion 20 U/kg/hr

**SURGERY/OTHER PROCEDURES**

Surgical therapy—revascularization:

- Technically limited
- Low graft patency rate in children <5 yr of age

**DISPOSITION**

Patients with any concern for acute MI will need admission, and the degree of cardiac compromise/decompensation determines the need for critical care admission.

**Admission Criteria**

- Clinical suspicion with or without ECG findings suggestive of acute MI
- Critical care admission criteria:
  - All patients with confirmed MI, those with evidence of existing or impending heart failure, or those in shock (compensated or decompensated) should be admitted to an ICU.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Children who develop MI will require cardiac re-evaluation to ensure improvement of cardiac function or continued evaluations to prevent progression or recurrence of disease
- If an underlying medical condition, follow up with the appropriate subspecialist.

**PROGNOSIS**

- Survival in neonatal MI is extremely rare.
- The prognosis varies depending on the etiology.

**COMPLICATIONS**

- Cardiac dysrhythmia
- Cardiac failure/Shock
- Irreversible cardiac damage
- Multiorgan failure
- Death

**ADDITIONAL READING**

- Kim DS. Kawasaki disease. *Yonsei Med J.* 2006; 47(6):759–772.

- Towbin JA, Bricker JT, Garson A. Electrocardiographic criteria for diagnosis of acute myocardial infarction in childhood. *Am J Cardiol.* 1992; 69:1545–1548.

**CODES**

**ICD9**

- 410.00 Acute myocardial infarction of anterolateral wall, episode of care unspecified
- 410.10 Acute myocardial infarction of other anterior wall, episode of care unspecified
- 410.90 Acute myocardial infarction of unspecified site, episode of care unspecified

**PEARLS AND PITFALLS**

- While MI is not a common condition in the pediatric population, many illnesses commonly seen in children predispose them to MI.
- Once the suspicion for MI exists, aggressive cardiac support is warranted in the pediatric patient.
- Administer medications cautiously in neonates, since cardiac maturity and activity differ from that of older children.

# MYOCARDITIS

Yamini Durani

## BASICS

### DESCRIPTION

- Myocarditis is inflammation of the myocardium, the muscular wall of the heart, resulting from etiologies other than MI.
- Myocarditis causes cardiac dysfunction and can lead to heart failure or sudden death.
- The presentation may range from mild subclinical disease to fulminant life-threatening disease.
- The diagnosis may be missed if a high index of suspicion is not maintained. Many patients are diagnosed postmortem after sudden unexpected death.
- Acute myocarditis may progress to dilated cardiomyopathy as a result of direct viral injury to myocytes and subsequent injury due to the host's inflammatory response.

### EPIDEMIOLOGY

- The estimated incidence of clinically significant disease is as high as 0.3%.
- May account for >15% of sudden infant death syndrome and 60% of cases of peripartum cardiomyopathy.
- More prevalent in summer months as a result of viruses commonly communicated during those months

### RISK FACTORS

- Autoimmune disease
- Cardiotoxic medication exposure
- Drug abuse

### PATHOPHYSIOLOGY

- Viral agents cause direct damage to myocytes, leading to inflammation of the myocardium.
- After primary viral injury, there is ongoing injury to the myocardium by host immune effectors including cytokines, autoantibodies, macrophages, natural killer cells, and lymphocytes.
- Studies have shown that persistence of virus may contribute to the development of dilated cardiomyopathy.
- Individuals who develop dilated cardiomyopathy may be a genetically predisposed subgroup (1).
- Receptors in the myocardium for certain viruses known to cause myocarditis have been identified (2).
- Damage to the myocardium leads to cardiac dysfunction that may lead to heart failure.

### ETIOLOGY

- Idiopathic
- Viral infection due to coxsackie B or adenovirus is the most common infectious cause
- Less commonly, other viruses associated with myocarditis include enteroviruses (polio, echovirus, coxsackie A), cytomegalovirus (CMV), respiratory syncytial virus, herpes simplex virus, influenza, HIV, parvovirus, hepatitis C virus, varicella, rubella, and Epstein-Barr virus (EBV).

- Bacterial causes include *Borrelia burgdorferi*, *Neisseria meningitidis*, *Haemophilus influenzae*, and *Brucella*.
- Worldwide, *Trypanosoma cruzi* (Chagas disease) and *Corynebacterium diphtheriae* (diphtheria) are common causes.
- Rarely, myocarditis may be due to protozoan infection (ie, *Toxoplasma gondii*), fungi, or parasites.
- Peripartum cardiomyopathy
- Toxins (arsenic, carbon monoxide), drugs (ethanol, cocaine) medications (chemotherapeutics, antipsychotics)
- Giant cell myocarditis results from autoimmune disease (systemic lupus erythematosus, Kawasaki disease, rheumatic fever, scleroderma) (3).

## DIAGNOSIS

### HISTORY

- Unless a high index of suspicion is maintained, the diagnosis may easily be missed.
- Duration of symptoms, travel history, medication history, sick contacts are important historical factors.
- Prodromal symptoms:
  - Nonspecific complaints, which may be associated with other common pediatric illnesses (ie, lower respiratory tract infections, acute gastroenteritis, and sepsis)
  - Numerous prodromal symptoms, including fussiness, flu-like illness, vomiting, diarrhea, fever, shortness of breath, malaise, poor feeding, chest pain, or syncope
- Cardiac symptoms:
  - Chest pain that often is pleuritic, precordial, or stabbing
  - If acute myocarditis has progressed to fulminant disease, there may be a history of more significant respiratory distress, dyspnea, lethargy, syncope, or apnea.

### PHYSICAL EXAM

Signs of cardiac dysfunction may be found:

- Respiratory findings: Tachypnea, retractions, rales, and wheezing
- Cardiovascular findings: S3 and S4 gallops, other heart murmurs, jugular venous distention, lateral displacement of point of maximal impulse, tachycardia, dysrhythmia
- Other signs of heart failure: Hypotension, compensatory tachycardia, diminished pulses, poor perfusion, hepatomegaly, poor urine output, altered mental status

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- ECG is usually abnormal:
  - The typical findings are sinus tachycardia with low-voltage QRS complexes and inverted T waves.
  - Other ECG findings that may be present include premature ventricular beats, premature atrial beats, supraventricular tachycardia, ventricular tachycardia, heart block, and infarct patterns.
- Elevations in troponin, creatine kinase (CK), and CK isoforms may be seen.
- Metabolic acidosis may be seen in severe disease due to poor perfusion.
- An elevated WBC count with lymphocytic predominance may be present in viral myocarditis.
- If viral infection is suspected as the cause, culture of rectal and nasal mucosa sometimes yields positive results.
- Specific viral antibody titers may also be helpful in diagnosis (ie, enteroviral, adenoviral, EBV, and CMV titers).

#### Imaging

- CXR is usually abnormal. Cardiomegaly and pulmonary vascular congestion are the most common findings.
- The echo is not absolutely diagnostic but usually shows evidence of globally decreased ventricular dysfunction.
- MRI helps to characterize the pattern of inflammation in the myocardium. In early disease, focal areas of myocardial injury are identified. As progression of symptoms occurs, more generalized patterns of inflammation are seen.
- MRI helps to diagnose and stage myocarditis as well as localize areas of inflammation for purposes of guiding endomyocardial biopsy (4).

#### Diagnostic Procedures/Other

Endomyocardial biopsy is the gold standard in diagnosing myocarditis. It is performed via cardiac catheterization. Biopsy helps to identify the severity of inflammation:

- The sensitivity of biopsy is low because typically the pattern of myocardial inflammation is patchy. Studies have demonstrated that only 20–50% of pediatric patients clinically suspected of having myocarditis had confirmation on biopsy (4).
- Molecular biology techniques on biopsy samples can detect the specific pathogen causing myocarditis.
- The rate of complication with endomyocardial biopsy in pediatric patients is about 1%. Perforation of the right ventricle is the most common complication.
- Endomyocardial biopsy helps to identify dilated cardiomyopathy due to other causes such as storage diseases and neuromuscular disease.

**Pathological Findings**

- The “Dallas Criteria” provide a histopathologic basis to establish a diagnosis, although there is not one universally accepted set of diagnostic criteria.
- Active disease is based on the presence of inflammatory infiltrates and myocyte destruction.

**DIFFERENTIAL DIAGNOSIS**

- Pericarditis
- Subacute bacterial endocarditis
- CHF from other causes
- Pneumonia
- Viral syndrome
- Kawasaki disease
- Sepsis
- MI
- Dilated cardiomyopathy
- Metabolic disorders
- Mitochondrial disorders

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Address issues of airway, breathing, and circulation according to the Pediatric Advanced Life Support (PALS) algorithm.
- The initial goal is to achieve hemodynamic stability and manage complications of heart failure and dysrhythmia.
- If there is severe deterioration, mechanical ventilation may be required to decrease metabolic demand and afterload.

**MEDICATION****First Line**

- After initial stabilization, further therapy should be initiated in consultation with a cardiologist.
- Pharmacotherapy, which increases left ventricular function, such as angiotensin inhibitors, are often prescribed.
- Other therapies to treat heart failure include inotropic support, diuretics, afterload reducers, digoxin, and aldosterone inhibitors.
- Antiarrhythmics as needed.

**Second Line**

- IV immunoglobulin in viral myocarditis is an accepted therapy, but studies thus far are limited in pediatrics.
- Antiviral therapy directed toward specific viral pathogens (ie, coxsackie B, CMV, HIV) has shown benefit.
- The beneficial effects of immunosuppressive therapy such as corticosteroids, azathioprine and cyclosporine are inconclusive in pediatric patients (5).

**SURGERY/OTHER PROCEDURES**

- Indications for extracorporeal membrane oxygenation (ECMO) and ventricular assist devices (VAD) include fulminant myocarditis and persistent arrhythmia causing significant hemodynamic instability.
- Pacing as needed for heart block
- Orthotopic heart transplant is the final treatment option, particularly in cases of advanced dilated cardiomyopathy.
- ECMO and VADs may be a bridge to heart transplant.

**DISPOSITION****Admission Criteria**

Patients with myocarditis who show signs of hemodynamic instability or dysrhythmia should be monitored in a pediatric ICU.

**Discharge Criteria**

Minimally symptomatic, hemodynamically stable patients who have transitioned to oral medication therapy, as directed by a cardiologist

**Issues for Referral**

All patients with myocarditis should have consultation with a pediatric cardiologist.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Patients should have follow-up and further outpatient therapy guided by a pediatric cardiologist.
- Activity:
  - Patients should slowly progress to resume normal activity after initial bed rest.
  - Avoid strenuous exertion.

**PROGNOSIS**

- Data on prognosis is limited in pediatrics. Conventional estimates are that 1/3 recover, 1/3 have residual cardiac dysfunction, and 1/3 have a poor outcome (chronic heart failure, need for heart transplant, and death) (1).
- The Pediatric Heart Transplant study reported a 70% 5-yr survival rate (6).
- Recurrent viral myocarditis has not been reported in children.
- The proportion of children with acute myocarditis who progress to dilated cardiomyopathy is not known.

**COMPLICATIONS**

- Progression to dilated cardiomyopathy
- Heart failure
- Dysrhythmia

**CODES****ICD9**

- 422.90 Acute myocarditis, unspecified
- 422.91 Idiopathic myocarditis
- 429.0 Myocarditis, unspecified

**PEARLS AND PITFALLS**

- Due to the potential for severe and fatal disease, early diagnosis and treatment is optimal.
- Symptoms associated with myocarditis are frequently attributed to other illnesses, such as viral syndrome, upper respiratory infection, and gastroenteritis.
- Acute myocarditis may be clinically silent until the degree of myocardial involvement leads to cardiogenic shock.

# NAIL BED INJURIES

Carla Maria P. Alcid

## BASICS

### DESCRIPTION

- Crush injuries of the fingertip involving the nail bed are the most common hand injuries seen in children.
- Injuries to the nail:
  - May have long-term cosmetic sequelae
  - Affect daily activities because the nail:
    - Provides protection for the fingertip and underlying nail bed
    - Serves to counter the forces when the finger pad touches or picks up an object
    - Plays a role in thermoregulation and tactile sensation

### EPIDEMIOLOGY

- Hand injuries account for 10% of trauma cases presenting to U.S. emergency departments:
  - Fingertip injuries account for 2/3 of hand injuries in children.
- Damage to the nail bed occurs in 15–24% of these injuries (1):
  - Crush or “jamming” injuries were the most common reason (48–64%), and most occurred at home (45–59%):
    - More in the <5-yr-old age group (38%)
  - The long middle finger (25%) and terminal phalanges of the 4th and 5th fingers (47%) were most commonly affected.
- Toddlers sustained soft tissue injuries predominantly (86%), and older children sustained more bony injuries (77%) involving the nail bed:
  - Nail injuries were seen in 48% of cases.
  - Right and left hands were affected equally (2).

### RISK FACTORS

- Young age (<5 yr)
- Lack of supervision
- Heavy-hinged metal doors/gates (eg, cars)

### GENERAL PREVENTION

- Observing home safety protocols, such as the acquisition of specific protective door devices
- Proper supervision of young children
- Parental education on home safety

### PATHOPHYSIOLOGY

- The nail bed is a thin layer of epithelial tissue overlying the cortex and bound to the periosteum of the distal phalanx:
  - The germinal matrix is the proximal portion and is responsible for 90% of nail formation
  - The sterile matrix is the more distal tissue of the nail bed and provides adherence between the nail and the nail bed.
- Longitudinal growth of the nail takes between 70–160 days to cover the entire length of the nail:
  - After an injury, nail growth is stunted or absent for 21 days, after which there is rapid nail growth over the next 50 days. This then slows again before a normal and sustained growth rate resumes (3).

- After trauma, there is a characteristic lump observed with new nail growth that reflects the changes in growth patterns.
- Blood supply to the fingertip is from the many branches of 2 digital arteries. The pad of the fingertip is composed of fatty and soft tissues that contain a multitude of exquisitely sensitive nerve endings. This explains the degree of pain and amount of blood seen in these types of injuries.

### ETIOLOGY

Crush injuries from:

- Doorways, hinges, car doors, metal gates, weights in toddlers and younger children
- Hammers, saws, drills, knives, and lawn mowers in adolescents
- Sports-related injuries in older youth

### COMMONLY ASSOCIATED CONDITIONS

- Subungual hematomas
- Lacerations to the surrounding skin
- Distal phalangeal fractures, especially involving the tuft, may also occur after fingertip injuries and are usually present in 50% of nail bed injuries (4).
- Fingertip avulsions are especially common after severe crush injuries.

## DIAGNOSIS

### HISTORY

- A complete history must include:
  - Time and mechanism of injury
  - Presence or absence of an associated open wound
  - Previous history of hand injury
  - Overall health status
  - Immunization status, particularly tetanus
  - Hand dominance
- In children, always inquire about the circumstances of the accident, as there is always the possibility of nonaccidental trauma.

### PHYSICAL EXAM

- Start with a general physical exam to rule out any other injuries.
- Perform and document a careful exam of the involved fingers with a focus on the assessment of the motor and sensory functions and the vascular structures:
  - It may be necessary to perform a digital nerve block in order to do an adequate exam (after assessment of sensation).
  - Assess the degree of contamination.
  - Motor function: Test for both muscular strength and tendon function by having the patient move the fingers with and without resistance.
  - Sensory function: Impaired sensation may significantly limit the overall function of the individual digit and hand.
  - Note the presence and extent of macerated and devascularized skin, active bleeding, and any subungual hematomas:
    - Patients with a subungual hematoma > 1/2 the size of the nail bed had a 60% incidence of a laceration requiring repair (5).

- Assess for nail avulsion, disruption of the nail bed, and any specific pattern of laceration (linear, stellate, flap).
- Examine the posture of the fingers, and look for the presence of deformities that may indicate an underlying fracture, dislocation, or tendon avulsion.
- Look for the presence of foreign bodies such as glass, wood, metal, or other fragments.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

Radiographs with AP, lateral, and oblique views are useful to look for foreign bodies, fractures, or dislocations.

### DIFFERENTIAL DIAGNOSIS

- See Commonly Associated Conditions.
- Subungual hematomas can occur in isolation or have an associated small nail bed laceration.
- Subungual foreign bodies may occur in the fingers and toes of any mobile child:
  - They are typically wedged between the nail and the nail bed, although penetration of either can occur. Bacteria can accompany the foreign body beneath the nail, causing an infection.

## TREATMENT

### PRE HOSPITAL

In the case of a known fingertip/nail bed avulsion injury, it is best to bring along the avulsed tip or nail for use in the repair.

### INITIAL STABILIZATION/THERAPY

The goal of pharmacotherapy is to reduce pain and swelling and to prevent and reduce the incidence of infection. Hand injuries are often considered to be at high risk for infection:

- Perform adequate irrigation and debridement.
- Antibiotic therapy should target all possible pathogens expected in the clinical setting:
  - Current standard practice is to use prophylaxis for grossly contaminated wounds and to withhold them in simple clean wounds.
  - A recent study suggests that routine prophylactic antibiotics do not reduce the rate of infection after repair of distal fingertip injuries (6).

### MEDICATION

#### First Line

- Antibiotics:
  - Cephalexin 25–100 mg/kg/day PO divided q6–8h
  - Clindamycin 10–30 mg/kg/day PO divided q6–8h or 25–40 mg/kg/day IV/IM divided q6–8h in the setting of possible MRSA
- Analgesics
- Primary analgesia by digital nerve block is preferred over systemic therapy.
- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2 µg/kg IV q2h PRN:
    - Initial dose of 1 µg/kg IV may be repeated q15–20min until pain controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone PO q4–6h PRN

- NSAIDs: Consider in anticipation of prolonged pain and inflammation:
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Ketorolac 0.5 mg/kg IV/IM q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN:
    - Some clinicians prefer to avoid due to theoretical concern over influence on coagulation and callus formation.
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

**Second Line**

Update tetanus immunization as needed.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

Simple trephination has been shown to be just as effective as removal of the nail with nail bed repair as long as the nail is still partially adherent to the nail bed or paronychia and is not displaced out of the nail fold and the subungual hematoma is not > 1/2 the size of the nail bed (5,7).

**SURGERY/OTHER PROCEDURES**

Principles of treatment include:

- Minimal debridement with preservation of as much tissue as possible
- Nail bed repair
- Splinting of the nail fold with the nail or other alternative material such as a hypodermic syringe splint or acrylic nail (8,9) to allow drainage and prevent a hematoma from separating the nail from the nail bed
- Anchor the nail or other material in place using sutures, tissue adhesives (10), or antibiotic ointments underneath the nail (11).
- Using a skin glue alone, such as Dermabond, on the nail bed may be used to repair nail bed lacerations and also serve as a protective barrier. This may be used without replacing the nail or use of any other splint.

**DISPOSITION**

**Admission Criteria**

Admission is generally not required.

**Discharge Criteria**

- No other associated life-threatening injuries
- No evidence of infection requiring IV antibiotics

**Issues for Referral**

Consultation with a hand specialist is warranted for:

- Significantly avulsed nail matrix requiring flap reconstruction or for severe crush injuries
- Any question as to the viability of the remaining tissue
- Soft tissue deficit/avulsion with bony protrusion. These injuries require rongiere procedure of the bone.

 **FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - The splint should remain in the nail fold for 3 wk, after which:
    - If sutures were placed during the initial repair, these will need to be removed.
    - If the original nail was used as a splint, it should fall out on its own if replaced with skin glue or absorbable sutures.
    - If acrylic nails, a hypodermic syringe sheath, or other materials were used, these need to be removed in 3 wk.

- Continue to keep a nonadherent dressing and finger splint on for 1–2 wk.
- Antibiotics and pain medications as indicated
- Activity:
  - Stay away from activities that may introduce dirt into the wound.

**Patient Monitoring**

- Close follow-up for wound check in 2–3 days, repacking the nail fold as needed
- Instructions on return criteria include uncontrolled bleeding, continued pain and swelling at the site, and purulent drainage.

**PROGNOSIS**

- Nail bed injuries heal well with appropriate therapy, but injuries may take months for the nail to grow back into its original shape.
- Crush and avulsion injuries and injuries with distal phalanx fractures fare worse, as do injuries that span the entire nail bed.

**COMPLICATIONS**

- Destruction of the nail with lack of new nail growth
- Abnormal nail with disrupted nail growth
- Infection
- Scarring with loss or obstruction of the nail fold

**See Also (Topic, Algorithm, Electronic Media Element)**

- Fracture, Hand
- Mallet Finger
- Trauma, Hand/Finger

 **CODES**

- ICD9**
- 883.0 Open wound of fingers, without mention of complication
  - 959.5 Other and unspecified injury to finger
  - 959.7 Other and unspecified injury to knee, leg, ankle, and foot

**PEARLS AND PITFALLS**

- Pearls:
  - Instruct the patient that it may take months to years before new nail growth appears.
  - All patients should be advised that a deformed nail is a possibility.
  - Though widely practiced is not necessary or clearly beneficial to use replace the nail or other material in the eponychium to keep it patent.
  - Assess for fractures, particularly if the skin is lacerated or avulsed, as associated fractures are considered open and at high risk for osteomyelitis.
- Pitfalls:
  - Inadequate assessment of the injured nail bed can lead to the possibility of a cosmetically unacceptable result.
  - Patients who are employed to do fine motor skills may lose their jobs due to hand and/or nail bed injuries that are not repaired correctly.

# NECK MASS

John T. Kanegaye

## BASICS

### DESCRIPTION

- Most pediatric neck masses are benign and often self-limited. Many arise from cervical nodes (see the Lymphadenopathy topic).
- A minority warrant further investigation due to malignant nature, compromise of adjacent structures, association with systemic disease, or potential for recurrent infection.
- The main categories of neck mass are congenital and acquired. The former include anomalies of embryogenesis and normal variants. The latter include inflammatory, infectious, neoplastic, vascular, and traumatic lesions.

### EPIDEMIOLOGY

#### Incidence

- Up to 90% of head and neck lesions are benign.
- Congenital lesions and malignant neoplasms account for 55% and 10–15%, respectively, of excised or biopsied neck lesions.
- Among congenital lesions, thyroglossal duct cysts account for 70%, branchial anomalies 20%, and vascular lesions 5%.

### PATHOPHYSIOLOGY

- Most neck masses result from minor viral and bacterial infections.
- Persistence of embryonic structures leads to branchial cleft anomalies and thyroglossal duct cysts.
- Previously asymptomatic cystic masses may become clinically apparent and potentially life threatening when they expand because of infection or hemorrhage.

### ETIOLOGY

- Inflammatory:
  - Anaphylaxis
  - Drug reaction
  - Rheumatologic
  - Kawasaki disease (KD). Rarely, fever and neck mass may be the 1st presenting signs (1).
  - Sarcoidosis
- Infection:
  - Reactive adenopathy, most commonly viral
  - Cervical adenitis, staphylococci and group A streptococci in 40–80% of unilateral cases, *Bartonella henselae* (cat scratch disease), diphtheria, fungi (*Histoplasma*, *Blastomyces*, *Coccidioides*)
  - Cellulitis and abscess, including deep neck space infection
  - Ludwig angina
  - Other infections: Epstein-Barr virus (EBV), cytomegalovirus, toxoplasmosis, HIV, syphilis, tularemia, brucellosis
  - Parotitis, sialadenitis
- Neoplastic:
  - Leukemia/Lymphoma (Non-Hodgkin and Hodgkin lymphoma have a 60:40 ratio of occurrence.)
  - Other (rhabdomyosarcoma, thyroid carcinoma, metastatic or primary cervical neuroblastoma, Langerhans cell histiocytosis, other sarcomas)
  - Hamartomas, choristomas

- Congenital mass with or without superinfection:
  - Thyroglossal duct cyst: Midline mass, usually infrahyoid, that may move with tongue protrusion or swallowing. Median ectopic thyroid may coexist as the patient's only active thyroid tissue.
  - Branchial cleft anomalies (sinuses, cysts, fistulas) (2). Most commonly, 2nd cleft anomalies present as draining sinuses anterior to the lower sternocleidomastoid (SCM) or masses in the high lateral neck in close relation to the SCM. May move with swallowing. Branchial vestiges of cartilage or bone may lie anterior to the inferior SCM. Less common 1st arch anomalies present between the external auditory canal and the angle of the mandible.
  - Cervical teratoma: Although usually benign, large lesions may cause newborn airway obstruction.
  - Lymphangioma (cystic hygroma): Painless, soft, transilluminating mass commonly in posterior triangle; may enlarge rapidly and encroach on other structures
  - Congenital muscular torticollis (fibromatosis colli, "fibrous tumor" of the SCM) results in tilt of head toward and rotation of neck away from the affected side.
  - Dermoid cysts: Painless midline subcutaneous masses
  - Midline cervical clefts: Vertical midline fibrous bands from the sternum to mandible
- Vascular:
  - Hemangioma: The majority involute by 5–9 yr of age, but those that affect vision or airway require treatment.
  - Arteriovenous malformations
- Traumatic:
  - Hematoma
  - Arteriovenous fistula
  - Pneumomediastinum
- Other:
  - Cystic lesions: Sialoceles, external laryngoceles, and plunging ranula (parotid, paratracheal, and submandibular regions, respectively)
  - Goiter (congenital hypothyroidism, iodine deficiency, Graves disease, thyroiditis)
  - Neurofibroma
  - Pterygium colli: Weblike folds of skin in Turner and Noonan syndromes
- Normal structure and variants:
  - Normal node in healthy child
  - C2 transverse process, hyoid bone, styloid process
  - Cervical rib
  - Thyroid (pyramidal lobe)

### COMMONLY ASSOCIATED CONDITIONS

Lymphangiomas and lymphomas of neck may have mediastinal components.

## DIAGNOSIS

### HISTORY

- Constitutional symptoms such as fever
- Duration and progression of mass
- Rate of growth:
  - Over days: Likely an inflammatory lesion
  - Over weeks: Suspicious for malignancy
  - Slow change or fluctuation since birth: Likely congenital
- Overlying skin changes, sinuses, and drainage
- Preceding respiratory infection (which may precipitate cervical adenitis or infection of congenital cyst), skin lesion, trauma, animal bites and scratches
- Local or regional pain
- Respiratory or feeding difficulties
- Facial, upper extremity swelling (mediastinal mass)
- Chronic otorrhea, rhinorrhea (suggests primary malignancy)
- Infectious exposures, travel history
- Recent medications, including anticonvulsants and immunosuppressive therapy
- Prior antineoplastic or radiation therapy

### PHYSICAL EXAM

- Airway patency, air entry, including tolerance of recumbent position
- Lesion size, location, other characteristics (induration, fluctuance, crepitation, pulsatility, bruit, mobility, transillumination, movement with swallowing or tongue protrusion):
  - Midline (thyroglossal duct and dermoid lesions) vs. lateral location
  - Anterior vs. posterior triangle
  - Solid (node, neoplasm) vs. cystic (congenital, vascular)
- Abdominal, axillary, or inguinal masses or adenopathy
- Facial, extremity swelling
- Associated head, neck, otologic lesions (foci of infection, sinus tracts, blunt and penetrating trauma)
- Hepatosplenomegaly
- Skin: Rash, petechiae, purpura, bruising; café-au-lait spots; neurofibromas; inoculation papule
- Neurologic: Spinal cord or root involvement, Horner syndrome

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- The diagnoses of most reactive, infectious, and congenital masses are made clinically. Many masses will have resolved with supportive care with or without empiric antibiotic therapy. Selected tests are useful in specific clinical situations.
- With exudative pharyngitis:
  - Rapid streptococcal antigen test (culture if antigen test negative)
  - *Arcanobacter hemolyticum* and gonococcal infections may occur in adolescents.
  - Heterophile antibody or serology for EBV
- Generalized adenopathy: Serologic tests for toxoplasmosis, cytomegalovirus, and HIV
- Midline masses: Thyroid hormone levels
- Suspected malignancy: CBC and differential; assessment for tumor lysis syndrome (potassium, calcium, phosphorus, uric acid)

**Imaging**

- Chest radiography if suspicion for granulomatous disease, mediastinal mass, or air leak
- Neck films if suspicion for cervical rib (AP) or retropharyngeal abscess (lateral)
- CT for evaluation of deep neck abscesses and extension of lesion into chest (eg, mediastinitis), impingement on intra- and extrathoracic airway and vessels, relationship of lesions to structures that may be injured during excision. Entails risks of radiation and airway or hemodynamic compromise if the patient cannot tolerate the supine position or sedation. MRI provides superior anatomic detail but has no role in emergency department management.
- US differentiates cystic from solid lesions, identifies abscess amenable to incision and drainage, distinguishes thyroglossal duct cysts from thyroid tissue and dermoid cysts, and characterizes the internal anatomy of noninfectious masses (septations in cystic hygroma, “cluster of grapes” in KD [3])
- Echo identifies coronary artery abnormalities in patients with suspected KD.

**Diagnostic Procedures/Other**

- Tuberculin skin testing
- Needle aspiration of purulent material may yield pathogen and decompress infected cysts. However, aspiration may be inadequate for pathologic exam. Furthermore, complete excision is preferred in atypical mycobacterial adenitis.
- Biopsy is appropriate when malignancy cannot be excluded or if the mass has not improved by 4–6 wk of outpatient observation/antibiotics.
- Other tests may be useful to the specialist: Serum tumor markers, catecholamines, genetic analysis, scintigraphy, cytology by fine-needle aspiration

**DIFFERENTIAL DIAGNOSIS**

See Etiology.

**TREATMENT****PRE HOSPITAL**

Airway stabilization, spinal immobilization if needed

**INITIAL STABILIZATION/THERAPY**

- Airway protection and stability of cervical spine. Large neonatal neck masses may require aggressive intrapartum airway management.
- Reversal of coagulopathy
- Precautions against tumor lysis in suspected lymphatic malignancies (hydration with potassium-free fluids, alkalization, and agents to lower uric acid levels)

**MEDICATION****First Line**

- Outpatient observation and supportive care are appropriate in mild viral or *Bartonella* disease.
- Cervical adenitis (staphylococci, streptococci):
  - Cephalexin 50 mg/kg/day divided b.i.d.–q.i.d. × 10 days
  - Penicillinase-resistant penicillin OR:
    - Amoxicillin/Clavulanate (if MRSA is unlikely) 45 mg/kg PO divided b.i.d. OR
    - Clindamycin (if MRSA is prevalent) 10 mg/kg/dose PO/IV t.i.d. × 10 days
  - Abscesses and infected congenital cysts (staphylococci, *Haemophilus* species, anaerobes): Amoxicillin/Clavulanate, clindamycin (with or without 2nd- or 3rd-generation cephalosporin)

– Other:

- For *Bartonella*, azithromycin 10 mg/kg PO day 1, then 5 mg/kg PO days 2–10
- Antimycobacterial agents

**Second Line**

If risk of tumor lysis, consult an oncologist regarding allopurinol (xanthine oxidase inhibitor) or rasburicase (recombinant urate oxidase).

**SURGERY/OTHER PROCEDURES**

- Hemangiomas that fail to involute or that compromise function may require intralesional or systemic corticosteroids, laser, interferon, or surgical excision as an outpatient.
- Surgical excision of thyroglossal duct cysts or branchial anomalies with their associated tracts (4). Simple incision of an infected cyst may complicate the subsequent surgical excision.
- Excisional biopsy for suspected malignancy
- A surgical airway may be required for obstructing masses.
- Excision of mycobacterial infections
- Sclerotherapy for extensive lymphangiomas
- Stretching exercises (4–6 times per day) for muscular torticollis or surgical release for persistent deformity
- Embolization of arteriovenous malformations

**DISPOSITION****Admission Criteria**

- Need for parenteral antimicrobial therapy or surgical drainage
- Unresolved suspicion for malignancy
- Critical care admission criteria:
  - Compromise of airway or vascular structures, including superior vena cava/mediastinal syndrome
  - Cervical spinal instability

**Discharge Criteria**

- Normal airway and perfusion
- The mass is highly likely to remain stable or resolve during outpatient observation
- Primary or specialty follow-up arranged

**Issues for Referral**

- Otorhinolaryngology or pediatric surgery: Congenital lesions, masses that fail to resolve after a period of outpatient observation with or without empiric antibiotics
- Oncology: Suspicion for malignancy

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Infected nodes or congenital cysts being treated with outpatient antibiotic therapy warrant re-exam in 2–3 days and in 2 wk to ensure improvement.
- Discharge instructions and medications:
  - Patients should return at any time for rapid enlargement or interference with respiration or feeding.

**COMPLICATIONS**

- Neonatal airway compromise may occur with teratomas or lymphangiomas (if in the anterior neck or floor of the mouth) and hemangiomas in a beard distribution.
- Congenital masses may recur if initial resection is incomplete (4).
- Large hemangiomas may lead to Kasabach-Merritt syndrome, and arteriovenous malformations may cause high-output cardiac failure.
- Tumor lysis syndrome with malignancy

**ICD9**

- 195.0 Malignant neoplasm of head, face, and neck
- 229.8 Benign neoplasm of other specified sites
- 784.2 Swelling, mass, or lump in head and neck

**PEARLS AND PITFALLS**

- Characteristics suspicious for malignancy: Constitutional symptoms, supraclavicular or posterior cervical location, matted nodes, absence of pain, size >3 cm or progressively enlarging, firmness, fixation, ulceration, duration of a single dominant mass >6 wk
- Neck neoplasms may be associated with masses that may compromise the intrathoracic airway.
- A thyroglossal duct cyst may contain the patient's only active thyroid tissue.
- Infections and drainage procedures may complicate the later definitive excision of congenital cysts. Incision and drainage in mycobacterial infection or cat scratch disease may lead to a persistently draining sinus.

# NECK STIFFNESS

Lynn Babcock Cimpello  
Alan T. Flanigan

## BASICS

### DESCRIPTION

- Usually refers to limited neck mobility
- Presentations include:
  - Normal resting position with decreased range of motion
  - Abnormal resting position
  - Absence or presence of neck pain
- Torticollis or “wry neck” is a common variation of neck stiffness associated with muscle spasm due to multiple etiologies.

### EPIDEMIOLOGY

- The overall incidence of neck stiffness is unknown.
- The frequency of neck pain in cervical spine injury (CSI) in children ranges from 41–55% (1).
- The frequency of neck stiffness in meningitis in children has been reported as <50% (2,3).

### RISK FACTORS

Varies with etiology of neck stiffness

### GENERAL PREVENTION

Directed at underlying cause

### PATHOPHYSIOLOGY

Irritation to the skeletal, muscular, ligamentous, and/or neurologic elements of the neck/cervical spine as a result of stretch, contracture, inflammation, or compression

### ETIOLOGY

- Trauma:
  - Muscular strain/contusion
  - CSI:
    - Fracture
    - Ligamentous injury
    - Subluxation (rotary, atlantoaxial)
    - Spinal cord injury
    - Spinal cord injury without radiographic findings (SCIWORA)
    - Spinal epidural hematoma
  - Clavicle fracture
  - Subarachnoid hemorrhage (SAH)
- Atraumatic:
  - Muscular spasm (torticollis)
  - Sternocleidomastoid (SCM) strain
  - Lymphadenopathy
  - Congenital muscular torticollis
  - Congenital vertebral anomaly
  - Tumor/Malignancy
  - Dystonic reaction
  - Myasthenia gravis
  - Guillain-Barré syndrome
  - SAH
  - Visual or vestibular disturbances
  - Intervertebral disc calcification
  - Collagen vascular disease
  - Pseudotumor cerebri
  - Migraine headaches
  - Sandifer syndrome: GERD
  - Grisel syndrome: Ligamentous laxity causing atlantoaxial subluxation from inflammation, infection, or otolaryngologic procedures
  - Spasmus nutans
  - Spontaneous pneumomediastinum
  - Psychogenic

- Atraumatic with fever:
  - Meningitis:
    - Neonates: Group B streptococcus, gram-negative bacilli, *Listeria* species infection
    - Children/Adults: *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Haemophilus influenzae* type b, viral
    - Neurosurgical patients: *Staphylococcus*, gram-negative organisms
    - Transplant and dialysis patients: As above, plus fungal, *Listeria* species
    - AIDS: As above, plus TB, syphilis, fungal
  - Retropharyngeal abscess
  - Tonsillitis or peritonsillar abscess
  - Deep neck infection
  - Otitis media
  - Mastoiditis
  - Lymphadenitis/Abscess
  - Infected branchial cleft/thyroglossal duct cyst
  - Infectious mononucleosis
  - TB
  - Cat scratch disease (*Bartonella henselae*)
  - Tumor/Malignancy
  - Osteomyelitis/discitis of spine
  - Viral myositis
  - Upper lobe pneumonia
  - Grisel syndrome (described above)

## DIAGNOSIS

### HISTORY

- Trauma:
  - Mechanism to indicate severity
  - In young children, trauma may be unwitnessed.
- Fever:
  - High index of suspicion for meningitis in the setting of headache, altered mental status, seizures, photophobia, rash, or CNS abnormalities
  - Without obvious source of infection, consider occult infections such as vertebral osteomyelitis, discitis, or spinal epidural abscess.
- Assess for symptoms of neurologic injury:
  - Headache, vision changes, ataxia, gait disturbance, paresthesia, sensory changes, and bowel or bladder dysfunction
- Other symptoms to discern etiology:
  - Throat pain: Pharyngitis, retropharyngeal abscess, peritonsillar abscess, epiglottitis
  - Ear pain: Otitis media, otitis externa, mastoiditis
  - Dental pain: Abscess, Ludwig angina
  - Painful neck swelling: Cervical lymphadenitis, branchial cleft cyst abscess, thyroglossal duct cyst
  - Respiratory symptoms: Upper lobe pneumonia, neoplasm
  - Medications: Dystonic reactions
  - ENT or dental procedures: Grisel syndrome

### PHYSICAL EXAM

- In the setting of trauma, perform cervical spinal immobilization prior to the comprehensive exam.
- Assess for the presence of fever.
- Neurologic: Perform a complete neurologic exam focusing on signs of spinal cord involvement, such as motor and sensory function, gait, deep tendon reflexes, and rectal tone:
  - In the setting of trauma, assess for tenderness and pain with range of motion. Consider cervical spine fracture, subluxation, SCIWORA, and spinal epidural hematoma.
  - In the setting of fever, evaluate for signs of meningeal irritation (meningismus, the Kernig sign, the Brudzinski sign). Consider meningitis, spinal epidural abscess, SAH, and osteomyelitis.
- HEENT: Perform a thorough exam evaluating for the presence of specific etiology and hallmark signs:
  - Specific etiologies: Mass, superficial abscess, cellulitis of the scalp, middle ear effusion, mastoid tenderness, dental tenderness, pharyngeal erythema, lymphadenopathy
  - Hallmark findings: Drooling, uvula deviation, exquisite anterior neck tenderness, or trismus suggest neck or throat abscesses.
  - In the setting of any of the above inflammatory findings or recent otolaryngologic/dental procedures, consider Grisel syndrome.
  - Craniofacial asymmetry: Consider a congenital process.
  - Visual changes or cranial nerve dysfunction: Consider neoplasm or other intracranial etiology.
- Neck: Evaluate for mass, abnormal positioning, bony step-offs, point tenderness, spasm, and range of motion if not immobilized:
  - Normal active range (touching chin to chest; ear to the ipsilateral shoulder; and turning the head 90 degrees left and right, touching the chin to the contralateral shoulder) decreases the likelihood of clinically significant CSI.
  - Passive range of motion testing should be performed with caution because of the risk of vertebral subluxation.
  - Spasm and tenderness ipsilateral to head rotation (chin points to pain) suggests rotary subluxation as the SCM attempts to reduce the deformity.
  - Spasm and tenderness contralateral to head rotation (chin points away from pain) suggests inflammatory or congenital muscular torticollis as the affected SCM is pathologically shortened.
- Chest: Exam may reveal decreased breath sounds, crackles, egophony, or dullness to percussion, indicating an upper lobe pneumonia, rarely associated with meningismus.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Labs indicated by suspected etiology
- For infectious processes, consider:
  - CBC with differential
  - ESR and/or C-reactive protein
  - Blood cultures
  - CSF cell count, glucose, protein, and culture:
    - CT before lumbar puncture (LP) when increased intracranial pressure is suspected
    - Do not delay antibiotics for LP.

**Imaging**

- Plain film:
  - Cervical spine series (AP, lateral, and odontoid views) for suspected trauma
  - Soft tissue lateral for abscess or mass lesions
- US for evaluation (and aspiration) of abscess
- CT provides more definitive evaluation of soft tissue, bones, and patency of the airway.
- MRI for spinal cord or ligamentous pathology

**TREATMENT****PRE HOSPITAL**

- ABCs
- Cervical spine immobilization for any history of trauma
- Analgesia

**INITIAL STABILIZATION/THERAPY**

- Cervical spine immobilization if CSI is suspected (1,4):
  - Altered mental status or Glasgow Coma Scale <13
  - Focal neurologic findings
  - Neck pain
  - Torticollis
  - Substantial torso injury
  - Conditions predisposing to CSI (previous injury, congenital abnormality)
  - Diving or other high-risk mechanisms (motor vehicle collisions)
  - Distracting injury with pain that may mask cervical spine instability
- If airway management is necessary, rapid sequence intubation with in-line stabilization is the method of choice.
- If spinal cord involvement is detected, perform imaging of the cervical spine and consult neurosurgery.

**MEDICATION****First Line**

- Analgesics:
  - NSAIDs:
    - Ibuprofen
    - Naproxen
    - Ketorolac
  - Acetaminophen
  - Narcotics
- Antibiotics:
  - Indicated as soon as possible if infection is suspected
  - For cellulitis or abscess: Coverage for *Staphylococcus aureus*, *Streptococcus* species, +/- anaerobes:
    - 1st-, 2nd-, or 3rd-generation cephalosporins, amoxicillin/clavulanic acid, clindamycin
    - Vancomycin, trimethoprim/sulfamethoxazole, or clindamycin for MRSA
  - For suspected meningitis: Broad coverage is needed until specific pathogen isolated:
    - 3rd-generation cephalosporin
    - +/- Acyclovir for possible herpes infection

**Second Line**

If spinal cord injury is suspected, steroid use remains controversial (5):

- May improve neurologic outcome if administered within 8 hr of injury
- If used, methylprednisolone dose regimen:
  - IV bolus 30 mg/kg over 15 min, then maintenance infusion of 5.4 mg/kg/hr for 23 hr.

**SURGERY/OTHER PROCEDURES**

Surgery may be required for certain cervical spine fractures, congenital torticollis, or deep tissue infections.

**DISPOSITION****Admission Criteria**

- Identified etiology that requires hospitalization, such as cervical spine fracture, meningitis, or deep neck infection
- Unclear etiology for further evaluation if child is ill appearing, has persistent abnormal vital signs, altered mental status, neurologic deficits, unable to maintain adequate fluid intake, and/or unable to follow up
- Critical care admission criteria:
  - Hemodynamic instability
  - Signs of or potential for airway compromise
  - Signs of or potential for spinal cord injury

**Discharge Criteria**

- If the etiology is identified and responsive to therapy, the child may be treated and discharged with close follow-up.
- When the etiology is not identified, if the child is nontoxic and hemodynamically stable, he or she may be discharged with close follow-up for serial exams until the resolution of symptoms or a cause is identified.

**Issues for Referral**

If the child has persistent symptoms or pain, appropriate referral to the primary care provider and/or subspecialists should be made.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- If the definitive diagnosis is not determined in the emergency setting, close follow-up is mandatory until the neck stiffness resolves or a cause is identified.
- In the setting of trauma, children with persistent neck pain, point tenderness, and normal neurologic exam can be discharged with a cervical collar, analgesia, and close follow-up within 1 wk.
- Discharge instructions and medications:
  - Analgesia
  - Directed at the underlying etiology
  - Follow up within 24–48 hr.
- Activity:
  - Determined by the etiology of neck stiffness

**PROGNOSIS**

Dependent on the etiology

**COMPLICATIONS**

- Paralysis secondary to missed CSI
- Encephalopathy
- Permanent neurologic injury secondary to missed meningitis
- Death

- Tzimenatos L. Neck stiffness. In Fleisher GR, Ludwig S, eds. *Textbook of Pediatric Emergency Medicine*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2010:437.

**CODES****ICD9**

- 723.5 Torticollis, unspecified
- 952.00 C1–C4 level spinal cord injury, unspecified
- 959.09 Other and unspecified injury to face and neck

**PEARLS AND PITFALLS**

- A high index of suspicion must be maintained for unwitnessed trauma and subsequent CSI in the pediatric population.
- Neck stiffness with fever and headache is meningitis until proven otherwise.
- Spinal cord symptoms require neuroimaging with MRI and prompt evaluation by neurosurgery.

# NECROTIZING ENTEROCOLITIS

Monika Goyal

## BASICS

### DESCRIPTION

- Necrotizing enterocolitis (NEC) is a condition of diffuse necrotic injury to the mucosa and submucosa of the gut.
- It is one of the most common GI emergencies in the newborn period and is characterized by inflammation and bacterial invasion of the bowel wall:
  - Most common cause of intestinal perforation in the newborn period
- Occurs rarely in older children and adults
  - May result from immunosuppression associated with chemotherapy or acquired immunodeficiency
  - May result from compromise of mesenteric blood flow as may occur with cocaine use or mesenteric infarction.

### EPIDEMIOLOGY

- NEC occurs in 1–3 per 1,000 live births (1):
  - The incidence of NEC decreases with increasing gestational age and birth weight. It affects close to 12% of infants with birth weight <1,500 g (2).
- Although it is more common in premature infants, term and near-term babies can also be affected by NEC.
- ~10% of cases occur in term infants (3).

### RISK FACTORS

- The most important risk factor is prematurity.
- In full-term infants, the following risk factors have been noted: Cyanotic congenital heart disease, intrauterine growth restriction, birth asphyxia, gastroschisis, polycythemia, hypoglycemia, sepsis, exchange transfusion, umbilical lines, milk allergy, premature rupture of membranes, gestational diabetes, congenital hypothyroidism, antenatal cocaine abuse, and maternal pre-eclampsia (3).

### PATHOPHYSIOLOGY

The pathogenesis of NEC likely involves 3 factors: Substrate (usually enteral formula), mucosal injury, and the presence of bacteria:

- Inflammation in the bowel causes mucosal ulcerations and submucosal edema and hemorrhage. This results in intestinal infarction leading to transmural coagulation necrosis and perforation.
- Although lesions have been seen throughout the intestine, the most common sites of NEC are in the ileum and proximal colon.

### ETIOLOGY

Although the exact etiology remains unclear, it is thought to be a multifactorial process:

- Prematurity leading to compromised intestinal host defenses
- Immature intestinal motility and digestion
- Impaired function of the intestinal barrier resulting in bacterial translocation and immature intestinal repair
- Intestinal ischemia leading to mucosal damage
- Abnormal bacterial colonization (*Klebsiella*, *Enterobacter*, and *Clostridium* organisms)
- Enteral feeding (aggressive feeding protocols, use of formula)

### COMMONLY ASSOCIATED CONDITIONS

In older children, NEC may be associated with congenital heart disease; children with embolic, thrombotic, or vasculitic diseases resulting in mesenteric ischemia; unrecognized Hirschsprung disease; intestinal volvulus or surgical adhesions; typhilitis; AIDS; children treated with high doses of corticosteroids

## DIAGNOSIS

### HISTORY

- Prematurity
- Poor feeding
- Vomiting
- Diarrhea

### PHYSICAL EXAM

Triad of abdominal distension, heme-positive stools, and bilious emesis after initiation or increase in enteral feeding:

- Systemic signs: Apnea, respiratory failure, lethargy, temperature instability, hypotension, shock, disseminated intravascular coagulation (DIC)
- Abdominal signs: Distension, gastric retention, tenderness, hematochezia, bilious drainage from enteral feeding tubes

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Lab tests are not used to confirm the diagnosis or stage the disease, though they may assist with patient management.
- Lab abnormalities may include:
  - Thrombocytopenia
  - Metabolic acidosis
  - Hyperglycemia
  - Neutropenia
  - DIC
  - Hyponatremia
  - Blood cultures are positive in ~30% of infants with advanced NEC.

#### Imaging

Abdominal radiographs confirm the diagnosis of NEC, but findings vary based on the stage of disease:

- Each of the following may be seen on supine films:
  - Dilated bowel loops and air-fluid levels demonstrating ileus pattern (early)
  - Pneumatosis intestinalis (bubbles of gas in the small bowel wall) is pathognomonic of NEC but can be subtle.
  - Pneumoperitoneum when bowel perforation occurs
  - Football sign: Large hypolucent area in the central abdomen with markings from the falciform ligament
  - Sentinel loops (loop of bowel in fixed position) suggestive of necrotic bowel

### DIFFERENTIAL DIAGNOSIS

- Sepsis
- Volvulus
- Malrotation
- Meconium ileus
- Hirschsprung disease
- Bowel perforation
- Milk protein allergy
- Pseudomembranous colitis

## TREATMENT

### INITIAL STABILIZATION/THERAPY

Management is largely supportive and directed at preventing progression of damage:

- Establish a stable airway, and support ventilation as indicated.
- Keep patient NPO.
- An orogastric/NG tube should be placed to decompress the abdomen.
- IV fluids to maintain adequate circulation
- Repeat abdominal radiographs q6h to assess progression of NEC and to identify perforation.
- Follow fluid and electrolyte status.

### MEDICATION

- Parenteral antibiotics: Specific dosing is based on postnatal age and weight as well as postconceptual age (gentamicin).
- Ampicillin
- Gentamicin
- Vancomycin
- Metronidazole or clindamycin if bowel perforation suspected

### SURGERY/OTHER PROCEDURES

Surgery is indicated for intestinal perforation, pneumoperitoneum, or cellulitis of the anterior abdominal wall (signs of perforation or a gangrenous bowel):

- Surgical intervention is required in 25–50% of all cases.

### DISPOSITION

#### Admission Criteria

All patients suspected of having NEC should be hospitalized.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Patients who had any operative procedures should be followed by surgery.
- Patients who have had a history of NEC and subsequently have emesis or abdominal distention should be evaluated for complications of NEC such as intestinal strictures.

### DIET

- Most patients with NEC should have bowel rest for 10–14 days, after which enteral feedings are gradually resumed based on the clinical condition.
- Most patients with NEC require total parenteral nutrition during bowel rest.

### PROGNOSIS

With treatment, 70–80% of infants with NEC survive.

### COMPLICATIONS

- Bowel perforation
- Peritonitis
- Intra-abdominal abscess
- Sepsis
- DIC
- Hypotension
- Shock
- Meningitis
- Late complications include stricture formation, intestinal obstruction, and short bowel syndrome.

## CODES

### ICD9

- 777.50 Necrotizing enterocolitis in newborn, unspecified
- 777.51 Stage I necrotizing enterocolitis in newborn
- 777.52 Stage II necrotizing enterocolitis in newborn

## PEARLS AND PITFALLS

- Although NEC is most commonly a disease seen in the neonatal ICU, it can also present in full-term infants who have been discharged home.
- The presentation of NEC can be nonspecific:
  - Obstruction should always be considered in patients who have had a history of NEC and present with vomiting, feeding intolerance, or abdominal distension.

# NEEDLE STICK

Jyothi Lagisetty

Nirupama Kannikeswaran

## BASICS

### DESCRIPTION

- Needle stick injury is percutaneous inoculation of and contact with broken skin or mucous membranes by contaminated blood or body fluids.
- Severe infections that can be transmitted via needle stick injuries include:
  - HIV
  - Hepatitis B virus (HBV)
  - Hepatitis C virus (HCV)

### EPIDEMIOLOGY

#### Incidence

- Estimates indicate that 600,000–800,000 needle stick and other percutaneous injuries occur annually (1):
  - The annual incidence of needle stick injuries in U.S. health care workers (HCWs) is ~10% (2).
- Risk of seroconversion from a single needle stick injury without prior immunization (1):
  - HBV: 2% if hepatitis B e antigen (HBeAg) absent, 40% if HBeAg present
  - Risk of seroconversion: 26% if hepatitis B surface antigen (HBsAg) positive
  - HCV: 0–7%
  - HIV: 0.09–0.3% depending on mode of exposure

#### Prevalence

- The CDC reports an average of 6,100 HBV infections annually from 2002–2007.
- There were 849 cases of confirmed acute HCV in 2007.
- There were 57 documented HIV seroconversions in HCWs as of 2003. Of these, 26 developed AIDS (3).
- There have been 139 documented cases of HIV infection/AIDS among HCWs who reported occupational exposure, but no seroconversion has been documented (3).

### RISK FACTORS

- Profession: HCWs, prison workers, inmates, janitors, and waste handlers
- Immunization status of the victim and host susceptibility
- Level of disease and viral load in the source patient
- Failure to adhere to universal precautions, using equipment designed without appropriate safety measures, transferring body fluids between containers, failure of proper disposal of used needles in puncture-resistant sharps containers

### GENERAL PREVENTION

- Universal precautions: Routine use of gloves, masks, and impervious gowns as appropriate for the procedure (1).
- Avoid bending, breaking, or recapping of needles; if necessary use the 1-handed technique.
- Proper disposal of used needles in puncture-resistant sharps containers. These containers should preferably be within arm's reach of the working area.
- Immunization of HCWs

### PATHOPHYSIOLOGY

The major pathogens of concern in occupational body fluid exposure are HIV, hepatitis A, HBV, HCV, and hepatitis D:

- These pathogens are viruses that require percutaneous or mucosal introduction.

### ETIOLOGY

Infectious body fluids, usually blood

## DIAGNOSIS

### HISTORY

- Date and time of exposure, type of needle (hollow, nonhollow, sharp instrument), presence of bleeding, location of injury, depth of inoculation, duration of contact, whether device was clean or contaminated, and type of bodily fluid exposure
- Focus on source patient's medical history, including the presence or absence of aforementioned diseases:
  - If disease is present, the stage and severity of disease (acute vs. chronic, viral load) are needed.
  - Ask about risk factors (IV drug user, dialysis patient, history of repeated infusions).
- Obtain the exposed patient's medical history, including history of liver, kidney, or blood disease; hepatitis immunization; tetanus immunization; current medications; and allergies to medications.

### PHYSICAL EXAM

- No abnormal physical findings other than reported trauma should be apparent.
- Baseline screening exam of lungs, heart, liver, and lymph nodes should be documented for future reference.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Source patients:
  - Hepatitis B surface antigen
  - Hepatitis C antibody
  - Antibody to HIV: Consider using an FDA-approved rapid antibody test kit rather than ELISA.
- HCWs:
  - Hepatitis B surface antibody
  - Hepatitis C antibody (test at 2, 4, and 8 wk)
  - HIV
  - Pregnancy testing for women of child-bearing age
- Prior to initiation of antiretroviral agents: CBC with differential, BUN, creatinine, AST/ALT, alkaline phosphatase, total bilirubin levels, and urinalysis with microscopic analysis

#### Imaging

There is no need for imaging unless there is concern for a retained foreign body or tissue.

### DIFFERENTIAL DIAGNOSIS

- Intentional injury
- Malingering

## TREATMENT

### PRE HOSPITAL

Wounds and skin sites that have been in contact with blood or body fluids should be washed with soap and copious amounts of water:

- Flush mucous membranes with water/saline for at least 15 min.
- Application of caustic agents (bleach) or injection of antiseptics or disinfectants into wounds is not recommended.

### INITIAL STABILIZATION/THERAPY

- Direct and immediate referral to occupational health services or a primary care physician, when available, or the emergency department for lab testing and treatment
- Expedite triage
- Determine need for tetanus immunization:
  - Needle stick injuries are not considered a high risk for tetanus, and recommendations are the same as in any other wound except that if the exposed patient has not had the primary series for tetanus and diphtheria, tetanus immune globulin is not generally indicated.
- Evaluate the need for prophylactic therapy in the emergency department.
- HBV (4):
  - Known HBsAg-positive source:
    - Complete immunization confirmed by titer, no treatment
    - Incomplete immunization: Hepatitis B vaccine booster
    - Nonresponder to previous vaccination: Hepatitis B immunoglobulin (HBIG) × 2 doses
    - Antibody response not known: Test exposed person for anti-hepatitis B's. If adequate, no treatment. If inadequate, give HBIG × 1 dose and vaccine booster.
  - Known HBsAg-negative source:
    - Immunized: No treatment
    - Unimmunized: Give Hepatitis B vaccine series
    - If source not tested or status unknown: Initiate vaccination series if exposed person is unvaccinated. If a high-risk source, treat as if the source is HBsAg positive.
- HCV (4):
  - No vaccine exists to prevent HCV infection, and neither immunoglobulin nor antiviral therapy is recommended as postexposure prophylaxis.
- HIV (5):
  - Is the source material blood, bodily fluid, other infectious material, or an instrument contaminated with one of these sources?
    - No: There is no risk of HIV
    - Yes: What type of exposure occurred?
  - Exposure to mucous membrane or integrity compromised skin:
    - Was the volume small or large?
    - Small: Exposure code 1
    - Large: Exposure code 2

- Exposure was percutaneous:
  - Solid needle or superficial scratch: Exposure code 2
  - Large-bore hollow needle, device with visible blood, or needle used in patient's vein or artery: Exposure code 3
- Determine HIV status of exposure source:
  - HIV negative: No postexposure prophylaxis needed
  - HIV positive: Exposure low or high
  - Low exposure: Asymptomatic patients with high CD4 counts; HIV status code 1
  - High exposure: High or increasing viral loads with low CD4 counts or advanced AIDS; HIV status code 2
- Postexposure prophylaxis (PEP) is indicated if:
  - Exposure code 1 + HIV status code 1: PEP may not be indicated.
  - Exposure code 1 + HIV status code 2: Consider a basic regimen (2 nucleoside reverse transcriptase inhibitors [NRTI] or 1 NRTI and 1 nucleotide reverse transcriptase inhibitor [NtRTI]).
  - Exposure code 2 + HIV status code 1: Recommend a basic regimen.
  - Exposure code 2 + HIV status code 2: Recommend an expanded regimen (basic regimen + protease inhibitor).
  - Exposure code 3 + HIV status code 1 or 2: Recommend an expanded regimen.

## MEDICATION

- HBV:
  - Hepatitis B immune globulin 0.06 mL/kg IM
  - Recombinant vaccine (provides immunizations against all known subtypes of hepatitis B virus)—unit dose vial:
    - Pregnancy class C
- HIV:
  - Preferably initiate treatment 1–2 hr post-exposure (6).
  - 2-drug regimen (typically use AZT and Efavirenz but can substitute d4T if needed secondary to side effects):
    - Zidovudine (AZT, ZDV, Retrovir): 90–180 mg/m<sup>2</sup>/dose PO q6h; adult dose 200 mg PO t.i.d. for 4 wk
    - Lamivudine (3TC, Epivir): 4 mg/kg PO b.i.d.; adult dose 150 mg PO b.i.d. for 4 wk
    - Stavudine (d4T, Zerit): Pediatric: <13 days of age: 0.5 mg/kg/dose PO b.i.d.; >13 days but <30 kg: 1 mg/kg/dose PO b.i.d. Adult: 30–40 mg PO b.i.d.
  - 3-drug regimen (previous 2 drugs with addition of PI):
    - Kaletra (Lopinavir/Ritonavir): 80/20 mg solution: 7–15 kg: 12 mg/kg b.i.d.; 15–40 kg: 10 mg/kg b.i.d.; >40 kg (adult dose): 400/100 mg, 3 tablets b.i.d.

## DISPOSITION

### Admission Criteria

Isolated needle stick or body fluid exposures do not require admission.

### Discharge Criteria

Patients can be managed as outpatients with appropriate follow-up in an occupational health clinic.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Mandatory follow-up with occupational health services or an infectious disease specialist within 24–72 hr
- Activity:
  - As tolerated, the patient may return to work.
  - Safe sex practices until follow-up lab testing is negative for HIV

### Patient Monitoring

- Follow-up lab work and screening at 6 wk, 12 wk, and 6 mo post-exposure
- Recommend additional follow-up at 12 mo post-exposure for health care personnel who become HCV positive after exposure to a source who was coinfecting with HIV and HCV (6).

## PROGNOSIS

- Most do not develop seroconversion.
- For those who do, the prognosis is the same as for other routes of transmission for HBV, HCV, and HIV.

## COMPLICATIONS

- Infection at wound site
- Complications associated with acquisition of bloodborne disease (HIV, hepatitis A, HBV, HCV, and hepatitis D)
- Side effects of HIV prophylaxis

## ADDITIONAL READING

### See Also (Topic, Algorithm, Electronic Media Element)

- Hepatitis, Acute
- Sexually Transmitted Infections

## ICD9

- 042 Human immunodeficiency virus (HIV) disease
- 070.30 Viral hepatitis B without mention of hepatic coma, acute or unspecified, without mention of hepatitis delta
- 070.70 Unspecified viral hepatitis C without hepatic coma

## PEARLS AND PITFALLS

- Failure to educate the patient on the existence of retroviral therapy could be a source of significant medicolegal trouble should they subsequently develop HIV.
- Provide the exposed patient with brochures on bloodborne pathogens and the likelihood of transmission, recommended testing schedules, risks and benefits of postexposure prophylaxis, and the schedule for subsequent follow-up.
- Prophylactic antiviral medications to prevent HIV seroconversion often result in significant adverse effects and may result in severe hepatotoxicity. Patients should consider this when deciding whether to take medications.

# NEOPLASM, BRAIN

Joseph B. House  
Stuart A. Bradin

## BASICS

### DESCRIPTION

- Neoplasm of the brain results from abnormal growth of a specific cell type.
- Patients rarely have extraneural dissemination at the time of diagnosis.
- The World Health Organization classification is based on the specific histology of the abnormal cells of origin.

### EPIDEMIOLOGY

#### Incidence

- 2nd most frequent malignancy in childhood and adolescence
- 1,500–3,200 of those <20 yr of age are diagnosed with primary brain tumors each year.
- 28 new cases per million children <19 yr of age
- 36 new cases per million children <8 yr of age
- Incidence has increased by 35% in the past 20 yr:
  - May reflect greater detection due to improvements in diagnostic imaging

#### Prevalence

For all brain tumors: 130.8/100,000 with ~350,000 estimated living in U.S. in 2000:

- For malignant tumors: 29.5/100,000
- For benign tumors: 97.5/100,000

### RISK FACTORS

- Parental exposure in oil refining, rubber manufacturing; chemists
- Exposure to radiation therapy to the head as part of prior treatment for other malignancies
- Radiation exposure from head CTs is believed to increase an individual's lifetime risk for brain tumors; younger children are more vulnerable.
- Male predominance for medulloblastoma and ependymoma
- Familial and hereditary syndromes associated with increased incidence and account for 5% of cases
- Simian virus 40 may have an etiologic role in choroid plexus tumors.

### PATHOPHYSIOLOGY

Majority are caused by errors in genes involved in cell cycle control causing uncontrolled growth:

- Alteration directly in the gene or chromosome rearrangement causing change in function of the gene

### ETIOLOGY

- Astrocytomas:
  - Account for 40% of brain tumors
  - Occur throughout the CNS
  - Predominantly low grade with an indolent course
- Juvenile pilocytic astrocytomas (JPAs):
  - 20% of all brain tumors
  - Classic location in cerebellum
  - Low metastatic potential
  - Rarely invasive
  - 15% incidence associated with neurofibromatosis type I

- Fibrillary infiltration astrocytomas:
  - 2nd most common astrocytoma
  - Characterized by pattern of infiltration of tumor cells among normal neural tissue
  - Potential to evolve to malignant astrocytomas
- Malignant astrocytomas:
  - Less common in children and adolescents than in adults
  - 7–10% of all brain tumors
- Oligodendrogliomas:
  - Uncommon infiltrating tumor
  - Predominantly in the cerebral cortex and originate in white matter
- Ependymal tumors:
  - From ependymal lining of the ventricular system
  - Ependymoma is the most common of this type.
  - 10% of childhood brain tumors
  - 70% occur in posterior fossa
  - High incidence of CSF dissemination
- Choroid plexus tumors:
  - 2–4% of childhood CNS tumors
  - Most common in children <1 yr of age
  - Intraventricular epithelial neoplasms
  - Present with signs of increased intracranial pressure (ICP)
  - Mostly supratentorial in lateral ventricles
- Choroid plexus carcinomas:
  - Malignant tumor with potential to seed into CSF
- Embryonal tumors or primitive neuroectodermal tumors (PNET):
  - Most common group of malignant CNS tumor of childhood
  - 20–25% of pediatric brain tumors
  - Includes medulloblastoma, supratentorial PNET, ependymoblastoma
- Medulloblastomas:
  - Account for 90% of embryonal tumors
  - Most are midline in the cerebellar vermis.
  - High incidence of dissemination in CSF
- Pineal parenchymal tumors:
  - 2nd most common malignancy in pineal region after germ cell tumors
- Neuronal/Mixed neuronal glial tumors:
  - Slow growing
  - Low malignant progression
- Craniopharyngiomas:
  - 7–10% of all childhood brain tumors
  - Occur within suprasellar region
  - Solid with cystic components
  - Minimally invasive
  - Associated with significant mortality
- Germ cell tumors:
  - 1–2% of pediatric brain tumors
  - High incidence of CSF dissemination
  - Predominantly in midline structures
  - Multifocal occurrence in 5–10% of cases

- Brainstem tumors:
  - Account for 10–15% of primary CNS tumors
  - 1st year of life: Supratentorial tumors predominate
- Choroid plexus complex tumors and teratomas:
  - From 1–10 yr of age, infratentorial tumors predominate.
- JPAs and medulloblastomas:
  - After 10 yr of age, the supratentorial type predominate.
  - Diffuse astrocytomas
- Tumors of the optic pathway and hypothalamus region, brainstem, and pineal-midbrain region are more common than those in adults.

### COMMONLY ASSOCIATED CONDITIONS

- Neurofibromatosis
- Von Hippel-Lindau disease
- Li-Fraumeni syndrome
- Retinoblastoma

## DIAGNOSIS

### HISTORY

- Symptoms depend on the size and location of the lesion and are related to obstruction of CSF drainage or focal brain dysfunction.
- Classic triad: Headaches, nausea and/or vomiting, and papilledema
  - Headache is improved with vomiting.
- Changes in personality, mentation, and speech; lethargy and irritability
- Loss of milestones
- New-onset seizure

### PHYSICAL EXAM

- Related to location of the tumor
- Initial exam: Complete neurologic exam, including reflexes, strength, and ophthalmologic assessment
- Supratentorial tumors:
  - Changes in personality, mentation, and speech
  - Focal disorders of motor weaknesses, sensory changes, speech disorders, seizures, and reflexes
  - Optic pathway tumors present with visual disturbances (decreased visual acuity, Marcus Gunn pupil, nystagmus, and/or visual field defects)
  - Suprasellar region and 3rd ventricle tumors may present with signs of neuroendocrine deficit (galactorrhea, precocious puberty, delayed puberty).
  - Diencephalic syndrome: Failure to thrive, emaciation, euphoric affect
  - Parinaud syndrome, pineal region tumors: Paresis of upward gaze, papillary dilation reactive to accommodation but not to light, nystagmus to convergence or retraction and eyelid retraction
- Infratentorial:
  - Disorders of equilibrium, gait, and coordination
- Brainstem:
  - Gaze palsy, multiple cranial nerve palsies, upper motor neuron deficits (hemiparesis, hyperreflexia, clonus)

**DIAGNOSTIC TESTS & INTERPRETATION****Lab****Initial Lab Tests**

- Levels of  $\beta$ -hCG and  $\alpha$ -fetoprotein in serum and CSF fluid can assist in the diagnosis of germ cell tumors and monitoring of treatment response.
- Cytologic analysis of CSF fluid

**Imaging**

- CT scan:
  - Often easier to obtain emergently than MRI
  - Allows evaluation of ventricle size
  - Calcified cortical mass in children with new-onset seizure suggestive of oligodendroglioma
- MRI:
  - Neuroimaging gold standard
  - No radiation exposure
  - Tumors in the posterior fossa, pituitary/suprasellar region, optic path, and infratentorial are better delineated.
  - Contrast may show enhancement of the lesion.
  - Fluid-attenuated inversion recovery (FLAIR) sequences are useful in determining tumor infiltration or peritumor edema.
- Positron emission tomography (PET) scan:
  - Sensitive and specific imaging
  - Measures tissue metabolism
- Magnetic resonance spectroscopy (MRS):
  - Measures biologically important molecules
- Bone scan:
  - To look for signs of metastasis
- Myelogram

**Diagnostic Procedures/Other**

- Lumbar puncture:
  - Delayed until after surgery or ventriculoperitoneal shunt (VPS) placement in those with signs of increased ICP; otherwise, may lead to herniation
- Biopsy:
  - Assists in establishing diagnosis

**Pathological Findings**

Most tumors show increased cellularity as compared to normal brain tissue.

**DIFFERENTIAL DIAGNOSIS**

- Migraine or sinus headache
- Meningitis
- Hemorrhagic or ischemic stroke
- Demyelinating disease
- Benign intracranial HTN
- Cerebral abscess or parasitic cyst
- Arteriovenous malformation

**TREATMENT****PRE HOSPITAL**

Assess and stabilize airway, breathing, and circulation:

- Immediate airway control for signs of airway depression due to increased ICP infatigability and impairment of growth

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Corticosteroid treatment:
  - Treats and prevents brain edema
- Anticonvulsants for seizures

**MEDICATION**

- Dexamethasone 1–2 mg/kg IV/IM  $\times$  1 loading dose
- Ibuprofen 10 mg/kg PO/IV q6h PRN for pain
- Acetaminophen 15 mg/kg PO/PR q4h PRN for pain
- Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
  - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
- Ondansetron 0.15 mg/kg IV q45min up to 0.45 mg/kg total, then q4–8h PRN for nausea, vomiting:
  - This dose is lower than required to treat nausea and vomiting from chemotherapy.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Radiation therapy:
  - Used when surgical resection is not feasible or is incomplete
- Bone marrow transplantation

**SURGERY/OTHER PROCEDURES**

- VPS to alleviate increased ICP
- Tumor resection is usually the 1st step:
  - The goal is to resect as much tumor as possible while maintaining maximal neurologic function.
  - Complete surgical resection of JPA is associated with survival of 80–100%; with partial (<80%) resection, survival decreases to 50–95%.

**DISPOSITION****Admission Criteria**

- Critical care admission criteria:
  - New diagnosis of tumor with signs of increased ICP
- All other stable patients with newly diagnosed brain tumors should be admitted to an oncology unit for further management.

**Issues for Referral**

- Neurosurgery for immediate intervention for signs of increased ICP
- Oncology for further workup and evaluation of tumors
- Rehabilitation:
  - If loss of motor skills or muscle strength

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- After stabilization and initiating treatment, patients may be discharged.
- Close follow-up with oncology
- Return for severe headache, focal weakness, intractable vomiting, altered mental status, or seizure.

**Patient Monitoring**

For signs of increased ICP

**PROGNOSIS**

- Highly variable and depends on the histologic type of tumor; extent of metastasis; size and location; response to therapy; age and overall health of child; and child's tolerance of specific medication, procedures, or therapies
- Mortality approaches 45%
- Highest morbidity of all childhood malignancies

**COMPLICATIONS**

- Increased ICP
- Cerebral herniation
- Seizure disorder

**ADDITIONAL READING**

- Cohen BH, Garvin JH Jr. Tumors of the central nervous system. In Rudolph AM, Rudolph CD, Hostetter MK, et al., eds. *Rudolph's Pediatrics*. 21st ed. New York, NY: McGraw-Hill; 2003:546–592.
- Davis FG, Kupelian V, Freels S, et al. Prevalence estimates for primary brain tumors in the United States by behavior and major histology groups. *Neuro Oncol*. 2001;3(30):152–158.
- Kuttesch JF Jr., Ater JL. Brain tumors in childhood. In Kliegman RM, Behrman RE, Jenson HB, et al., eds. *Nelson Textbook of Pediatrics*. 18th ed. Philadelphia, PA: WB Saunders; 2007:2128–2137.
- Packer RJ. Brain tumors in children. *Arch Neurol*. 1999;56:421–425.

**CODES****ICD9**

- 191.9 Malignant neoplasm of brain, unspecified site
- 225.0 Benign neoplasm of brain
- 239.6 Neoplasm of unspecified nature of brain

**PEARLS AND PITFALLS**

- Consider brain tumor when evaluating a child with vomiting without fever or diarrhea, especially if associated with headache.
- Prior to performing a lumbar puncture, ensure that the patient does not have increased ICP.

# NEOPLASM, LYMPHOMA

Karen Y. Kwan

## BASICS

### DESCRIPTION

- Lymphomas are a heterogeneous group of malignancies arising from lymphoid cells, within lymphoid organs.
- Lymphomas are categorized into 2 major categories: Hodgkin lymphoma or Hodgkin disease (HD) and others known collectively as non-Hodgkin lymphomas (NHLs).

### EPIDEMIOLOGY

#### Incidence

- The 2005 U.S. age-adjusted incidence was 25.2 per 1,000,000 persons 0–19 yr of age.
- In the U.S., ~1,700 children and adolescents <20 yr of age are diagnosed with lymphomas per year, of which ~60% are NHL.
- Predominance for NHL in children, with 70% of cases occurring in males

#### Prevalence

- Lymphomas account for 3% cases of all cancers in the U.S.
- ~15% of childhood malignancies are lymphomas (3% for those <5 yr of age to 24% for those 15–19 yr of age).
- 3rd most common cancer in children after leukemia and malignant brain neoplasms

### RISK FACTORS

- HD:
  - Genetics: Monozygotic twins have a 99-fold increased risk; other siblings have a 3–7 times increase.
  - Epstein-Barr virus infection with history of infectious mononucleosis and high titer antibodies
  - In children <10 yr of age, increased risk is associated with lower socioeconomic status.
- NHL:
  - Immunodeficiency including immunosuppressive therapy, congenital immunodeficiency syndromes (eg, ataxia telangiectasia), AIDS
  - Epstein-Barr virus in patients with immunodeficiency and “African-type” Burkitt lymphoma, with chronic immune suppression due to malaria as a cofactor

### PATHOPHYSIOLOGY

- HD:
  - Malignancy of lymphoid cells, defined by the presence of Reed-Sternberg cells, which appear clonal and from B-lymphocyte lineage
  - There are 4 histologic subtypes of HD.
    - Nodular sclerosing, the most common subtype, affects 40% of younger patients and 70% of adolescents.
    - Mixed cellularity (30%) is seen more commonly in children <10 yr of age and in those with HIV infections.
    - Lymphocytic predominance (10%), usually more common in males and presenting with localized disease
    - The lymphocytic depletion subtype accounts for <2–5% of cases in patients <20 yr of age.
- NHL:
  - Pediatric NHLs are all *high-grade* malignancies, divided into 3 major categories.
    - Small, noncleaved cell lymphoma (SNCL) (Burkitt and non-Burkitt subtypes), found in 50% of pediatric cases. SNCLs express surface immunoglobulins, mostly IgM, identifying them as B-cell malignancies. They are due to translocation of chromosome 8.
    - Lymphoblastic lymphoma, which comprises 35% of pediatric cases, is predominantly of thymic T-cell origin. It is due to translocations with T-cell receptor genes on chromosome 14.
    - Large cell NHL comprises 15% of cases.

### COMMONLY ASSOCIATED CONDITIONS

- Lymphoma is the lead point for intussusception in up to 50% of children >6 yr of age.
- Superior vena cava syndrome due to compression of the great vessel may be found in NHLs.

## DIAGNOSIS

### HISTORY

- Symptoms may be general and nonspecific.
- Generalized malaise, fever, adenopathy
- Headache, nausea, vomiting
- Constitutional symptoms with fever, night sweats, and weight loss (more common in HD)
- Abdominal pain, intussusception, bowel obstruction, diarrhea (more common in NHL)
- Cough, shortness of breath without fever, or new onset of reactive airway disease (more common in NHL)
- Swelling of the neck and face (more common in NHL)

### PHYSICAL EXAM

- The most common physical exam finding in HD is firm, fixed superficial lymphadenopathy; 60–80% present with cervical and/or supraclavicular nodes, and 30% have axillary adenopathy.
- Common physical exam findings in NHL include nontender, firm, fixed superficial lymphadenopathy; symptomatic airway compromise; and abdominal obstruction.
- Endemic or African Burkitt lymphoma classically presents in children as a jaw or facial bone tumor.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC with differential
- ESR
- Serum electrolytes, with BUN, creatinine, calcium, magnesium, phosphorus
- Hepatic function tests, bilirubin, liver enzymes, protein, albumin
- Serum lactate dehydrogenase, uric acid, and alkaline phosphatase to evaluate for tumor lysis syndrome
- Tumor lysis syndrome is a direct result of breakdown products from dying cancer cells. Metabolic derangements include hyperkalemia, hyperphosphatemia, hyperuricemia, hyperuricosuria, hypocalcemia, and consequent acute uric acid nephropathy leading to acute renal failure.
- If the patient is febrile, obtain blood and urine cultures. Consider stool and throat cultures.

#### Imaging

- Chest radiography (PA/lateral) to assess for mediastinal mass and to evaluate airway patency
- CT of the neck and chest; CT or MRI of abdomen and pelvis for staging of lesions
- Bone scan, gallium scan, or lymphangiogram to identify additional disease sites and for staging.

#### Diagnostic Procedures/Other

- Baseline ECG
- Biopsy of lymph node or tissue biopsy is mandatory to determine the histologic diagnosis.
- Bone marrow aspiration to assess for evidence of bone marrow involvement
- Lumbar puncture to determine spread/staging
- HD (Ann Arbor):
  - Stage 1: Single lymph node region (I) or a single extralymphatic organ or site (I<sub>e</sub>)
  - Stage 2: ≥2 lymph node regions on the same side of diaphragm (II) or extralymphatic organ/site and ≥1 lymph node regions on the same side of the diaphragm (II<sub>e</sub>)
  - Stage 3: Both sides of diaphragm (III), may involve spleen (III<sub>s</sub>) or localized extralymphatic organ (III<sub>e</sub>) or both (III<sub>s,e</sub>)
  - Stage 4: Diffuse or disseminated involvement of ≥1 extralymphatic organs or tissues with/without associated lymph node involvement

- NHL (St. Jude/Murphy):
  - Stage 1: Single tumor (extranodal) or a single anatomic area (nodal), excluding the mediastinum and abdomen
  - Stage 2: Single tumor (extranodal) with regional node involvement;  $\geq 2$  nodal areas or 2 single (extranodal) tumors with/without regional node on the same side of the diaphragm; a primary GI tumor (usually ileocecal area) with/without local mesenteric nodes
  - Stage 3: Tumors or lymph node groups (extranodal) on both sides of the diaphragm, or any primary intrathoracic tumor (mediastinal, pleural, thymic), or extensive intra-abdominal disease, or any paraspinal or epidural tumor
  - Stage 4: Any of the above findings with involvement of the CNS, bone marrow, or both

### Pathological Findings

Histopathologic hallmark of HD is the Reed-Sternberg cell, a large cell with abundant cytoplasm and multiple or multilobulated nuclei.

### DIFFERENTIAL DIAGNOSIS

- Leukemia and other malignancies
- Infectious: Epstein-Barr virus, toxoplasmosis, cytomegalovirus, bartonella disease, group A streptococcus, gonococcus, TB, secondary syphilis, hepatitis B, lymphogranuloma venereum, HIV, histoplasmosis
- Rheumatologic/Autoimmune: Systemic lupus erythematosus, rheumatoid arthritis, sarcoidosis, Kawasaki disease
- Mediastinal masses: Lymphoid tumor, thyroid tumor, aortic aneurysm, bronchogenic cyst, esophageal lesion, hernias

### TREATMENT

#### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Assess patients for tumor lysis syndrome; if suspected/confirmed, administer IV fluids at twice maintenance rates, with sodium bicarbonate (40–80 mEq/L  $\text{NaHCO}_3$ ) for alkalinization of urine (goal pH of  $\sim 7$ –7.5 for maximum uric acid solubility).
- May need to administer allopurinol or recombinant urate oxidase
- Acute renal failure requires dialysis.

### MEDICATION

#### First Line

Treatment of tumor lysis syndrome:

- Hyperuricemia:
  - Uricase- (enzyme urate oxidase) catalyzes oxidation of uric acid
  - Allopurinol 3 mg/kg/dose PO t.i.d.:
    - Inhibits formation of uric acid to prevent or correct hyperuricemia
  - Furosemide 1 mg/kg IV t.i.d.:
    - To maintain urine output  $> 100 \text{ mL/m}^2/\text{hr}$
- Hyperkalemia associated with tumor lysis syndrome:
  - Sodium polystyrene sulfonate 1 g/kg PO q6h
    - To maintain urine output  $> 100 \text{ mL/m}^2/\text{hr}$
  - Calcium gluconate 100–200 mg/kg IV
  - Insulin (0.1 U/kg) plus 10% glucose (5 mL/kg)
  - Albuterol 0.05 cc/kg 0.5% solution nebulized
- Hyperphosphatemia associated with tumor lysis syndrome:
  - Aluminum hydroxide 25 mg/kg PO q6h

- Hypocalcemia associated with tumor lysis syndrome:
  - Calcium gluconate 100–200 mg/kg
- IV Antibiotics for fever and neutropenia and/or signs of sepsis
  - Broad gram-positive and gram-negative coverage:
    - Vancomycin 10 mg/kg IV q8h
    - Ceftriaxone 50 mg/kg IV per day

### Second Line

Current multiagent chemotherapy treatment regimens are based on the histopathology and staging of the particular lymphoma and should be initiated by an oncologist.

### DISPOSITION

#### Admission Criteria

- Most children with newly diagnosed lymphoma will require hospitalization for stabilization and initiation of staging and treatment.
- In particular, patients who have tumor lysis syndrome, are ill appearing or septic, have airway compromise, or have acute renal failure require admission to the critical care setting.

#### Discharge Criteria

After the initial hospitalization, children without airway compromise, metabolic derangements, tumor lysis syndrome, or infection may be discharged with oncologic follow-up.

### FOLLOW-UP

#### FOLLOW-UP RECOMMENDATIONS

- The management of children with lymphoma requires a multidisciplinary approach led by a pediatric oncologist.
- Referral to a pediatric cancer center is highly preferable.

#### PROGNOSIS

- Depends on the results of histopathology, diagnostic imaging, and staging of the particular lymphoma.
- From 1985–1994, the 5-yr survival rate for children  $< 20$  yr of age with NHL was 72%.
- From 1985–1994, the 5-yr survival rate for children  $< 20$  yr of age with HD was 91%.

#### COMPLICATIONS

- Recurrence
- Tumor lysis syndrome
- Airway obstruction
- Renal failure
- Sepsis
- Shock
- Death

### CODES

#### ICD9

- 200.20 Burkitt's tumor or lymphoma, unspecified site
- 201.90 Hodgkin's disease, unspecified type, unspecified site
- 202.80 Other malignant lymphomas, unspecified site

### PEARLS AND PITFALLS

- A mediastinal or cervical lymphoma may cause airway compromise. In this case, an artificial airway may need to be inserted prior to sedating a child about to undergo a staging CT or MRI.
- Due to their high-grade nature, NHLs typically grow rapidly. Delay between diagnosis and start of chemotherapy must be minimized.

# NEOPLASM, NEUROBLASTOMA

Monika Goyal

## BASICS

### DESCRIPTION

- Neuroblastoma is a neoplasm of the sympathetic nervous system.
- Neuroblastomas are derived from neural crest cells.
- The most common extracranial solid tumor, usually occurring in the abdomen

### EPIDEMIOLOGY

#### Incidence

- Overall incidence estimated at 1 case per 1,000 live births:
  - >600 new cases are diagnosed in the U.S. each year (1).
  - Incidence peaks between 0 and 4 yr of age, and the median age of diagnosis is at 2 yr of age.
- Accounts for >7% of malignancies in patients <15 yr of age
- Accounts for almost 15% of all pediatric cancer-related deaths

### RISK FACTORS

- Genetic factors (1):
  - Familial neuroblastoma accounts for <5% of all cases and seems to follow an autosomal-dominant pattern of inheritance with incomplete penetrance.
- Maternal factors (1):
  - Recreational drug use: 1 study identified marijuana use in the 1st trimester and another study identified maternal opiate use to be associated with neuroblastoma in offspring.
  - Protective factors: Maternal folate consumption

### PATHOPHYSIOLOGY

Arises from primordial neural crest cells, which migrate during embryogenesis to form the adrenal medulla and sympathetic ganglia:

- Tumors may arise anywhere along the sympathetic nervous system, but the majority are found in the adrenal glands (40%), followed by abdominal (25%), thoracic (20%), cervical (5%), and pelvic sympathetic ganglia (5%).
- The tumor typically spreads to regional lymph nodes, bone, and bone marrow but can also metastasize to the skin, liver, orbits, and soft tissues.

### ETIOLOGY

- Little is known about the etiology of neuroblastoma.
- Pathogenesis thought to be related to a succession of mutational events, prenatally and perinatally, that may be caused by environmental and genetic factors (see Risk Factors).

### COMMONLY ASSOCIATED CONDITIONS

Association with congenital anomalies: Congenital anomalies co-occur with neuroblastoma in 5% of cases. These include:

- Turner syndrome
- Hirschsprung disease
- Central hypoventilation
- Neurofibromatosis type 1
- Beckwith-Wiedemann syndrome
- Von Recklinghausen syndrome
- Rubenstein-Taybi syndrome
- Congenital heart disease

## DIAGNOSIS

### HISTORY

Symptoms depend on the size and location of the primary tumor and/or whether the tumor has metastasized:

- Patients with localized disease can be asymptomatic, whereas children with advanced disease appear ill at presentation with systemic symptoms.
- Symptoms based on tumor location:
  - Abdominal pain or constipation
  - Bony pain
  - Localized back pain or weakness (from spinal cord compression)
  - Bowel or bladder dysfunction
  - Secretory diarrhea (from paraneoplastic production of vasoactive intestinal polypeptide [VIP])
  - Dysphagia, dyspnea, chronic cough from thoracic tumors
  - Systemic symptoms (fever, weight loss, malaise)
  - Bone pain
  - Unilateral nasal obstruction

### PHYSICAL EXAM

- Signs depend on size and location of primary tumor and/or whether the tumor has metastasized.
- Signs can be related to a local mass effect of the tumor or metastasis and include the following:
  - HTN
  - Paraplegia from paraspinal tumors
  - Horner syndrome (ptosis, miosis, and anhydrosis) from cervical masses
  - Heterochromia from cervical masses
  - Proptosis from orbital involvement
  - “Raccoon eyes” (periorbital ecchymoses) from orbital involvement
  - Limping from involvement of long bones
  - Abdominal mass: Usually hard, smooth, and nontender

- Nontender subcutaneous nodules
- Scrotal and lower extremity edema from compression of venous or lymphatic systems
- Up to 5% of newly diagnosed cases will present with neurologic signs related to cord impingement, including motor weakness, pain, and sensory loss (2).
- Opsoclonus-myooclonus ataxia syndrome: Seen in 2–4% of patients with neuroblastoma; a paraneoplastic phenomena that consists of rapid eye movements, ataxia, and irregular muscle movements (“dancing eyes/dancing feet”) thought to be cerebellar responses to antibodies against the neural tissue of the tumor

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC: Decreased hemoglobin, platelets, and/or WBC counts from marrow infiltrate
- Lactate dehydrogenase and ferritin: May be elevated
- Urine vanillylmandelic acid, homovanillic acid: Elevated in 95% of cases
- Electrolytes: Vasoactive intestinal peptide secretion can cause a secretory diarrhea with associated hypokalemia
- Renal and hepatic function tests

#### Imaging

- Chest radiograph to evaluate for mediastinal tumor if respiratory complaints or presence of Horner syndrome
- If an abdominal mass is palpated, US should be obtained to initiate the workup. If the US suggests neuroblastoma as a possible etiology, an abdominal and pelvic CT or MRI should be obtained:
  - Spinal MRI if concern for paraspinal tumors
  - Iodine-131-meta-iodobenzylguanidine (MIBG) scan: Ultimately, patients with suspected neuroblastoma undergo an MIBG scan, a chemical analog of norepinephrine, which is both sensitive and specific for neuroblastoma, as it is taken up by neuroblastoma but not by normal bone.

#### Diagnostic Procedures/Other

Tissue biopsy confirms the diagnosis.

### DIFFERENTIAL DIAGNOSIS

Tumors:

- Abdominal: Wilms tumor, hepatoblastoma, lymphoma, and germ cell tumor should be considered.

- Thoracic and retroperitoneal: Lymphoma, germ cell tumors, and infection
- Spinal: Desmoid tumors, epidermoid tumors, teratomas, and astrocytomas
- Opsoclonus-myoclonus ataxia syndrome can occur with other conditions besides neuroblastoma: Idiopathic opsoclonus-myoclonus syndrome, infections, ingestions, metabolic derangements.

## TREATMENT

Treatment is based on tumor risk classification and consists of a combination of:

- Surgical resection
- Chemotherapy
- Radiation

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation:
  - Thoracic tumors may present with respiratory compromise.
  - Central hypoventilation may occur.
- Obtain IV access, and provide hemodynamic support as indicated:
  - Some tumors may present with intra-abdominal hemorrhage.
- 5% of children with neuroblastoma present with spinal cord compression. If suspected, administer corticosteroids and obtain a neurosurgical consult.
- Oncology consult

### DISPOSITION

#### Admission Criteria

- Patients diagnosed with neuroblastoma or with suspected neuroblastoma should be admitted to the hospital to undergo further workup for diagnosis and staging.
- Critical care admission criteria:
  - If presenting with respiratory and/or hemodynamic compromise or cord compression, admission to an ICU is warranted.

#### Issues for Referral

All patients should be followed by a pediatric oncologist.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- As per pediatric oncologist

### Patient Monitoring

Monitor for complications as an outpatient (see Complications).

### PROGNOSIS

Outcome is variable, and neuroblastoma tends to exhibit 3 different patterns—rapid progression to life-threatening illness, maturation to benign ganglioneuroma, and spontaneous regression:

- Likelihood of survival is dependent on the age of the patient, stage, and biologic characteristics of the disease.
- Poorest prognosis is seen in children diagnosed at an older age (> 15 mo), in those diagnosed at later stages of disease, and in those positive for certain molecular biologic markers.
- Prognosis is also dependent on the degree of cellular differentiation within the tumor that has been categorized into an international neuroblastoma staging system.

### COMPLICATIONS

- Sepsis
- Shock
- Airway or breathing compromise
- Central hypoventilation
- Vasoactive intestinal peptide syndrome with profuse diarrhea and electrolyte imbalance
- Sympathomimetic symptoms similar to pheochromocytoma due to catecholamine excess
- Recurrence

## CODES

### ICD9

- 194.0 Malignant neoplasm of adrenal gland
- 195.1 Malignant neoplasm of thorax
- 195.2 Malignant neoplasm of abdomen

## PEARLS AND PITFALLS

- Although most commonly found in the abdomen, neuroblastoma can arise anywhere throughout the sympathetic nervous system.
- Clinical presentation of opsoclonus and myoclonus should prompt an immediate evaluation for neuroblastoma.
- Neuroblastoma should be considered in patients presenting with unexplained periorbital ecchymoses (raccoon eyes).
- Neuroblastomas are unique in their highly variable disease severity, which may involve spontaneous regression, maturation to a benign ganglioneuroma, or aggressive disease with metastatic dissemination and death.

# NEPHROTIC SYNDROME

Jennifer R. Marin

## BASICS

### DESCRIPTION

- Nephrotic syndrome is characterized by proteinuria, hypoalbuminemia, edema, and hyperlipidemia (2).
- It is caused by renal diseases that increase the permeability across the glomerular filtration barrier (1).

### EPIDEMIOLOGY

#### Incidence

- Incidence is reportedly 2–7 cases per 100,000 children per year (3).
- 16/100,000 children have nephrotic syndrome.
- Most children with nephrotic syndrome present before the age of 6 yr (1).

### RISK FACTORS

- Male gender
- Age <6 yr
- Glomerulonephritis

### PATHOPHYSIOLOGY

- The proteinuria is due to increased filtration of macromolecules such as albumin across the glomerular capillary wall.
- Water movement from the intravascular space to the interstitial space causes edema, ascites, and effusions (3).
- There are several disease-specific mechanisms that are responsible for the increase in permeability in the glomerulus, such as immune and nonimmune factors and mutations in podocytes and proteins within the kidney (3).

### ETIOLOGY

- Nephrotic syndrome is classified into primary (idiopathic), secondary, and congenital.
- Idiopathic nephrotic syndrome is present when there is no identifiable systemic disease and is based on the histopathologic findings from renal biopsy:
  - Minimal change disease (MCD): Most common cause in children
  - Focal segmental glomerulosclerosis (FSGS)
  - Mesangial proliferation
- Secondary nephrotic syndrome is associated with a systemic disease or is secondary to another process causing glomerular injury:
  - Systemic lupus erythematosus (SLE)
  - Postinfectious glomerulonephritis
  - Infective endocarditis
  - Vasculitides such as Henoch-Schönlein purpura (HSP) or Wegener granulomatosis
  - Alport syndrome
  - Hemolytic uremic syndrome
  - Medication induced

- Infants <3 mo of age with nephrotic syndrome are considered to have congenital nephrotic syndrome (1):
  - The most common cause is an autosomal recessive disorder resulting from a gene mutation common in the Scandinavian population.
  - Other causes include congenital infections (syphilis, toxoplasmosis, rubella, HIV, etc.).

## DIAGNOSIS

### HISTORY

- Most often, a parent or caregiver will notice swelling, particularly in the periorbital or genital areas:
  - The edema is dependent; over the course of the day, edema will increase in the lower extremities and decrease on the face.
  - The swelling may be concentrated in the sacral area while in the recumbent position.
  - If there is significant ascites, a family member may comment on the size of the abdomen or note weight gain, or the child may complain of abdominal discomfort.
  - Patients may develop umbilical or inguinal hernias.
  - There may be respiratory symptoms if there are pleural effusions.
- Fatigue, malaise, and decreased appetite may be reported.
- Past medical history should focus on medication use, comorbidities, renal disease, or vasculitis.

### PHYSICAL EXAM

- Many patients, despite the appearance of fluid overload, have depleted intravascular volume:
  - They may be tachycardic with weak pulses and poor peripheral perfusion.
- As noted, edema is soft and pitting:
  - Assess for edema in the lower extremities, scrotum or labia, and face.
- Ascites may be detected.
- If pleural effusions are present, decreased breath sounds may be detected.
- HTN may be seen with nephrotic syndrome; however, it is an uncommon feature of MCD.
- Rashes may suggest associated conditions such as SLE or HSP.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

The diagnosis is made by demonstrating nephritic-range proteinuria and hypoalbuminemia.

#### Initial Lab Tests

- Urine: Nephrotic-range proteinuria is defined as urinary protein excretion >50 mg/kg/day or 40 mg/m<sup>2</sup>/hr (4).
  - Measurement is done via a 24-hr urine collection

- Alternatively, urine protein excretion can be estimated by the total protein to creatinine ratio on a spot urine sample, with >0.2 mg protein/mg creatinine indicating nephritic-range proteinuria (1).
- A urinary dipstick can be used as a screen for proteinuria, with 3+ to 4+ suggesting significant protein excretion (1).
- Hematuria is not a common feature of nephrotic syndrome, but it can be present in FSGS and less often with MCD.
- CBC
- Serum electrolytes, BUN, creatinine, serum albumin, and total protein
- Consider C3 and C4 complement levels and total cholesterol.
- Lab values:
  - Serum albumin is typically <3 g/dL and can be as low as 1 g/dL (5).
  - Serum total cholesterol, triglycerides, and total lipids are elevated.
  - Cholesterol is inversely related to the serum albumin.
  - Serum creatinine may be elevated secondary to hypovolemia or renal insufficiency.
  - Hyponatremia may be seen due to decreased free water excretion secondary to stimulation of antidiuretic hormone from hypovolemia.
  - Hemoglobin/Hematocrit may be elevated secondary to hypovolemia or may be low due to poor free water excretion secondary to the loss of iron-binding factors in the urine causing an iron-deficiency anemia (5).
  - Serum complement levels may be useful in defining the etiology of nephrotic syndrome.
  - Low C3 levels are seen in MPGN and postinfectious glomerulonephritis, and low C3 and C4 are seen in patients with SLE nephritis.

#### Diagnostic Procedures/Other

- Most cases of pediatric nephrotic syndrome are secondary to MCD; however, when the diagnosis is in question, a renal biopsy should be performed.
- A presumptive diagnosis of MCD can be made based on clinical findings predictive of MCD (3):
  - <6 yr of age
  - Absence of HTN
  - Absence of hematuria
  - Normal complement levels
  - Normal renal function

**Pathological Findings**

Described under Etiology

**DIFFERENTIAL DIAGNOSIS**

- Heart failure
- Other causes of hypoalbuminemia, such as protein-losing enteropathy or malnutrition
- Cirrhosis
- Allergic reaction
- Hereditary angioedema

**TREATMENT**

Treatment decisions should be made together with a pediatric nephrologist (6).

**INITIAL STABILIZATION/THERAPY**

- For the patient in shock, despite the presence of peripheral edema, initial management includes boluses of 20 mL/kg of normal saline until circulation is restored (5).
- For dehydration without shock, sodium-deficient fluids should be administered orally at twice maintenance, or hypotonic IV fluids (D5 0.25 normal saline) may be started if oral rehydration is not tolerated (5).
- In the case of adequate hydration but massive edema, a diuretic should be used, such as furosemide.
- If the serum albumin is  $<1.5$  g/dL, diuretics may not be effective; therefore, a combination of albumin infusions followed by IV furosemide may be warranted (5).

**MEDICATION****First Line**

- Corticosteroids are first-line therapy.
- Treatment is based on whether patients are corticosteroid responsive or resistant; this correlates with the histologic type of nephrotic syndrome, and therapy should be initiated with the assistance of a pediatric nephrologist.
- Empiric corticosteroid therapy can be initiated in patients with suspected MCD, and  $>90\%$  will respond within 8 wk:
  - 60 mg/m<sup>2</sup>/day (max 60 mg/day) until proteinuria disappears, then taper (2)
  - 15–20% of patients with FSGS will also respond to corticosteroid therapy (1).
- Spontaneous remission will occur in 5% of cases within 1–2 wk, so treatment may not need to be started immediately.

**Second Line**

Immunosuppressants, such as cyclophosphamide, cyclosporine, and chlorambucil, and mycophenolate are reserved for those who frequently relapse or who are corticosteroid dependent.

**DISPOSITION****Admission Criteria**

- Critical care admission criteria:
  - Severe symptoms such as hypertensive emergency, cardiac failure, pulmonary edema, renal failure
- Hospitalization should be considered if there is significant edema causing respiratory distress (2), tense scrotum or labia, complications (see below), or if family compliance with treatment and follow-up is not assured.

**Discharge Criteria**

Patients who are diagnosed with nephrotic syndrome in the emergency department may be discharged if they have no HTN, renal insufficiency, respiratory distress, or significant edema.

**Issues for Referral**

All children with a diagnosis of nephrotic syndrome should be referred to a nephrologist for further management upon discharge.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Patients should be followed closely by a pediatric nephrologist for remission, relapse, and tolerance to therapy.
- While on corticosteroid therapy, caregivers should be vigilant to note fever or abdominal pain that herald infection secondary to immunosuppression.

**Patient Monitoring**

Parents should be instructed on how to regularly monitor their child's urine and record results in a diary.

**DIET**

Patients must follow a strict low-salt diet, and those with severe edema may need to restrict their fluid intake.

**PROGNOSIS**

- Prognosis depends on the histologic type.
- Patients with MCD have an excellent prognosis since 95% respond to corticosteroid therapy; steroid response is usually within 2–3 wk after beginning treatment (4).
- Only 20% of patients with FSGS undergo remission (1), and up to 60% of cases develop end-stage renal disease by 10 yr.
- ~50% of patients with mesangial proliferation will respond to steroid therapy (1).
- Prognosis is worse with congenital nephrotic syndrome, with most cases resulting in death from renal failure within 2 yr.

**COMPLICATIONS**

- Infection (eg, bacterial peritonitis)
- Thromboembolism (eg, renal vein thrombosis)
- HTN
- Renal insufficiency as a result of hypovolemia and/or underlying glomerular pathology
- Anasarca
- Hypovolemia
- Growth failure

**CODES****ICD9**

- 581.3 Nephrotic syndrome with lesion of minimal change glomerulonephritis
- 581.9 Nephrotic syndrome with unspecified pathological lesion in kidney
- 583.9 Nephritis and nephropathy, not specified as acute or chronic, with unspecified pathological lesion in kidney

**PEARLS AND PITFALLS**

- The edema of nephrotic syndrome is pitting and often is noted as periorbital swelling.
- A urine dipstick of  $>3+$  protein should prompt a spot urine protein to creatinine ratio to evaluate for nephritic-range proteinuria.
- Clinicians should be careful to detect intravascular hypovolemia that may be present despite overall fluid overload and weight gain.
- Though uncommon in children, those with nephrotic syndrome are at an increased risk of thromboembolic events, such as pulmonary embolism and renal vein thrombosis.

# NEUROLEPTIC MALIGNANT SYNDROME

Daniel M. Lugassy

## BASICS

### DESCRIPTION

- Neuroleptic malignant syndrome (NMS) is a rare, idiosyncratic, potentially fatal complication of neuroleptic (antipsychotic) medications.
- Most commonly occurs with therapeutic use of antipsychotics
- Characterized by severe muscle rigidity and hyperthermia, altered mental status, and autonomic instability
- Is a diagnosis of exclusion, requiring that the current clinical presentation is not accounted for by another diagnosis
- No gold standard for diagnosis; consider when evaluating patients with altered mental status, behavioral change, hyperthermia, or muscle rigidity after neuroleptic use
- *DSM-IV-TR* 2000 defines NMS in an individual exposed to a neuroleptic by severe muscle rigidity and hyperthermia:
  - In addition to 2 of the following:
    - Diaphoresis
    - Dysphagia
    - Tremor
    - Incontinence
    - Changes in level of consciousness (ranging from confusion to coma)
    - Mutism
    - Tachycardia
    - Elevated or labile BP
    - Leukocytosis
    - Lab evidence of muscle injury (increased creatine phosphokinase [CPK])
- NMS occurs in all ages. The clinical presentation is similar regardless of age.

### EPIDEMIOLOGY

- Although the incidence once was 3–4%, currently with earlier recognition, NMS occurs in 0.01–0.02% of patients treated with antipsychotics.
- 2,000 cases of NMS annually in the U.S.

### RISK FACTORS

- Previous history of NMS
- Antipsychotic use
- Rapid dose escalation
- High-potency antipsychotics
- Depot antipsychotic preparations
- Multiple drug combinations of neuroleptics
- Concomitant lithium use
- Adolescent and young adult patients
- Male gender

### GENERAL PREVENTION

- No known preventative measures
- Avoid risk factors, particularly medication, dose, route, and dose escalation
- Coadministration of an antihistamine or a benzodiazepine with a neuroleptic may prevent extrapyramidal symptoms, but there is no evidence that this will prevent NMS.

### PATHOPHYSIOLOGY

- The exact cause is unknown.
- Central dopamine blockade clearly plays a pivotal role in the development of NMS.
- Drugs that block dopamine have been known to cause NMS, and even withdrawal from dopamine agonists (eg, Parkinson disease) produces an NMS-like syndrome:
  - Central dopaminergic inhibition likely contributes to muscle rigidity, tremor, autonomic instability, and altered thermoregulation.
  - Sympathomimetic and adrenal-medullary dysfunction causes tachycardia, diaphoresis, and labile BP.

### ETIOLOGY

- Not all neuroleptics that may cause NMS are used to treat psychosis, such as promethazine used to treat nausea.
- Implicated medications:
  - Butyrophenones: Haloperidol, droperidol
  - Phenothiazines: Chlorpromazine, fluphenazine, perphenazine, prochlorperazine, thioridazine
  - Trifluoperazine, mesoridazine, pericyazine, promazine, triflupromazine, levomepromazine, promethazine, pimozide
  - Thioxanthenes: Chlorprothixene, flupenthixol, thiothixene, zuclopenthixol
  - 2nd-generation antipsychotics: Clozapine, olanzapine, risperidone, quetiapine, ziprasidone, amisulpride, aripiprazole, paliperidone, zotepine, sertindole, iloperidone
  - 3rd-generation antipsychotics: Aripiprazole

## DIAGNOSIS

### HISTORY

- Obtaining a detailed history of recent exposure or current use of neuroleptics:
  - NMS may occur immediately after neuroleptic use but usually occurs over days to weeks:
    - 16% of cases occur <24 hr, 66% <1 wk, and almost all cases within 30 days
  - Family or caregivers may notice subtle changes in patients' behavior or muscle tone in the early stages of NMS
  - Decreased activity, speech, and oral intake of food and prescribed medications observed in NMS may be mistakenly interpreted as worsening of underlying illness
- Consider this diagnosis in any patient with altered mental status, agitation, or confusion especially in the setting of physical exam findings noted below and in Description section.

### PHYSICAL EXAM

- Assess vital signs; hyperthermia and autonomic instability are common
- Examine the patient for neuromuscular abnormalities and altered mental status
- Hyperthermia:
  - Usually defined as  $\geq 38.0^{\circ}\text{C}$  or  $100.4^{\circ}\text{F}$
  - It is a pitfall to assume that all cases of NMS have an elevated temperature.
  - May not be present in all cases
  - The location and method of measurement of temperature may affect the result.
  - It is best to obtain a rectal temperature.

- Autonomic instability:
  - Diaphoresis
  - Incontinence
  - Tachycardia
  - Elevated or labile BP
- Neuromuscular abnormalities:
  - Usually bilateral, involving the upper and lower extremities as well as muscles of the face and those involving swallowing, speech, and respiration
  - Muscle rigidity: May present as a mild increase in tone to severe “lead pipe” rigidity
  - Tremor
  - Decreased reflexes
  - Cogwheel rigidity
  - Dysphagia
- Altered mental status:
  - Confusion
  - Agitation
  - Coma
  - Mutism
  - Catatonia

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Assess serum glucose for all patients with altered mental status.
- Basic metabolic panel, which includes electrolytes and renal function (BUN, creatinine)
- CPK:
  - The most common lab abnormality in NMS is an elevated CPK.
  - Elevated CPK is found in nearly all cases of NMS but is not specific to this disease.
  - Rhabdomyolysis causing renal failure/dysfunction is a very common complication of NMS.
- Other lab tests may be indicated:
  - CBC
  - Blood gas analysis
  - Urinalysis
  - Blood cultures
  - CSF analysis
  - LFTs
  - ECG

#### Imaging

CT of the brain to rule out intracranial pathology as a cause of altered mental status

#### Diagnostic Procedures/Other

- Lumbar puncture for CSF analysis should be considered in all patients with altered mental status +/- an elevated temperature:
- Encephalitis or meningitis may have similar clinical presentation as NMS.

### DIFFERENTIAL DIAGNOSIS

- Serotonin syndrome (SS):
  - Also has neuromuscular abnormalities, hyperthermia, altered mental status, and autonomic instability
  - Unlike NMS, SS develops over hours after exposure to serotonergic agents.
  - SS presents with rigidity and hypertonicity; NMS appears as a catatonic-type state.

- Malignant hyperthermia (MH):
  - Severe muscle rigidity and hyperthermia are hallmarks of this disease.
  - Associated with exposure to general anesthetics and succinylcholine
  - MH usually occurs within minutes of exposure to agents mentioned above.
  - Rarely develops later, up to 24 hr
- Heat exertion/stroke
- Infectious: Sepsis, meningitis/encephalitis
- Neurologic abnormality; intracranial lesion, Parkinson disease
- Sympathomimetic poisoning
- Anticholinergic poisoning
- Lithium toxicity
- Other toxins causing hyperthermia (eg, salicylate; cyanide; carbon monoxide; 2,4 dinitrophenol)

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Check bedside glucose and ECG.
- Employ measures for cooling, including medications, passive cooling, or active cooling.
- Discontinue any medication that may be contributing to the development of NMS.

### ALERT

- Obtain a rectal temperature immediately in patients with possible NMS or a toxicologic or environmental cause of hyperthermia.
- Significant hyperthermia ( $\geq 39.0$ – $40.0^\circ\text{C}$  or  $102.2$ – $104^\circ\text{F}$ ) requires passive cooling or mild active cooling and medications:
  - Life-threatening hyperthermia ( $> 41.5^\circ$ – $42.0^\circ\text{C}$ ,  $> 106.7$ – $107.6^\circ\text{F}$ ) should be treated by immersion in an ice bath. Other cooling measures are inadequate:
    - Wrapping the patient in sheets with ice or placing patient in a body bag with ice are reasonable approaches.

### MEDICATION

#### First Line

Benzodiazepines:

- Diazepam 0.1 mg/kg IV, 0.5 mg/kg PR
- May repeat IV dose q5min PRN:
  - Short-acting benzodiazepine: IV route is preferred but may be given PR.
- Lorazepam 0.05 mg/kg IV:
  - May repeat IV dose q10min PRN
- These drugs may significantly improve the muscular rigidity and agitation seen in NMS.
- No specific benzodiazepine appears to offer any specific additional benefit in treatment.
- Titrate the administration of benzodiazepine to the effect.
- Large doses may be required.

### Second Line

Bromocriptine 2.5 mg PO b.i.d.–t.i.d.:

- Central dopamine agonist that may reverse the effects of NMS
- No randomized trials to demonstrate benefit
- It may exacerbate psychosis by stimulating dopaminergic neuronal transmission.
- Once initiated, prompt cessation should be avoided, as this may cause a rebound in symptoms.

### COMPLEMENTARY & ALTERNATIVE THERAPIES

- Dantrolene:
  - Dosing: 1–2.5 mg/kg IV initially followed by 1 mg/kg IV q6h PRN. It may be used orally.
  - Reduces skeletal muscle activity by interfering with calcium release from the sarcoplasmic reticulum within the cell.
  - Used as a rescue agent in MH
  - Used alone or in conjunction with benzodiazepines or bromocriptine
  - Utility in NMS is unclear. Consider only for the most severe life-threatening hyperthermia.
  - No randomized trials to demonstrate benefit
  - It may cause respiratory compromise.
- Electroconvulsive therapy (ECT):
  - Enhances central dopaminergic transmission, therefore improving the symptoms of NMS
  - No randomized trials to demonstrate benefit
  - There are no clear guidelines for ECT use, but it may be indicated in cases lasting  $> 2$  wk.

### DISPOSITION

#### Admission Criteria

All patients require admission.

#### Discharge Criteria

Return to baseline mental status, normal neuromuscular exam, and normal vital signs after hospitalization

## FOLLOW-UP

Discharge instructions and medications:

- Most patients who are diagnosed with NMS require treatment with antipsychotics at some point after the clinical symptoms of NMS resolve.
- Neuroleptics (antipsychotics) should not be introduced until at least after 2 wk of NMS resolution; in addition, several considerations should be taken to prevent recurrence of NMS.
- Use nonneuroleptic therapy if possible.
- Restart therapy at a low dose using lower-potency typical antipsychotics, or switch to an atypical antipsychotic.
- Risk factors for NMS should be reduced.
- Closely monitor for early signs of NMS.

### PROGNOSIS

- Usually complete recovery, though symptoms last for weeks
- Morbidity and mortality of NMS depends on the associated severity of its complications such as rhabdomyolysis or aspiration pneumonia.
- Recurs in 30% if re-exposed to neuroleptics
- Mortality from NMS is 10% in the U.S.

### COMPLICATIONS

- Aspiration pneumonia is common.
- Pressure ulcers
- Deep vein thrombosis prevention
- Life-threatening hyperthermia
- Rhabdomyolysis
- Renal failure
- Respiratory failure
- Infection (eg, aspiration pneumonia, urinary tract infection, cellulitis, etc.)
- Venous thrombosis
- Muscle atrophy
- Nutritional deficiency
- Shock
- Multisystem organ failure
- Death

### CODES

#### ICD9

333.92 Neuroleptic malignant syndrome

### PEARLS AND PITFALLS

- Hyperthermia, altered mental status, neuromuscular changes, and autonomic instability are characteristic of NMS.
- SS may have a similar presentation but is more abrupt in onset.
- Rarely, patients may have NMS without hyperthermia.
- Discontinue all offending medications.
- NMS is a diagnosis of exclusion.

# NONSTEROIDAL ANTI-INFLAMMATORY DRUG (NSAID) POISONING

Daniel M. Lugassy

## BASICS

### DESCRIPTION

- NSAIDs exert anti-inflammatory, antipyretic, and analgesic effects by the inhibition of prostaglandin synthesis, which is mediated by the ability of NSAIDs to block cyclooxygenase (COX).
- They are among the most commonly used medications.
- Acute effects depend of the specific drug, but toxicity is usually limited to GI distress (nausea, vomiting, abdominal pain) and rarely, mild CNS depression.
- In massive overdoses or with certain NSAIDs, the following effects may rarely occur: Metabolic acidosis, respiratory depression, hypotension, renal failure, hepatotoxicity, and seizures.
- Management of most NSAID exposures is usually limited to general supportive care and the search for coingestants.
- Although extremely rare, deaths have been reported from all classes of NSAIDs.
- Salicylates (eg, aspirin) technically fall under the chemical class of NSAIDs, but its toxicity will not be discussed in this section.

### EPIDEMIOLOGY

- NSAID overdose in the U.S. is very common; ~100,000 exposures were reported to national poison centers in 2007.
- Ibuprofen is responsible for most of these exposures, accounting for ~79,000, followed by naproxen with 12,000.
- There were no deaths reported due to ibuprofen and 2 deaths from naproxen.

### RISK FACTORS

- Existing CHF, cirrhosis, intrinsic renal disease, or hypovolemia
- Pediatric patients who ingest >400 mg/kg of ibuprofen are more likely to suffer severe complications of overdose such as seizures, metabolic acidosis, and renal dysfunction.

### PATHOPHYSIOLOGY

- NSAIDs encompass a large class of >20 drugs that competitively inhibit COX, an enzyme responsible for the production of inflammatory mediators such as prostaglandins, prostacyclin, and thromboxanes:
  - COX can be further differentiated into 2 isoforms: COX-1 and COX-2.
- COX-1 is in the GI tract and kidney and involved with hemostasis (by interfering with platelet aggregation), GI wall integrity, and renal function.
- COX-2 mediates vasodilatation, vascular permeability, and sensitization to pain at the site of inflammation.

- NSAIDs may inhibit both COX-1 and COX-2 or be selective toward 1 isoform.
- Most of the acute toxicity seen in overdose is due to the effects of COX-1 inhibition.
- NSAIDs are directly toxic to the gastric mucosa, and COX-1 inhibition leads to decreased protective prostaglandins, accounting for the nausea, vomiting, abdominal pain, and GI hemorrhage.
- An elevated anion gap metabolic acidosis may arise in rare cases due to seizures, or in massive ingestions of the NSAID itself or its metabolite may be responsible (eg, ibuprofen is a propionic acid).
- Renal dysfunction may occur from inhibition of inflammatory mediators that regulate renal blood flow or possible direct nephrotoxic effects.
- Hematologic toxicity may occur because of the inhibitor effects that NSAIDs have on platelet aggregation:
  - Phenylbutazone may also cause aplastic anemia.
- CNS system effects of lethargy, seizure, and coma are rare and the mechanism is unclear, but it could be related to the metabolic acidosis that is often seen concurrently with these effects.
- Seizure occurs with particular NSAIDs: Naproxen, mefenamic acid, oxyphenbutazone, phenylbutazone, piroxicam.

### ETIOLOGY

- Below are 6 different NSAID classes and some of the drugs in that class. The brand name is in parentheses.
- Phenylbutazone is one of the most deadly NSAIDs, accounting for 50 related deaths in children:
  - It has been removed from human use but is still accessible as commonly prescribed veterinary medicine and is used outside the U.S.
- Pyrazolone:
  - Phenylbutazone (Butazolidin)
- Fenamate (anthranilic acids):
  - Mefenamic acid (Ponstel)
  - Meclofenamate (Meclomen)
- Acetic acids:
  - Diclofenac (Cataflam, Voltaren)
  - Etodolac (Lodine)
  - Indomethacin (Indocin)
  - Ketorolac (Toradol)
  - Nabumetone (Relafen)
  - Sulindac (Clinoril)
  - Tolmetin (Tolectin)
- Propionic acids:
  - Fenoprofen (Nalfon)
  - Flurbiprofen (Ansaid)
  - Ibuprofen (Motrin, Advil, Medipren)
  - Ketoprofen (Orudis)
  - Naproxen (Naprosyn, Anaprox, Aleve)
  - Oxaprozin (Daypro)

- Oxicam:
  - Piroxicam (Feldene)
  - Meloxicam (Mobic)
- COX-2 inhibitors:
  - Celecoxib (Celebrex)

### COMMONLY ASSOCIATED CONDITIONS

- Chronic abuse may lead to renal dysfunction, impaired clotting, and GI hemorrhage.
- Coingestion of other medications

## DIAGNOSIS

### HISTORY

- Obtain as much information as possible about ingestion, including possible exposure medications belonging to family members, friends, or pets.
- Clinical manifestations from acute ingestions of NSAIDs depend on the class of drug, but most effects will present within 2–4 hr.
- Most acute NSAID ingestions are limited to GI distress, manifested by nausea, vomiting, abdominal pain, and sometimes intestinal hemorrhage.
- CNS effects are rare but may include headache, confusion, delirium, and seizures.

### PHYSICAL EXAM

- NSAID overdose is not associated with any specific toxidrome of exam findings. Patients often have a normal physical exam other than mild tachycardia or hypotension from fluid losses due to GI distress.
- In rare cases, seizures, altered mental status, and coma may occur.
- If significant physical exam abnormalities are noted on physical exam after reported NSAID ingestion, suspect other causes of poisoning or consider that it may be a massive NSAID overdose.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Assess blood glucose in all patients with altered mental status or behavior changes.
- General approach to the intentional NSAID poisoned patient includes assessing:
  - CBC, electrolytes, BUN and creatinine, hepatic function panel
- If significant exposure is suspected or chronic abuse is suspected, a coagulation panel (PT, PTT, INR) may be measured.
- In patients with seizure, altered mental status, coma, or respiratory distress, acid-base abnormalities should be examined with additional blood gas sampling with lactate measurement.
- Serum acetaminophen concentration should be sent on all patients with intentional ingestions.

**Diagnostic Procedures/Other**  
ECG

**DIFFERENTIAL DIAGNOSIS**

- Gastritis
- Pancreatitis
- Food poisoning
- Other drug ingestion

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Most NSAID poisonings rarely need more than supportive care, and there is no antidote for these exposures.
- Establish IV access and initiate fluid resuscitation as needed, given that many patients may suffer from GI fluid losses.
- Antiemetics or antacids may provide patients with symptomatic relief.
- GI decontamination:
  - Most NSAIDs (excluding sustained-release formulations) are rapidly absorbed within 2 hr of ingestion. Symptoms usually will be apparent within 4–6 hr
  - Most NSAID ingestions are not life threatening, so overly aggressive GI decontamination risk outweighs the benefit.
  - Activated charcoal may offer a benefit if administered within 1 hr after ingestion, but this has not been proven:
    - In patients with active vomiting or altered mental status, the risk of aspiration of charcoal most likely outweighs the potential benefit.
  - Gastric emptying/lavage should only be reserved for the most severe cases or suspected pyrazolone or fenamate ingestion.

**MEDICATION**

**First Line**

- Antiemetics:
  - Ondansetron 0.15–0.2 mg/kg IV q6–8h PRN
  - Metoclopramide 0.1 mg/kg IV q6H PRN
- GI medications:
  - Magnesium oxide 5–10 mg/kg/24 hr PO divided t.i.d.–q.i.d.; adult, max 200 mg PO q8h
  - H2 blockers:
    - Ranitidine 5 mg/kg PO q12h, 1–2 mg/kg IV/IM q6h; adult, 150 mg PO b.i.d., 50 mg/kg/dose IM/IV
    - Famotidine 0.6 mg/kg/24 hr IV divided q8–12h, 1–2 mg/kg/24 hr PO divided q12h; adult, 20 mg PO/IV b.i.d.
  - Pantoprazole 1 mg/kg/dose PO/IV per day, max dose 80 mg

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

Misoprostol is often administered to prevent the GI effects of NSAIDs in chronic use, but there is no evidence to support its use in acute overdose.

**SURGERY/OTHER PROCEDURES**

In rare cases, hemodialysis may be necessary to correct severe acid-base disturbances, but the pharmacokinetics of NSAIDs do not result in removal of the NSAID by hemodialysis:

- This procedure only corrects electrolyte imbalance and acid-base imbalance.

**DISPOSITION**

**Admission Criteria**

- Severe intravascular volume loss from the GI effects may require admission for continued IV fluid resuscitation.
- Those with metabolic acidosis, altered mental status, seizures, coma, or other systemic effects should also be admitted for supportive care.

**Discharge Criteria**

Patients with normal vitals signs, physical exam, mental status, and no significant lab abnormalities after 4–6 hr of observation may be safely discharged from the emergency department or inpatient unit, but they should also have no evidence of other toxicity such as acetaminophen ingestion.

**Issues for Referral**

Consider consulting a medical toxicologist or poison control center.

**FOLLOW-UP**

**PROGNOSIS**

- Most patients with NSAID ingestions have very few life-threatening events and are expected to make a full recovery without permanent sequelae.
- Rarely, in massive overdose or with exposure to atypical NSAIDs such as phenylbutazone or mefenamic acid, severe toxicity such as seizure, metabolic acidemia, aplastic anemia, or death may occur.

**COMPLICATIONS**

- Nausea, vomiting, and abdominal pain are the most common effects of acute NSAID overdose.
- GI hemorrhage, seizures, coma, respiratory distress, renal failure, metabolic acidosis, and death are rare but potential complications of massive NSAID ingestions.
- The phenylbutazone and fenamate class are associated with the most severe toxicity.

**ADDITIONAL READING**

- Belson M, Watson W. Nonsteroidal anti-inflammatory drugs. In Goldfrank LR, Flomenbaum NE, Lewin NA, et al., eds. *Goldfrank's Toxicologic Emergencies*. 8th ed. Stamford, CT: Appleton & Lange; 2006.

**See Also (Topic, Algorithm, Electronic Media Element)**

- Abdominal Pain
- Gastrointestinal Hemorrhage
- Seizure
- Status Epilepticus

**CODES**

**ICD9**

- 965.7 Poisoning by other non-narcotic analgesics
- 965.9 Poisoning by unspecified analgesic and antipyretic

**PEARLS AND PITFALLS**

- Most NSAID ingestions result in mild or moderate toxicity, typically limited to GI symptoms.
- Rarely, massive overdose or exposure to particularly toxic NSAIDs such as phenylbutazone or mefenamic acid may cause severe toxicity, with seizure, metabolic acidosis, or death.

# NURSEMAID'S ELBOW

*Ee Tein Tay*

## BASICS

### DESCRIPTION

- Nursemaid's elbow is also known as annular ligament displacement, radial head subluxation, or pulled elbow.
- It typically is caused by acute axial traction applied to the pronated arm, though it also occurs in association with a fall onto the extended arm.

### EPIDEMIOLOGY

- The most common upper extremity injury presenting to the emergency department in children <6 yr of age (1,2)
- Peak incidence at 2 yr of age
- More common in males than females
- The left forearm is more commonly affected due to most caretakers being right-hand dominant.

### RISK FACTORS

- Children who are lifted up by holding the forearm in traction, especially with traction on the radius
- Previous occurrence of a subluxed radial head increases the risk of subsequent occurrence.
- Children <5 yr of age:
  - By 5 yr, the annular ligament is thick, strong, and less likely to be susceptible to tearing or displacement (1).

### GENERAL PREVENTION

- The caretaker may prevent injury by lifting the child under the arms instead of pulling the arms.
- Avoid excessive arm pulling while playing or dressing.

### PATHOPHYSIOLOGY

- Axial traction on the forearm causes annular ligament displacement and resulting entrapment between the humeral capitellum and radial head.
- The radial head is more pliable in children due to late ossification center development; therefore, it is more likely to slip compared to older children.

### ETIOLOGY

- Pulling of the child's arm in 1 direction while the child is moving in the opposite direction
- Fall
- Caretaker lifting the child by the arm
- Pulling the arm through a tight coat sleeve while dressing
- Unwitnessed mechanism

## DIAGNOSIS

### HISTORY

- The caretaker reports the child's refusal to use the affected arm due to pain with movement.
- Some caretakers may be unable to explain mechanism of injury or a history of arm pulling.
- The child favors holding the affected arm to the side of the body in slight elbow flexion and forearm pronation.

### PHYSICAL EXAM

- The child is in no distress unless the affected arm is moved.
- Children who present with radial head subluxation will often hold the affected arm close to the body with the forearm pronated and the elbow either fully or partially flexed or extended.
- No swelling, warmth, deformity, or change in neurovascular status
- Most children will not have any palpable tenderness. However, some may have palpable tenderness over the anterolateral aspect of the radial head.
- In anxious or crying children, it may be helpful to have the parent palpate the extremity and the physician observe the child's reaction.
- Palpation of the clavicle as well as the arm is recommended due to the occasional similarity in presentation of clavicular fracture.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- Nursemaid's elbow is a clinical diagnosis, and radiographs are not necessary. Radiographs are not necessary prior to reduction manipulation and should be obtained only when the diagnosis is not clear.
- 95–100% of radiographs are normal:
  - May see displacement of the radiocapitellar line, which does not alter management or outcome
- Consider imaging if:
  - History suggests presence of fractures
  - Joint effusion or ecchymosis on physical exam
  - Multiple reduction attempts are unsuccessful.

### DIFFERENTIAL DIAGNOSIS

- Forearm fracture
- Elbow fracture
- Clavicular fracture
- Elbow dislocation
- Elbow or wrist sprain
- Contusion

## TREATMENT

### MEDICATION

- Reducing the subluxation usually treats pain.
- Consider pain control with NSAIDs or acetaminophen if needed:
  - Ibuprofen 10 mg/kg/dose PO q6h PRN
  - Acetaminophen 15 mg/kg/dose PO/PR q4h PRN

### SURGERY/OTHER PROCEDURES

- Reduce subluxation by supination of the wrist followed by elbow flexion while applying gentle pressure and traction to the radial head:
  - Use of this method without flexion is also effective, as reduction of subluxation occurs during supination motion.

- May also reduce by forced pronation (hyperpronation) of wrist followed by elbow flexion or extension:
  - Forced pronation method may be a less painful and more successful technique (3).
  - Both methods have high reduction success rates.
- May hear or palpate “click” as annular ligament returns to a normal position during manipulation

#### DISPOSITION

- Observe the patient for arm use or movement after reduction, usually <15 min after manipulation.
- Reduction is successful if the patient is able to move the affected arm in full range of motion:
  - Ability to actively reach upward to raise the hand of the affected arm above the head while standing confirms reduction.
- The child may be hesitant to move the affected arm after reduction due to pain experienced prior to and during manipulation:
  - May require prolonged observation or analgesics prior to arm use
- If the patient is not moving the arm after prolonged observation, consider a radiograph to exclude fractures.
- A posterior long arm splint may be required if reduction is unsuccessful or if the patient is unable or unwilling to move the arm after prolonged observation and a normal radiograph:
  - In this situation, schedule follow-up within a few days with the primary care provider or an orthopedic surgeon for further imaging and then possible reattempt at reduction.

#### Discharge Criteria

- Well appearing
- Affected extremity is neurovascularly intact

#### Issues for Referral

Orthopedic physician referral if attempted reductions are unsuccessful

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Analgesics may assist in pain control after injury and manipulation.
  - Follow up with the primary care physician or orthopedic physician if the patient continues to not move the arm after 24 hr.
- Activity:
  - A child usually resumes normal physical activity after reduction.

### PROGNOSIS

- Recurrence varies from 27–39%.
- Recurrence is usually in the same arm and is more common in children <2 yr of age.
- No permanent disability

## CODES

### ICD9

832.2 Nursemaid's elbow

### PEARLS AND PITFALLS

- Pearls:
  - Early administration of analgesics may encourage the patient to use the affected arm after reduction.
  - Encourage the patient to use the arm after reduction by offering a toy to the affected arm.
  - For patients with recurrent occurrences, it is reasonable to teach parents/caregivers how to attempt reduction.
- Pitfalls:
  - Failing to perform a thorough physical exam (ie, missing point tenderness over distal elbow) to exclude supracondylar fracture before attempted reduction

# OBSTRUCTIVE SLEEP APNEA SYNDROME

Susanne Kost

## BASICS

### DESCRIPTION

Obstructive sleep apnea syndrome (OSAS) is defined as recurrent episodes of partial or complete upper airway obstruction during sleep, resulting in:

- Disruption of normal gas exchange (intermittent hypoxia and hypercarbia)
- Interrupted sleep

### EPIDEMIOLOGY

- No definitive population-based studies have been published, but experts estimate a prevalence of 5–6% in the general pediatric population.
- Peak incidence is between 2 and 6 yr.

### RISK FACTORS

- Obesity
- Adenotonsillar hypertrophy
- Craniofacial anomalies:
  - Micro-/Retrognathia
  - Midface hypoplasia
  - High-arched/narrow palate
- Neuromuscular disorders:
  - Cerebral palsy
  - Muscular dystrophy
- Certain genetic syndromes:
  - Trisomy 21
  - Beckwith-Wiedemann
  - Mucopolysaccharidoses
- Family history of OSAS
- Drugs (alcohol, sedatives, and narcotics)

### PATHOPHYSIOLOGY

- OSAS is caused by soft tissue obstructing the airway during sleep:
  - Anatomic narrowing in the upper airway AND/OR decreased neuromuscular tone of the pharyngeal dilator muscles
- Sleep architecture is disrupted, resulting in daytime somnolence, behavioral disorders, HTN.
- Central apnea of up to 20 sec may be normal in the 1st few months of life.

### ETIOLOGY

Children are more likely to have prolonged periods of hypoventilation, which is worse during REM sleep; less likely than adults to completely obstruct.

- Ultimately, obstruction leads to arousal from sleep.

### COMMONLY ASSOCIATED CONDITIONS

- Daytime fatigue
- Learning/Memory problems
- ADHD
- Headaches
- Sleep disorders (night terrors, sleep talking or walking)
- Enuresis
- HTN
- Obesity
- Laryngomalacia
- Tracheomalacia

## DIAGNOSIS

### HISTORY

- Patients report a history of snoring or restless sleep.
- May also have history of:
  - ADHD, daytime somnolence, behavioral disorders
  - Unexplained HTN or pulmonary HTN
- History of apnea: Cessation of breathing for  $\geq 15$  sec
- Parental questionnaires for patient history have been utilized as screening tools but are not sufficiently sensitive or specific to definitively diagnose OSAS.

### PHYSICAL EXAM

- Growth curve:
  - Both poor growth and obesity are linked to OSAS.
- HEENT:
  - Tonsillar hypertrophy
  - Craniofacial anomalies (hypoplastic or long narrow “adenoidal” face), nasal septal deviation, macroglossia, retrognathia
  - “Allergic shiners”
  - Orthodontic problems (overlapped or crowded teeth, high palate)
  - Drooling or poor pharyngeal tone
  - Mouth breathing
- Cardiopulmonary findings:
  - Check for HTN
  - Careful auscultation for evidence of pulmonary HTN

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

Routine lab studies such as metabolic panels and CBC are generally not helpful; polycythemia and metabolic alkalosis are supportive but rare findings.

#### Imaging

- Soft tissue lateral radiographs of the upper airway can confirm adenotonsillar hypertrophy but are not diagnostic for OSAS.
- Chest radiographs or echo may reveal right or left ventricular hypertrophy with long-standing OSAS.
- Dynamic MRI scanning of the upper airway can confirm the diagnosis of OSAS but is generally reserved for planning therapy in high-risk children with unusual anatomic abnormalities.

#### Diagnostic Procedures/Other

- Polysomnography (PSG) is the gold standard for the diagnosis of OSAS.
- Other home monitoring modalities such as overnight pulse oximetry and audio or video recordings have a low negative predictive value.

#### Pathological Findings

- Apnea (obstructive or central)
- Hypopnea
- Apnea-Hypopnea Index (AHI) is the number of apneic plus hypopneic episodes per hour of sleep:
  - Mild OSA = AHI 1–4, room air oxygen saturation (SPO<sub>2</sub>) nadir 86–91%, end-tidal carbon dioxide (ETCO<sub>2</sub>) peak >53
  - Moderate = AHI 5–10, SPO<sub>2</sub> nadir 76–85%, ETCO<sub>2</sub> peak >60
  - Severe = AHI >10, SPO<sub>2</sub> nadir <75%, ETCO<sub>2</sub> peak >65

#### DIFFERENTIAL DIAGNOSIS

- Nonpathologic snoring
- Other sleep pathology
- Narcolepsy
- Epilepsy
- Pulmonary embolism
- Pulmonary HTN
- Asthma
- Left heart failure
- Brainstem pathology (Chiari malformation, brainstem tumors)

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Rarely, patients may be symptomatic while awake and may benefit from the insertion of a nasopharyngeal airway.

**MEDICATION**

Intranasal corticosteroids may be useful in the treatment of mild OSAS.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Nighttime positive airway pressure (CPAP or BPAP) can be effective in cases where surgery is deemed too risky.
- Nasal insufflation with high-flow oxygen via a nasal cannula is also effective.
- Avoid environmental irritants (eg, cigarette smoke).
- Weight loss is often completely curative in cases of obesity but difficult to achieve.

**SURGERY/OTHER PROCEDURES**

- Adenotonsillectomy is the first-line therapy for otherwise healthy children with adenotonsillar hypertrophy who are diagnosed with OSAS:
  - Meta-analysis showed normalized PSG in 83%; reduced the AHI in most.
- Uvula and other palate surgeries are not generally recommended in children due to risk of complications with swallowing and speech.
- Orthodontia (palate expanders, jaw-lengthening procedures) can be a useful treatment adjunct.
- Tracheotomy is a last resort, generally reserved for children with complex anatomic or neuromuscular disorders.

**DISPOSITION**

**Admission Criteria**

- Witnessed moderate to severe sleep apnea with significant apnea or hypoxia
- Any signs of cardiorespiratory failure

**Issues for Referral**

- Uncomplicated patients with symptoms of OSAS can be referred directly for overnight PSG by a primary care provider; referred to a specialist if a positive study.
- Patients with significant comorbidities (craniofacial disorder, genetic syndrome, neuromuscular disorder, chronic lung disease) should be referred directly to a specialist:
  - A specialist is defined as an expert in pediatric sleep disorders, such as an otolaryngologist, a pulmonologist, a neurologist, or an intensivist.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

**Patient Monitoring**

- Patients with significant comorbidities should be monitored as inpatients postoperatively.
- All patients should be monitored clinically on an ongoing basis until symptoms resolve.

**COMPLICATIONS**

- Left untreated, OSAS can lead to severe morbidity, as listed in the Commonly Associated Conditions section.
- Complications of adenotonsillectomy include increased risk of airway obstruction in children with OSAS as compared to other indications for tonsillectomy.

**ICD9**  
327.23 Obstructive sleep apnea (adult) (pediatric)

**PEARLS AND PITFALLS**

- Not all snoring represents OSAS, but nightly snoring is an indication for a workup.
- PSG is the gold standard for the diagnosis of OSAS.
- Home monitoring, such as overnight pulse oximetry and audio or video recordings, cannot be used to definitely rule out OSAS.

# OMPHALITIS

Mercedes M. Blackstone

## BASICS

### DESCRIPTION

- Omphalitis is a neonatal infection of the umbilicus that can spread to the surrounding tissues.
- This may progress to necrotizing fasciitis.
- In the preantibiotic era, omphalitis was a major cause of neonatal mortality.

### EPIDEMIOLOGY

- Typically presents at 5–9 days in term infants and at 3–5 days in preterm infants.
- Outbreaks in nurseries can occur:
  - These are presumed to result from poor hand hygiene by staff.
  - Often the bacteria involved have high virulence.

### Incidence

- Omphalitis has an estimated incidence of 0.7% in the developed world but occurs in up to 6% of neonates in developing countries (1).
- Incidence is higher in preterm vs. term infants.

### RISK FACTORS

- Low birth weight
- Home birth or nonsterile delivery
- Maternal infection, prolonged rupture of membranes
- Male gender has been identified as a risk factor in some studies.
- Umbilical catheterization
- Immune deficiency
- Improper cord care (including cultural applications of cow dung, ash, or mustard oil commonly used in developing nations)

### GENERAL PREVENTION

- Sterile delivery
- Good hand washing prior to cord care
- Topical antibiotics applied to the umbilicus decrease bacterial colonization:
  - Triple dye as a single application followed by alcohol daily

- Daily application until cord separation:
  - Triple dye
  - Bacitracin
  - Povidine
- Topical antiseptics and skin-to-skin contact have been found to be protective in developing nations (2,3).
- In wealthy nations, prior reviews concluded that there is no evidence that antibiotics applied to the cord provide any benefit over routine dry cord care (4).
- Recent data, however, suggest that there may be a benefit to topical antibiotics in these settings as well (5).

### PATHOPHYSIOLOGY

- Omphalitis is caused by bacteria that colonize the umbilical stump.
- The devitalized umbilical tissue provides a medium for bacterial proliferation, invasion, and infection that may spread to surrounding tissues.
- The nearby umbilical vessels may allow infection to spread into the bloodstream.
- Omphalitis can be fairly localized and consist of only a surrounding cellulitis or can spread deeper into the soft tissues (myonecrosis or necrotizing fasciitis), causing significant skin and intra-abdominal pathology.

### ETIOLOGY

- Omphalitis is usually a polymicrobial infection.
- Cases of omphalitis have historically been attributed largely to gram-positive infections, but the widespread use of antistaphylococcal cord care has led to an increased number of gram-negative infections.
- Pathogens include:
  - Gram positives: *Staphylococcus aureus*, *Staphylococcus epidermidis*, groups A and B streptococcus
  - Gram negatives: *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus mirabilis*, *Pseudomonas* species
  - Anaerobes: *Clostridium tetani*, *Clostridium perfringens*, *Clostridium difficile*, *Bacteroides fragilis*
- Tetanus infections are very rare in developed nations.

## DIAGNOSIS

### HISTORY

- Review pregnancy, birth, and postnatal history, including umbilical cord/stump care.
- Ask about the risk factors. Note any prenatal infections or umbilical catheterization.
- Duration, degree, and quality of discharge from umbilicus
- Fevers, irritability, lethargy, or poor feeding may suggest systemic infection.

### PHYSICAL EXAM

- Erythema of the umbilical stump and surrounding skin, induration, purulent drainage, and localized abdominal tenderness
- Bleeding from the umbilical stump may also occur due to delayed obliteration of vessels.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Obtain a culture of the umbilical drainage whenever possible prior to initiation of antibiotics.
- Gram stain may give an indication of the causal organism.
- A full sepsis evaluation including blood, urine, and CSF cultures should be strongly considered.
- A CBC may reveal:
  - Neutropenia (either due to sepsis or an underlying disease process)
  - Neutrophilia
  - Thrombocytopenia
- Coagulation studies are indicated in septic infants.

### DIFFERENTIAL DIAGNOSIS

- Physiologic drainage from the umbilicus
- Caustic burn from silver nitrate application
- Umbilical granuloma
- Funisitis
- Patent urachus
- Infants with leukocyte adhesion deficiency, a rare genetic disorder of neutrophil migration, may present with delayed cord separation and infection.

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Address airway, breathing, and circulation issues.
- IV access should be promptly obtained.
- Sick neonates are often hypothermic or hypoglycemic, so temperature and blood glucose should be rapidly assessed and treated.
- In the toxic-appearing infant, completion of the sepsis workup should not delay the immediate administration of broad-spectrum antibiotics.

### MEDICATION

- Parenteral broad-spectrum antibiotics are the mainstay of treatment.
- Antibiotic dosing recommendations below are for full-term newborns. Appropriate dosing may be less for premature infants; consult with hospital pharmacy or infectious diseases specialist.
- Antistaphylococcal penicillins and aminoglycoside agents have typically been the drugs of choice for the treatment and prevention of complications in omphalitis:
  - Oxacillin, IV: Initial dose for neonates is 25 mg/kg t.i.d.–q.i.d.
  - Gentamycin, IV: Initial dose for neonates is 2.5 mg/kg t.i.d.
  - A 3rd-generation cephalosporin such as IV cefotaxime (50 mg/kg t.i.d.) may be substituted for the aminoglycoside.
- In communities with high MRSA prevalence, IV vancomycin (10 mg/kg t.i.d.) should replace the antistaphylococcal penicillin.
- Consider adding anaerobic coverage such as IV metronidazole (15 mg/kg b.i.d.) or IV clindamycin (5 mg/kg t.i.d.) in cases of foul-smelling drainage, known maternal infection at the time of delivery, or deep infection such as myonecrosis or necrotizing fasciitis.

### SURGERY/OTHER PROCEDURES

Rare complications of omphalitis such as necrotizing fasciitis can require prompt surgical debridement.

## DISPOSITION

### Admission Criteria

- All patients with the diagnosis of omphalitis require inpatient admission for parenteral antibiotics.
- Critical care admission criteria:
  - Patients with signs of associated sepsis, peritoneal complications, or necrotizing fasciitis should be admitted to a critical care setting.

## FOLLOW-UP

### PROGNOSIS

- When promptly recognized and treated, patients with omphalitis have a good prognosis.
- Mortality rates have been estimated at 5–13%, with the higher rates in developing countries (6):
  - Factors such as septic delivery, preterm delivery, and abnormal temperature at presentation have been associated with higher mortality.
  - Complicated omphalitis (see below) also has significantly higher morbidity and mortality.

### COMPLICATIONS

- Bacteremia
- Systemic sepsis
- Necrotizing fasciitis
- Peritonitis

## CODES

### ICD9

771.4 Omphalitis of the newborn

## PEARLS AND PITFALLS

- Even mild periumbilical infection must be treated with caution due to potential morbidity and mortality.
- Patients with omphalitis should have immediate antibiotic therapy without delay.
- There is no role for oral outpatient therapy in the treatment of omphalitis.
- Evaluation for leukocyte adhesion deficiency or other immunocompromise is not routinely necessary in neonates with omphalitis.

# OPIOID POISONING

Dean Olsen

## BASICS

### DESCRIPTION

- An opioid is any synthetic or natural agent that stimulates opioid receptors and produces opiumlike effects.
- Opiates are naturally derived from the opium poppy *Papaver somniferum* and include morphine and codeine.
- Opioids are used in clinical practice for treatment of pain and to a lesser extent for other purposes such as antitussives or antidiarrheals.
- Opioids are often abused and sold illicitly:
  - An overdose occurs when larger quantities than physically tolerated are taken.
  - The classic opioid toxidrome includes the triad of respiratory depression, CNS depression, and miosis, and can be fatal.
  - Pediatric patients are often at greater risk of overdose because of the lack of tolerance to respiratory depressant effects.
- Opioids are drugs considered “deadly in a dose”; a small dose may be fatal in a young child.

### EPIDEMIOLOGY

- Each year, ~37,000 opioid exposures are reported to poison centers. This is probably a fraction of the actual number of cases.
- ~30% are reported in children <19 yr of age.

### RISK FACTORS

- Children living in households where other cohabitants are prescribed opioids for pain or opioid maintenance programs are at risk for exposure to opioids.
- Recent detoxification, incarceration, or other circumstance of inaccessibility to opioids in which patients lose their opioid tolerance place patients at risk for subsequent overdose:
  - The common scenario is that the patient resumes using the same dose that he or she was previously able to tolerate and become apneic.

### GENERAL PREVENTION

- Opioid medications should be kept out of reach of children.
- Child-resistant containers may be useful in preventing unintentional exposures in young children.

### PATHOPHYSIOLOGY

- The 3 main opioid receptors that mediate the clinical effects of opioids with distinct clinical effects are mu, kappa, and delta:
  - Mu receptors mediate analgesia, sedation, respiratory depression, euphoria, GI dysmotility, and physical dependence.
  - Kappa receptors mediate analgesia, miosis, diuresis, and dysphoria.
  - Delta receptors mediate analgesia, inhibition of dopamine release, and cough suppression.

- Opioids are classified as agonists, partial agonists, or agonist-antagonists of the opioid receptors, which contributes to the specific clinical effects in overdose:
  - The greatest danger from opioids is respiratory depression. The respiratory effects are primarily mediated by mu<sub>2</sub> receptors:
    - Through these receptors, opioid agonists reduce ventilation by diminishing the sensitivity of the medullary chemoreceptors to hypercapnia.
    - In addition to loss of hypercarbic stimulation, opioids depress the ventilatory response to hypoxia.
- Many synthetic opioids have unusual or unique toxicities:
  - Serotonin syndrome—results from serotonergic activity:
    - Meperidine, rarely tramadol, propoxyphene, or fentanyl
  - Cardiac dysrhythmia by blocking sodium channels (propoxyphene) or prolonging QT interval (methadone) and other effects:
    - Methadone, propoxyphene, meperidine, and rarely tramadol
  - Wooden chest syndrome: Rigid chest wall resulting from unclear etiology with rapid fentanyl administration:
  - Meperidine can cause seizures with prolonged use, especially in patients with renal insufficiency due to accumulation of the metabolite normeperidine.

### ETIOLOGY

Specific agents:

- Morphine
- Codeine
- Heroin
- Methadone
- Meperidine
- Oxycodone
- Hydrocodone
- Hydromorphone
- Propoxyphene
- Fentanyl
- Diphenoxylate

### COMMONLY ASSOCIATED CONDITIONS

- Drug addiction
- HIV

## DIAGNOSIS

### HISTORY

- The diagnosis of opioid overdose is primarily based on the physical exam, but a history of opioid exposure or use is helpful.
- The patient in question is typically comatose at the time of presentation, and the history may be obtained from family or bystanders.

### PHYSICAL EXAM

- CNS depression, respiratory depression, and miosis with decreased GI motility and a relative bradycardia
- Respiratory:
  - Respiratory depression is present in moderate or severe overdose of most opioids.
  - In adults, a respiratory rate of  $\leq 12$ /min alone or in constellation with miosis or circumstantial evidence of opiate abuse is highly sensitive in diagnosing opiate overdose in the prehospital setting.
  - Hypoxia and cyanosis may be seen.
  - Acute lung injury with hypoxemia, pulmonary rales, and occasionally frothy pink sputum may occur.
- CNS:
  - CNS depression or coma is typical with opioid overdose.
  - Occasionally, seizure may occur as a direct effect of the opioid as well as a result of severe hypoxia.
  - Miosis is typically present with the use of most opioids, though there are exceptions, such as propoxyphene.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- No lab testing is typically necessary.
- Blood glucose testing should be obtained in patients with depressed mental status.
- No lab tests confirm or exclude the diagnosis of opioid overdose.
- Urine toxicology screens can test for opioids, but most are immunoassays that are specific for morphine and may not detect other synthetic opioids.
- Lab drug testing is not indicated in most cases and should not be used for clinical management.
- Drug of abuse screening may be useful for forensic purposes in cases of suspected malicious administration of opioids or suspected child neglect/abuse.

##### Imaging

CXR may be helpful in diagnosing acute lung injury.

##### Diagnostic Procedures/Other

A dramatic response to a trial dose of the opioid antagonist naloxone is diagnostic for opioid overdose. After administration, the patient will promptly awaken.

### DIFFERENTIAL DIAGNOSIS

- Sedative hypnotic overdose
- Antipsychotic overdose
- Clonidine overdose
- Pontine hemorrhage
- Ketamine overdose
- Phencyclidine overdose
- Alcohol intoxication

## TREATMENT

### PRE HOSPITAL

Assess and stabilize airway, breathing, and circulation:

- Administer naloxone as per local protocol.
- Prior to naloxone administration, perform bag-valve-mask ventilation on patients with respiratory depression or apnea.
- Doing so decreases the likelihood of developing acute lung injury.

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation:
  - Administer naloxone as per local protocol.
  - Prior to naloxone administration, perform bag-valve-mask ventilation on patients with respiratory depression or apnea.
  - Doing so decreases the likelihood of developing acute lung injury.
- The primary treatment depends on whether respiratory depression is present or not:
  - If so, naloxone administration to restore respiratory drive is indicated.
  - Is not, supportive care and monitoring is indicated.

### MEDICATION

- Naloxone:
  - 2 mg IV/IM/SC q15–90min PRN is the appropriate dose in patients without opioid tolerance.
  - Rarely, a naloxone infusion may be needed. Dosing involves taking 2/3 of the dose that achieved arousal and administering this dose each hour by infusion. This dose may be increased if necessary.
  - In opioid-tolerant patients, an initial dose of 0.1 mg IV may be given and repeated q5min until the patient is spontaneously breathing.
  - Administration of larger doses may induce withdrawal, which is an unnecessary risk.
- The endpoint for naloxone therapy is adequate spontaneous ventilation.
- If the patient is not opioid tolerant, naloxone may be administered to the endpoint of normal mental status.
- In opioid-tolerant patients, the use of naloxone to restore mental status may induce withdrawal, which is an unnecessary risk:
  - The duration of effect of most opioids is  $\leq 4$  hr, but some may last significantly longer. The effects of methadone and buprenorphine can last from 24–72 hr.
  - The duration of effect of naloxone is 30–90 min, so patients should be observed after this time frame for resedation.
  - Patients who have taken longer-acting opioids may require further IV bolus doses or an infusion of naloxone.

## DISPOSITION

### Admission Criteria

Critical care admission criteria:

- All children suspected of ingestion of an opioid should be admitted to the hospital for continuous pulse oximetry monitoring and 24 hr of observation.
- Children who require naloxone therapy should be admitted to the ICU for 24-hr monitoring.

### Discharge Criteria

- Return to baseline neurologic function and respiratory function
- Due to the possibility of resedation after the effects of naloxone wear off, patients should be held 60–90 min after the last naloxone administration to detect resedation.

### Issues for Referral

- For cases involving uncommon complications such as serotonin syndrome, seizures, or cardiac dysrhythmia, consult a medical toxicologist or poison control center.
- Patients with drug abuse should be referred for substance abuse counseling.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

Discharge instructions and medications:

- Counsel patients to avoid opioid abuse.

### Patient Monitoring

- Consider a drug abstinence program for patients who may be abusing opioids.
- Consider contacting child protective services for any case of opioid overdose in a young child who may have been the victim of abuse or neglect.

### PROGNOSIS

Patients who arrive to health care without cerebral hypoxia and have respiratory function restored with naloxone typically have an excellent prognosis:

- Patients who remain hypoxemic may develop anoxic encephalopathy with a poor prognosis.
- Acute lung injury carries a guarded prognosis, as this injury may cause significant morbidity or mortality.

### COMPLICATIONS

- Seizure
- Cardiac dysrhythmia
- Encephalopathy
- Permanent neurologic injury
- Death

## CODES

### ICD9

- 965.00 Poisoning by opium (alkaloids), unspecified
- 970.1 Poisoning by opiate antagonists

## PEARLS AND PITFALLS

- Opioids classically cause a toxidrome of coma, respiratory depression, and miosis.
- Naloxone is a highly effective and safe antidote that reverses respiratory depression and CNS depression.
- Because the half-life of opioids is significantly longer than that of naloxone, it is necessary to observe the patient for 60–90 min after the last naloxone administration before discharge from the emergency department.

# ORAL LESIONS

Audrey Le  
Sandip Godambe

## BASICS

### DESCRIPTION

- Children may present with a variety of oral lesions.
- These may often be normal developmental variants. Many are found most commonly during the neonatal period.
- Other etiologies are wide ranging and include trauma, infections, cysts, and tumors.
- It is important to recognize the clinical presentation of common childhood infections and those associated with systemic diseases.

### EPIDEMIOLOGY

#### Incidence

- 33% and 37% of schoolchildren have reported a history of recurrent herpes labialis and recurrent aphthous ulcers, respectively (1).
- In 1 study with 2,258 neonates, 64.3% had cysts on the palate (2).

#### Prevalence

- In a single multicenter study of 39,206 schoolchildren, 4% had  $\geq 1$  mucosal lesions. Of these, the most prevalent lesions were (1):
  - Aphthous ulcers in 1.23%
  - Recurrent herpes labialis in 0.78%
  - Chewing tobacco lesions in 0.71%
  - Geographic tongue in 0.60%
- 20% of the general population during their lifetime has recurrent aphthous stomatitis.

### PATHOPHYSIOLOGY

Lesions in the oral cavity may be the result of a developmental anomaly, infection, trauma, or accompanying systemic disease.

### ETIOLOGY

- Congenital:
  - Epstein pearls are self-limited epithelial inclusion cysts that are remnants of epithelial tissue entrapped during palatal fusion. They occur in the midline at the junction of the hard and soft palates and have the appearance of small yellow-white bumps or cysts.
  - Bohn nodules originate from heterotopic salivary glands. These are self-limited yellow-white cysts found on alveolar ridges and on the palate distal from the midline.
  - Dental lamina cysts, alveolar cysts, or gingival cysts are trapped remnants of dental lamina. They occur over the alveolar ridge and resolve spontaneously.
  - Premature eruption of primary teeth can occur antenatally (natal teeth) or during the 1st month of life (neonatal teeth).
  - Hemangiomas are the most common benign oral mucosal tumor of childhood. They are vascular malformations, typically spongy, red to blue, and poorly circumscribed and may become more apparent over time.
  - Lymphangiomas are less common oral tumors resulting from malformation of lymphatic vessels. They occur most commonly on the tongue but may be seen elsewhere. Superficial lesions can appear papillated or vesicular, whereas deeper lesions are nodular.

- Congenital ranula is a pseudocyst that is the result of malformation of, or injury to, the sublingual or submandibular salivary gland duct. It occurs just lateral to the lingual frenulum as a soft tissue swelling.
- Congenital epulis, or gingival granular cell tumor of the newborn, is a rare benign tumor that may appear as a firm pedunculated growth on the alveolar ridge originating from the periosteum of the mandible or maxilla.
- Mucoceles occur after trauma to the salivary glands. They appear as translucent or blue fluid-filled papules or nodules most commonly on the lower lip, but they also are seen elsewhere in the mouth.
- Eruption cysts occur when fluid accumulates in the dental follicle and precedes tooth eruption. When trauma occurs, accumulation of blood in this space causes an eruption hematoma.
- Multiple oral papules are a feature of various genodermatoses, including neurofibromatosis and Darier disease.
- Ulcers may occur anywhere in mouth as a result of mechanical, thermal, or chemical trauma.
- Infections cause stomatitis, which is inflammation of the mucosa and/or ulcers:
  - Viral infections:
    - Herpes simplex virus (HSV) primary or recurrent infection
    - Herpangina, usually caused by group A coxsackieviruses
    - Epstein-Barr virus, mononucleosis
    - Varicella
    - Measles
  - Fungal infections:
    - *Candida albicans*
    - Rare in immunocompetent children beyond the early childhood years
  - Bacterial infections:
    - A parulis is a subperiosteal abscess on the gingiva that accumulates from a fistulous tract of a primary tooth abscess.
    - Acute necrotizing ulcerative gingivitis is seen less commonly in children.
    - HIV gingivitis occurs with infection from multiple organisms, primarily gram-negative anaerobes, enteric bacteria, and yeast.
- Systemic diseases with oral findings:
  - Erythema multiforme major
  - Stevens-Johnson syndrome/Toxic epidermal necrolysis, caused by medications or infections
  - Inflammatory bowel disease
  - Immunodeficiency syndromes
  - Kawasaki disease
  - Chemotherapy medications
  - Radiation mucositis
  - Nutritional deficiencies
- Malignant growths do occur but are rare.
- Chewing tobacco-related lesions

## DIAGNOSIS

### HISTORY

- A detailed history including time course, associated symptoms, and possible exposures will help make the diagnosis.
- History of immunodeficiency should be sought out in children with suspected fungal infections and in those with recurrent complex aphthous stomatitis occurring more than 4 times a year, characterized by numerous large lesions that heal slowly ( $> 2$  wk) and may scar when healed.

### PHYSICAL EXAM

- Note the character and location of the oral lesions.
- Fever may accompany infectious lesions.
- In erythema multiforme major, lesions may appear only as poorly circumscribed areas of erythema or as central vesicles that form tender erosions or deeper ulcers when ruptured. Patients have characteristic target lesions on the skin.
- Koplik spots: Small white lesions found on the buccal mucosa that occur during the prodromal period of measles infection prior to development of the skin rash.
- Candidiasis, or oral thrush: Superficial white plaques on the mucous membranes that may follow antibiotic treatment, systemic corticosteroid use, or concurrent genetic syndromes or illnesses that compromise the immune system.
- HSV infection: Clusters of small vesicles that rupture, surrounded by a red halo. Vesicles may coalesce into large, painful ulcers. Patients may have fever, malaise, myalgia, and headache. Recurrent infection may manifest only over the vermilion border of the lip as a cold sore or fever blister (herpes labialis), or in the oral cavity (herpes oralis).
- Lesions accompanying varicella zoster virus infection, or chickenpox, appear as grouped vesicles and erosions, but lesions are typically larger than that seen with HSV. They may be accompanied by cutaneous lesions and typically fever and generalized malaise.
- Herpangina causes vesicles or small gray-based ulcers over the tonsils and soft palate; it is often accompanied by fever, pain, and malaise. Hand, foot, and mouth disease, caused by coxsackieviruses, is characterized by small lesions on the palate, tongue, buccal mucosa, hands, feet, and buttocks.
- Infectious mononucleosis presents with white or gray tonsillar exudates, palatal petechiae, and gingivitis, which is very similar to infection with group A streptococcus bacteria. Children may have fever and marked cervical lymphadenopathy. Palpate the abdomen for splenomegaly, as the spleen may be at increased risk for rupture or with exposure to traumatic forces.

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

- The most common diagnoses are made clinically.
- Labs are not commonly performed. Consider lab testing when immunodeficiency or systemic disease is suspected.

### Pathological Findings

- Biopsies should be performed on lesions suspicious for malignancy or for persistent lesions of indeterminate etiology.
- Epulis on histologic studies are seen as packed granular cells surrounded by fibrovascular stroma.

## DIFFERENTIAL DIAGNOSIS

The patient's age, past medical history, accompanying symptoms, and appearance and location of the lesions can narrow the differential. See the Etiology section.

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Assess and stabilize airway, breathing, and circulation.
- Large lesions may cause airway obstruction and require prompt intervention.
- Painful oral lesions can cause difficulty swallowing and decrease intake of fluids. Younger children are particularly vulnerable to dehydration:
  - IV fluid resuscitation may be required in those with threatened circulation.
  - Maintenance IV fluid may be required in those who are unable to take fluids by mouth either secondary to pain or obstruction.
- Care for the most common lesions is usually supportive only.

### MEDICATION

- Dental abscesses and acute necrotizing gingivitis require antibiotic treatment. Consider consultation with and/or referral to a dentist for follow-up care:
  - Amoxicillin 80–90 mg/kg PO divided b.i.d., max 3 g/day
  - Clindamycin 20–30 mg/kg PO divided t.i.d., max 1.8 g/day
- Acyclovir 40–80 mg/kg/day in 3–4 divided doses for 5–10 days (max dose 1.6 g/day); adult dose 800 mg PO q12h:
  - Initiated in 1st 3 days of onset of HSV lesions, acyclovir may shorten illness (3,4).
  - Other forms such as valacyclovir and famciclovir are likely to be equally or more effective.
- Valacyclovir:
  - Recurrent herpes labialis: 2–12 yr, 20 mg/kg/dose PO t.i.d. × 2 days for recurrence
  - Primary oral herpes outbreak: 2–12 yr, same dose as above but 5–7 days
    - Adolescent/Adult: 2 g PO b.i.d. × 2 days
    - Initiate at 1st onset of symptoms.
- Famciclovir:
  - Use in adolescents or adults only.
  - Initiate at 1st onset of symptoms.
  - Recurrent herpes labialis: 1,500 mg PO single dose
  - Primary herpes labialis outbreak: 250 mg PO t.i.d. × 7–10 days; discontinue if lesions clear in <7–10 days.

- Uncomplicated thrush, or candidiasis, can be treated with oral antifungal medications.
  - Nystatin suspension 100,000 U/mL: 1 mL to each side of the mouth q.i.d. for infants and 4–6 mL swish and swallow q.i.d. for older children; or clotrimazole 10-mg oral troche for children >3 yr of age: 1 troche 5 times a day for 14 days.
- Refractory cases of thrush may require systemic treatments:
  - Fluconazole 6 mg/kg PO on 1st day, then 3 mg/kg daily for 13 days (5)
  - Ketoconazole 3.3–6.6 g/kg PO per day × 5–10 days

## SURGERY/OTHER PROCEDURES

- Natal and neonatal teeth, if loose, should be removed to prevent aspiration.
- A congenital epulis may be excised if it causes difficulty feeding or poses a threat to the airway. Surgery is generally curative.
- The expected course of hemangiomas is rapid growth followed by slow involution and regression. When ability to feed, maintaining a patent airway, or cosmetic appearance becomes a concern, the patient may require treatment with pulsed dye laser or intralesional injection of corticosteroids or interferon. This care may be performed as an outpatient with dermatology.
- Surgical excision is usually required for mucoceles. Ranulas generally resolve spontaneously but occasionally require surgical excision.
- Eruption cysts may have to be incised and drained if they become too painful or if the underlying tooth does not erupt.
- Suspicious lesions may be biopsied and/or excised and sent for pathologic determination.

## DISPOSITION

- Most oral lesions require solely supportive care, and children can be managed as outpatients.
- If lesions interfere with oral intake or threaten the patency of the airway, patients should be admitted for close observation. More aggressive interventions may also be required.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

If discharged home, periodic follow-up should be arranged until the resolution of symptoms. The expediency of follow-up is determined by the clinical state of the child and the expected course of the disease.

### See Also (Topic, Algorithm, Electronic Media Element)

- Hand-Foot-and-Mouth Disease
- Herpes Simplex

### ICD9

- 054.9 Herpes simplex without mention of complication
- 528.2 Oral aphthae
- 528.9 Other and unspecified diseases of the oral soft tissues

## PEARLS AND PITFALLS

- Most congenital oral lesions are self-limited and require no intervention unless they interfere with function.
- Considering accompanying symptoms such as fever or rash in addition to the appearance of the oral lesions themselves can help delineate the underlying cause.
- When oral lesions occur without systemic signs, the most likely cause is congenital or tumorous growths.

# ORBITAL CELLULITIS

Parul B. Patel

## BASICS

### DESCRIPTION

- Orbital or postseptal cellulitis is a microbial infection involving the orbital structures posterior to the orbital septum.
- It is distinguished from periorbital or preseptal cellulitis, which is an infection involving the soft tissues of the eyelids and periocular area anterior to the orbital septum.
- The most common cause is the extension of infection from sinusitis.
- Orbital cellulitis is a sight-threatening and life-threatening disease.

### EPIDEMIOLOGY

#### Incidence

Increased incidence in winter due to increased incidence of bacterial sinusitis

#### Prevalence

- In children, the male to female ratio is 2:1.
- Median age of children hospitalized is 7–12 yr.

### RISK FACTORS

- Sinusitis
- Ophthalmologic surgery
- Orbital trauma
- Dental abscess

### GENERAL PREVENTION

- Proper and prompt treatment of above precipitating conditions
- *Haemophilus influenzae* type b vaccine has been shown to cause a decline in orbital cellulitis due to *H. influenzae*.

### PATHOPHYSIOLOGY

- Orbital cellulitis is infection within the muscle, fat, and connective tissue within the bony orbit.
- The orbital septum is a thin membrane that extends from the periosteum and reflects into the upper and lower eyelids.
- The septum separates the periorbital soft tissues (preseptal region) from the orbital space (septal) and provides a barrier to the spread of infection between the 2 regions.

- Orbital infections typically represent an extension of bacterial sinusitis:
  - The eye is surrounded by paranasal sinuses on 3 of its 4 walls and is connected by a valveless venous system that predisposes the spread of anterograde and retrograde infections between anatomic sites.
  - The roof of the orbit is the floor of frontal sinus, and the floor of the orbit is the roof of the maxillary sinus.
  - The medial orbital wall is a thin, perforated bone that allows for the passage of infection between the ethmoid sinuses and subperiosteal space.
- Orbital trauma, accidental or surgical, has been noted to lead to cellulitis.
- Hematogenous dissemination, though less common than contiguous spread from the sinuses, can be a cause.

### ETIOLOGY

- Bacterial causes are commonly due to *Streptococcus pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis*. Other bacterial etiologies include *Staphylococcus aureus*, *Streptococcus pyogenes*, and anaerobes such as *Bacteroides* species.
- Immunocompromised patients may have a fungal etiology, most commonly due to *Mucor* or *Aspergillus* species.

### COMMONLY ASSOCIATED CONDITIONS

- Sinusitis
- Orbital trauma
- Dental abscess

## DIAGNOSIS

### HISTORY

- Fever
- Eye pain, worse with eye movement
- Visual disturbance
- Complaint of eyelid swelling and/or eye redness
- Recent or concurrent sinusitis or upper respiratory infection
- Recent facial trauma, eye surgery, or dental procedures
- Infection elsewhere
- Headache

### PHYSICAL EXAM

- Lid warmth, edema, erythema, and tenderness. The degree of lid tenderness is typically less than that associated with periorbital cellulitis.
- Ophthalmoplegia: Decreased ocular movement
- Proptosis
- Pain with eye movement
- Decreased visual acuity or diplopia. This is a late finding. Normal visual acuity does not exclude the diagnosis.
- Chemosis
- Conjunctival injection
- Periocular pain
- Increased intraocular pressure
- All eye abnormalities are usually unilateral.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- CBC with differential typically shows leukocytosis.
- C-reactive protein is typically elevated.
- Culture of eye drainage
- Obtain blood cultures prior to antibiotic administration.

#### Imaging

- CT scan with axial and coronal views of the orbits and sinuses with IV contrast
- CT scan of the brain if severe and suspicious for brain abscess
- MRI of the brain may be helpful in diagnosing cavernous sinus thrombosis—a rare but serious complication.

#### Diagnostic Procedures/Other

- Surgical drainage
- Lumbar puncture if signs of meningitis or cerebral involvement

### DIFFERENTIAL DIAGNOSIS

- Preseptal cellulitis
- Allergic reaction
- Trauma
- Conjunctivitis
- Tumor: Retinoblastoma, neuroblastoma, rhabdomyosarcoma
- Pseudotumor
- Thyroid dysfunction

**TREATMENT**

**MEDICATION**

**First Line**

- Broad-spectrum antibiotics should be used until specific organisms are identified by cultures.
- Antibiotic should be aimed at the most likely pathogens, typically respiratory pathogens and anaerobes originating from the paranasal sinuses.
- Ampicillin/Sulbactam or cefuroxime are appropriate initial choices:
  - IV ampicillin/sulbactam 40 mg/kg IV q8h:
    - Dose should be doubled if resistant pneumococcus is suspected or prevalent.
  - Cefuroxime 25 mg/kg IV q8h
- For MRSA coverage, include vancomycin or clindamycin:
  - Vancomycin 10 mg/kg IV q8h
  - Clindamycin 10 mg/kg IV q8h
- For immunocompromised patients in whom fungal infection is considered, use amphotericin.

**Second Line**

- Nasal decongestants may aid sinus drainage:
  - Oxymetazoline 2 sprays in each nostril b.i.d.
  - Phenylephrine 2 drops in each nostril q4h
  - Pseudoephedrine 60 mg/dose PP q8h
- Diuretics such as acetazolamide can reduce intraocular pressure.
- Consider ocular antihypertensives in consultation with an ophthalmologist if secondary glaucoma is suspected.
- Consider tetanus prophylaxis in a patient with ocular trauma.

**SURGERY/OTHER PROCEDURES**

- Surgical drainage is indicated if there is a large abscess; complete ophthalmoplegia or vision impairment; poor response within the 1st 48 hr of IV antibiotic therapy; or if the patient develops decrease in vision, afferent papillary defect, or increase in proptosis.
- Craniotomy is indicated if a brain abscess develops and does not respond to antibiotic therapy.

**DISPOSITION**

**Admission Criteria**

- Critical care admission criteria:
  - Consider ICU admissions for rapidly progressing or neurologic complications requiring close monitoring.
- All patients should be admitted to the hospital for IV antibiotics.

**Discharge Criteria**

If the patient is improving and afebrile for 48 hr, then discharge from an inpatient unit with oral antibiotics may be considered.

**Issues for Referral**

- All patients should have an ophthalmology consult.
- If sinuses are involved or there is an abscess, consider an otorhinolaryngology consult.
- Consult an infectious disease specialist to help guide antibiotic therapy.
- Neurosurgery should be consulted to assist with the management of a brain abscess.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Oral antibiotics for 2–3 wk and close follow-up with an ophthalmologist and infectious disease specialist
- Activity:
  - As tolerated, but consider bed rest initially if the patient has signs of increased intraocular pressure

**Patient Monitoring**

- Monitor antibiotic coverage and vision at least daily while the patient is hospitalized.
- Monitoring by an infectious disease specialist and an ophthalmologist as an outpatient until antibiotics can be discontinued per infectious disease protocol

**PROGNOSIS**

- Complete recovery can occur with prompt treatment.
- Mortality is significantly increased with cavernous sinus thrombosis.

**COMPLICATIONS**

- Cavernous sinus thrombosis
- Blindness
- Meningitis
- Subdural empyema
- Brain abscess

**See Also (Topic, Algorithm, Electronic Media Element)**

- Orbital Cellulitis
- Periorbital Cellulitis

ICD9  
376.01 Orbital cellulitis

**PEARLS AND PITFALLS**

- Proptosis and pain or restriction with eye movement is characteristic of orbital cellulitis and helps distinguish from preseptal cellulitis.
- Orbital cellulitis should be suspected in patients with eye pain, erythema, proptosis and recent sinusitis, dental pain, or eye or dental surgery.
- Not all patients with orbital cellulitis have a fever.
- Decreased visual acuity is a late finding. Normal visual acuity does not exclude the diagnosis.
- The orbital septum helps to prevent posterior spread of preseptal cellulitis.

# ORCHITIS

Denise G. Karasic

## BASICS

### DESCRIPTION

Orchitis is an inflammation or infection of the testes. It is most commonly associated with epididymitis.

### EPIDEMIOLOGY

#### Incidence

- The incidence of orchitis alone in prepubertal boys is rare.
- Orchitis may occur in infants <3 mo of age and may be associated with bacteremia.
- Mumps is a common cause of orchitis; the highest rate of mumps orchitis is in postpubertal males between the ages of 15 and 29 yr:
  - 30–38% of this age group who have mumps develop orchitis.
- Rarely, orchitis and fever can be seen after immunization with the measles, mumps, and rubella (MMR) vaccine. This may be associated with parotitis.

### RISK FACTORS

- Patients who have never been immunized or who have waning immunity to mumps are at increased risk for mumps orchitis.
- Orchitis can result from the MMR vaccine.
- Anatomic abnormalities of the urinary tract have been associated with bacterial epididymo-orchitis (EO):
  - Sexually active patients are at higher risk for EO associated with *Neisseria gonorrhoea* and *Chlamydia trachomatis*.
  - Anal intercourse is associated with EO caused by coliform bacteria.

### GENERAL PREVENTION

- Mumps immunization
- Condom use

### PATHOPHYSIOLOGY

- The infection or inflammation commonly extends from the epididymis.
- Hematogenous spread, though rare in children, is the most common source of isolated testicular bacterial infection.
- Vasculitis of the testes may be seen with Henoch-Schönlein purpura.

### ETIOLOGY

- Viral:
  - Mumps virus
  - Epstein-Barr virus
  - Coxsackievirus
  - Rubella
  - Echovirus
  - Parvovirus
  - West Nile virus
- Bacterial:
  - *N. gonorrhoea*
  - *C. trachomatis*
  - Brucellosis
  - Mycobacteria
  - Infants <3 months: *Escherichia coli*, *Enterococcus faecalis*, *Neisseria meningitidis*
- Other:
  - Filariasis
  - Henoch-Schönlein purpura

### COMMONLY ASSOCIATED CONDITIONS

- Parotitis
- Epididymitis
- Urinary tract infections
- Bacteremia

## DIAGNOSIS

### HISTORY

- Testicular pain may be acute or gradual in onset.
- Testicular pain may be bilateral.
- Complaints may include scrotal swelling, fever, and chills.
- Symptoms associated with a urinary tract infection such as fever, dysuria, frequency, urgency, and hematuria may be present.
- Nausea and vomiting may be seen with both EO and testicular torsion.
- Ask patients about sexual activity.
- Inquire if there is a history of scrotal trauma.

### PHYSICAL EXAM

- Testicles are usually in normal anatomic position:
  - Testicles that are high riding and have a transverse lie may be torsed.
- Testicles are swollen and tender.
- The epididymis may also be swollen and tender.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Clean catch urine for urinalysis and urine culture
- Urethral cultures in patients who are sexually active
- CBC and/or C-reactive protein to screen for infection/inflammation
- Infants with suspected bacterial orchitis: Consider a full sepsis evaluation including blood, urine, and CSF cultures.

#### Imaging

Testicular US, especially if testicular torsion is a consideration

#### Diagnostic Procedures/Other

Patients with *E. coli* or *Enterobacter* as the proven cause of orchitis or EO should be evaluated for abnormalities of the urinary tract.

### DIFFERENTIAL DIAGNOSIS

- Torsion of the testes
- Torsion of the appendix testes
- Epididymitis
- Scrotal trauma/hematoma
- Scrotal cellulitis
- Testicular tumor with acute hemorrhage
- Hernia
- Hydrocele
- Referred pain to the scrotum from an abdominal etiology

## TREATMENT

### INITIAL STABILIZATION/THERAPY

Initial treatment should focus on pain relief.

### MEDICATION

- Analgesic:
  - Ibuprofen 10 mg/kg PO/IV q6h PRN
  - Acetaminophen 15 mg/kg PO/PR q4h PRN
  - Codeine 1 mg/kg/dose IV/PO q4h PRN
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
- Antibiotic (if bacterial etiology suspected):
  - Trimethoprim (TMP)/sulfamethoxazole 6–12 mg of TMP component/kg/day IV/PO divided q12h for 10 days
  - Cefdinir 14 mg/kg PO in 1 or 2 divided doses (max 600 mg/day) for 10 days
  - Cephalexin 25–50 mg/kg/day PO q6–8h for 10 days
- Adolescent males with orchitis/epididymitis and gonorrhea or chlamydia as likely pathogens require treatment:
  - Ceftriaxone 250 mg IM single dose
  - Doxycycline 100 mg PO b.i.d. for 10 days
- Adolescent males with orchitis/epididymitis and enteric organisms as likely pathogens require treatment:
  - Ofloxacin 300 mg PO b.i.d. for 10 days
  - Levofloxacin 500 mg PO per day for 10 days:
    - Not recommended for presumed STI due to resistance.

### COMPLEMENTARY & ALTERNATIVE THERAPIES

- Scrotal elevation
- Rest
- Cold packs

### SURGERY/OTHER PROCEDURES

Drainage of testicular abscess

### DISPOSITION

#### Admission Criteria

- Ill infants suspected to have bacterial orchitis or abscess require admission.
- Patients with an abscess should be evaluated by a pediatric surgeon or urologist.
- Intractable pain, inability to take oral antibiotics, vomiting, or failure of outpatient therapy are also reasons for hospitalization.

#### Discharge Criteria

Most patients with orchitis or EO can be discharged with appropriate treatment and close follow-up plans.

#### Issues for Referral

Young infants with orchitis that is thought to be bacterial in origin, or associated with abscess, should be transferred to a pediatric specialty hospital.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Patients diagnosed with orchitis or EO may be treated with NSAIDs.
  - They may also require treatment with antibiotics as outlined in the medication section.
  - Cold packs and scrotal elevation may give additional relief.
- Activity:
  - Rest

### PROGNOSIS

- The prognosis for orchitis is dependent upon the etiology. Patients with mumps are at higher risk for testicular atrophy and less commonly infertility.
- Patients with other etiologies of viral orchitis should have full recovery. Complete resolution of symptoms, however, may be slow.
- Patients with bacterial orchitis or EO should have resolution of symptoms after completion of antibiotic therapy.

### COMPLICATIONS

- Abscess formation
- Testicular atrophy
- Infertility
- Patients with mumps orchitis may have associated meningitis, encephalitis, and parotitis.

### See Also (Topic, Algorithm, Electronic Media Element)

- Epididymitis/Orchitis
- Mumps
- Parotitis
- Scrotal Mass
- Sexually Transmitted Infections
- Testicular Torsion

### CODES

#### ICD9

- 604.90 Orchitis and epididymitis, unspecified
- 604.91 Orchitis and epididymitis in diseases classified elsewhere
- 604.99 Other orchitis, epididymitis, and epididymo-orchitis, without mention of abscess

### PEARLS AND PITFALLS

- Orchitis may involve 1 or both testes.
- Be highly suspicious of testicular torsion in the adolescent boy with abrupt onset of severe, unilateral scrotal pain.
- Most adolescent males with orchitis should be assumed to have an STI and treated with appropriate antibiotics.

# OSGOOD-SCHLATTER DISEASE

Maria Carmen G. Diaz

## BASICS

### DESCRIPTION

- Osgood-Schlatter disease is characterized by traction apophysitis of the tibial tubercle.
- It occurs due to repetitive strain and chronic avulsion of the secondary ossification center of tibial tuberosity.
- It usually occurs in athletic children.
- Fusion of the tubercle to the tibia upon reaching skeletal maturity eliminates occurrence.

### EPIDEMIOLOGY

#### Incidence

- Seen in boys between 10 and 15 yr of age
- Seen in girls between 8 and 13 yr of age
- Usually unilateral, although bilateral in 20–30% of patients (1)
- Incidence of 1 in 5 patients who participate in sports (2)
- Incidence of 1 in 20 patients who do not participate in sports (2)

### RISK FACTORS

- Participation in impact or deceleration activities
- Participation in sports involving running, cutting, and jumping, including (3):
  - Soccer
  - Basketball
  - Gymnastics
  - Volleyball
  - Track

### PATHOPHYSIOLOGY

- Traction apophysitis of tibial tubercle
- Occurs due to repetitive strain and chronic avulsion of the secondary ossification center of the tibial tuberosity
- Sporting activities cause quadriceps muscle to pull and strain the patellar tendon, causing trauma to the tibial tubercle

- Fragments of the tibial tubercle may develop.
- Avulsed bone or cartilage continues to grow, ossify, and enlarge.

### ETIOLOGY

Repetitive microtrauma

## DIAGNOSIS

### HISTORY

- May be asymptomatic at time of presentation to the emergency department
- Patients usually have a vague history of gradual onset of pain and swelling in the region of tibial tuberosity.
- May complain of pain at the site of insertion of the distal patellar ligament
- Pain is initially mild and intermittent.
- Pain then may become acute and severe.
- Pain is exacerbated by running, jumping, and kneeling.

### PHYSICAL EXAM

- Anterior knee pain and swelling
- Tibial tubercle: Tender and swollen on exam
- May have tenderness with passive knee flexion
- May have tenderness with knee extension against resistance (4)
- No laxity or deformity of the knee
- No knee effusion
- No erythema of overlying epidermis

### DIAGNOSTIC TESTS & INTERPRETATION

#### Imaging

- X-ray of the knee may occasionally be indicated if pain is unilateral or diagnosis is uncertain.
- This can rule out other causes of knee pain such as osteosarcoma, Ewing sarcoma, and osteoid osteoma.
- Plain films may show fragmentation of the tibial tubercle.
- Plain films may be normal in early stages.

### DIFFERENTIAL DIAGNOSIS

- Arthritis
- Tendonitis
- Bursitis
- Myositis
- Tibial tubercle fracture:
  - May occur with violent contraction of the quadriceps
  - May occur with forceful flexion of the knee with contracted quadriceps
  - Patients have pain, swelling, effusion, and decreased knee extension.
  - Plain films may show an avulsed fragment or fracture line extending into the knee joint.
- Sinding-Larsen-Johansson syndrome:
  - Traction apophysitis of the inferior patellar pole
  - Seen in children age 10–12 yr
  - Patients present with pain localized to inferior patella.
- Hoffa syndrome:
  - Injury to the inferior patellar fat pad
  - Patients have anterior knee pain.
  - Maximal tenderness in the anterior joint line lateral to the patellar tendon
- Synovial plica injury (5):
  - Trauma and repetitive motion causes thickening, fibrosis, and hemorrhage in plica (normal synovial folds within the knee joint).
  - Patients present with anterior knee pain.
- Slipped capital femoral epiphysis with referred pain from the hip
- Tumor
- Infection

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Rest
- Ice
- Elevation
- NSAIDs
- Immobilization, as might be achieved with splinting, is generally not recommended.
- Non-weight bearing, as with use of crutches, is generally not recommended.

### COMPLEMENTARY & ALTERNATIVE THERAPIES

- Infrapatellar strap for 6–8 wk may provide symptomatic relief during activity.
- Physical therapy: Quadriceps stretching as part of a strengthening program once symptoms are controlled:
  - Low-intensity quadriceps strengthening exercises initially
  - High-intensity quadriceps exercises and hamstring stretching gradually introduced

### SURGERY/OTHER PROCEDURES

- Surgery is indicated only if symptoms persist in skeletally mature patients despite conservative measures (rest, NSAIDs, physical therapy).
- Patients may have the following persistent symptoms:
  - Local pain
  - Difficulty kneeling
  - Restricted activity into adulthood
- Persistence of symptoms despite conservative measures is seen in ~5–10% of patients (1).
- Surgical options include:
  - Shaving or excision of the tibial tuberosity
  - Removing intratendinous fragments/ossicles/free cartilaginous fragments
  - Longitudinal incision in the patellar tendon

### DISPOSITION

#### Issues for Referral

Patients may have outpatient follow-up with their primary care physicians:

- Referral to an orthopedic surgeon is indicated only for persistent pain or if the diagnosis is in doubt.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Rest, ice, elevation, use of NSAIDs
  - Ibuprofen 10 mg/kg PO q6h PRN, max dose 800 mg
  - Naproxen 5 mg/kg PO q12h PRN, max dose 1,250 mg/24 hr
- Activity:
  - Rest
  - After an acute exacerbation, most patients are able to return to full activity within 2–3 wk with conservative management.
    - However, symptoms may wax and wane for 12–24 mo before complete resolution.

### Patient Monitoring

Physical therapy as indicated above

### PROGNOSIS

- Self-limiting process with good outcomes
- Resolution of symptoms occurs with closure of the tibial growth plate.
- Resolution of symptoms is seen in >90% of patients (1).

## CODES

### ICD9

732.4 Juvenile osteochondrosis of lower extremity, excluding foot

## PEARLS AND PITFALLS

- Osgood-Schlatter disease is an overuse injury seen in growing children.
- Patients present with localized pain, swelling, and tenderness over the tibial tuberosity.
- Treatment is conservative and consists of rest, ice, elevation, and NSAIDs.
- This is a self-limiting process, with resolution of symptoms occurring when the tibial growth plate closes.
- Malignancies such as osteosarcoma and Ewing sarcoma may present with knee pain in the same age group:
  - If diagnosis is uncertain, such as with location of pain or if unilateral pain, consider x-ray.

# OSTEOGENESIS IMPERFECTA

Brenda J. Bender

## BASICS

### DESCRIPTION

- Osteogenesis imperfecta (OI) is a heterogeneous group of inherited connective tissue disorders affecting bone and soft tissue.
- OI has many phenotypic presentations.
- Both bone quality and bone mass are affected.
- The hallmark of OI is fragile bones that fracture easily, sometimes with minimal or no trauma. Progressive deformity may ensue.

### EPIDEMIOLOGY

- The incidence of OI is 1/12,000–1/15,000 births.
- OI occurs equally among females and males and across all races and ethnic groups.
- In most families, OI is inherited in an autosomal dominant pattern.
- Spontaneous new mutations are common.
- Recessive inheritance patterns have been described.
- Many of the defects in type I collagen seen in OI are due to mutations in COL1A1 or COL1A2 genes that encode type I collagen.
  - These genes are found on chromosomes 7 and 17.
  - >800 mutations have been discovered.

### PATHOPHYSIOLOGY

- The cause of all cases of OI is not known.
- Affected patients have bones with less than normal collagen, or their collagen is of poor quality.

### ETIOLOGY

- OI is classified into 4 major subtypes based on clinical, radiographic, and genetic factors.
- 4 additional subtypes have been described.
- Type I:
  - Mildest and most common form
  - Blue sclera
  - Hearing loss
  - Some forms are associated with dentinogenesis imperfecta.
- Type II:
  - Most severe form
  - Stillbirth or neonatal death

- Type III:
  - Severe bone fragility
  - Scoliosis and chest wall deformity
  - Growth retardation and short stature
  - White or blue sclera
  - Dentinogenesis imperfecta is common.
- Type IV:
  - Moderate bone fragility
  - Growth retardation
  - Sclera white, in most cases
- Type V:
  - Moderate bone fragility
  - Short stature
  - White sclera
  - No dentinogenesis imperfecta
- Type VI:
  - Extremely rare
  - Moderate bone fragility and short stature
  - White sclera
  - No dentinogenesis imperfecta
- Type VII:
  - Moderate bone fragility
  - White sclera, small head, and round faces
  - Short stature
  - Coxa vara
- Type VIII:
  - Severe growth deficiency
  - White sclera

## DIAGNOSIS

### HISTORY

- There often is a family history.
- Variable history of fractures resulting from minor trauma depending on the subtype
- Deformity from multiple fractures in severe subtypes
- Mild and moderate subtypes:
  - Short stature
  - Bowing of legs, hypermobility of joints, subluxations and dislocations, spinal deformity
- Ectoderm: Easy bruising, blue sclera, dentinogenesis imperfecta, discolored teeth, broken teeth

### PHYSICAL EXAM

- Excessive number of or atypical fractures (brittle bones).
- Short stature
- Scoliosis and kyphosis
- Basilar skull deformities
- Blue sclera
- Hearing loss
- Dentinogenesis imperfecta (opalescent teeth that wear quickly)
- Increased laxity of the ligaments and skin
- Wormian bones (small, irregular bones along the cranial sutures)
- Easy bruisability
- Restrictive pulmonary disease
- Decreased muscle strength
- Compression fractures of the spine
- Scars from sutures
- Gross motor development delay
- Myopia
- Flat feet
- Hernias usually present at birth
- Triangular-shaped face
- Enlarged head circumference

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- No routine lab testing necessary in the emergency department
- Diagnostic testing, such as collagen molecular testing and collagen biochemical testing, are available.

##### Imaging

- Radiograph findings can include:
  - Osteopenia
  - Fractures
  - Bowing of the long bones
  - Vertebral compressions
- Wormian bones in the skull
- Bone mineral density may be lower than normal.

**Diagnostic Procedures/Other**

- A biopsy of the iliac bone can be obtained to help identify forms of OI.
- 90% of all collagen type 1 mutations can be detected from the patient's fibroblasts or WBCs.
- From the patient's cultured skin fibroblasts, analysis of the collagen type 1 genes can determine the amount and structure of type 1 procollagen molecules.
- From the patient's WBCs, genomic DNA can be extracted, and the coding region of the COL1A1 and COL1A2 genes can be screened for mutations.

**Pathological Findings**

- Bone histology may show woven, disorganized bone.
- Normal mineralization with reductions in cortical width, cancellous bone volume, trabecular number, and trabecular width
- Increased bone remodeling

**DIFFERENTIAL DIAGNOSIS**

- Child abuse
- Rickets
- Osteomalacia
- Bruck syndrome
- Osteoporosis-pseudoglioma syndrome
- Juvenile Paget disease
- Hypophosphatasia
- Parosteotic fibrous dysplasia
- Cole-Carpenter syndrome
- Idiopathic juvenile osteoporosis
- Cushing disease
- Calcium deficiency
- Malabsorption
- Ehlers-Danlos syndrome types VIIA and VIIB
- Achondroplasia

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Assess respiratory and cardiac stability, as these can be compromised secondary to fractures.
- Fracture stabilization

**MEDICATION****First Line**

- Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
  - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
- Ibuprofen 10 mg/kg PO q6h PRN
- Bisphosphonates are potent inhibitors of bone resorption.
- Bisphosphonate therapy is not approved specifically for use in OI.

- In children, cyclic IV pamidronate has been used in moderate-severe OI and has been found to have good short-term safety.
- Positive effects seen with pamidronate therapy include reduction in chronic bone pain, gain in muscle force, increase in size and density of vertebral bodies, thickening of bone cortex, and gain in growth rate.

**Second Line**

- Therapies currently under investigation include growth hormone and parathyroid hormone.
- Other treatments that have been tried include IV neridronate, oral olpadronate, and oral alendronate.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

Behavioral and lifestyle modification

**SURGERY/OTHER PROCEDURES**

- Orthopedic care includes bracing, splinting, orthotic supports, casting, and intramedullary rodding with osteotomy.
- Gene therapy and bone marrow transplantation is under investigation.

**DISPOSITION****Admission Criteria**

- Patients requiring surgery need to be admitted.
- Some children may need to be hospitalized for pain management and/or monitoring for compartment syndrome following a fracture.
- Critical care admission criteria:
  - Any patient with respiratory or cardiac compromise needs admission, treatment, and monitoring.

**Discharge Criteria**

Most patients with fractures requiring immobilization or casting can be discharged.

**Issues for Referral**

- Patients often need emotional and psychological support and referral to social work services.
- After fractures and/or surgical procedures, patient needs referral to rehabilitation medicine.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Patients should be immobilized for as brief a time as possible.
- Pain medication as needed
- Patients need to follow closely with orthopedics and rehabilitation medicine.

**PROGNOSIS**

- The prognosis depends on the form of OI.
- Patients with type I OI present with few childhood fractures and no long bone deformity and have a normal life expectancy. Fracture incidence decreases after puberty.
- Patients with OI types III–VII have an increased rate of premature death.

**COMPLICATIONS**

- Respiratory and cardiac complications secondary to fractures
- Basilar invagination can be a fatal complication.
- Prolonged immobilization due to surgery can increase osteopenia and loss of muscle mass.

**ADDITIONAL READING**

ICD9

756.51 Osteogenesis imperfecta

**PEARLS AND PITFALLS**

- Family members should carry documentation of OI with them to avoid accusations of child abuse in the emergency room.
- Bones affected by OI mostly heal at the same rate as healthy bone.
- It is a myth that children with OI feel less pain than other patients.

# OSTEOMYELITIS

Arezoo Zomorodi

## BASICS

### DESCRIPTION

- Osteomyelitis (OM) is infection of bone.
- Usually the infection is bacterial, but fungal and viral OM does very rarely occur:
  - Bacteria most commonly seed the bone hematogenously.
  - Infection can also occur as a result of direct spread from a contiguous site or from direct inoculation into bone.

### EPIDEMIOLOGY

#### Prevalence

- OM occurs most commonly in the 1st 2 decades of life.
- Boys are affected twice as often as girls (2).

### RISK FACTORS

- Sickle cell disease
- Indwelling catheters
- Closed trauma, penetrating injury, or open fracture
- Immune suppression
- Skin infections
- Injection of illicit drugs

### PATHOPHYSIOLOGY

- Hematogenous OM is most common in the metaphysis of long bones:
  - The terminal arteriolar branches of the nutrient artery make hairpin loops at the physis and empty into venous sinusoids of the metaphysis. Sluggish blood flow and a paucity of phagocytes at this site enable bacterial overgrowth.
  - The ensuing inflammatory process causes osteolysis, tissue destruction, and increased pressure via the haversian system and Volkmann canals into the subperiosteum.
  - Bone necrosis results from decreased blood supply to the cortex.
  - In newborns and young infants, the metaphysis and epiphysis are connected through transphyseal blood vessels, enabling infection from the metaphysis to enter the joint space. The thin cortex of newborn bone also allows infection to spread to the soft tissue.
  - Chronic OM may develop as thrombosis of additional vessels cause bone infarction. This avascular bone becomes inaccessible to antibiotics and the immune system.
- Direct inoculation can occur following puncture wounds or trauma:
  - During coincidental bacteremia, trauma can cause thrombosis of metaphyseal microcirculation, further acting as a nidus for infection.
- The least common mechanism for OM in children is local invasion from a contiguous infection.

### ETIOLOGY

- *Staphylococcus aureus* is the most common organism causing OM in all patients.
- Common pathogens in neonates include group A and group B streptococcus and gram-negative enteric bacilli.
- Other pathogens in children include *Kingella kingae*, *Streptococcus*, and *Pseudomonas aeruginosa*:
  - *P. aeruginosa* is common after penetrating injury to the foot through a shoe.
  - *S. pneumoniae* and *Salmonella* can cause infections in patients with sickle cell anemia.
- Fungal infection can occur when there is disseminated multisystem infection.
- Viral OM is exceedingly rare.
- The specific bacterial pathogen is not found in almost half of patients (3,4).

### COMMONLY ASSOCIATED CONDITIONS

In neonates, infection can spread to the epiphysis and joint space, causing septic arthritis.

## DIAGNOSIS

### HISTORY

- Children with acute OM typically present with a few days to a week of localized bone pain and decreased use of the involved limb:
  - Limp is common when the lower extremities are involved.
  - Range of motion is often limited due to muscle splinting.
  - Pain may be difficult to localize in OM of the pelvis or spine.
  - Systemic symptoms including fever, lethargy, and irritability are common.
- Neonates are more likely to have multifocal involvement, redness, swelling, poor feeding, and pseudoparalysis. Only half of neonates with OM have fever.
- Subacute OM presents with weeks to months of symptoms, less severe pain, and fewer constitutional symptoms.
- Chronic OM is diagnosed in patients with recurrence of symptoms after treatment completion.

### PHYSICAL EXAM

- Exam reveals point tenderness of the affected bone.
- Local redness, heat, or swelling indicates extension of the infection through the cortex, which is more common in neonates and young children.
- With gentle manipulation, full range of motion can usually be demonstrated in non-neonates. This is in contrast to the limited range of motion seen in septic arthritis.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

Neither the WBC, ESR, nor the C-reactive protein (CRP) are specific tests for OM, but all 3 should be initially obtained.

- Their primary utility is to monitor the response to treatment rather than to establish a diagnosis:
  - The WBC is elevated in 35–58% of patients (5,6).
  - The ESR is elevated in 92–100% of patients (5,6).
  - The CRP is elevated in 82–98% of patients (5,6).
- Obtain blood cultures.

#### Imaging

- Plain radiographs:
  - Plain radiographs are useful at symptom onset to rule out other causes of bone pain such as malignancy or trauma.
  - Within 72 hr, plain radiographs may show nonspecific displacement of deep muscle planes from the metaphysis.
  - Bone abnormalities including bone rarefaction, necrosis, and periosteal thickening develop 10–14 days after symptom onset.
- Bone scan:
  - Bone scan can detect OM 24–48 hr after symptom onset.
  - Bone scan is most useful when there are multiple foci of infection and when the area of infection cannot be localized.
  - Bone scan is advantageous over MRI because sedation is not required.
  - Disadvantages of bone scan include low specificity with difficulty distinguishing OM from overlying cellulitis or adjacent septic arthritis. Also, bone scan has low sensitivity in neonates.
- MRI:
  - MRI provides precise localization of inflammation and distinguishes between soft tissue and bony involvement.
    - However, MRI lacks specificity and cannot distinguish between trauma, neoplasm, or infection.
  - Computerized axial tomography (CT) scan:
    - CT scan provides detail of bone structure and localization of pathology. It also identifies extraosseous abscesses.
    - The radiation dose is its greatest disadvantage.
- Approach to imaging:
  - Plain radiographs should be obtained to look for other causes of bone pain.
  - MRI is best when the diagnosis is still obscure or in cases of vertebral or pelvic disease, complicated chronic OM, or when anatomic detail is necessary for surgical intervention.
  - Bone scan should be used when the infection cannot be localized or when there are multiple foci of infection.
  - CT scan should be used when MRI is impractical to obtain.

**Diagnostic Procedures/Other**

Bone aspiration for Gram stain and culture remains the definitive diagnostic technique and provides the optimal culture specimen for diagnosis and selection of appropriate antibiotics.

**DIFFERENTIAL DIAGNOSIS**

- Trauma
- Septic joint
- Acute rheumatic arthritis
- Malignancy
- Bone infarction
- Thrombophlebitis
- Toxic synovitis

**TREATMENT****INITIAL STABILIZATION/THERAPY**

- Most patients are stable, but patients can be critically ill or even septic.
- Initial focus should be on airway, breathing, and circulation.
- For most patients, pain can be managed with NSAIDs or oral opioids.

**MEDICATION**

- Empiric IV antibiotics should be instituted after appropriate cultures are obtained but prior to culture results.
- Antibiotics should later be tailored according to isolated pathogen susceptibility.
- Birth to 3 mo of age:
  - Treat with a 3rd-generation cephalosporin and antistaphylococcal agent.
- Older infants and children:
  - Administer monotherapy with nafcillin, vancomycin, or clindamycin depending on the rate of and resistance patterns for MRSA in the community.
  - Consider *K. kingae* in patients in day care, in patients with oral ulcers, or in patients not otherwise improving. *K. kingae* can be treated with nafcillin or a cephalosporin.
- Special considerations:
  - Patients with sickle cell disease are at risk for *Salmonella* infection and should be treated with a 3rd-generation cephalosporin.
  - Patients with urinary tract anomalies or recent GI surgery should be treated with an aminoglycoside or a 3rd-generation cephalosporin to cover enteric gram-negative organisms.
  - *P. aeruginosa* may be an etiology for OM resulting from a penetrating injury through a shoe or from the use of illicit drugs.
- Patients can be transitioned to oral therapy in ~1 wk if they have shown a response to parenteral antibiotics marked by defervescence, improved local symptoms, and decreased ESR and CRP. IV antibiotic administration >7 days has not been proven to be beneficial over <7 days (7).
- Total duration of parenteral and oral antibiotic treatment is between 4 and 6 wk.

**SURGERY/OTHER PROCEDURES**

Patients will require surgical debridement and/or drainage if they have subperiosteal or soft tissue abscesses, a retained foreign body, progressive bone destruction, or if they are not improving with appropriate antimicrobial therapy.

**DISPOSITION****Admission Criteria**

All patients with suspected OM who will receive empiric therapy should be admitted to the hospital for IV antibiotic administration.

**Discharge Criteria**

- Patients strongly suspected to have OM should not be discharged home from the emergency department.
- Well-appearing patients with equivocal physical exam, lab, and plain radiograph findings may be closely monitored as an outpatient and should have further imaging obtained within a few days of emergency department discharge, if symptoms persist or worsen.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Patients with equivocal findings who are discharged from the emergency department should have follow-up with an orthopedic specialist within a few days.
- After discharge from the inpatient unit, patients should be seen in 1–2-wk intervals and evaluated for clinical improvement as well as for evaluation of antibiotic side effects. Lab values including CBC, ESR, and CRP should be followed.
- Long-term follow-up with meticulous attention to range of motion of joints and bone length is essential to ensure proper bone growth.

**PROGNOSIS**

Cure rates for children with OM who are appropriately treated in a timely fashion are >95% (7).

**COMPLICATIONS**

- Permanent bone damage, particularly shortening and angulation resulting from physeal damage of long bones
- Chronic OM
- Venous thrombosis
- Septic emboli

**CODES****ICD9**

- 730.20 Unspecified osteomyelitis, site unspecified
- 730.21 Unspecified osteomyelitis involving shoulder region
- 730.22 Unspecified osteomyelitis involving upper arm

**PEARLS AND PITFALLS**

- The diagnosis of OM should be entertained whenever a child presents with acute onset of bone pain or limited motion of an extremity, even in the absence of fever.
- Screening lab tests may suggest the diagnosis; imaging studies are more sensitive for confirming the diagnosis.
- Neonates more typically present with pseudoparalysis of an extremity and frequently have coexisting OM and septic arthritis.

# OSTEOSARCOMA

Antoinette W. Lindberg  
Alexandre Arkader

## BASICS

### DESCRIPTION

- Osteosarcoma, also referred to as osteogenic sarcoma, is a tumor of the bone composed of spindle cells that produce malignant osteoid.
- It is the most common primary bone sarcoma among children and young adults:
  - Accounts for 20% of all primary malignant bone tumors
  - Affects areas of rapid growth but can occur in any bone
  - >60% cases occur in the 2nd decade of life.
  - ~90% of these tumors occur at the metaphyseal ends of long bones, most commonly the distal femur, followed by the proximal tibia, then the proximal humerus.

### EPIDEMIOLOGY

#### Incidence

- 5.25 cases per million per year in the U.S.
- 2 cases per million per year in patients 0–14 yr of age

### RISK FACTORS

- Prior radiation therapy
- Paget disease in adult patients
- Genetic predisposition seen in certain syndromes:
  - Li-Fraumeni syndrome: Abnormal p53 gene
  - Retinoblastoma: Abnormal Rb gene

### PATHOPHYSIOLOGY

- Malignant spindle cells and malignant osteoblasts produce osteoid (bone):
  - 75% of conventional osteosarcomas are high-grade lesions that begin in the intramedullary cavity and expand to disrupt the cortex and possibly the periosteum.
  - A soft tissue component may be associated with the bone tumor.
- Metastases occur by hematogenous spread. Lung followed by other bone are the most common sites for metastases.

### ETIOLOGY

- Most cases are due to sporadic genetic mutation. ~70% demonstrate some chromosomal abnormality.
- <5% cases are postirradiation osteosarcomas.

## DIAGNOSIS

### HISTORY

- Pain is the most common presenting symptom:
  - Pain increases gradually and does not improve with conservative measures.
  - Night and rest pain are especially worrisome.
- Minor trauma may draw attention to pain and prompt patients to seek medical attention. 5–10% of cases present with pathologic fracture or fracture during preoperative chemotherapy (1).
- Constitutional symptoms such as fever, fatigue, and weight loss are late signs.

### PHYSICAL EXAM

- Most common locations: Distal femur (40%), proximal tibia (20%), and proximal humerus (10%):
  - Usually located in the metaphysis
  - Patients present with a firm, nonmobile, tender mass associated with the bone.
  - A large soft tissue component can be present.
- <10% of pediatric osteosarcoma involves the axial skeleton.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Lab tests are generally not helpful or necessary for osteosarcoma.
- Elevation of WBC count, ESR, C-reactive protein, or positive blood cultures may suggest osteomyelitis and can be useful to distinguish osteomyelitis from osteosarcoma.
- CBC with differential, basic metabolic panel, LFTs, urinalysis. These tests are needed before starting chemotherapy.
- Alkaline phosphatase and lactate dehydrogenase (LDH). Elevated levels of serum alkaline phosphatase and LDH at diagnosis are associated with a worse prognosis (2,3).

#### Imaging

- Plain radiographs:
  - X-ray can demonstrate a poorly defined blastic or mixed lesion.
  - Destructive and aggressive-appearing lesions usually are seen in the metaphyses of the long bones.
  - Codman triangle: New subperiosteal bone elevating the periosteum as the tumor breaks through the normal cortex
  - “Sunburst” or “hair-on-end” periosteal reactions are commonly seen as the tumor extends into the soft tissues and creates a radiodense spiculated pattern.
  - X-ray can appear normal in very early stages.
- MRI with and without contrast:
  - Heterogeneous-appearing mass with increased signal intensity on T2 and enhancement with gadolinium
  - Delineates extent of both bony and soft tissue components of tumor
  - The intramedullary component can be better determined on T1-weighted images.
  - Shows tumor proximity to neurovascular structures
  - Image the entire bone (eg, entire femur for a distal femur lesion) to evaluate for skip lesions.
  - MRI is essential for preoperative and prebiopsy planning.
  - MRI is also repeated prior to the definitive procedure.
- CT of the chest without contrast:
  - Staging study for lung metastases
  - Lung is the most common site of metastasis.
  - Lesions often are peripherally located and calcified.
  - Lung metastases are found in 25% of cases at presentation (4).

- Whole-body technetium bone scan: Staging study for bone metastases
- PET-CT: Not widely done but increasingly used for staging and evaluation of tumor response to therapy
- All staging studies (MRI, CT chest, bone scan) should be completed prior to biopsy.

### Diagnostic Procedures/Other

#### Open incisional biopsy:

- Needle/Core biopsy can be considered in certain scenarios, but open biopsy is still the most accurate method for histologic diagnosis and tumor grading.
- Biopsy placement is critical, as the biopsy tract must be excised with the definitive tumor resection.
- Poorly placed biopsy sites can be a contraindication to limb-salvage procedures and may lead to worse outcomes (5).

### Pathological Findings

#### High-grade malignancy:

- Stroma consists of pleomorphic spindle cells.
- A characteristic finding is the presence of osteoid.

### DIFFERENTIAL DIAGNOSIS

- Malignant tumors:
  - Ewing sarcoma
  - Chondrosarcoma
  - Fibrosarcoma
  - Leukemia
  - Metastatic lesions
- Infections:
  - Osteomyelitis
  - Septic arthritis
- Benign tumors:
  - Unicameral bone cyst
  - Osteoblastoma
  - Osteoid osteoma
  - Eosinophilic granuloma
  - Osteochondroma
  - Fibrous dysplasia
  - Langerhans cell histiocytosis
- Trauma/Stress fracture

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Pathologic fractures:
  - Splint fractures initially.
  - External fixators or other internal fixation may cause contamination of surrounding tissues by tumor cells but are indicated in selected situations.
- Aspiration of joint/bone should be avoided if tumor is suspected. Contamination of normal tissue can occur.
- Keep the patient non-weight bearing on the affected extremity. Bone is weakened by tumor and prone to fracture.
- Refer patients to an orthopedic surgeon for further testing and biopsy of the affected area.

**MEDICATION**

- Neoadjuvant (presurgery) and adjuvant (postresection) chemotherapy. Combinations of doxorubicin, ifosfamide, cisplatin and high-dose methotrexate are used.
- Chemotherapy pre- and postsurgery have dramatically improved survival rates:
  - 20–30% 5-yr survival rate prior to chemotherapy
  - 5-yr survival is >70% on current chemotherapy protocols (6).

**SURGERY/OTHER PROCEDURES**

- Radiation therapy:
  - Osteosarcoma is radiation resistant.
  - Used only in palliative treatment
- Resection with limb salvage:
  - Tumor is removed along with a cuff of normal tissue for a wide resection.
  - Limb reconstruction is accomplished with osteochondral allografts or endoprostheses.
  - Extendible endoprostheses are available for patients with growth remaining.
  - Pathologic fracture is not an absolute contraindication for limb salvage (1).
- Amputation:
  - Used in cases where tumor cannot be safely resected with a wide margin (~10% of cases)
  - Also used in cases where function will be better with a prosthetic than with salvage
- Van Ness rotationplasty:
  - Can be considered in certain younger patients with lesions near the knee
  - The distal femur and proximal tibia are resected and the residual tibia is reattached to the femur with the foot rotated 180 degrees posteriorly.
  - The rotated ankle serves as a “knee” once a prosthesis is fit.
- Resection of lung metastases:
  - Can be done by thoracotomy or thoracoscopically

**DISPOSITION****Admission Criteria**

- Inpatient admission can be considered to complete all needed staging studies and expedite biopsy.
- Patients who are stable and have adequate pain control can be given a referral for outpatient oncologic evaluation but should be seen promptly.

**Issues for Referral**

- Patients should be referred to a center with experience managing children with this diagnosis and where comprehensive care is available.
- Biopsy should be performed by the same surgeon who will perform the definitive resection.

 **FOLLOW-UP**
**FOLLOW-UP RECOMMENDATIONS****Activity:**

- Keep patients non-weight bearing on affected extremities and restrict sports and other activities until they can be fully evaluated by an orthopedic oncologist.

**PROGNOSIS**

- 5-yr survival is 63–78% for patients without metastases at presentation (6–8) and <20% for patients who present with metastatic disease.
- 30–40% relapse rate within 3 yr of diagnosis

- Poor prognostic factors:
  - Axial location
  - Large tumor (>8 cm)
  - Metastases or skip lesions at presentation
  - <90% tumor necrosis rate after chemotherapy
  - Elevated alkaline phosphatase levels at diagnosis (2)

**COMPLICATIONS**

- Metastatic disease:
  - >20% of patients present with signs of metastases (4).
  - Micrometastases in the lungs are estimated to be present in 80% of patients.
  - Death usually is related to respiratory failure from pulmonary metastases.
- Local recurrence:
  - 5–10% of patients after limb salvage
  - Pathologic fracture is an independent risk factor for local recurrence.
- Surgical complications:
  - Infections: Surgical wound, periprosthetic, osteomyelitis
  - Mechanical failure: Component loosening, breakage, or wear
  - Nonunion of allograft constructs
  - Pediatric patients have higher failure rates than adults with endoprosthetic reconstruction; aseptic loosening is the primary mode of failure.
  - Complex revision surgery may be required following complications associated with endoprosthetic or allograft reconstruction.
- Chemotherapy complications: May include fever, myelosuppression, heart failure, deep vein thrombosis/pulmonary embolus, renal/hepatic toxicity, and wound-healing complications

 **CODES**
**ICD9**

- 170.9 Malignant neoplasm of bone and articular cartilage, site unspecified
- 170.0 Malignant neoplasm of bones of skull and face, except mandible
- 170.1 Malignant neoplasm of mandible

**PEARLS AND PITFALLS**

- Definitive diagnosis between osteosarcoma and a benign bone lesion should be made by biopsy result.
- Diagnostic biopsy preferably should be done by the orthopedic surgeon who will be doing the definitive resection to avoid inadvertent tissue contamination, sampling error, and potential adverse outcomes.
- All staging studies should be done prior to biopsy and starting treatment.
- Cultures should be obtained at every biopsy, and biopsy should be done with any cultures.
- Pathologic fractures associated with osteosarcoma should be managed with the final definitive surgery in mind.

# OTITIS EXTERNA

Kate Cronan

## BASICS

### DESCRIPTION

- Otitis externa (OE) is a condition characterized by acute inflammation and infection of the external auditory canal (EAC) resulting in concentric swelling of the canal and sometimes the auricle.
- An EAC infection can be OE or secondary to acute otitis media with perforation.
- The diagnosis is made clinically.
- OE is characterized by ear pain, often with accompanying otorrhea.
- The condition ranges from acute localized infection (OE) or furunculosis to the rare condition of malignant or necrotizing OE, which is a severe form of OE but not cancerous.
- The most common etiologic organisms are *Pseudomonas aeruginosa* and *Staphylococcus aureus* (1).

### EPIDEMIOLOGY

#### Incidence

- 10% of the population will develop OE at some point (2).
- 4 per 1,000 persons present with OE per year (3).

#### Prevalence

- The peak prevalence is between 7 and 12 yr of age (1).
- The majority of cases are unilateral (3).
- OE occurs more often in warm climates.

### RISK FACTORS

- Excessive wetness of the EAC due to swimming and bathing leads to skin maceration.
- Local trauma to the EAC, including excoriation, allows organisms to gain access.
- Dermatoses such as seborrhea and eczema predispose to OE.
- OE is more common in summer months.
- Devices that block the EAC such as headphones and hearing aids may predispose to OE.
- Foreign body in the EAC may lead to OE.

### GENERAL PREVENTION

- Instillation of dilute alcohol or acetic acid immediately after bathing and swimming may prevent infection.
- Wearing ear plugs or cotton wool with petroleum jelly while swimming
- Drying the ear with a hair dryer on a low setting from 1 foot away may prevent OE.
- OE can be prevented by avoiding trauma such as scratching of the ear canal and vigorous cleaning to remove cerumen.

### PATHOPHYSIOLOGY

- Cerumen inhibits bacterial and fungal growth and is hydrophobic.
- Moisture or local trauma leads to breakdown of the cerumen barrier.
- Edema of the skin leads to blockage of the EAC and pruritus.
- Scratching leads to further injury of the EAC.
- Moderate inflammation follows with increased pain and swelling as well as seropurulent drainage.
- The canal lumen becomes obstructed.

### ETIOLOGY

- Bacterial: *P. aeruginosa* is most common, but *S. aureus*, *Enterobacter aerogenes*, *Proteus mirabilis*, *Klebsiella pneumoniae*, streptococci, coagulase-negative staphylococci, and diphtheroids are other etiologic organisms.
- Fungal: *Candida* and *Aspergillus*
- Viral: Herpes simplex virus and varicella

### COMMONLY ASSOCIATED CONDITIONS

- Dermatologic conditions such as seborrhea, eczema, and contact dermatitis
- EAC foreign body

## DIAGNOSIS

### HISTORY

- Symptoms often follow swimming and bathing.
- Acute unilateral otalgia that is often severe
- Sensation of fullness
- Decreased hearing
- Pain exacerbated by chewing
- Itching may be a precursor to pain.

- Recent ear cleaning or other trauma affecting the skin of the EAC
- History of preauricular erythema or swelling
- History of atopic dermatitis, seborrhea, or other dermatitis
- History of thick otorrhea as well as crusting of the EAC

### PHYSICAL EXAM

- Swelling and inflammation of the EAC
- Otorrhea that may be thick
- The tympanic membrane may not be visualized due to swelling of the EAC, obscuring the view.
- Pain elicited with manipulation of the pinna or pressure on the tragus
- Palpable periauricular nodes
- In fungal infection of the EAC, there may be white fluffy discharge with black spores.
- Swollen pinna and periauricular region

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Diagnosis is made clinically; testing is usually not indicated.
- Bacterial culture and Gram stain as well as fungal culture of ear discharge are indicated if infection is not responsive to usual treatment modalities or if OE is severe and associated with cellulitis or fever.
- If vesicles are present, consider herpetic cultures.

#### Imaging

CT scan of mastoid process if mastoiditis is suspected

### DIFFERENTIAL DIAGNOSIS

- Auricular foreign body
- Otitis media with perforation
- Otitis media with otorrhea through tympanostomy tubes
- Mastoiditis
- Furunculosis

## TREATMENT

### MEDICATION

#### First Line

- Thorough cleansing of the EAC with 1:1 dilution of 3% hydrogen peroxide enhances the efficacy of antibiotic drops. This should be done if the tympanic membrane is visualized.
- Topical treatment containing neomycin, polymyxin, and corticosteroids is effective:
  - Dosing is 3–4 gtt to affected ear t.i.d.–q.i.d.
  - There is increasing bacterial resistance.
- Topical fluoroquinolones:
  - Ciprofloxacin/Dexamethasone 4 gtt b.i.d. × 7 days
  - Ofloxacin: 6 mo to 13 yr, 5 gtt per day × 7 days; > 13 yr, 10 gtt per day × 7 days
  - Ciprofloxacin and ofloxacin have similar efficacy.

- When the TM is perforated, treatment should include ototopics with low acidity and low ototoxicity.
- Ofloxacin combined with oral systemic antibiotics is preferred.
- Augmentin 45–85 mg/kg PO divided b.i.d.–t.i.d.
- Analgesics should be given for ear pain:
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
  - Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
- In otomycosis (infection of the EAC with fungi), cleansing followed by application of antifungal solutions:
  - Clotrimazole 1% topical solution applied b.i.d.
  - Nystatin may be compounded into a topical solution for such use.
- During recovery from OE, the ear should be protected from water by placing a cotton ball with petroleum jelly in the ear canal while bathing.
- Swimming should be avoided for 7–10 days.

### Second Line

- In more advanced cases, placement of a wick is recommended. Antibiotics can be applied directly to the wick three times per day for 48 hr. The wick should stay in place for 2–3 days.
- Oral antibiotics are indicated in severe cases that have progressed to cellulitis with fever and lymphadenitis.
- Treatment duration is 10 days with agents against *P. aeruginosa* and *S. aureus*:
  - Ciprofloxacin 20–30 mg/kg/day divided b.i.d. may be used.

### SURGERY/OTHER PROCEDURES

Surgical drainage of mastoid if mastoiditis is diagnosed

### DISPOSITION

#### Admission Criteria

Consider hospitalization for those with chronic suppurative OE or if there is coexisting mastoiditis.

#### Discharge Criteria

Almost all immunocompetent children with OE may be managed as outpatients.

#### Issues for Referral

Consider referring children with recurrent OE, chronic suppurative OE, or persistent inflammation of the EAC to an otolaryngologist.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Ofloxacin: 6 mo to 13 yr, 5 drops per day for 7 days; > 13 yr, 10 drops per day for 7 days OR
  - Ciprofloxacin/Dexamethasone 4 gtt b.i.d. × 7 days OR
  - Polymyxin B/Neomycin/Hydrocortisone: 3 drops 3–4 times per day for 7 days
  - Analgesics: Ibuprofen and opioids as needed
- Activity:
  - No water sports or swimming for 7–10 days

### Patient Monitoring

- If OE is moderate, follow up in 1–2 wk.
- If a wick has been placed, return is recommended in 1–3 days.

### PROGNOSIS

- Complete recovery from infection of EAC is expected.
- Recurrent OE is unusual.

### COMPLICATIONS

- Conductive hearing loss due to edema in EAC
- Otitis media
- Cellulitis of nearby skin
- Facial nerve paralysis
- Malignant otitis media is also known as necrotizing OE. This occurs when the infection spreads from the EAC skin to the soft tissues and deeper, including the bone of the temporal region and skull base.
- Perichondritis
- Parotitis

## CODES

### ICD9

- 380.10 Infective otitis externa, unspecified
- 380.11 Acute infection of pinna
- 380.12 Acute swimmers' ear

### PEARLS AND PITFALLS

- Before initiating treatment for OE, it is crucial to determine if the tympanic membrane is perforated, if possible.
- Pain on manipulation of the tragus or pinna is usually absent in cases of acute otitis media with perforation.
- Fluoroquinolones cause less pain during administration compared to other topical therapy due to their neutral pH.

# OTITIS MEDIA

Suzanne Schmidt

## BASICS

### DESCRIPTION

- Otitis media refers to the presence of inflammation or infection in the middle ear space.
- A middle ear effusion (MEE) without infection is called otitis media with effusion (OME) or serous otitis. Infection of fluid in the middle ear is called acute otitis media (AOM).

### EPIDEMIOLOGY

The peak incidence of AOM occurs between 6 and 24 mo of age.

### Prevalence

- MEEs are common, with 90% of children having at least 1 episode before school age (1).
- ~2/3 of children will have at least 1 episode of AOM before age 6 yr (2).
- Children <2 yr of age are more likely to have resistant infections and are less likely to have resolution of AOM without antibiotics (3).

### RISK FACTORS

- Day care attendance
- Smoke exposure
- Pacifier use
- Craniofacial anomaly (cleft palate)
- Genetic predisposition
- Previous AOM
- Persistent MEE/OME

### GENERAL PREVENTION

- Breast-feeding appears to be protective in the 1st year of life.
- Pneumococcal conjugate vaccine has decreased the incidence of *Streptococcus pneumoniae*-associated AOM (4).
- Influenza vaccine decreases AOM occurrence.
- Antibiotic prophylaxis is not routinely recommended for the prevention of AOM in otherwise healthy children.

### PATHOPHYSIOLOGY

- Viral upper respiratory tract infections often precede AOM.
- The eustachian tube in children is shorter and more horizontal than in adults. Eustachian tube dysfunction can lead to a MEE and OME.
- Bacterial pathogens in the nasopharynx ascend via the eustachian tube, leading to infection in the middle ear (AOM).

### ETIOLOGY

- AOM is bacterial in 70–80% of cases (2,5):
  - S. pneumoniae* (28–35%)
  - Nontypable *Haemophilus influenzae* (26–57%)
  - Less commonly *Moraxella catarrhalis*
- Since widespread use of the pneumococcal conjugate vaccine (PCV7), there has been an overall decrease in disease caused by *S. pneumoniae* but an increase in nonvaccine serotypes, with emerging multidrug-resistant strains. There has also been an increase in cases of AOM caused by *H. influenzae* and *M. catarrhalis* (2,4).
- Purulent otorrhea may also yield *S. aureus* or *Pseudomonas aeruginosa*.

### COMMONLY ASSOCIATED CONDITIONS

Viral upper respiratory tract infections (URIs)

## DIAGNOSIS

### HISTORY

- The course of illness is important. With AOM, there is often a preceding URI, followed by acute onset of signs and symptoms of inflammation from AOM, such as fever and otalgia.
- Fever is nonspecific and is present in ~50% of cases.
- Otalgia has a high specificity but low sensitivity.
- Restless sleeping or crying is neither sensitive nor specific.
- Previous episodes of AOM, including most recent infection and antibiotic use, may influence therapy.

### PHYSICAL EXAM

- Exam of the head and neck, including the oropharynx, teeth, jaw, and lymph nodes, should be done to search for other causes of otalgia.
- Diagnosis of AOM or OME is made by otoscopic exam of the tympanic membrane (TM):
  - Good visualization of the TM requires adequate patient immobilization, an external auditory canal (EAC) free of cerumen, adequate lighting, and the largest speculum that will fit comfortably into the EAC.
  - Pneumatic otoscopy is the best way to evaluate TM mobility. Decreased or absent mobility suggests the presence of an MEE or other abnormality of the TM.
- In cases of perforated AOM, visualization of the TM may be impossible, and diagnosis is made by visualizing purulent fluid in the EAC with the absence of signs of otitis externa.
- Diagnosis is made by assessing TM characteristics:
  - Translucency (translucent vs. opaque)
  - Color (clear, amber, red, white/yellow)
  - Position (normal, retracted, bulging)
  - Mobility (normal, decreased, absent)
- A normal TM is translucent and clear, with a normal position and brisk mobility with positive and negative pressure.
- Presence of an MEE is suggested by cloudiness or opacification of the TM, an air-fluid level or bubbles behind the TM, a bulging TM, decreased or absent mobility of the TM, or otorrhea.
- An MEE is present in both OME and AOM.
- OME is an MEE without acute infection or inflammation (1). Characteristics associated with OME include:
  - Normal or retracted TM
  - Clear, amber, or cloudy TM
  - Impaired TM mobility
- AOM is defined as the presence of an MEE with acute onset of signs or symptoms of inflammation (ear pain, distinct erythema of the TM) (3). Characteristics most associated with AOM:
  - Bulging TM
  - Purulent effusion (opaque, white TM)
  - Distinct erythema of the TM with an MEE
  - Erythema alone, however, is a poor predictor of AOM.

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

Gram stain and culture of middle ear fluid obtained by tympanocentesis may be helpful in directing antibiotic therapy in complicated or resistant infections but is not routinely performed.

### Imaging

Consider CT scan if there is concern for associated mastoiditis or other intracranial infections.

### Diagnostic Procedures/Other

- Pneumatic otoscopy is recommended to assess TM mobility.
- Tympanometry can be a useful adjunct to determine the presence of an MEE. A “type B” or flat tympanogram suggests poor mobility and possible MEE.
- Tympanocentesis may be used for pain relief and to obtain cultures to guide antibiotic therapy.

## DIFFERENTIAL DIAGNOSIS

- AOM should be distinguished from OME and otitis externa (OE):
  - OE is infection/inflammation of the EAC. Findings include purulent material in the EAC, erythema and edema of the EAC, pain with manipulation of the tragus and pinna, and pain with otoscopy.
- Other causes of otalgia:
  - Impacted cerumen
  - Foreign body in the EAC
  - Referred pain from pharyngitis, dental pain, parotitis, or pain from the temporomandibular joint
- Other ear disease with distinct TM findings include:
  - Hemotympanum
  - Cholesteatoma

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- OME:
  - No therapy required
  - Antihistamines and decongestants are ineffective.
  - Antibiotics and corticosteroids have no long-term efficacy.
- AOM: Children <2 yr of age:
  - Oral antibiotics recommended
- AOM: Children ≥2 yr of age:
  - Observation without antibiotics is an option for uncomplicated AOM since most will resolve without treatment.
  - “Wait-and-see” prescription is another option for uncomplicated AOM and consists of giving the parents an antibiotic prescription to be filled if the child’s symptoms do not improve in 48–72 hr (3,6).
  - Immediate antibiotic therapy is preferred for severe otalgia and/or high fever.
- Analgesia should always be provided when otalgia is present, independent of patient age or the decision to treat with antibiotics. Oral acetaminophen or ibuprofen may be given. Consider topical analgesics (benzocaine) if there is no concern for TM perforation.

- Perforated AOM or AOM with tympanostomy tubes:
  - Oral antibiotic therapy alone or in conjunction with ototopical antibiotic drops.
  - For AOM with tympanostomy tubes, ototopical drops alone are an option.

**MEDICATION**

**First Line**

- Amoxicillin (high dose) 80–90 mg/kg/day PO divided b.i.d.:
  - High-dose amoxicillin is needed to overcome *S. pneumoniae* resistance.
- Duration of antibiotic therapy: 10 days in children <2 yr of age, 5–7 days in children ≥2 yr of age with uncomplicated AOM
- Consider a 10-day course in older children if frequent or recurrent AOM.

**Second Line**

- Amoxicillin/Clavulanic acid 80–90 mg/kg/day divided b.i.d.:
  - Consider use of high-dose amoxicillin/clavulanic acid; high-dose amoxicillin may be combined with a relatively lower-dose clavulanic acid (Augmentin ES).
  - When prescribing high-dose amoxicillin component, choose a preparation with a lower dose of clavulanic acid to lessen risk of diarrhea (Augmentin ES).
  - Treats beta-lactamase producing *H. influenzae* and *M. catarrhalis*
  - May be considered first line in “severe” cases, defined as fever ≥39°C or severe otalgia
- Cephalosporins (cefdinir 14 mg/kg/d in 1–2 doses, cefuroxime 30 mg/kg/d divided b.i.d., cefpodoxime 10 mg/kg/d once daily):
  - Ceftriaxone 50mg/kg IM/IV may be used to treat AOM in patients who are vomiting and unable to tolerate oral antibiotics: 1 dose for initial treatment; 3 doses over 3 days for treatment failures.
- Macrolides have poor efficacy against resistant *S. pneumoniae* and most *H. influenzae*.
- For patients with penicillin allergy:
  - Non–type I hypersensitivity: Cephalosporin
  - Type I hypersensitivity: Clindamycin for *S. pneumoniae*; azithromycin, clarithromycin, erythromycin/sulfisoxazole, or trimethoprim/sulfamethoxazole are options, but provide suboptimal coverage.
- Treatment failures are defined as no improvement in 48–72 hr.
  - If high-dose amoxicillin was initially used, beta-lactamase producing bacteria are likely present and amoxicillin/clavulanic acid should be given.
  - If amoxicillin/clavulanic acid was initially used, a cephalosporin should be given with consideration for IM/IV ceftriaxone.
  - Recent report of a few cases of resistant AOM requiring treatment with myringotomy and fluoroquinolones

- Ototopical drops:
  - Used alone or in conjunction with oral antibiotics to treat AOM with perforation or tympanostomy tubes
  - Use otic drops with steroid component when tympanostomy tubes are present. Consider topical antibiotic without steroid with perforated TM.
  - Neomycin/Polymyxin B sulfate/hydrocortisone (Polytrim): 2 gtt in affected ear q.i.d. × 5 days; use suspension if perforated TM
  - Ofloxacin otic: 1–12 yr, 5 gtt b.i.d. to affected ear × 10 days; > 12 yr, 10 gtt b.i.d. to affected ear × 10 days, has no steroid component
  - Ciprofloxacin/Dexamethasone: 4 gtt to affected ear b.i.d. × 7 days; ciprofloxacin/hydrocortisone 3 gtt to affected ear b.i.d. × 7 days

**SURGERY/OTHER PROCEDURES**

Myringotomy with or without tympanostomy tube placement for resistant/recurrent infections

**DISPOSITION**

**Admission Criteria**

Complications such as mastoiditis or intracranial abscess

**Discharge Criteria**

Non–toxic-appearing children without complications of AOM may be discharged.

**Issues for Referral**

- Consider hearing testing when:
  - OME persists >3 mo
  - Concern for language delay, learning problems, or significant hearing loss
  - Comorbidities with OME such as developmental delay, blindness, craniofacial disorders
- Referral to otolaryngologist when:
  - Concerned for a structural abnormality of the TM or middle ear, such as cholesteatoma
  - Hearing loss is suspected or present
  - Resistant or recurrent AOM

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Give clear instructions for the treatment option chosen: Immediate antibiotic therapy, wait-and-see prescription, or observation alone.
  - Analgesics and antipyretics should be used as needed, especially in the 1st 24–48 hr.
  - Follow up with the primary care provider in 48–72 hr if not improving; earlier follow-up if worsening or if signs/symptoms of complications, especially when immediate antibiotic therapy is not prescribed.
- Activity:
  - If TM perforation, avoid getting water in the ear.

**PROGNOSIS**

- OME:
  - The majority of MEE (90%) resolve spontaneously in 3 mo without therapy.
  - Only 5–10% last ≥ 1 yr (1).
- AOM:
  - Most resolve without antibiotics

**COMPLICATIONS**

- Common complications of AOM are TM perforation and persistent effusion.
- Other complications include tympanosclerosis, cholesteatoma, chronic otitis, hearing loss, tinnitus, balance problems, facial nerve injury, mastoiditis, meningitis, intracranial abscess, and venous sinus thrombosis.

**ICD9**

- 381.00 Acute nonsuppurative otitis media, unspecified
- 381.01 Acute serous otitis media
- 382.9 Unspecified otitis media

**PEARLS AND PITFALLS**

- Otitis-conjunctivitis syndrome is more likely to be caused by *H. influenzae*, and amoxicillin/clavulanic acid should be given.
- Bullous myringitis (blisters on the TM) may be caused by the typical bacterial pathogens or *M. pneumoniae*.

# OVARIAN CYST

Raemma Paredes Luck

## BASICS

### DESCRIPTION

- Ovarian cysts are fluid-filled structures arising from the ovary.
- They are divided into simple or complex cysts depending on their characteristics on US
- Also divided into cyst types:
  - Follicular cysts are most commonly unilocular, are thin-walled, and rupture easily with minimal bleeding.
  - Corpus luteal cysts rupture just before menstruation begins and may result in severe bleeding.

### EPIDEMIOLOGY

#### Prevalence

- Ovarian cysts are observed in all age groups, even in the fetus, and especially in women of child-bearing age.
- Ovarian cysts are seen in up to 5% of prepubertal girls undergoing ultrasonographic studies. 65% of these cysts are found incidentally.
- The majority of ovarian cysts in the pediatric population are benign.

### RISK FACTORS

- Agents used to induce ovulation such as clomiphene citrate and gonadotropins may increase the development of ovarian cysts.
- Mutations in the GNAS 1 gene seen in McCune-Albright syndrome are associated with sexual precocity and ovarian cysts.

### PATHOPHYSIOLOGY

- Primordial follicles in the ovary are stimulated by the follicle-stimulating hormone (FSH). A dominant follicle develops that releases an ovum after stimulation by the luteinizing hormone (LH). The dominant follicle then becomes the corpus luteum.

- Functional or physiologic ovarian cysts develop when there is failure of the follicles to normally involute; the dominant follicle fails to ovulate, and the corpus luteum persists more than its typical 2-wk life span.
- Excessive FSH stimulation or the lack of the LH surge results in follicular cysts.
- Excessive hemorrhage into the cavity of the corpus luteum after ovulation leads to a persistent corpus luteum cyst.

### ETIOLOGY

- Follicular cyst
- Corpus luteal cyst
- Endometrioma
- Cystic teratoma

### COMMONLY ASSOCIATED CONDITIONS

- Ovarian cysts, precocious puberty, and café-au-lait spots are seen in McCune-Albright syndrome:
  - These cysts are hormonally active and result in precocious puberty.
- Cystic ovaries are also seen in polycystic ovary syndrome, a disorder presenting with irregular menses, signs of hyperandrogenism or insulin resistance, and cystic ovaries.

## DIAGNOSIS

### HISTORY

- Most ovarian cysts are asymptomatic.
- Infants or children may present with a painless abdominal mass; increasing abdominal girth; or vague symptoms such as intermittent abdominal pain, vomiting, urinary frequency, or constipation.
- Adolescents may present with pelvic discomfort, menstrual irregularities, dysmenorrhea, or urinary complaints.
- The presence of severe symptoms such as acute abdominal pain or tenderness, fever, vomiting, and pallor can mimic an acute surgical abdomen.
- Inquire about early-onset or irregular menses, early puberty, any abnormal skin pigmentation, excessive body or facial hair, or treatment-resistant acne.

### PHYSICAL EXAM

- Assess vital signs with attention to heart rate and BP to detect hypovolemia secondary to hemorrhagic cyst.
- In most cases, the abdominal exam is normal. In some cases, an adnexal mass or fullness may be felt.
- Note signs of hyperandrogenism such as severe acne, hirsutism or alopecia, or signs of hyperinsulinism such as central abdominal adiposity or acanthosis nigricans, as these may suggest other associated conditions.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Pregnancy testing if appropriate for sexual maturity
- Depending on history, consider:
  - Urinalysis, urine culture
  - CBC
  - Blood type and cross-match
  - Chlamydia, gonorrhea, and other STIs
- Further testing to rule out other pathology when necessary such as if acute abdomen is suspected or malignancy is likely

#### Imaging

- US is the preferred modality in assessing cyst size and consistency:
  - Simple cysts usually have a diameter <5 cm and are unilocular, with few internal echoes suggestive of hemorrhage.
  - Complex cysts have a diameter >5 cm and have septations or calcifications on US.
- Doppler US may be helpful in evaluating blood flow if ovarian torsion is suspected.
- CT and MRI may be useful to demonstrate cysts as well as to detect other pathology.

### DIFFERENTIAL DIAGNOSIS

- Ovarian torsion
- Ectopic pregnancy
- Endometriosis
- Tubo-ovarian abscess
- Pelvic inflammatory disease
- Appendicitis
- Inflammatory bowel disease
- Nephrolithiasis
- Neoplasm

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- Have large-bore IV access available if the potential for ruptured ovarian cyst exists.
- Patients with severe abdominal pain should be quickly assessed to rule out other life-threatening conditions or complications arising from ovarian cysts.
- Parenteral analgesics should be administered in patients with moderate to severe abdominal pain.
- IV fluids should administered in patients who are dehydrated or have hemodynamic instability.

**MEDICATION**

- Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
  - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
- Ibuprofen 10 mg/kg PO/IV q6h PRN for pain

**SURGERY/OTHER PROCEDURES**

- Although controversial, surgical removal of the cyst is generally considered in the following circumstances:
  - Severely symptomatic patients
  - Cyst size > 5 cm and rapidly enlarging
  - Solid cysts
  - Large cysts that persist >3–4 mo
- Laparoscopy is preferred.
- Indications for laparotomy include ovarian cysts with malignant features, morbid obesity, previous abdominal or pelvic adhesions, or a hemodynamically unstable patient.

**DISPOSITION**

**Admission Criteria**

- Moderate to severe abdominal pain
- Dehydration
- Critical care admission criteria:
  - Hemodynamic instability

**Discharge Criteria**

Upon adequate control of pain that can be maintained with outpatient medication, stable patients may be discharged.

**Issues for Referral**

Referral to a gynecologist or surgeon is indicated to monitor cyst size or if a more serious pathology is considered.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

Discharge instructions and medications:

- Patients should return for severe abdominal pain
- Oral analgesics should be prescribed; NSAIDs and/or opioids are commonly used.

**PROGNOSIS**

Ovarian cysts can be followed expectantly with serial US every 4–6 wk:

- The majority of ovarian cysts regress spontaneously within 4–8 wk.

**COMPLICATIONS**

- Cyst rupture
- Hemorrhage
- Hypovolemic shock
- Cyst infection

**See Also (Topic, Algorithm, Electronic Media Element)**

- Ovarian Torsion
- Pain, Abdomen

**CODES**

**ICD9**

- 620.0 Follicular cyst of ovary
- 620.1 Corpus luteum cyst or hematoma
- 620.2 Other and unspecified ovarian cyst

**PEARLS AND PITFALLS**

- The majority of ovarian cysts are functional in nature and resolve on their own.
- Most ovarian cysts are asymptomatic and incidentally discovered during the evaluation of other conditions.
- Ovarian cysts rarely require surgical removal.
- Hemorrhage of a cyst may result in hemodynamic compromise and shock.

# OVARIAN TORSION

Magdy W. Attia

## BASICS

### DESCRIPTION

- Ovarian torsion is the twisting of the ovary on suspensory ligament.
- Ovarian torsion may result in necrosis of the ovary by impinging on its blood supply, as the artery and vein serving the ovary lay within the same stalk of tissues.
- Ovarian cysts and other neoplasms are often associated with the occurrence of ovarian torsion.
- Rapid operative intervention is key to preventing ovarian loss.

### EPIDEMIOLOGY

#### Incidence

- Ovarian torsion constitutes 2–3% of surgical emergencies in women.
- Although it is rare in premenarchal girls, it may be encountered in the perinatal period (1).
- In one case series of 22 children, the mean age at presentation was 10 yr, with a range of 3–15 years (2).

#### Prevalence

~70–75% of patients are <30 yr of age (3).

### RISK FACTORS

- Ovarian cysts and tumors
- Pregnancy
- Elongated utero-ovarian ligament, which is typically an intraoperative observation
- History of pelvic inflammatory disease

### GENERAL PREVENTION

- In general, ovarian torsion is not preventable.
- Ovariopexy, if performed in the setting of ovarian torsion on one side, can prevent torsion of the opposite ovary.

### PATHOPHYSIOLOGY

- Twisting of the ovarian pedicle initially impedes the lymphatic and venous return, which leads to engorgement and edema.
- If uncorrected, interruption of the arterial supply ensues, leading to ischemia and necrosis.

### ETIOLOGY

- Most cases of ovarian torsion occur in menstruating females and are typically associated with other pathology such as cysts and tumors.
- Normal ovaries are capable of torsion possibly due to an elongated utero-ovarian ligament allowing excessive movement of the ovary.
- There are some reports indicating that sudden exercise precipitates ovarian torsion.

### COMMONLY ASSOCIATED CONDITIONS

- Ovarian cyst
- Corpus luteal cyst
- Follicular cyst
- Ovarian tumor

## DIAGNOSIS

### HISTORY

- Sudden onset of sharp pelvic or lower abdominal pain (80–100%)
- The pain could be intermittent (15%) and often leads to delayed diagnosis.
- In the younger child, the pain could be nonspecific and difficult to describe.
- Nausea and vomiting (75%)
- In infants, feeding intolerance and irritability are often the presenting symptoms.
- Low-grade fever is also described (2–25%) (1).

### PHYSICAL EXAM

- Elevated heart rate and/or BP may reflect abdominal or pelvic pain.
- Abdomen: Lower quadrant tenderness
- Pelvic: Adnexal tenderness, sometimes palpable adnexal mass
- Peritoneal signs such as involuntary guarding or rebound tenderness are less common.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Pregnancy test
- Lab studies are not diagnostic but are ordered in the context of evaluating acutely tender abdomen (4,5). Consider:
  - CBC: The patient may have leukocytosis.
  - C-reactive protein: In one study, patients with ovarian torsion had a mean of  $3.5 \pm 5$  mg/dL (1).
  - Hepatic enzymes
  - Amylase and lipase

### Imaging

- US with Doppler is the study of choice. Findings may include (6):
  - An enlarged ovary that is more than twice the size of the opposite ovary.
  - Heterogeneous mass
  - Absent arterial flow
  - Fluid in the cul de sac
- US assists in detection of other etiologies such as ovarian cyst, tubo-ovarian abscess, ectopic pregnancy, or appendicitis.
- CT/MRI is sensitive but not specific (5,6).
  - A disadvantage of CT compared to US is the very high levels of radiation; the radiation dose is equivalent to that of several hundred chest radiographs
- CT is associated with very high levels of radiation. Findings may include:
  - Edema, enlarged smooth adnexa
  - Hemorrhagic infarcts
  - Pelvic ascites

### DIFFERENTIAL DIAGNOSIS

The differential diagnosis of acute abdominal pain is lengthy. Consider anatomic factors and age to narrow down the possible etiologies (4,7).

- Neonatal:
  - Differential diagnosis of fussy infant including malrotation, inflicted injury, and hernia
- Premenarchal girl:
  - Surgical, life threatening:
    - Malrotation, midgut volvulus
    - Intussusception
    - Hernia: Incarcerated, strangulated
    - Appendicitis
    - Small bowel obstruction (adhesions)
    - Trauma (inflicted)
    - Foreign body ingestion
    - Meckel diverticulum
- Postmenarchal girl:
  - Hemorrhagic/Ruptured ovarian cyst
  - Pelvic inflammatory disease
  - Ectopic pregnancy
  - Fallopian tube torsion
  - Appendicitis
  - Endometriosis

- Common/Medical—all ages:
  - Constipation
  - Gastroenteritis
  - Febrile illness
  - Mesenteric adenitis
  - Urinary tract infection
  - Lower lobe pneumonia
  - Henoch-Schönlein purpura
  - Sickle cell anemia with pain crisis
  - Pancreatitis
  - Hepatitis
  - Hemolytic uremic syndrome
  - Renal calculi
  - Toxins
  - Peritonitis

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

- The airway, breathing, and circulation should be assessed as in all patients.
- NPO for possible operative intervention
- Establish IV for hydration and medication administration.
- The initial management is focused on pain control and suppression of nausea and/or vomiting and preparation for operative intervention.

**MEDICATION**

- Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
  - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
- Metoclopramide 0.1 mg/kg IV q6h for nausea/vomiting:
  - Administer metoclopramide over 30 min, as rapid administration is associated with akathisia.
- Ondansetron 0.15 mg/kg IV q8h
- Ibuprofen 10 mg/kg IV/PO q6h has analgesic and anti-inflammatory effects:
  - Ibuprofen alone is inadequate for analgesia.

**SURGERY/OTHER PROCEDURES**

- Initiate surgical or gynecologic consultation immediately with strong clinical suspicion for ovarian torsion.
- The goal is to preserve the viability of the ovary.
- Definitive treatment is surgical:
  - Either laparoscopic or open detorsion and ovariopexy, if the ovary is viable.
  - Ovariopexy of the contralateral side is typically performed.
  - Even if the organ appears inviable, most surgeons will avoid ovariectomy based on recent case series (3).

**DISPOSITION**

**Admission Criteria**

- Nearly all patients with ovarian torsion will receive operative intervention and subsequent hospital stay.
- When history and imaging suggests prolonged ovarian ischemia, the procedure may be delayed or become unwarranted:
  - However, admission for observation to detect hemorrhage as well as for pain control could be indicated.
- Critical care admission criteria:
  - In hemodynamically unstable patients, admission to an ICU setting should be considered. This is rarely indicated.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

- Patients who are discharged home after surgery must follow up with gynecology or surgery.
- If the diagnosis is suspected but studies were negative, a close follow-up should be arranged with either the primary care physician or the surgical service to avoid missing an intermittent torsion.

**PROGNOSIS**

In a small case series, prolonged duration of symptoms prior to initial exam was not significantly associated with ovarian necrosis:

- In this report, the mean time of symptoms prior to care was 76 hr for both salvaged and nonsalvaged ovaries (range 7–159 hr).
- However, the mean time from initial exam to operation was 11 hr for salvaged ovaries (range 1–23 hr) and 21 hr for nonsalvaged ovaries (range 2–71 hr) (3). Therefore, the likelihood of preserving a functioning ovary is greater if the diagnosis and treatment are initiated very early in the clinical course.

**COMPLICATIONS**

- Ovarian necrosis
- Ovarian cyst
- Hemorrhage

**CODES**

**ICD9**  
620.5 Torsion of ovary, ovarian pedicle, or fallopian tube

**PEARLS AND PITFALLS**

- The differential diagnosis of acute abdominal pain is lengthy and should be modified based on the patient’s age and gender.
- Maintain a high index of suspicion for ovarian torsion.
- Acute and abrupt onset of abdominal pain helps to distinguish ovarian torsion from other etiologies such as appendicitis.
- Unlike appendicitis in which patients tend to remain still due to pain, girls with ovarian torsion often have colicky pain.
- Unlike with suspected appendicitis, admission for serial abdominal exams is never warranted for patients suspected to have ovarian torsion.
- Delays in diagnosis may lead to necrosis of the ovary.

# PAIN, ABDOMEN

M. Colleen Costello

Barbara M. Garcia Peña

## BASICS

### DESCRIPTION

- Abdominal pain is a common complaint in children presenting to the emergency department. A thorough evaluation is needed to exclude potentially life-threatening causes.
- Abdominal pain may be classified as acute or chronic/recurrent (at least 3 episodes in 3 mo and interfering with function).

### EPIDEMIOLOGY

- Abdominal pain accounts for 5–6.8% of all nonscheduled clinic or emergency department visits (1,2).
- Abdominal pain is the most common pain complaint (15.6%) among new outpatient visits for pain among persons of all ages (3).
- The prevalence of recurrent abdominal pain in children has been reported to range from 3.8–11.8% in children 2–6 yr of age (4).

### PATHOPHYSIOLOGY

The pathophysiology of abdominal pain falls into 3 categories: Visceral (splanchnic) pain, parietal (somatic) pain, and referred pain (5).

- Viscus organ irritation stimulates visceral pain fibers, which are bilateral and enter the spinal cord at multiple levels. Therefore, visceral pain is usually poorly localized and felt centrally in the abdomen.
- Parietal pain occurs when sensory impulses resulting from ischemia, inflammation, or stretching of the parietal peritoneum are transmitted through afferent fibers to specific dorsal root ganglia on the same side and at the same dermatomal level as the origin of the pain. As a result, parietal pain is usually localized.
- Referred pain results from irritation or insult to other areas because they are innervated by the same dermatome. Pain is felt in areas remote from the affected organ.

### ETIOLOGY

- Abdominal pain will usually originate from GI and genitourinary causes.
- Some extra-abdominal conditions such as pneumonia or streptococcal pharyngitis can also cause abdominal pain (6).
- Epigastric pain:
  - Gastritis or peptic ulcer disease
  - Esophagitis
  - Pancreatitis
- Left upper quadrant pain:
  - Splenic rupture
  - Splenic infarction
- Right upper quadrant pain:
  - Hepatitis
  - Cholecystitis
  - Cholelithiasis
  - Liver abscess
  - Fitz-Hugh-Curtis syndrome
- Left lower quadrant pain:
  - Ovarian torsion
  - Mittelschmerz
  - Psoas abscess
  - Ectopic pregnancy
  - Renal stone

- Right lower quadrant pain:
  - Appendicitis
  - Mesenteric adenitis
  - Ovarian torsion
  - Mittelschmerz
  - Psoas abscess
  - Ectopic pregnancy
  - Renal stone
- Hypogastric/Suprapubic pain:
  - Cystitis/Urinary tract infection (UTI)
  - Pelvic inflammatory disease (PID)
  - Testicular torsion/trauma
  - Dysmenorrhea
  - Endometriosis
- Generalized pain:
  - Any of the above conditions
  - Constipation
  - Gastroenteritis
  - Intussusception
  - Bowel obstruction
  - Pregnancy
  - Inflammatory bowel disease (IBD)
  - Irritable bowel syndrome
  - Lactose intolerance
  - Trauma
  - Intestinal adhesions
  - Sickle cell crisis
  - Diabetic ketoacidosis
  - Porphyria
  - Ingestions (lead, anticholinergics, etc.)
  - Colic
- Functional pain:
  - Depression
  - Malingering
  - Munchausen syndrome (or by proxy)
- Extra-abdominal causes of abdominal pain:
  - Abdominal epilepsy
  - Abdominal migraine
  - Black widow spider bite
  - Henoch-Schönlein purpura
  - Pharyngitis (streptococcal infection)
  - Pneumonia
  - Sepsis

## DIAGNOSIS

### HISTORY

- Timing: Determine whether the pain is acute vs. chronic/recurrent as well as the onset, duration, and progression of the abdominal pain.
- Location of the pain
- Quality: Inquire about the quality of the pain as well as the presence of radiation.
- Other factors:
  - Identify exacerbating and relieving factors.
  - Nausea, vomiting, diarrhea, quality of stools, cough, dysuria, history of trauma, testicular pain or swelling, and rash
- Identify chronic medical conditions, previous surgeries, food intolerances, and dietary history.
- In an adolescent female, a menstrual and sexual history will be required.

### PHYSICAL EXAM

- A complete physical exam is essential.
- Inspection of the abdomen:
  - Distention or visible peristalsis
  - Ecchymoses or evidence of trauma
- Auscultate the bowel sounds
- Palpate the abdomen:
  - Confirm the presence and location of tenderness, masses, or organomegaly.
  - Guarding and rebound tenderness suggests peritonitis.
  - Costovertebral angle tenderness
- A rectal exam may aid in the diagnosis of GI bleeding, intussusception, rectal abscess, or stool impaction.
- The genitourinary exam:
  - May reveal a hair tourniquet, hernia, or testicular torsion.
  - In an adolescent female, a pelvic exam may reveal vaginal discharge, bleeding, lesions, or cervical motion tenderness.

### DIAGNOSTIC TESTS & INTERPRETATION

The appropriate diagnostic testing will be dictated by the child's history and physical exam findings.

#### Lab

- CBC with differential: An elevated WBC is present in infectious and inflammatory processes; however, this is neither sensitive nor specific.
- C-reactive protein: Elevation occurs due to infection, particularly bacterial, and is not specific.
- Serum chemistries, including LFTs, may provide evidence of metabolic causes of abdominal pain such as diabetic ketoacidosis or porphyria as well as hepatobiliary causes such as hepatitis or gallstones.
- Urinalysis will provide evidence of UTI or suggest renal stones.
- A urine pregnancy test should be done in the sexually mature.
- If pancreatitis is suspected, serum lipase and amylase should be obtained.
- Stool studies: Occult blood, stool WBCs, stool ova and parasites, and cultures as well as *Clostridium difficile* toxin may be helpful.
- Streptococcal pharyngitis, UTIs, and PID will require appropriate assays.

#### Imaging

- Flat and upright abdominal x-rays:
  - Frequently used as a screening procedure in a child with a nonspecific presentation
  - May provide evidence of ileus, small or large bowel obstruction, appendicolith, free air, intussusception, or constipation
- US:
  - Noninvasive, rapid, no radiation exposure, and can be done on an actively moving child, however, it is heavily user-dependent
  - A focused assessment by sonography in trauma (FAST) may be performed at bedside in cases of abdominal trauma.
  - Helpful in the diagnosis of appendicitis, intussusception, pyloric stenosis, testicular torsion, and renal and biliary disease as well as gynecologic pathologies such as ovarian torsion or ectopic pregnancy

- CT scan:
  - Differentiates soft tissue and bony conditions with greater detail but exposes the child to larger doses of ionizing radiation
  - In situations when acute appendicitis is suspected but the US is negative or indeterminate, CT is highly sensitive and specific in the diagnosis of appendicitis in children (7).
  - May require that the child be sedated and often requires IV, oral, or rectal contrast

### Diagnostic Procedures/Other

Once intussusception is confirmed on US, an air or a barium enema is performed, which acts as both a diagnostic and therapeutic study by reducing the intussuscepted bowel.

### DIFFERENTIAL DIAGNOSIS

See Etiology.

## TREATMENT

### PRE HOSPITAL

Address ABCs.

### INITIAL STABILIZATION/THERAPY

- Address ABCs, providing supportive care PRN.
- Do not delay IV antibiotics if there is a suspicion of sepsis or a serious infection (6).
- The child who is stable and does not exhibit signs and symptoms of a life-threatening process may be managed expectantly.

### MEDICATION

- Judicious use of analgesics: Current literature suggests that the appropriate use of parenteral analgesics may enhance diagnostic accuracy by permitting the complete exam of a more cooperative patient (8).
- UTI or PID: Appropriate antibiotics
- Toxic or environmental exposures: Appropriate antidotes and/or supportive care
- Gastritis or GERD: Oral antacids and H<sub>2</sub> receptor antagonists used in combination with proton pump inhibitors. See relevant topics.
- IBD: Anti-inflammatory medications and aggressive nutrition intervention
- Nausea and vomiting may resolve with antiemetics such as 5-HT<sub>3</sub> antagonists (ondansetron, dolasetron, etc.) or H<sub>1</sub> receptor antagonists (promethazine).

### SURGERY/OTHER PROCEDURES

- Surgical consultation is mandatory if the child presents with an acute abdomen.
- Most cases of abdominal pain with a history of trauma will also mandate a surgical consult.
- Suspected cases of appendicitis, malrotation, volvulus, intussusception, incarcerated hernias, ovarian or testicular torsion, Meckel diverticulum, abdominal masses or abscesses, and obstructed or perforated viscus all warrant surgical consultation.
- Ectopic pregnancy will require gynecologic consult and surgery.

## DISPOSITION

### Admission Criteria

- Any child with a condition that will warrant IV therapy or IV hydration
- Consider admission in children with GI bleeding, chronic diarrhea of uncertain etiology, acute or chronic liver disease syndromes, or abdominal pain of unexplained etiology that does not respond to initial treatment.
- Critical care admission criteria:
  - Any child who presents with signs of critical illness such as shock or evidence of sepsis
  - If there is a possibility of progression to a life-threatening situation (severe pancreatitis, evidence of bowel ischemia, multiple comorbid conditions)

### Discharge Criteria

- Acute pathology has been addressed
- Stable vital signs
- Improving symptoms

### Issues for Referral

Persistent or recurrent abdominal pain of an unknown etiology, as well as the diagnosis of a chronic GI disease, will warrant referral to a pediatric gastroenterologist.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

If pain persists, the patient should follow up with his or her primary care provider.

### DIET

- IBD or specific food intolerance will require appropriate dietary restrictions.
- Patients with a history of gastritis should avoid exacerbating foods.
- In cases of gastroenteritis, resuming regular feeding as soon as possible should be encouraged. There is no need to restrict milk products or formula (5).

### COMPLICATIONS

- Bowel obstruction
- Bowel perforation
- Sepsis
- Shock
- Death
- The failure to diagnose an ovarian or testicular torsion promptly may result in the loss of function of that organ.

## CODES

### ICD9

- 540 Appendicitis
- 564 Constipation
- 789.00 Abdominal pain, unspecified site

## PEARLS AND PITFALLS

- Pearls:
  - When you are suspecting a surgical abdomen, consult surgery early, even if the definitive diagnosis has not been made.
  - Abdominal pain in an adolescent female warrants a pregnancy test and pelvic exam.
  - Analgesics should be used judiciously when dealing with acute cases of abdominal pain.
- Pitfalls:
  - Missing an extra-abdominal cause of abdominal pain
  - Not exploring the history adequately. “Normal” to the patient may not be normal to others.

# PAIN, BACK

Christopher S. Cavagnaro

## BASICS

### DESCRIPTION

- The majority of pediatric and adolescent complaints of back pain are mild, nonspecific, and self-limited.
- While most cases may be idiopathic or musculoskeletal, the challenge is to identify the rare cases of back pain caused by more serious etiologies, such as a tumor or infection.

### EPIDEMIOLOGY

#### Incidence

- Recent studies demonstrate an increasing incidence of back pain in pediatric patients, but despite previous beliefs, it is rarely associated with serious pathology (1–4).
- Rates are highest in older children and girls.
- The 1-yr incidence in 8–13 yr olds ranges from 16–22% (2).
- The incidence may be as high as 37% in teenage patients, especially competitive athletes (1).

### RISK FACTORS

Competitive sports participation

### GENERAL PREVENTION

Though a causal relationship between backpack weight and back pain has not been established, the American Academy of Pediatrics recommends that backpacks not exceed 10–20% of a child's weight (5).

### PATHOPHYSIOLOGY

- Back pain may arise from numerous sites with nociceptive receptors including the vertebral column, muscles, tendons, ligaments, and fascia.
- With musculoskeletal pain, stretching, tearing, or contusion occurs to these sites after trauma or a sudden unexpected force.
- Injured muscles may become shortened with increased tone and tension.
- Facet joint pain at adjacent vertebral laminae can occur with mechanical trauma and subsequent inflammation.
- Pain from direct pressure or edema may occur secondary to neoplasm, hematomas, abscesses, or inflammatory conditions.
- Radicular pain from a herniated nucleus pulposus, fracture, or mass occurs secondary to compression of nociceptors in the dural lining of the spinal nerve root sleeve.

### ETIOLOGY

- The most common causes of back pain in pediatric patients presenting to the emergency department are muscle strain, trauma, sickle cell crisis, urinary tract infections, and viral syndromes (5). Back pain may also be idiopathic.
- Musculoskeletal back pain is the most common but should be a diagnosis of exclusion.

- Traumatic causes of back pain include contusions, muscle strain, compression fractures, spondylolysis, herniated discs, and more seriously spondylolisthesis or epidural hematomas (2).
- Sickle cell disease may present with back pain as a manifestation of a vaso-occlusive crisis.
- Infectious causes include discitis, vertebral osteomyelitis, sacroiliac joint infections, and abscesses (epidural, paraspinal, or retroperitoneal).
- Neoplasms:
  - Benign neoplasms include osteoid osteomas and osteoblastomas.
  - Malignant neoplasms may be primary solid tumors such as Ewing sarcoma or osteogenic sarcoma, metastatic lesions from neuroblastoma, rhabdomyosarcoma, or Wilms tumor or secondary to leukemia or lymphoma.
- Rheumatologic causes of back pain include ankylosing spondylitis and juvenile idiopathic arthritis.
- Back pain may also be referred from medical conditions such as pyelonephritis, nephrolithiasis, pneumonia, pancreatitis, or peptic ulcer disease.
- Other diagnoses to consider include lumbar Scheuermann disease, Scheuermann kyphosis, or significant scoliosis (2).

### COMMONLY ASSOCIATED CONDITIONS

Idiopathic low back pain is more common in children and adolescents with psychosocial difficulties, conduct problems, and other somatic disorders (5).

## DIAGNOSIS

### HISTORY

- Sudden in onset or chronic:
  - Acute pain may be associated with muscular strain, a herniated disc, spondylolysis, or fracture (5).
  - Chronic pain may be due to musculoskeletal back pain, Scheuermann kyphosis, inflammatory spondyloarthropathies, scoliosis, or psychological problems.
- Localized or generalized
- Preceding trauma or overuse activity
- Positional exacerbation:
  - Pain with flexion is more common with a herniated disc, slipped apophysis fracture, or infection.
  - Pain with extension is more common with spondylolysis or spondylolisthesis (5).
- Quality: Sharp, dull, shooting, or radiating:
  - Musculoskeletal pain has a more insidious onset, is poorly localized, and may radiate to the buttocks or thighs but rarely radiates below the knees.
  - Pain radiating below the knee is more likely radicular pain associated with a herniated disc or slipped apophysis fracture.

- Interference with sleep or daily activity
- Associated symptoms such as fever, dysuria, vomiting, malaise, weight loss, or neurologic dysfunction (2)
- Evaluating psychosocial stressors is also important.
- Red flags for tumor or infection include nighttime pain, systemic symptoms such as fever or weight loss, neurologic symptoms, self-imposed activity limitation, and constant or worsening pain for > 1 mo (5).

### PHYSICAL EXAM

- Observe the patient's gait and posture.
- Palpate for:
  - Reproducible tenderness:
    - Midline spinal tenderness
    - Paraspinal tenderness
  - Masses
  - Edema or swelling
- Evaluate the patient's range of motion and reproducibility of pain with flexion, extension, lateral bending, and rotation.
- Perform a neurologic exam including strength, sensation, and deep tendon reflexes.
- Perform a straight leg raise to evaluate the onset of shooting radicular pain (though this is less reliable in children and adolescents).
- Be certain to also examine the lung fields, abdomen, sacroiliac joints, and hips.

### DIAGNOSTIC TESTS & INTERPRETATION

Patients without any significant physical exam findings, with a short duration of pain, and with a history of a minor injury can usually be treated conservatively without any lab or radiographic studies (5).

#### Lab

- A CBC, ESR, and/or C-reactive protein should be sent if there is concern for infection, malignancy, or inflammatory conditions.
- Depending on the differential diagnosis, others labs may include a urinalysis, antinuclear antibody, HLA-B27, blood culture, or sickle cell screen.

#### Imaging

- If necessary, AP and lateral plain radiographs are the best screening test. Oblique views are helpful if there is a higher suspicion for spondylolysis or spondylolisthesis (2).
- If plain radiographs are nondiagnostic but there is a high suspicion for infection, neoplasm, or fracture, a bone scan would be a very sensitive though not specific test.
- CT may be useful in the setting of a positive bone scan that is not diagnostic.
- MRI is most helpful in detecting tumors, infection, disc herniation, or spinal cord pathology (5).
- MRI is the preferred study for constant pain, radicular pain, nighttime pain, or neurologic abnormalities.

**Diagnostic Procedures/Other**

In the setting of persistent infection (eg, vertebral osteomyelitis) despite antibiotic treatment, CT-guided aspiration for culture should be considered (2).

**DIFFERENTIAL DIAGNOSIS**

See Etiology.

**TREATMENT**

Treatment is diverse and dependent on the etiology.

**MEDICATION**

- NSAIDs are first-line therapy for most causes of back pain.
- NSAIDs:
  - Consider NSAID medication in anticipation of prolonged pain and inflammation.
    - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
    - Ketorolac 0.5 mg/kg IV/IM q6h PRN
    - Naproxen 5 mg/kg PO q8h PRN
  - Some clinicians prefer to avoid due to theoretical concern over influence on coagulation and callus formation.
- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- Opioids:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Fentanyl 1–2  $\mu$ g/kg IV q2h PRN:
    - Initial dose of 1  $\mu$ g/kg IV may be repeated q15–20min until pain controlled, then q2h PRN
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
  - Hydrocodone or hydrocodone/acetaminophen dosed as 0.1 mg/kg of hydrocodone component PO q4–6h PRN
- Other medications depend on the etiology of back pain.

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Physical therapy and home-based exercise are important for core muscle conditioning and increased flexibility (2).
- Heat therapy may alleviate pain and allow more activity.
- For fractures including spondylolysis, activity modification, physical therapy, and bracing are necessary (2).

**SURGERY/OTHER PROCEDURES**

Surgery may be necessary for tumors, fractures not responding to conservative therapy, and herniated discs that do not resolve spontaneously.

**DISPOSITION****Admission Criteria**

Admission may be necessary to work up tumors, infection, or pain requiring parenteral analgesics.

**Discharge Criteria**

- Well appearing
- Pain adequately controlled with oral medications

**Issues for Referral**

If the diagnosis remains uncertain or response to conservative treatment is poor, referral to a physical therapist, orthopedic surgeon, or rheumatologist should be considered.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Instructions are specific to diagnosis, though NSAIDs as needed are helpful for most pediatric and adolescent back pain.
- Activity:
  - For musculoskeletal back pain, it is important for patients to remain active in order to preserve function and normal lifestyle.
  - For fractures and spondylolysis, activity modification and decreased sports participation are necessary.

**Patient Monitoring**

The patient and primary care physician should monitor for any historical red flags.

**PROGNOSIS**

- Constant pain and male gender are more significantly associated with a positive diagnosis.
- Nighttime pain, constant pain, and symptom duration <3 mo are more significantly associated with a tumor (4).
- Early-onset idiopathic back pain in pediatric and adolescent patients is associated with chronic back pain as adults (2).

**COMPLICATIONS**

- Depends on the etiology
- Musculoskeletal back pain may be chronic, causing decreased participation in sports and school activity.

**CODES****ICD9**

- 724.2 Lumbago
- 724.5 Backache, unspecified
- 847.9 Sprain of unspecified site of back

**PEARLS AND PITFALLS**

- A short duration of back pain without significant physical exam findings and a history of a minor injury can be treated conservatively without any lab or radiographic studies.
- Symptoms requiring further evaluation include nighttime pain, systemic symptoms, neurologic symptoms, radicular pain, and constant or worsening pain.
- When the diagnosis of back pain is uncertain, an appropriate initial workup in the emergency department includes a CBC, ESR, C-reactive protein, and plain radiographs.

# PAIN, CHEST

Sanjay Mehta

## BASICS

### DESCRIPTION

- Chest pain is a common complaint in children. Most chest pain is due to non-life-threatening etiologies. Cardiac etiologies are rare, and the spectrum of causes is diverse.
- In the largest study on pediatric chest pain, which included 407 patients, chest pain was categorized as (1):
  - Acute (<48 hr) in 43%
  - Persistent (48 hr to 6 mo) in 50%
  - Chronic (>6 mo) in 7%
- Daily in 37%
- Awakens from sleep in 31%
- Leads to school absence in 30%
- No gender or race predilection

### EPIDEMIOLOGY

#### Prevalence

- 6 per 1,000 who visit an urban emergency department (1)
- 7th leading health problem in teens

### RISK FACTORS

- Congenital heart disease
- Hyperlipidemia
- Diabetes mellitus

### PATHOPHYSIOLOGY

- Irritation, stretching, or abnormal movements of tissues or organs lead to sensory nerve pain transmission of different types and locations.
- Musculoskeletal is the most common organic etiology.
- Cardiorespiratory etiology is more likely in younger children.
- Functional etiology is more likely in older children.
- MI in adults is caused by coronary vasospasm or occlusion, which is exceedingly rare in children:
  - Conditions that predispose to this are:
    - Kawasaki disease (KD)
    - Rheumatic fever
    - Sickle cell disease (SCD)
    - Cardiac surgery

### ETIOLOGY

- Idiopathic (21%) (1)
- Musculoskeletal (21%):
  - Costochondritis (9%)
  - Precordial catch syndrome (Texidor's twinge)
  - Slipping rib syndrome
  - Tietze syndrome
- Trauma:
  - Contusion
  - Strain or sprain
  - Rib fracture
  - Hemothorax

- Cardiac (4%):
  - Angina or MI (eg, coronary anomaly, hypercoagulability, toxic ingestion):
    - Coronary aneurysms (KD)
    - Protein C or S deficiency
    - Cocaine
    - Epinephrine
    - Atropine
    - Ipratropium bromide
    - Albuterol or salbutamol
    - Isoproterenol
  - Arrhythmia
  - Obstructive (eg, hypertrophic cardiomyopathy or aortic stenosis)
  - Pericarditis or myocarditis
  - Aortic aneurysm or dissection (eg, Marfan, Ehlers-Danlos, Turner, coarctation, aortic stenosis, endocarditis, or cocaine use)
  - Valvular (eg, mitral valve prolapse)
- Infection:
  - Zoster
  - Myositis
  - Pleurodynia
- Respiratory:
  - Asthma (7%)
  - Pneumonia (4%)
  - Pleural (eg, effusion or pleuritis)
  - Pneumothorax or pneumomediastinum
  - Pulmonary embolism
- GI:
  - Gastroesophagitis (eg, reflux or medication induced) (7%)
  - Caustic ingestion
  - Foreign body ingestion
- Other (9%):
  - Malignancy
  - Breast related (eg, mastalgia or mastitis)
  - SCD crisis (2%)
- Functional (9%)
- Anxiety

### COMMONLY ASSOCIATED CONDITIONS

- Anxiety
- Chronic medical conditions such as asthma, SCD, cystic fibrosis, etc.

## DIAGNOSIS

### HISTORY

- Severity
- Frequency
- Duration
- Type
- Location
- Onset
- Precipitating factors
- Radiation
- Associated complaints (eg, fever, dyspnea)
- Previous episodes
- Underlying heart disease (eg, KD)

- Significant medical history (eg, diabetes mellitus, SCD, or hypercholesterolemia)
- Smoking or substance abuse history
- Family history, including history of family member with recent cardiac pathology or death, that may trigger anxiety or psychological sequelae in relatives

### PHYSICAL EXAM

- Ill appearance (eg, cyanosis, respiratory distress, or pallor)
- Abnormal vital signs (eg, fever, hypotension, or pulsus paradoxus)
- Patient's preferred position (eg, dyspnea with supination)
- General body habitus (eg, Marfanoid, chronically ill, or obese)
- Chest wall:
  - Inspection:
    - Trauma
    - Asymmetry
    - Chest excursion pattern
  - Auscultation:
    - Tachycardia
    - Arrhythmia
    - Gallop rhythm
    - Rub
    - Click
    - Muffled heart sounds
    - Extra heart sounds
    - Murmur
    - Crackles
    - Wheeze
  - Palpation:
    - Reproducible tenderness
    - Subcutaneous emphysema, crepitus
    - Peripheral perfusion
    - Elevated jugular venous distension
- Abdominal pathology:
  - Hepatomegaly
  - Abdominal pain
- Rash or ecchymoses
- Arthritis
- General psychiatric presentation:
  - Panic or anxiety with hyperventilation, particularly in adolescent females

### DIAGNOSTIC TESTS & INTERPRETATION

- Consider investigation when:
  - Concerning history:
    - Acute onset
    - Exertional pain
    - Associated syncope or palpitations
    - Underlying heart disease (eg, KD, history of cardiac surgery)
    - Significant trauma
    - Cocaine use
    - Fever
    - Foreign body ingestion
  - Concerning exam:
    - Respiratory distress
    - Abnormal cardiorespiratory findings
    - Fever
    - Significant trauma
    - Subcutaneous emphysema

**Initial Lab Tests**

- Consider blood assays depending on the clinical suspicion (eg, risk factors for MI, arrhythmias, fever):
  - CBC and differential
  - Electrolyte panel
  - Cardiac enzymes (creatinine kinase–MB isoforms, troponins)
  - Inflammatory markers (ESR, C-reactive protein)
  - LFTs (AST, ALT)
- Consider toxicology screen:
  - Cocaine

**Imaging**

- Consider CXR (abnormal in 27%) depending on the clinical situation:
  - CXR may reveal:
    - Cardiomegaly
    - Abnormal cardiac silhouette or shadow
    - Pulmonary congestion or edema (eg, Kerley B lines)
    - Pneumonia
    - Pneumothorax
    - Pleural thickening or effusion
- Consider VQ scan or chest spiral CT scan for pulmonary embolism

**Diagnostic Procedures/Other**

- Consider ECG (abnormal in 16%):
  - Tachycardia
  - Arrhythmia
  - Absent P or T waves or QRS complexes
  - Diminished QRS voltages
  - Deep Q waves
  - Poor precordial lead R-wave progression
  - ST elevation
  - Left ventricular hypertrophy
  - Left axis deviation
  - AV conduction disturbances
  - Prolonged QTc
  - Prolonged PR
  - Electric alternans
- Consider echo (abnormal in 12%):
  - Wall or valve hypokinesis
  - Impaired global function
  - Septal changes
- Consider Holter monitor

**DIFFERENTIAL DIAGNOSIS**

See Etiology.

**TREATMENT****PRE HOSPITAL**

- Assess and stabilize airway, breathing, and circulation.

**INITIAL STABILIZATION/THERAPY**

- Assess and stabilize airway, breathing, and circulation.
- The initial stabilization is dependent on the etiology of chest pain. See related topics for treatment, including medications.
- Therapy is usually supportive.

**MEDICATION**

- Costochondritis:
  - NSAIDs:
    - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
    - Ketorolac 0.5 mg/kg IV/IM q6h PRN
    - Naproxen 5 mg/kg PO q8h PRN
  - Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- Anxiety: Benzodiazepines:
  - Lorazepam 0.05 mg/kg IV/PO q4h PRN, max single dose 2 mg
  - Alprazolam 0.005 mg/kg PO q6h PRN
- Gastroesophagitis: See Gastritis topic.
- Supraventricular tachycardia: See Dysrhythmia, Atrial topic.
- Asthma: See Asthma topic.
- SCD: See Sickle Cell Disease topic.

**DISPOSITION**

Most pediatric patients with chest pain are discharged home because of the likely benign etiology of pediatric chest pain (2).

**Admission Criteria**

- Significant hemodynamic abnormalities
- Concerning acute organic etiology (eg, MI or ventricular arrhythmia)
- Need for hospital treatments or workup (eg, oxygen-dependent pneumonia or significant pleural effusion)
- Anticipated clinical decompensation
- Critical care admission criteria:
  - Treatment-refractory arrhythmia (eg, ventricular etiology)
  - Significantly concerning abnormal echo (eg, pericardial effusion or cardiac tamponade)

**Discharge Criteria**

- Hemodynamically stable
- No concerning acute organic etiology

**Issues for Referral**

- Consultation in the emergency department:
  - Cardiology:
    - Known heart disease (eg, Kawasaki disease)
    - Refractory arrhythmias
    - Exertional symptoms
  - General surgery:
    - Significant trauma
  - Interventional radiology:
    - Pneumothorax or pneumomediastinum
    - Pleural effusion
  - Otolaryngology:
    - Caustic ingestion
- Outpatient consultation:
  - Cardiology:
    - Nonexertional syncope
    - Intermittent palpitations
  - Pain service:
    - Difficult to manage pain
  - Psychiatry:
    - Severe anxiety

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Discharge instructions and medications:
  - Costochondritis: NSAIDs, rest
  - Gastroesophagitis: Antacid, proton pump inhibitor, H2 blocker
  - Asthma: Bronchodilator, corticosteroids
- Activity:
  - Restrict physical activities, if any exertional symptoms, pending cardiology assessment.

**Patient Monitoring**

- Close primary care provider follow-up
- Consultant appointment as necessary
- Arrhythmia: Holter monitor

**DIET**

Avoid acidic, greasy, and spicy foods with GI etiologies.

**REFERENCES**

1. Selbst SM, Ruddy RM, Hentretig FM, et al. Pediatric chest pain: A prospective study. *Pediatrics*. 1988;82:319–323.
2. Rowe BH, Dulberg CS, Peterson RG, et al. Characteristics of children presenting with chest pain to a pediatric emergency department. *CMAJ*. 1990;143:388–394.

**ADDITIONAL READING**

- Byer RL. Pain—chest. In Fleisher GR, Ludwig S, eds. *Textbook of Pediatric Emergency Medicine*. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2010.
- Lalani A, Schneeweiss S. *Handbook of pediatric emergency medicine*. Toronto, Canada: Jones & Bartlett; 2008.

**CODES****ICD9**

- 786.50 Unspecified chest pain
- 786.51 Precordial pain
- 786.52 Painful respiration

**PEARLS AND PITFALLS**

- Parents and patients are often most concerned about potential cardiac etiology.
- Cardiac etiology is the least common of all etiologies.
- Look for organic etiologies with red flags:
  - Associated syncope or palpitations
  - Exertional symptoms
  - Cardiac risk factors
  - Strong family history
  - Subcutaneous emphysema
- Most diagnoses can be ruled out by history and physical exam.

# PAIN, EXTREMITY

Lois K. Lee  
Young-Jo Kim

## BASICS

### DESCRIPTION

- Pain of the extremity may be in the limb, the adjacent joint(s), or both.
- The extremity pain may be referred pain, with the pathologic site proximal to the area of pain. Patients may complain of lateral thigh and/or knee pain secondary to diseases of the hip or spine.
- Extremity pain may be from life-threatening and benign causes.
- This topic will focus on nontraumatic causes of pain. Please see the associated Trauma topics for specific injuries.

### EPIDEMIOLOGY

#### Incidence

- Osteomyelitis occurs more commonly in children <5 yr of age.
- Malignant bone tumors occur more commonly in young men in their 2nd decade of life.

#### Prevalence

Limping accounted for 4 per 1,000 emergency department visits in 1 study (1).

### RISK FACTORS

See Commonly Associated Conditions.

### GENERAL PREVENTION

Control of the underlying disease (eg, sickle cell disease [SCD]).

### PATHOPHYSIOLOGY

- Septic arthritis and osteomyelitis most commonly occur from the hematogenous spread of bacteria to the metaphysis and then the bone marrow, bone cortex, and subperiosteal space (2).
- Myositis can also result in focal limb pain.
- SCD-related vaso-occlusive crises result from microvascular occlusion involving a complex interaction of leukocytes, platelets, endothelial cells, and S-containing erythrocytes, most commonly occurring in the bone marrow or epiphysis (3).

### ETIOLOGY

- Septic arthritis:
  - *Staphylococcus aureus*
  - Non-group A beta-hemolytic streptococcus
  - *Kingella kingae*
  - *Streptococcus pneumoniae*
  - *Streptococcus pyogenes* (group A)
  - *Haemophilus influenzae* type b
  - *Neisseria* species
  - Salmonella in SCD
  - Group B *Streptococcus* (in neonates)
  - Gram-negative bacilli (in neonates)
  - *Borrelia burgdorferi*
- Osteomyelitis:
  - *S. aureus*
  - *S. pyogenes* (group A)
  - *S. pneumoniae*
  - *H. influenzae* type b
  - Salmonella (in SCD)
  - *Pseudomonas* species
- Influenza A and B

- Orthopedic causes:
  - Slipped capital femoral epiphysis (SCFE)
  - Legg-Calvé-Perthes
  - Congenital hip dislocation
  - Bone cyst
- Neoplastic causes:
  - Osteogenic sarcoma
  - Leukemia
  - Lymphoma
  - Neuroblastoma
  - Ewing sarcoma
  - Osteoid osteoma
  - Eosinophilic granuloma
  - Metastatic disease to bone
- Rheumatologic
  - Transient synovitis/postviral reactive arthritis
  - Henoch-Schönlein purpura (HSP)
  - Spondyloarthropathies
- Hematologic:
  - SCD vaso-occlusive crisis pain
  - Hemophilia hemarthroses
- Activity-related causes:
  - Overuse injuries
  - Carpal/Tarsal tunnel syndrome
  - Tendinitis
  - Stress fractures
  - Plantar fasciitis
  - Rhabdomyolysis
- Complex regional pain syndrome (CRPS)
- Reflex sympathetic dystrophy (RSD)
- Growing pains

### COMMONLY ASSOCIATED CONDITIONS

- SCD
- Rheumatologic diseases:
  - Systemic lupus erythematosus
  - Juvenile rheumatoid arthritis
  - Polyarteritis nodosa
  - Dermatomyositis
  - Reiter syndrome
- Inflammatory bowel disease (IBD)
- Cerebral palsy
- Obesity

## DIAGNOSIS

### HISTORY

- There may be a history of extremity pain and/or associated limp:
  - The pain may be worse with activity.
  - Toddlers may present with a refusal to walk or refusal to bear weight.
  - There may be a history of acute or subacute trauma (eg, in CRPS or a foot puncture wound) leading to osteomyelitis of the foot.
- Fractures or dislocations usually have a history of traumatic injury.
- Neoplastic causes may have a history of fevers, night sweats, weight loss, pain without associated activity, or bone pain that awakens the patient from sleep.
- There may be a history of a viral infection (upper respiratory tract infection or GI infection) in the weeks preceding the extremity pain in the setting of transient synovitis or postviral arthritis.

- For growing pains, the pain is episodic, usually occurring in the evening or awakening the child during sleep (nap, nighttime). It usually involves the bilateral lower extremities.
- Rheumatologic diseases may have a history of fevers, arthralgias, uveitis/iritis, or rash.
- IBD-associated arthritis is usually associated with bloody diarrhea, fever, and weight loss.

### PHYSICAL EXAM

- Fever may be present in ~70% of children with septic hip (4).
- The extremity exam should include:
  - Position of the limb at rest
  - Assessment for erythema, swelling, deformity, or warmth of the extremity or joint
  - Palpation of the bone and muscle for tenderness of the extremity
  - Assessment of range of motion of the joints above and below the painful extremity AND
  - Evaluation of the patients' weight-bearing status, including any abnormality of gait
  - The hip may be in a flexed and externally rotated position in patients with septic hip, transient synovitis, and Perthes disease. There may also be decreased flexion, abduction, and internal rotation.
  - With SCFE, the hip externally rotates as it is being flexed.
- Pallor/Bruising/Petechiae or lymphadenopathy may be present in a child with leukemia.
- Rashes or skin lesions may be present in a child with a rheumatologic case of extremity pain.
- Hyperesthesia, coolness, edema, and increased perspiration may be present in CRPS.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- The need for testing depends on the suspected diagnoses. For example, no testing is necessary for some diagnoses such as transient synovitis, growing pains, or tendinitis.
- CBC with differential for suspected infectious or neoplastic etiologies; blood smear if concerned for leukemia
- ESR and C-reactive protein may be elevated in infectious, inflammatory, and rheumatologic causes.
- Lyme titers (EIA and Western blot) for suspected Lyme arthritis
- Influenza A and B testing is not usually necessary but may be obtained in indeterminate cases.
- Urinalysis and BUN/creatinine may be considered for the diagnosis of HSP or rhabdomyolysis.
- Serum creatinine kinase for myositis/myopathies and rhabdomyolysis

#### Imaging

- The need for imaging depends on the suspected diagnoses. For example, no imaging is necessary for some diagnoses such as leukemia, growing pains, HSP, or tendinitis.

- X-ray of the extremity or joint:
  - Obtain at least 2 views for extremities and usually 3 views for joints.
  - For hips, AP and Lauenstein (frog-leg) views should be obtained.
- US of the hips should be obtained if there is concern for septic joint (5). US will show an effusion, if present.
- Further evaluation as an inpatient or outpatient may include:
  - Bone scan for suspected osteomyelitis
  - MRI for suspected:
    - Osteomyelitis
    - Stress fractures
    - Bone tumors
    - Legg-Calvé-Perthes disease

#### Diagnostic Procedures/Other

- Bone marrow biopsy for malignant neoplasms
- Synovial fluid aspiration for septic arthritis:
  - WBC count
  - Gram stain and culture
- Bone aspiration for osteomyelitis (usually done in the operating suite)

#### DIFFERENTIAL DIAGNOSIS

- Trauma:
  - Fracture
  - Overuse injuries
  - Soft tissue injuries
  - Radial head subluxation
- Postinfectious, inflammatory:
  - Rheumatic fever
  - Serum sickness
- Neurologic:
  - Peripheral neuropathy
  - Muscular dystrophy
- Other:
  - Fibromyalgia
  - Conversion disorder
  - Gout

## TREATMENT

#### INITIAL STABILIZATION/THERAPY

- Depends on the etiology of the extremity pain
- Provide analgesics (eg, narcotics) if the patient complains of significant pain.

#### MEDICATION

##### First Line

- NSAIDs:
  - Ibuprofen 10 mg/kg/dose PO q6h, max 800 mg/dose
  - Naproxen 5–7 mg/kg/dose PO q8–12h, max dose 1,000 mg/day
- Ketorolac (for SCD):
  - 8–12.5 kg: 4 mg IV/IM q6h
  - 12.5–25 kg: 7.5 mg IV/IM q6h
  - >25–50 kg: 15 mg IV/IM q6h
  - >50 kg: 30 mg IV/IM q6h
- IV antibiotics for infectious causes, depending on the etiology
  - Cefazolin 50–150 mg/kg/day IV divided q8h, max dose 6 g/day

#### Second Line

- Narcotics should be administered for pain if NSAIDs do not provide adequate pain relief, especially in patients with SCD:
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Consider other opioids based on practitioner and institution preference/practice
- Corticosteroids may be considered for certain rheumatologic processes.

#### COMPLEMENTARY & ALTERNATIVE THERAPIES

- Physical therapy
- Chemotherapy for malignancies

#### SURGERY/OTHER PROCEDURES

- Joint drainage for septic arthritis.
- Surgical management for bone tumors

#### DISPOSITION

##### Admission Criteria

- Inpatient admission criteria:
  - Patients with osteomyelitis and septic arthritis should be admitted for IV antibiotics and may require operative irrigation and/or debridement.
  - Refractory pain in SCD patients with vaso-occlusive crises or in hemophilia patients with severe hemarthroses
  - SCFE for orthopedic surgical management
  - Patients with bony tumors who will require chemotherapy and surgical resection
  - Patients with a new diagnosis of probable neoplasm will need admission for medical therapy.
- Critical care admission criteria:
  - SCD patients who require exchange transfusions for refractory pain crises or severe anemia
  - Septic shock from infection requiring pressor support and ICU monitoring (eg, in oncology patients)

##### Discharge Criteria

Well-appearing patients with adequate pain control for whom critical diagnoses have been ruled out

##### Issues for Referral

Depending on the etiology of the extremity pain, subspecialty follow-up may be required, such as with orthopedics, oncology, hematology, rheumatology, etc.

## FOLLOW-UP

#### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - NSAIDs and/or opioids as needed for pain
- Activity:
  - As tolerated based on pain

#### PROGNOSIS

- The prognosis varies depending on the etiology of limb pain.
- For septic arthritis, early treatment is the most important factor for a good outcome.

#### COMPLICATIONS

- Damage to the growth plate or joint from infection, trauma, or tumor may lead to growth disturbance, thus leading to limb length discrepancy and/or functional limitations.
- Delayed diagnosis of a septic arthritis can lead to joint destruction and long-term morbidity.

#### REFERENCES

- SCFE

#### CODES

##### ICD9

- 729.5 Pain in limb
- 719.40 Pain in joint, site unspecified

#### PEARLS AND PITFALLS

- Neonates and infants with septic arthritis of the hip may be irritable and appear to have pseudoparalysis of the hip.
- Hip pathology (eg, SCFE) may present as referred pain to the knee, so both joints and the leg must be examined for patients complaining of knee pain.
- Failure to obtain radiographs of both hips may result in failure to detect a clinically unapparent lesion.
- Failure to obtain a radiograph in a patient with pain but no history of trauma may result in failure to detect consequential neoplasm such as Ewing sarcoma, osteosarcoma, etc.
- Malignancy may present as a pathologic fracture, so a CBC and inflammatory markers should be considered based on the history.

# PAIN, EYE

Rachel Gallagher  
Atima Chumpa Delaney

## BASICS

### DESCRIPTION

- Eye pain may result from trauma, congenital anomalies, infections, environmental exposures, and acquired eye disease.
- Exam by an ophthalmologist is often required for definitive diagnosis and treatment.

### PATHOPHYSIOLOGY

- Corneal abrasions result from disruption of the epithelium of the eye as a result of trauma.
- Blunt trauma or penetrating foreign bodies (FBs) can lacerate or puncture the sclera and cornea, causing rupture of the globe.
- Traumatic hyphema results from hemorrhage in the anterior chamber. Blunt trauma can also cause vitreous hemorrhage.
- Iritis often occurs after trauma to the eye produces inflammation in the anterior chamber, but iritis may also be idiopathic.
- Optic neuritis is caused by inflammatory demyelination of the optic nerve and is often immune mediated.
- Glaucoma develops in the setting of anatomic abnormalities or posttraumatic changes that prevent drainage of aqueous humor leading to increased intraocular pressure (IOP) and damage to the optic nerve.
- Infection:
  - Endophthalmitis is an infection in the intraocular tissues.
  - Orbital cellulitis is an infection of the extraocular tissues.
  - Infectious keratitis is an infection of the cornea.
- Chemical burns:
  - Acidic agents cause coagulation of the epithelium.
  - Alkali agents and weak acids may penetrate the cornea, damaging the anterior segment.

### ETIOLOGY

- Trauma: Corneal abrasion, ruptured globe, hyphema, iritis, chemical burn, thermal burn, corneal ulceration
- Posttraumatic: Glaucoma, iritis
- Optic neuritis
- Infection:
  - Keratitis caused by herpes simplex virus (HSV), *Staphylococcus aureus*, *Pseudomonas* species, *Acanthamoeba* species, and fungus
  - Endophthalmitis and iritis caused by *S. aureus*, *Streptococcus* species, *Candida* species
  - Orbital cellulitis often is polymicrobial secondary to sinusitis.
  - Conjunctivitis: Viral, bacterial
  - Blepharitis
- Congenital: Glaucoma
- Migraine
- Hordeolum
- Chalazion
- Sinusitis

- See respective topics on Orbital Cellulitis; Fracture, Orbital; Corneal Abrasion; Hyphema; Sinusitis; Migraine Headaches; Neoplasm, Brain; Foreign Body, Cornea; Burn, Chemical; Hydrocephalus; and Pseudotumor Cerebri.

### COMMONLY ASSOCIATED CONDITIONS

- Corneal abrasion
- Conjunctivitis
- FB
- Hordeolum

## DIAGNOSIS

### HISTORY

- Trauma:
  - Superficial minor trauma with immediate onset of irritation: Corneal abrasion
  - Penetrating trauma or significant blunt-force trauma and visual changes: Ruptured globe
  - Pain onset hours or days after trauma: Iritis
  - Exposure to caustic substance: Chemical burn
- Atraumatic:
  - Insidious onset of pain with visual changes: Glaucoma, keratitis, orbital cellulitis
  - Rapid pain with visual changes: Optic neuritis
  - FB sensation: Infectious keratitis, FB
  - Severe dull pain with decreased vision and purulent drainage: Endophthalmitis
  - Sharp, superficial pain in persons wearing contact lenses: Infectious keratitis
  - Swelling and inflammation of the eye often preceded by sinusitis and pain with extraocular movements (EOMs): Orbital cellulitis
  - Eye pain with headache: Angle-closure glaucoma, cluster headache

### PHYSICAL EXAM

- Visual acuity: Field cuts or decreased acuity with ruptured globe, corneal abrasions involving the pupil, hyphema, glaucoma, keratitis, and chemical burns
- Visual inspection of the eye surface to detect FBs, lacerations, superficial inflammation, and other facial trauma
- Enlarged eye with firm globe: Glaucoma
- Corneal opacity: Infectious keratitis, glaucoma
- Conjunctival injection: Ruptured globe, glaucoma, endophthalmitis, iritis (with limbic sparing), keratitis, chemical burn
- Visible defect in the superficial tissue: Corneal abrasion, ruptured globe (protrusion of the sclera), chemical burns
- Abnormally shaped pupil: Ruptured globe (a teardrop-shaped pupil)
- Blood visible in the anterior chamber on direct or slit lamp exam: Hyphema
- Purulent discharge and pus in the anterior chamber: Endophthalmitis
- Direct and indirect penlight exam: Afferent pupillary defect in optic neuritis and ruptured globe, pain on accommodation with glaucoma, pain with pupillary contraction in hyphema
- Photophobia: Chemical burns, ruptured globe, infectious keratitis

- Miosis and ciliary flush (red ring around the iris): Iritis
- Visual field exam: Field cuts with optic neuritis, large corneal abrasions, hyphema, and chemical burns
- Pain with EOM: Optic neuritis, orbital cellulitis, extraocular muscle entrapment
- Eyelid eversion: FB causing corneal abrasion or ruptured globe (Do not remove the FB prior to repair of ruptured globe.)
- Funduscopic exam: Papilledema in optic neuritis and glaucoma; splinter hemorrhages in glaucoma

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Most patients do not require lab testing.
- Patients with systemic illness or other injuries resulting from trauma should have selective lab testing performed.
- CBC, PT, PTT in patients with coagulopathies
- Blood culture if suspecting endophthalmitis
- Hemoglobin electrophoresis in patients with hyphema in whom sickle cell disease is suspected
- Send HSV culture/direct fluorescent antibody from vesicular lesions if suspecting HSV keratoconjunctivitis.

#### Imaging

- CT with axial and coronal images of the orbit in patients with ruptured globe, suspected intraocular FB, suspected orbital fractures, or orbital cellulitis
- Head CT if indicated for head trauma
- MRI if optic neuritis to detect demyelinating diseases (may be done in the emergency department or as outpatient)

#### Diagnostic Procedures/Other

- Fluorescein stain: Disruptions in the superficial cornea will appear green when exposed to a cobalt blue light:
  - If multiple linear corneal stains (corneal abrasions) are noted, explore the eyelids for a FB.
  - Staining with a dendritic pattern is seen in herpetic keratitis.
  - Staining with circular infiltrates is seen in bacterial keratitis.
- Slit-lamp exam may show abnormal specks of floating material in the anterior chamber, indicating inflammation of the iris:
  - Microhyphema shows scattered RBCs on slit-lamp exam.
- Tonometric measurement of IOP after ruling out ruptured globe (normal IOP = 10–21 mm Hg) if concerned for glaucoma, orbital cellulitis, and endophthalmitis

### DIFFERENTIAL DIAGNOSIS

See Etiology.

## TREATMENT

### PRE HOSPITAL

- An eye shield (not eye patch) should be placed if there is concern for ruptured globe or if accommodation is painful.
- Patients with a history of chemical burn should have immediate eye irrigation initiated.

### INITIAL STABILIZATION/THERAPY

- Corneal abrasion: See Corneal Abrasion topic.
- Ruptured globe: Eye shield, emergent exam by ophthalmologist, and operative repair
- Hyphema: See Hyphema topic.
- Iritis: Cycloplegics for dilation and steroid drops if recommended by ophthalmology
- Optic neuritis: Treatment for infection. Patients with multiple sclerosis receive corticosteroids or immunomodulating agents.
- Orbital cellulitis: See Orbital Cellulitis topic.
- Endophthalmitis: Broad-spectrum IV antibiotics
- Infectious keratitis: Topical antibacterial or antiviral treatment for epithelial disease; IV therapy for invasive infection
- Chemical burn: Irrigate with normal saline for 30 min and continue until the ocular surface has a normal pH of 6.5–7.5. See Burn, Chemical topic.
- Glaucoma: In consultation with an ophthalmologist, a variety of topical agents, IV mannitol, or carbonic anhydrase inhibitors

### MEDICATION

- Topical anesthetic for pain. Topical anesthetics should be used only after a ruptured globe has been excluded.
- Topical anesthetic agents:
  - Proparacaine 0.5% solution: 1 gtt in affected eye q5–10min
  - Tetracaine solution: 1–2 gtt in eye once
- Systemic analgesics:
  - Ibuprofen 10 mg/kg/dose PO/IV q6h PRN
  - Ketorolac 0.5 mg/kg IV/IM q6h PRN
  - Naproxen 5 mg/kg PO q8h PRN
  - Morphine 0.1 mg/kg IV/IM/SC q2h PRN:
    - Initial morphine dose of 0.1 mg/kg IV/SC may be repeated q15–20min until pain is controlled, then q2h PRN.
  - Codeine or codeine/acetaminophen dosed as 0.5–1 mg/kg of codeine component PO q4h PRN
- Topical antibiotics:
  - Moxifloxacin solution: 1 gtt in eye t.i.d. (1)
  - Erythromycin ointment: 0.5-cm ribbon in eye b.i.d.
- Cycloplegic agents:
  - Cyclopentolate 0.5% or 1% solution: 1 gtt in eye followed by 1 drop in 5 min
  - Scopolamine 0.25% solution: 1 gtt in eye up to t.i.d.
  - Homatropine 2% solution: 1 gtt b.i.d.
  - Pilocarpine 1% solution: 1–2 gtt up to 6 times per day
- Carbonic anhydrase inhibitor:
  - Acetazolamide 8–30 mg/kg/day PO divided t.i.d. or 20–40 mg/kg/day IV divided q6h

- Parenteral antibiotics:
  - Ampicillin/Sulbactam 200–400 mg ampicillin/kg/day IV divided q6h, max 8 g ampicillin/day
  - Vancomycin 40–60 mg/kg/day IV divided q6–8h, max 1 g/dose (4 g/day)
  - Ceftazidime 150 mg/kg/day IV divided q8h, max 6 g/day
- Antiviral agents:
  - Acyclovir 80 mg/kg/day PO divided 3–5 times per day
  - Trifluridine 1% solution: 1 gtt q2h while awake (9 times per day)
  - Vidarabine 3% ointment: 1-cm ribbon applied 5 times per day

### SURGERY/OTHER PROCEDURES

- While everting the eyelid, remove the FB from the eyelid using a soft, cotton-tipped tool.
- Emergent surgical repair is indicated in patients with a ruptured globe.
- Hyphema causing elevation of IOP unresponsive to medical management or corneal bloodstaining requires surgical intervention.

### DISPOSITION

#### Admission Criteria

- Hyphema: High-risk patients with large hyphema, elevated IOP, bleeding dyscrasia or sickle hemoglobinopathy, or rebleeding require inpatient management for activity restriction and serial exams.
- Ruptured globe
- Endophthalmitis
- Orbital cellulitis or severe periorbital cellulitis

#### Discharge Criteria

- Uncomplicated corneal abrasions
- Ophthalmologists may approve outpatient management of patients with low-risk hyphema.

#### Issues for Referral

- Emergent evaluation by an ophthalmologist when suspecting a ruptured globe.
- Ophthalmology consultation when suspecting complicated eye pathology including iritis, endophthalmitis, infectious keratitis, or corneal abrasion or ulcer in the visual axis.
- When infectious etiology is unclear, an infectious disease consultation should be obtained.
- Complex orbital trauma requires consultation with plastic or otorhinolaryngology surgeons.
- Neurology consultation in patients with optic neuritis to evaluate possible underlying demyelinating disease

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

#### Patient Monitoring

- Most patients with eye pain need to follow up with an ophthalmologist.
- Avoid contact lens use until an ophthalmologist has documented complete healing of the injury.

### COMPLICATIONS

- Hyphema: Rebleeding predisposes to glaucoma, optic neuropathy, and vision loss.
- Herpetic keratitis: High rate of recurrence
- Children <7 yr of age are at risk for amblyopia if patching or injury causes long-term visual deprivation.

### ICD-9 CODES

#### ICD9

379.91 Pain in or around eye

### PEARLS AND PITFALLS

- Pearls:
  - Relief of pain after the instillation of anesthetic drops strongly suggests corneal epithelial disease as the etiology of pain.
  - Patients should never be prescribed topical anesthetic drops. When used chronically, they can inhibit epithelial healing.
  - All patients with suspected orbital fractures need an ophthalmologic evaluation to rule out intraocular injury.
- Pitfalls:
  - Patching of contact lens–related epithelial defect can result in severe *Pseudomonas* ulcers.
  - Prescribing topical steroids in patients with infectious epithelial disease

# PAIN, THROAT

Garth Meckler

## BASICS

### DESCRIPTION

- Throat pain, or sore throat, in children is a common complaint and refers to subjective pain that localizes to the pharynx or surrounding areas but may originate from the structures of the mouth, pharynx, larynx, esophagus, or inner ear.
- Throat pain in preverbal children may be inferred by parents from decreased oral intake or oral aversion.

### EPIDEMIOLOGY

#### Incidence

- Sore throat accounts for 6% of pediatric visits to primary care providers in the U.S. annually (1).
- Though the exact incidence of all causes of throat pain is not known, acute pharyngitis or tonsillitis is diagnosed in 7.3 million children annually in the U.S. (1).

#### Prevalence

The prevalence of sore throat is not known.

### RISK FACTORS

- Day care attendance is a risk factor for many infectious etiologies of acute pharyngitis.
- Children with inborn or acquired immunodeficiency may be at increased risk for unusual infectious causes of sore throat.

### GENERAL PREVENTION

Careful hand washing may decrease transmission of some infectious causes of sore throat.

### PATHOPHYSIOLOGY

- Throat pain is perceived through the sensory fibers of the glossopharyngeal nerve (cranial nerve [CN] IX), which innervates the pharynx, posterior tongue, and tonsils, and to a lesser degree, the mandibular division of the trigeminal nerve (CN V3), which innervates part of the tongue and the floor of the mouth.
- The pathophysiology of throat pain varies according to the specific etiology.

### ETIOLOGY

- The most common cause of sore throat is infection:
  - Viral is most common (eg, rhinovirus, enterovirus, herpesviruses [HSVs])
  - Bacterial agents: Group A beta-hemolytic streptococcus (GABS) in 15–30% of acute pharyngitis
  - Less common bacterial infections not found by routine testing: Non-group A types, such as B,C,G, *Fusobacterium*, *Arcanobacterium*, tularemia, gonorrhea
  - Yeast or fungi
  - Life-threatening infections causing sore throat include peritonsillar abscess, epiglottitis, retropharyngeal abscess, and diphtheria.
- Noninfectious causes of sore throat include irritation (chemical, environmental), foreign body, trauma (eg, pencil-tip injuries to the posterior pharynx), Stevens-Johnson syndrome (SJS), Kawasaki disease (KD), and Lemierre syndrome.

### COMMONLY ASSOCIATED CONDITIONS

Associated conditions depend on the etiology of sore throat (eg, rhinitis in viral causes of acute pharyngitis).

## DIAGNOSIS

### HISTORY

- Associated symptoms such as fever, upper respiratory symptoms, GI complaints, headache, rash, arthralgias, and myalgias may help narrow the differential diagnosis when infectious causes of sore throat are suspected.
- A history of past or recurrent infections, or infections in family members or close contacts, may be useful in certain infectious causes of acute pharyngitis (eg, GABS, HSV).
- The clinician should inquire about difficulty breathing or swallowing, drooling, change in voice or cry, trismus, pain or difficulty moving the neck, or torticollis, as these are symptoms suggestive of potentially life-threatening causes of sore throat.
- A thorough medical history is important to identify immunocompromised patients and unvaccinated patients, as the potential infectious etiologies for sore throat in this population differ from immunocompetent and immunized children.
- Circumstances surrounding trauma associated with throat pain (eg, running with a pencil in the mouth) should be elicited, as should the nature of potentially irritating chemical ingestions.

### PHYSICAL EXAM

- Attention to vital signs including temperature, heart rate, respiratory rate, BP, and pulse oximetry is important, as life-threatening infections may perturb vital signs.
- The eyes, ears, nose, mouth, and throat should be carefully inspected:
  - Conjunctivitis associated with sore throat may suggest viral upper respiratory infection or may be associated with KD or SJS.
  - Otitis media may occasionally be associated with perceived throat pain.
  - Inflammation of nasal mucosa suggests a viral etiology of acute pharyngitis.
  - The mouth should be inspected for lesions of the lips, tongue, gingiva, and buccal mucosa that may suggest viral stomatitis or candidal thrush.
  - The posterior pharynx should be inspected for:
    - Palatal ulcers suggestive of viral infection
    - Palatal petechiae (seen in both viral and bacterial pharyngitis)
    - The position and size of the uvula (swelling and erythema suggest uvulitis or trauma, while deviation from an enlarged tonsil suggests tonsillar or peritonsillar abscess.)
    - The appearance of the tonsils (symmetry, size, presence or absence of exudates)
    - The appearance of the posterior soft palate (fullness or bulging may suggest retropharyngeal abscess.)
  - The location of traumatic injuries should be carefully noted and suggest potential injury to adjacent structures (eg, carotid arteries).
- The jaw should be tested for range of motion:
  - Limitation suggests trismus, which may be associated with deep space infections.

- Drooling should be noted, if present.
- The neck should be examined for range of motion. (Limited flexion/extension may be seen in retropharyngeal abscess, and torticollis may suggest parapharyngeal abscess.)
- A thorough respiratory exam will identify stridor, which may be associated with epiglottitis, tracheitis, or croup.
- Splenomegaly may be seen in Epstein-Barr virus (EBV)-associated pharyngitis.
- Skin: Viral exanthema, scarlatiniform rash suggestive of GABS, or characteristic lesions of KD or SJS

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

Lab testing varies widely by etiology of sore throat and includes:

- Rapid strep test (antigen based—70–90% sensitive): Rapid strep test or culture should be performed in most patients.
- Bacterial culture:
  - Streptococcal culture on chocolate agar:
    - In sexually active adolescents in whom gonorrhea is a consideration, cultures require plating on Thayer-Martin media.
    - When diphtheria is a consideration, nose and throat swabs should be obtained and require tellurite media.
  - Monospot (heterophile antibodies) is a rapid diagnostic test for EBV infection in older children but has low overall sensitivity (64–84%), especially in children <5 yr of age and early in disease (<7 days of symptoms).
- Viral culture or serology:
  - HSV, EBV, cytomegalovirus: IgM and IgG titers

#### Imaging

Imaging depends on the etiology of sore throat, such as:

- Soft tissue films of the neck for suspected foreign body
- CT of the neck for suspected abscess, such as retropharyngeal, prevertebral, peritonsillar, parapharyngeal, Ludwig angina
- Angiography for penetrating injuries to the medial posterior pharynx

#### Diagnostic Procedures/Other

Diagnostic procedures such as biopsy, fine-needle aspiration, incision and drainage, or endoscopy depending on the suspected etiology

### DIFFERENTIAL DIAGNOSIS

- Infectious pharyngitis or tonsillitis
- Viral
- Bacterial
- Infectious mononucleosis
- Uvulitis
- Epiglottitis
- Abscess:
  - Peritonsillar
  - Parapharyngeal/Lateral pharyngeal
  - Retropharyngeal
  - Prevertebral

- Diphtheria
- Lemierre syndrome
- Nonpharyngeal causes of referred pain include:
  - Otitis media
  - Sinusitis
  - Dental infection
  - Cervical adenitis
  - Esophagitis
  - Mediastinitis

## TREATMENT

### PRE HOSPITAL

If suspected epiglottitis, maintain a position of comfort and do not agitate the patient.

### INITIAL STABILIZATION/THERAPY

The initial stabilization and treatment of sore throat depends on the specific etiology:

- IV fluids for patients with moderate to severe dehydration
- NPO for surgery

### MEDICATION

- Analgesics may provide symptomatic relief of throat pain (2) and include:
  - Acetaminophen 15 mg/kg PO/PR q4h
  - Ibuprofen 10 mg/kg PO q6h
  - Morphine 0.1 mg/kg IV q2–4h as needed
- The role of steroids for pain and tonsillar enlargement is not fully defined (3).
- Antibiotic treatment of bacterial infections depends on the type of infection.

### COMPLEMENTARY & ALTERNATIVE THERAPIES

Demulcent herbs (eg, "Throat Coat," which combines elm bark, licorice root, and marshmallow root) may reduce symptoms of sore throat (4).

### SURGERY/OTHER PROCEDURES

Some etiologies of sore throat require surgical procedures such as incision and drainage in the case of retropharyngeal abscess.

### DISPOSITION

#### Admission Criteria

- Inability to maintain hydration status despite oral analgesics
- Requirement for surgical incision and drainage of abscesses may require hospitalization.
- Life-threatening systemic disease associated with sore throat (eg, epiglottitis, KD, SJS, Lemierre disease) requires hospitalization.
- Critical care admission criteria:
  - Patients with sore throat associated with potential airway compromise should be admitted to the ICU.

#### Discharge Criteria

If life-threatening causes are ruled out, oral hydration is adequate, and caretakers are reliable, patients should be discharged.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Discharge instructions and medications:
  - Specific discharge instructions and medications vary by the etiology of the sore throat.
- Activity:
  - Most causes of sore throat do not require limitation of activity:
    - EBV pharyngitis associated with splenomegaly, however, requires withdrawal from contact sports until splenomegaly resolves.

### Patient Monitoring

- Hydration and respiratory status should be carefully monitored.
- Children with sore throat should be observed for symptoms suggestive of potentially serious disease, such as drooling and stridor.

### PROGNOSIS

The prognosis depends on the etiology, but the majority of causes of sore throat are benign and self-limited without specific medical treatment.

### COMPLICATIONS

Complications of sore throat vary according to etiology but may include:

- Dehydration (inability to take oral fluids due to pain)
- Rheumatic heart disease (GABS)
- Mediastinitis (eg, retropharyngeal abscess, caustic ingestion with esophageal perforation)
- Vascular thrombosis (eg, penetrating pharyngeal trauma, Lemierre disease)

## CODES

### ICD9

- 784.1 Throat pain
- 462 Acute pharyngitis
- 463 Acute tonsillitis

## PEARLS AND PITFALLS

- Consider foreign body in young children even without a suggestive history.
- Drooling, torticollis, change in voice, and stridor may be signs of potential life-threatening etiologies of sore throat.
- There are no clinical scoring or criteria sensitive enough to adequately rule out or clinically diagnose group A streptococcus pharyngitis in children: Lab testing is necessary for this.

# PALPITATIONS

Adam Vella  
Lana Friedman

## BASICS

### DESCRIPTION

- Palpitations are defined as a subjective feeling or awareness of an irregular or rapid beating of the heart. They may also be described as pounding in the chest, skipped beats, or fluttering.
- Palpitations are one of the most common cardiac complaints encountered, but they correspond poorly to demonstrable abnormalities.

### EPIDEMIOLOGY

#### Incidence

- In the primary care setting, the incidence of palpitations is reported to be up to 16% (1).
- Panic disorder was identified as the cause of palpitations in 20% of patients in 1 study (2).

#### Prevalence

The prevalence of pediatric patients with identifiable arrhythmias is on the rise secondary to prolonged survival following cardiac surgery.

### PATHOPHYSIOLOGY

- Palpitations can be the result of a true dysrhythmia or a physiologic reaction of the heart to noncardiac stimuli.
- The pathophysiology of dysrhythmias is complex and is presented in the respective topics elsewhere in this textbook.
- Increased heart rate (HR) and contractility are physiologic responses to catecholamine release, which may occur with exercise, emotional arousal, hypoglycemia, or a pheochromocytoma.
- Similarly, increased cardiac work occurs with conditions that increase the basal metabolic rate such as fever, anemia, and hyperthyroidism.
- Sympathomimetic and anticholinergic drugs are among groups of commonly available substances that directly modulate the autonomic nervous system, leading to tachycardia, hyperdynamic cardiac activity, and palpitations.

### ETIOLOGY

- Normal physiologic event:
  - Exercise
  - Excitement
  - Fever
- Psychological or psychiatric:
  - Fear
  - Anger
  - Stress
  - Anxiety disorder
  - Panic attack/disorder
- Drugs:
  - Stimulants: caffeine (coffee, tea, soda, chocolate), some energy drinks, nicotine
  - Over-the-counter drugs: Decongestants, diet pills
  - Drugs that cause tachycardia: Theophylline, amphetamines, hydralazine, minoxidil, cocaine
  - Drugs that cause bradycardia: Beta-blockers, antihypertensives, calcium channel blockers
  - Drugs that cause arrhythmias: antiarrhythmics (some of which are proarrhythmic), tricyclic antidepressants (TCAs), phenothiazines

- Medical conditions:
  - Anemia
  - Hyperthyroidism
  - Hypoglycemia
  - Hyperventilation
  - Poor physical condition
  - Pheochromocytoma
- Heart diseases:
  - Certain congenital heart defects/diseases (CHDs) that are susceptible to arrhythmias or result in poor physical condition
  - Following surgeries for CHD (eg, Fontan procedure)
  - Mitral valve prolapse (MVP)
  - Hypertrophic cardiomyopathy
  - Dilated cardiomyopathy
  - Valvular disease: Aortic stenosis
  - Cardiac tumors or infiltrative disease
- Cardiac arrhythmias:
  - Tachycardia
  - Bradycardia
  - Premature atrial contractions
  - Premature ventricular contractions (PVCs)
  - Supraventricular tachycardia (SVT)
  - Ventricular tachycardia
  - Atrial fibrillation
  - Wolff-Parkinson-White pre-excitation (WPW)
  - Sick sinus syndrome

### COMMONLY ASSOCIATED CONDITIONS

Symptoms frequently associated with palpitations include chest pain, headaches, dizziness, shortness of breath, diaphoresis, and syncope.

## DIAGNOSIS

### HISTORY

- Important features of the history include the mode of onset of palpitations, relationship to exertion, the frequency and duration of symptoms, and any associated symptoms.
- A thorough review of systems is also important and should include any history of weight loss, sleep disturbance, drug or medication use, and social or emotional stress.
- Family history of any cardiac or psychiatric disorders should be ascertained.

### PHYSICAL EXAM

- Vital signs: HR and BP should be referenced to normal values for age in both the supine and upright positions.
- Skin: Examine the color and for signs of hyperthyroidism or anemia.
- HEENT: Examine the eyes for exophthalmos and the neck for goiter.
- Lungs: Examine for tachypnea and rales suggestive of CHF.
- Cardiovascular: Auscultate for any heart murmur, gallop, click, rhythm irregularities, and splitting of the 2nd heart sound. The extremities should be assessed for the quality of peripheral pulses and any evidence of edema.
- Psychiatric: Evaluation of the mental status should include assessing for any evidence of anxiety, depression, panic disorder, or substance abuse.

### DIAGNOSTIC TESTS & INTERPRETATION

ECG: The diagnostic evaluation of all patients presenting with palpitations should include an ECG. A resting 12-lead ECG should be obtained to evaluate for cardiac arrhythmias, hypertrophy, conduction abnormalities (including WPW), abnormal Q and T waves, and an abnormal QT interval.

#### Lab

##### Initial Lab Tests

- A blood glucose level is an easy, rapid test that should be performed on all patients with a presentation suggestive of hypoglycemia.
- Patients who either report illicit drug use on the history or if suspected on the physical exam should have a toxicology screen sent.
- Patients with signs of fatigue or anemia require a CBC.
- Those with suspected thyroid abnormality require thyroid-stimulating hormone and T4 levels.
- Additional testing includes specific drug levels on patients taking medications and 24-hr urine for vanillylmandelic acid for patients with suspected pheochromocytoma, which may be done on either an in- or outpatient basis.

#### Imaging

- Chest radiograph may be performed to evaluate for pulmonary pathology, cardiac size and silhouette, and pulmonary vascularity in patients with abnormal vital signs, such as hypoxemia, respiratory complaints, or findings on physical exam.
- Echo: Patients suspected of having structural heart disease based on an abnormal physical exam, ECG, or CXR require a comprehensive echo. Particular features assessed by an echo include valvular lesions, such as MVP, cardiomyopathy, or CHD associated with conduction abnormalities, such as physiologically corrected transposition of the great arteries. The echo may be performed on an outpatient basis in most cases. However, patients with a clinically significant arrhythmia discovered on ECG, those presenting with hemodynamic instability, and those with persistent symptoms necessitate obtaining an echo on an emergent basis.

#### Diagnostic Procedures/Other

- Ambulatory ECG: Further diagnostic testing is indicated for 3 groups of patients: Those in whom the initial diagnostic evaluation (history, physical exam, and ECG) suggests an arrhythmic cause, those who are at high risk for an arrhythmia, and those who remain anxious and require reassurance of a documented benign cause. A Holter monitor or event recorder (3-lead ECG) can be performed to correlate symptoms to objective ECG data. This device can be placed on the patient either in the emergency department or at outpatient cardiology follow-up and is typically worn for 1–2 days while the patient simultaneously keeps a diary recording the timing and characteristics of symptoms.
- Exercise stress testing is a useful tool in patients whose palpitations are associated with activity to assess for ischemia secondary to coronary artery disease, cardiomyopathy, or catecholamine-induced arrhythmias.

## TREATMENT

### PRE HOSPITAL

Support ABCs.

### INITIAL STABILIZATION/THERAPY

- Due to the underlying benign etiology in the majority of cases, most patients presenting with palpitations require no stabilizing interventions.
- The ill-appearing child with palpitations requires rapid assessment for hypoxemia, shock, hypoglycemia, or a life-threatening arrhythmia.
- Prompt evaluation of the ABCs is essential.
- Administer supplemental oxygen as needed.
- The presence of heart disease should be assessed by a 12-lead ECG and rhythm strip, followed by continuous monitoring, frequent vital signs, and a chest radiograph.
- If the ECG reveals a benign rhythm such as sinus tachycardia, therapy is directed toward identifying and treating the underlying cause.
- If the ECG reveals a dysrhythmia, pediatric advanced life support (PALS) algorithms should be followed. See various topics on arrhythmias. Use synchronized cardioversion (1 J/kg) to treat SVT, atrial fibrillation, and atrial flutter in patients with signs of hemodynamic compromise. If initial cardioversion is unsuccessful, double the dose to 2 J/kg.

### MEDICATION

- In hemodynamically stable children with SVT, adenosine is the drug of choice. Additional details regarding the pharmacologic treatment of SVT may be found in that topic.
- In the hemodynamically stable patient with atrial flutter, attempt pharmacologic treatment with IV digoxin.
- Patients with ventricular tachycardia who are hemodynamically stable should be given amiodarone, procainamide, or lidocaine as outlined in the corresponding topic.

### SURGERY/OTHER PROCEDURES

An electrophysiology study is an invasive measure used as a diagnostic test to assess for inducibility of an arrhythmia and also a therapeutic tool to treat an arrhythmia with radiofrequency ablation.

### DISPOSITION

#### Admission Criteria

- New-onset atrial flutter, atrial fibrillation, SVT
- Chronic atrial fibrillation with an increase in ventricular rate requiring treatment with a new antiarrhythmic medication
- Difficult to control atrial flutter or ventricular tachycardia for observation or for electrical or drug therapy
- SVT causing hemodynamic compromise
- Patients receiving a medication with proarrhythmic potential (flecainide, sotalol, amiodarone)
- Ominous PVCs: Multiform, paired, and associated with a prolonged QTc interval, R-on-T phenomenon, or structural heart disease
- Any patient who survives after treatment for ventricular fibrillation

### Discharge Criteria

- Most cases of palpitations are benign and may be safely discharged to follow-up with their primary care provider.
- Sinus tachycardia with an identifiable underlying etiology
- SVT, without hemodynamic compromise, terminated in the emergency department
- Benign PVCs: Uniform, single, and infrequent

### Issues for Referral

The following are some of the indications for referral of stable patients to a cardiologist:

- Abnormal findings in the cardiac exam
- Abnormalities in the chest radiograph or ECG
- Positive family history for cardiomyopathy, long QT syndrome, sudden unexpected death, or other hereditary diseases commonly associated with cardiac abnormalities
- Chronic, recurring nature of the palpitations

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

#### PROGNOSIS

- The prognosis is dependent on the underlying etiology of the palpitations.
- SVT has an excellent prognosis. When it occurs in early infancy, 90% will respond to initial treatment. ~30% will recur at an average age of 8 yr.
- The prognosis for atrial flutter and fibrillation in neonates without structural heart disease is excellent; after conversion, these patients may need no further treatment.

#### COMPLICATIONS

- Patients with palpitations secondary to an underlying noncardiac cause are at risk for any of the complications associated with that particular disease.
- Some untreated arrhythmias can progress to unstable ventricular fibrillation and ultimate death.

## CODES

### ICD9

- 427.9 Cardiac dysrhythmia, unspecified
- 785.1 Palpitations

## PEARLS AND PITFALLS

- Palpitations are a common complaint in the pediatric population; however, this symptom is rarely associated with cardiac abnormalities.
- In the vast majority of patients with palpitations, the cause is benign, and extensive and costly investigation is not warranted.
- A thorough history and physical exam can often lead to the etiology of the symptoms.
- ECG may be the only necessary test.

# PANCREATITIS

John M. Loisel

## BASICS

### DESCRIPTION

Pancreatitis is an inflammation of the pancreas. It is differentiated into acute pancreatitis, which is a self-limited process with return of normal function, and chronic pancreatitis, resulting in irreversible damage to the pancreas and its endocrine and exocrine functions.

### EPIDEMIOLOGY

#### Incidence

- The incidence of pancreatitis in children is not reported.
- The condition is less common in children than adults.

#### Prevalence

- Pancreatitis occurs in 2% of patients with cystic fibrosis (1).
- It is equally present in males and females (2).

### RISK FACTORS

- Cystic fibrosis
- Biliary tract disease
- Family history of pancreatitis
- Medications
- Trauma

### PATHOPHYSIOLOGY

- Damage to the pancreatic acinar cells results in the early activation of digestive enzymes within the cells. This triggers an inflammatory response.
- Pancreatic damage is due to a combination of enzymatic injury and the release of cytokines from the inflammatory cascade.
- Chronic pancreatitis occurs when the inflammatory response fails to resolve:
  - Continued damage to the parenchyma through necrosis or scarring leads to endocrine and exocrine dysfunction.

### ETIOLOGY

- Acute pancreatitis is the most common form of pancreatitis in children, followed by pancreatitis associated with cystic fibrosis.
- 25% of acute pancreatitis cases in children are idiopathic (2,3).
- Hereditary pancreatitis is an autosomal dominant inherited condition and accounts for 1% of chronic pancreatitis (4).
- Etiologies are numerous but can be generally categorized into traumatic, infectious, medication related, biliary tract disease, anatomic abnormalities, hereditary, and metabolic.
- Blunt traumatic pancreatitis is the most common cause of acute pancreatitis in children (4):
  - Traumatic pancreatitis results from motor vehicle accidents, bicycle handlebar injuries, and inflicted abdominal blows in child abuse.
  - Pseudocyst formation is common following traumatic pancreatitis (4).

- Infectious causes include bacterial, viral, or parasitic.
- Common medications associated with acute pancreatitis in children include valproic acid, thiazides, sulfonamides, high-dose corticosteroids, and vincristine.
- Biliary tract disease is more common in adolescents and includes obstruction by biliary stones and sludge.
- Congenital malformations such as pancreatic divisum, choledochal cyst, annular pancreas, or congenital stenosis of the sphincter of Oddi may result in recurrent bouts of pancreatitis and lead to chronic pancreatitis.
- Pancreatic divisum is the incomplete fusion of the pancreatic ducts during embryonic development and occurs in up to 10% of the population (4).

### COMMONLY ASSOCIATED CONDITIONS

- Cystic fibrosis
- Gallstones (especially in adolescent females)

## DIAGNOSIS

### HISTORY

- Sharp, constant abdominal pain located in the epigastric area
- Pain may radiate to the back or sides
- Nausea, vomiting, and anorexia are common.
- Pain and vomiting is worse with eating.
- Abdominal trauma
- History of gallstones
- Cystic fibrosis
- Family history of pancreatitis may suggest hereditary pancreatitis.
- Medication use

### PHYSICAL EXAM

- Low-grade fever in 50% (5)
- Hypotension (uncommon)
- Tachycardia
- Mild icterus
- The abdomen is often distended with decreased bowel sounds, diffuse tenderness to deep palpation, and mild guarding.
- Pain may improve with the knees and trunk flexed.
- Grey-Turner sign: Blue discoloration of the flanks
- Cullen sign: Blue discoloration in the umbilical area:
  - Presence of the Grey-Turner or Cullen signs is suggestive of severe hemorrhagic or necrotic pancreatitis.
- Necrotizing pancreatitis is suggested by the presence of fever > 101°F, hemodynamic instability, or signs of peritonitis (3).

## DIAGNOSTIC TESTS & INTERPRETATION

### Lab

#### Initial Lab Tests

- Amylase:
  - Typically rises within hours of onset of illness and returns to normal in 4–5 days
  - Not a highly sensitive or specific marker
  - May be elevated in other conditions such as parotitis
  - Amylase isoenzymes may be useful in differentiating the etiology.
  - Levels do not correlate with the severity of illness.
- An elevated lipase level 3 times above normal has a sensitivity and specificity of 99% (1):
  - Lipase levels remain elevated for 14 days after disease onset.
- The trypsinogen level has superior sensitivity and specificity for pancreatitis but is generally not available in the acute setting.
- Additional recommended lab studies include CBC with differential, chemistry panel, BUN, glucose, calcium, liver enzymes, bilirubin, and alkaline phosphatase:
  - Leukocytosis, hyperglycemia, hypocalcemia, and elevated alkaline phosphatase, aspartate aminotransferase, alanine aminotransferase, and total bilirubin levels are common.
- Decreased pancreatic enzyme levels (amylase and lipase) and evidence of malabsorption, such as the presence of fecal fat, are suggestive of chronic pancreatitis and pancreatic dysfunction.
- Shwachman-Diamond syndrome and cystic fibrosis are often diagnosed at birth by elevated serum trypsinogen levels.

#### Imaging

- Abdominal films may be normal or include ileus, distended colon, sentinel loop of small bowel, loss of psoas margins, or a circumferential area of radiolucency surrounding the left kidney.
- Calcifications may be visible in chronic pancreatitis.
- Chest radiograph may be useful to evaluate for the presence of pleural effusions.
- US is the imaging test of choice for pancreatitis. Such imaging can assess the pancreatic size and texture and can detect pseudocysts or abscesses.
- CT is indicated for guidance in needle aspiration and drainage of a pancreatic abscess, phlegmon, or pseudocyst.

#### Diagnostic Procedures/Other

- Endoscopic retrograde cholangiopancreatography (ERCP) is the preferred study of pancreatic and biliary anatomy:
  - It is useful in detecting anatomic anomalies that may lead to recurrent pancreatitis.
  - It may also be therapeutic in performing ductal dilatation or biliary stone removal to relieve an obstruction causing pancreatitis (6).
  - ERCP is indicated in patients with chronic or recurrent pancreatitis.
- Magnetic resonance cholangiopancreatography is considered to be as sensitive as ERCP in detecting common bile duct abnormalities and common bile duct stones. It does not provide the same high resolution as endoscopic ERCP.

**Pathological Findings**

- Rarely used for diagnosis
- Pathologic findings include inflammatory infiltration, necrotic parenchyma, and blood vessels.
- Chronic pancreatitis may result in calcification.

**DIFFERENTIAL DIAGNOSIS**

- Pancreatitis is frequently confused with common causes of acute abdominal pain and vomiting, such as acute gastritis, gastroenteritis, or esophagitis.
- The diffuse nature of the pain helps to distinguish it from ovarian torsion, renal calculi, or appendicitis.
- Biliary colic
- Ulcer disease
- Cholecystitis
- Appendicitis
- Hepatitis
- Duodenal hematoma

**TREATMENT**

**INITIAL STABILIZATION/THERAPY**

- IV hydration
- Pain control
- Pancreatic rest:
  - No oral intake
  - NG suction to alleviate vomiting and ileus and reduce pancreatic stimulation
  - Parenteral nutrition if unable to feed >3 days

**MEDICATION**

**First Line**

- Opiates may worsen pain by increasing spasm of the sphincter of Oddi.
- Meperidine 1–2 mg/kg/dose, max 100 mg; minimizes enterobiliary pressure increases that may occur with opioids
- Nalbuphine 0.1 mg/kg/dose, max 20 mg

**Second Line**

- Broad-spectrum antibiotics are indicated for evidence of sepsis, pancreatic abscess, or necrotic pancreatitis.
- Pancreatic enzyme replacement and insulin are required in chronic pancreatitis associated with pancreatic insufficiency.
- Dosing of these medications must be titrated to the individual patient. Initial dosing of pancreatic enzymes in adults consists of a combination therapy including 16,000 units of lipase, 30,000 units of protease, and 30,000 units of amylase with each meal.

**SURGERY/OTHER PROCEDURES**

- Surgery is indicated for pancreatic abscess, infected pseudocyst, or infected pancreatic necrosis. Partial surgical debridement is preferred (1).
- Additional indications for surgery include intraperitoneal bleeding, biliary duct obstruction, or traumatic transection (5).

**DISPOSITION**

**Admission Criteria**

- Intractable vomiting
- Pain control
- Critical care admission criteria:
  - Hemodynamic instability
  - Hypocalcemia
  - High fever or sepsis
  - Hemorrhagic or necrotic pancreatitis

**Discharge Criteria**

- Declining enzyme levels
- Pain resolution
- Ability to maintain adequate caloric intake

**Issues for Referral**

A pediatric gastroenterologist should be consulted for cases of severe acute pancreatitis, pancreatitis with complications, and all cases of chronic or recurrent pancreatitis.

**FOLLOW-UP**

**FOLLOW-UP RECOMMENDATIONS**

**Patient Monitoring**

- While in the hospital, close monitoring of hemodynamic stability, urine output, heart rate and BP, and electrolyte balance (in particular calcium, glucose, and magnesium) is necessary.
- As an outpatient, periodic monitoring of amylase and lipase levels is recommended.

**DIET**

- NPO until abdominal pain and ileus have resolved and serum amylase levels have returned to normal
- Initial enteral feeding should be restricted to carbohydrates in order to minimize overstimulation of pancreas.

**PROGNOSIS**

- The overall prognosis is dependent on associated complications.
- Most cases of acute pancreatitis are self-limited and last 5–7 days.
- Mortality is 20–40% in the setting of hemorrhagic or necrotizing pancreatitis (2,5).
- The presence of hypocalcemia, hyperglycemia, clinical signs of shock, presence of ascites, or PaO<sub>2</sub> <60 mm Hg are signs of necrotizing or hemorrhagic pancreatitis.
- Recurrent or chronic pancreatitis is suggestive of an underlying disorder or predisposition.

**COMPLICATIONS**

- Pseudocyst formation is the most common complication of acute pancreatitis and can occur in up to 15% of children (3):
  - Pseudocyst formation is especially common following traumatic pancreatitis.
- Sepsis is the major cause of mortality associated with pancreatitis:
  - Infection can lead to pancreatic pseudocyst formation, abscess, or necrotic pancreatitis.
  - CT-guided aspiration with Gram stain and culture may be used to confirm the presence of infected necrotizing pancreatitis (3).
  - Infection is most frequently due to intestinal pathogens such as *Escherichia coli*, *Klebsiella*, or other gram-negative bacteria.

- Gastroenteritis
- Pain, Abdomen
- Vomiting

**CODES**

- ICD9
- 577.0 Acute pancreatitis
- 577.1 Chronic pancreatitis

**PEARLS AND PITFALLS**

- Abdominal pain is a common feature in pancreatitis, although tenderness may be minimal.
- Lipase is more sensitive and specific for pancreatitis than amylase and is the preferred assay.
- Opiates may worsen pain by causing spasm of the sphincter of Oddi.
- Suspect pancreatitis if pain follows abdominal trauma.
- Pancreatitis is frequently mistaken for acute gastritis.
- Pseudocyst formation is the most common complication of acute pancreatitis.

# PANIC ATTACK

Raemma Paredes Luck

## BASICS

### DESCRIPTION

- Panic attack is an acute episode of sudden, intense fear or anxiety associated with  $\geq 4$  of the following symptoms:
  - Sweating, hot flushes, or chills
  - Trembling or shaking
  - Feeling of choking
  - Shortness of breath or feeling smothered
  - Palpitations
  - Chest pain or discomfort
  - Nausea or abdominal distress
  - Feeling dizzy, light-headed, or faint
  - Paresthesias
  - Feelings of unreality or detachment to one's self
  - Fear of losing control or going crazy
  - Fear of dying
- The majority of episodes reach a peak within 10 min and last for  $\sim 30$  min.
- The most common presentation of a panic attack is hyperventilation, characterized by an acute episode of rapid and shallow breathing, accompanied by somatic symptoms such as palpitations, tingling of the hands and mouth, feeling faint, and abdominal discomfort.
- In contrast, panic disorder is a psychiatric condition that is characterized by recurrent panic attacks in association with at least 1 mo duration of excessive worry, change in behavior due to an impending attack, and avoidance of situations that may lead to future panic attacks.

### EPIDEMIOLOGY

#### Incidence

The onset of panic attacks is common during late adolescent years.

#### Prevalence

- As many as 23% of the population has had 1 panic attack in their lifetime.
- Females are affected twice as often as males.

### RISK FACTORS

- Significant life stressors such as death of a loved one, illness, birth of a child, sexual abuse, or trauma can increase the risk of developing a panic attack.
- A family history of panic or anxiety disorder also increases the risk of developing a panic disorder.

### PATHOPHYSIOLOGY

- Hyperventilation-induced alkalosis causes vasoconstriction. Diminished blood flow to the brain leads to a sensation of light-headedness.
- Alkalinization of plasma proteins such as albumin increases their calcium binding. The subsequent reduction in free ionized calcium levels can cause paresthesias and tetany.

### ETIOLOGY

Recurrent panic attacks are believed to be due to increased sensitivity of the areas of the brain that control fear responses, such as the prefrontal cortex and limbic system, to certain neurotransmitters such as serotonin, norepinephrine, and GABA.

### COMMONLY ASSOCIATED CONDITIONS

- Phobias
- Substance abuse
- Asthma
- Migraine headaches
- Posttraumatic stress disorder
- Depression
- Obsessive-compulsive disorder

## DIAGNOSIS

### HISTORY

- Episodes of sudden onset of intense fear or anxiety associated with severe somatic symptoms
- Episodes often partially or completely resolved by the time the patients are seen in the emergency department
- Inquire if the patient has had similar previous episodes:
  - A history of excessive and extensive use of medical resources such as frequent emergency department visits and hospitalizations without an organic etiology being uncovered should heighten suspicion of a panic disorder.
- Inquire about suicidal or homicidal ideations, hallucinations, depression, or medication use or withdrawal.
- A panic attack associated with agoraphobia is highly suggestive of a panic disorder.

### PHYSICAL EXAM

- Physical exam is usually normal other than tachypnea/hyperventilation but may show signs of increased sympathetic or autonomic activity:
  - Tachycardia
  - Sweating
  - Hypertension
- Patients who are hyperventilating may show signs of hypocalcemia from acute respiratory alkalosis.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

- Lab testing is often not necessary when panic attacks are recognized by the physician.
- Panic attacks can be misleading and mimic life-threatening conditions.
- The workup depends on the predominant presenting symptom and is performed to rule out other medical disorders.
- Commonly obtained tests include:
  - Electrolytes including calcium
  - CBC
  - Thyroid function studies
  - ECG

#### Diagnostic Procedures/Other

- Consider EEG to rule out a seizure.
- Consider echo to rule out structural cardiac abnormality.

### DIFFERENTIAL DIAGNOSIS

- Hypoglycemia
- Drug abuse
- Pheochromocytoma
- Cardiac dysrhythmia
- Hyperthyroidism
- Hyperparathyroidism
- Transient ischemic attacks
- Seizure
- Asthma
- Pulmonary embolus
- Major depression
- Anxiety disorder
- Somatization disorder
- Phobias
- Neuroleptics
- DKA
- Aspirin overdose

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Address issues of airway, breathing, and circulation according to Pediatric Advanced Life Support (PALS) guidelines.
- Provide reassurance by addressing the patient's specific fears.
- Hyperventilation with symptoms of hypocalcemia may be treated with rebreathing into a paper/plastic bag until improvement.

### MEDICATION

- Children with panic attacks rarely require medications, although benzodiazepines may be helpful:
  - Alprazolam 0.5 mg/dose PO in adolescents; children <40 kg use initial dose of 0.005 mg/kg PO
  - Clonazepam: Same dosing as alprazolam
  - Lorazepam 1 mg/dose PO in adolescents; children <40 kg use initial dose of 0.01 mg/kg PO
- Patients with recurrent panic attacks may benefit from long-term treatment with a selective serotonin reuptake inhibitor (SSRIs).

### DISPOSITION

#### Admission Criteria

- Patients with panic attacks who are suicidal, homicidal, or severely depressed need psychiatric admission.
- Hospitalization may also be necessary to evaluate for organic etiology.

#### Discharge Criteria

- Most patients with panic attacks do not require hospitalization.
- Patients can be safely discharged home when they are determined to not be suicidal or homicidal and life-threatening medical conditions have been ruled out.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Counsel the patient on how to recognize and adjust to anxiety-provoking events.
- Teach the patient some relaxation techniques to slow the breathing during the acute attack.
- Patients with recurrent panic attacks or panic disorder will benefit from either cognitive behavioral therapy or pharmacologic treatment. Both are equally effective in controlling symptoms.

### PROGNOSIS

- Panic attacks often become recurrent.
- Panic attacks significantly increase the risk of the subsequent development of mental disorders in young adults such as anxiety disorder, depression, phobias, and substance abuse disorder.

- Anxiety Disorders Association of America: <http://www.adaa.org>
- National Institute of Mental Health: <http://www.nimh.nih.gov/health/topics/anxiety-disorders/index.shtml>

## CODES

### ICD9

- 300.01 Panic disorder
- 308.0 Predominant disturbance of emotions

### PEARLS AND PITFALLS

- Panic attacks can mimic other life-threatening conditions.
- Panic disorder should be considered in patients with recurring symptoms but normal medical evaluations.
- Patients with recurrent panic attacks should be evaluated for an underlying psychiatric condition.

# PANNICULITIS

Kate Cronan

## BASICS

### DESCRIPTION

- Panniculitis is a disorder marked by inflammation in the subcutaneous fat.
- Cold panniculitis is characterized by benign localized lesions of the skin that occur after prolonged exposure to cold substances.
- Cold panniculitis is most common in infants and young children.
- The lesions are usually located on each facial cheek, as in popsicle panniculitis.
- Cold panniculitis can also occur from contact points of cooling blankets and on the thighs and buttocks of young equestrians (1).

### Incidence

- The incidence of panniculitis in children is unknown.
- More common in infants and young children
- No difference in gender (1)

### RISK FACTORS

- Exposure of the skin to localized cold substances for prolonged periods (eg, popsicles, teething rings, ice bags used to treat supraventricular tachycardia) (2)
- Primarily seen in infants and young children

### GENERAL PREVENTION

Avoid prolonged exposure of infant and toddler skin to cold substances.

### PATHOPHYSIOLOGY

Increased propensity of fat to solidify in younger infants when skin is exposed to lower temperatures (2)

### ETIOLOGY

- Prolonged exposure of infants' and toddlers' skin to cold substances
- No microorganisms are involved in the etiology.

## DIAGNOSIS

### HISTORY

- Symptoms include red to bluish areas on the face and pain when these areas are touched.
- History of prolonged exposure to cold substances such as frozen teething rings, ice cubes, or popsicles
- Lesions arise within hours to a couple of days after cold exposure.
- Lesions last for several weeks to several months.
- There may be a history of having the same problem previously.
- Inquire about trauma or insect bites.
- Inquire about prior history of skin abscess or furunculosis.
- No history of fever or reports of systemic illness

### PHYSICAL EXAM

- Erythematous and bluish indurated plaques or nodules on 1 or both facial cheeks, buttocks, thighs, or other exposed skin
- Mildly tender when palpated
- In contrast to cellulitis, no increased warmth of the skin
- Afebrile
- Well appearing

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- Panniculitis is a clinical diagnosis.
- No lab tests are indicated unless there is concern for buccal cellulitis or other skin infection. In this case, a blood culture is warranted.

##### Pathological Findings

- Characterized by a lobular panniculitis, which consists of an infiltrate of lymphocytes and histiocytes within the fat lobules
- There is a superficial and deep perivascular infiltrate in the dermis (1).

### DIFFERENTIAL DIAGNOSIS

- Buccal cellulitis
- Chilblains (pernio) frostbite
- Bruises
- Insect bites or bee stings
- If associated with unilateral cheek or facial swelling, abscess, dental infection, and parotitis should be considered.

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- Treatment is supportive, particularly to minimize pain or discomfort.
- No antibiotics are indicated.

### MEDICATION

- Acetaminophen 15 mg/kg/dose PO/PR q4h PRN
- Ibuprofen 10 mg/kg/dose PO/IV q6h PRN

### DISPOSITION

#### Discharge Criteria

Discharge if there are no concerns for facial or other forms of cellulitis.

## FOLLOW-UP

### FOLLOW-UP RECOMMENDATIONS

- Follow up with the primary care provider if lesions do not resolve in 2–3 mo.
- Reassurance
- Provide education regarding avoiding prolonged exposure to cold objects.

### PROGNOSIS

- Temporary residual hyperpigmentation
- No permanent sequelae

- 729.39 Panniculitis affecting other sites

## PEARLS AND PITFALLS

- Bilateral erythematous lesions on the face are unlikely to be due to infection.
- Cold panniculitis tends to occur in the cheeks and chin in infants because these areas are rich in subcutaneous fat and most exposed to cold.
- Children with cold panniculitis are usually healthy and well appearing and do not require intervention.
- If the infant or child is underimmunized and has a unilateral, erythematous, tender area of facial swelling, consider buccal cellulitis.

# PARAPHIMOSIS

Jennifer Adu-Frimpong

## BASICS

### DESCRIPTION

- Paraphimosis is the occurrence of foreskin retraction that cannot be returned to the normal resting position.
- Often, the precipitant is retraction of the foreskin for cleaning by a caregiver.
- This can become a urologic emergency in which foreskin distal swelling results and ultimately ischemic changes may ensue (1).

### EPIDEMIOLOGY

#### Prevalence

- Paraphimosis occurs in uncircumcised or partially circumcised individuals and can occur at any age.
- More common in adolescence. In the U.S., paraphimosis occurs in ~1% of males > 16 yr of age (2).

### RISK FACTORS

- Only occurs in uncircumcised males
- Bacterial infection (eg, balanoposthitis)
- Catheterization (ie, if the foreskin is not returned to its original position after a urethral catheter is inserted)
- Poor hygiene
- Trauma
- Adolescents may present with paraphimosis in the setting of vigorous sexual activity.
- Penile body piercing (3)

### PATHOPHYSIOLOGY

- Foreskin is retracted behind the coronal sulcus of the glans penis and cannot return to its original position
- Distal vascular engorgement and edema occurs at the glans and prepuce.

### ETIOLOGY

- Often involves a predisposing condition such as infection or trauma in an uncircumcised male.
- In sexually mature males, erection may result in paraphimosis, as may failure to return the foreskin over the glans after sex.

## DIAGNOSIS

### HISTORY

- Penile pain
- Penile erythema and swelling
- Dysuria
- Urinary retention (especially if long-standing phimosis)
- Hematuria
- Inquire about penile manipulation, instrumentation, or endoscopic surgery of the bladder or urethra.
- Any history of self-retraction should also be elicited.
- Since changes in skin texture and color from swelling often make it difficult to determine if the penis has been circumcised, it should be noted whether or not the patient is circumcised or partially circumcised.

### PHYSICAL EXAM

- The physical exam should focus on the penis and scrotum.
- The penis should be inspected for the presence of foreskin, the color of the glans, the degree of constriction around the penile corona, and turgor of the prepuce.
- The foreskin usually forms a tight, constricting ring around the glans and cannot be retracted.
- Physical exam distinguishes paraphimosis from phimosis. Phimosis is an inability to retract the foreskin from the head of the penis; there is no constricting ring.
- Flaccidity of the penile shaft proximal to the area of paraphimosis is seen (unless there is accompanying balanoposthitis or infection of the penis).
- Absence of foreskin excludes the diagnosis of paraphimosis.
- A pink or salmon hue to the glans indicates a good blood supply. If the glans or prepuce appears to be black, necrosis has begun.
- Penile necrosis should be suspected if palpation of the glans reveals firmness and inelasticity along with black discoloration.
- Scrotal skin should be inspected for color, texture, and turgor. Scrotal contents should be palpated for tenderness, hydrocele, or tumor.

## DIAGNOSTIC TESTS & INTERPRETATION

Paraphimosis is a clinical diagnosis. No lab tests or imaging are needed.

## DIFFERENTIAL DIAGNOSIS

- Phimosis
- Priapism
- Hair tourniquet
- Angioedema
- Balanitis
- Anasarca
- Insect bites
- Penile hematoma
- Penile fracture

## TREATMENT

### INITIAL STABILIZATION/THERAPY

- The goal of treatment is to return the glans within the foreskin.
- To do so, penile edema must be reduced enough to allow the foreskin to return to its original position.
- Various reduction techniques have been described, but comparative clinical trials have not been conducted:
  - All techniques may require procedural sedation and/or analgesia (4,5).
- Manual reduction is the least invasive method of reduction:
  - The clinician places a thumb on the glans and fingers behind the retracted prepuce. Slow, steady pressure is exerted to reduce swelling and push the foreskin over the coronal sulcus (6).
  - The head of the penis must be squeezed very tightly between thumb and forefinger. This forces blood out of the head and reduces the size. The foreskin can then be brought forward to its normal position.
- In addition, application of ice packs has been known to allow swelling to decrease and may increase the success rate of manual reduction. Ice packs are also useful in reducing swelling of the penis and prepuce (7):
  - The penis is 1st wrapped in plastic, with ice packs applied intermittently until the swelling subsides.
  - To reduce edema, a compressive elastic dressing is then wrapped circumferentially around the penis from the glans to the base.
  - This dressing should be left in place for 5–7 min (8).
  - The penis should be checked periodically to monitor the resolution of swelling. Once the swelling has subsided, the wrap should be removed.

**Second Line**

- Aspiration-puncture methods, one originally described as the Dundee-Perth technique, involve expressing fluid from multiple puncture holes.
- The holes are created with a 21-gauge needle, inserted in the edematous foreskin, after a regional, ring-block penile anesthesia (6).

**COMPLEMENTARY & ALTERNATIVE THERAPIES**

- Several other methods to effectively reduce the edema prior to reduction of the foreskin have been described in the literature.
- Osmotic agents, such as sugar and hyaluronidase, may help to reduce swelling (9,10):
  - Injection of hyaluronidase into the edematous prepuce is effective in resolving edema and allowing the foreskin to be easily reduced.
  - Degradation of hyaluronic acid by hyaluronidase enhances diffusion of trapped fluid between the tissue planes to decrease the preputial swelling.
  - Hyaluronidase is well suited for use in infants and children.
  - Granulated sugar has shown to be effective in the treatment of paraphimosis, based on the principle of fluid transfer occurring through osmotic gradient.
  - Granulated sugar is generously spread on the surface of the edematous prepuce and glans. The hypotonic fluid from the edematous prepuce is drawn out by the sugar, reducing the swelling and allowing for manual reduction.
  - The disadvantage of using osmotic agents is that it takes a longer time to achieve reduction compared to other techniques.

**SURGERY/OTHER PROCEDURES**

If less invasive therapy fails, an emergency dorsal slit should be performed:

- This procedure should be performed with the use of a local anesthetic by a physician experienced with the technique.
- The penis and prepuce are prepared with a povidone-iodine solution.
- 2 straight hemostats are applied to crush the foreskin at the 12 o'clock position perpendicular to the corona.
- After 2 min, the prepuce between the hemostats is sharply incised, releasing the constricting band of tissue. The incisions are approximated with 4-0 absorbable suture.
- Circumcision, a definitive therapy, should be performed at a later date to prevent recurrent episodes, regardless of the method of reduction used.

**DISPOSITION****Admission Criteria**

Patients who require surgery due to failure of minimally invasive methods of reduction should be admitted for observation.

**Issues for Referral**

Patients may need to be referred to a urologist for evaluation for circumcision.

**FOLLOW-UP****FOLLOW-UP RECOMMENDATIONS**

- Patients generally have a follow-up exam in 2–3 wk to check the wound after a dorsal split procedure.
- Outcome after a dorsal slit procedure or a circumcision is excellent.

**PROGNOSIS**

- Full recovery from paraphimosis is expected with prompt treatment.
- Paraphimosis does not recur after a proper circumcision.

**COMPLICATIONS**

- Infection
- Necrosis
- Hemorrhage after surgical treatment

**ICD9**  
605 Redundant prepuce and phimosis

**PEARLS AND PITFALLS**

- Delays in diagnosis of paraphimosis may lead to tissue necrosis.
- Unlike phimosis, paraphimosis is a urologic emergency.
- Urinary retention is a late finding and warrants immediate reduction by whatever means necessary.

# PARONYCHIA

Sandra H. Schwab

## BASICS

### DESCRIPTION

Paronychia is infection with associated inflammation of the skin and soft tissue adjacent to the cuticle and nail edge:

- Paronychia can occur on any of the digits.
- Paronychia is usually acute but may be chronic.
- Pus may or may not be present.

### EPIDEMIOLOGY

#### Incidence

Although the exact incidence is unknown, paronychia is one of the most common infections of the hand.

### RISK FACTORS

- Poor nail hygiene
- Nail biting
- Trimming nails too closely to the skin
- Onychocryptosis: "Ingrown nail"
- Chronic diseases such as diabetes
- Treatment with protease inhibitors
- Occupations where fluids or irritants are used

### GENERAL PREVENTION

- Avoidance of nail biting or finger sucking
- Avoidance of artificial nails
- Use of gloves when appropriate

### PATHOPHYSIOLOGY

Disruption of the seal between the eponychium (cuticle) and the nail plate serves as an entry point for infectious organisms:

- Initially, this results in inflammation and a simple cellulitis or eponychia.
- As the infection progresses, a collection of pus under the cuticle and around the nail edge forms a paronychia.

### ETIOLOGY

- Acute paronychia is usually bacterial in origin:
  - Staphylococcal and streptococcal organisms are the most frequent causes of infection.
  - Other causes include *Bacteroides* and *Fusobacterium* species as well as *Klebsiella pneumoniae* and *Eikenella corrodens* (1,2).
- Chronic paronychia may be caused by yeast, fungus, or an irritant:
  - *Candida albicans* is found in 15% of cases (1,2).
- Rarely, paronychia may result from vitamin deficiency or malignancy.

### COMMONLY ASSOCIATED CONDITIONS

Children and adolescents with insulin-dependent diabetes mellitus are at higher risk of getting paronychia (3).

## DIAGNOSIS

### HISTORY

- Patients usually give a history of acute onset of digit pain, redness, and swelling around the edge of the nail.
- Because this is a localized process, systemic symptoms such as fever are rarely present.
- Trauma may precede the onset of digital swelling.
- Inquire about nail-biting behavior.

### PHYSICAL EXAM

- Erythema, warmth, and edema around the nail are usually present.
- A collection of purulent material may be visible under the epidermis.
- Signs of poor nail hygiene such as nail biting or artificial nails should be noted.

- Careful exam to rule out felon (abscess of the pulp space) and tenosynovitis is important:
  - A tense digital pad as well as diffuse edema, erythema, and pain of the fingertip are found with a felon.
  - Tenosynovitis results in sausage-like swelling of a digit held in partial flexion, pain with passive extension, and tenderness along the palmar tendon sheath.
- Herpetic whitlow is distinguished from paronychia by the presence of grouped vesicles on an intensely painful, swollen digit.

### DIAGNOSTIC TESTS & INTERPRETATION

#### Lab

##### Initial Lab Tests

- For simple acute paronychia, no lab tests are needed.
- For chronic paronychia or those unresponsive to treatment, a culture of the area should be obtained.

#### Imaging

A radiograph of the affected digit should be considered to evaluate for underlying fracture or osteomyelitis if there is a clear history of trauma or the paronychia is unresponsive to usual therapy.

### DIFFERENTIAL DIAGNOSIS

- Felon
- Cellulitis
- Herpetic whitlow
- Contact dermatitis
- Trauma
- Fracture
- Other, rare diagnoses include vitamin deficiencies, neoplasms, or granulomas.

## TREATMENT

### MEDICATION

#### First Line

Antistaphylococcal and antistreptococcal antibiotics should be considered if there is a significant cellulitis.

#### Second Line

Antifungal agents are useful in treatment of chronic paronychia.

### COMPLEMENTARY & ALTERNATIVE THERAPIES

Warm soaks and gentle manual compression may be sufficient to treat the paronychia.

### SURGERY/OTHER PROCEDURES

Incision and drainage is recommended if the paronychia is associated with pus that does not drain with warm soaks and manual compression:

- Simple incision and drainage can be performed in the following manner:
  - Soak the digit in a warm solution containing an antibacterial agent such as povidone-iodine.
  - Restrain the child as necessary.
  - Anesthetize the area if indicated with a topical anesthetic such as ethyl chloride or local digital block.
  - Position the scalpel blade parallel to the nail. Enter the skin between the nail edge and the cuticle, lifting the skin away from the nail when possible. Make a small incision at the area of greatest fluctuance.
  - Express the purulent material.
  - Apply a clean dressing.
  - Eponychial marsupialization and nail removal may be necessary for chronic paronychia.

### DISPOSITION

#### Admission Criteria

Patients with simple paronychia do not require admission to the hospital.

#### Issues for Referral

Patients requiring therapeutic nail removal should be referred to an appropriate surgical subspecialist or podiatrist.

## FOLLOW-UP

### PROGNOSIS

Complete resolution with normal nail growth is the usual course for patients with paronychia.

### COMPLICATIONS

Nail irregularities may result from chronic paronychia.

### CODES

#### ICD9

681.02 Onychia and paronychia of finger

## PEARLS AND PITFALLS

- Patients with chronic paronychia likely have an irritant exposure or fungal etiology.
- Careful exam to rule out felon or tenosynovitis is important.
- Routine and careful exam of the hands and feet of immunocompromised children and those with diabetes mellitus is necessary.

# PAROTITIS

Sujit Iyer

## BASICS

### DESCRIPTION

- Parotitis is inflammation of the parotid glands, small exocrine glands, most commonly caused by infection.
- Other causes include noninfectious systemic disease, trauma, obstruction, or a combination of these factors
- Acute bacterial parotitis can be rapidly progressive and fatal in neonates.
- Inflammation of the parotid can cause lifting of the earlobe upward and outward and obscure the angle of the mandible.

### EPIDEMIOLOGY

Disease due to the mumps virus is the most common cause of parotitis:

- Prior to vaccination, the incidence of mumps peaked at 250 per 100,000 (1). By 1985, this was reduced to 1.1 per 100,000 due to vaccination (1).
- In 2006, the largest mumps outbreak in 20 yr led to a national incidence of 2.2 per 100,000, thought due mainly to 2-dose vaccine failure (1).
- In 2010, a mumps outbreak originating in the New York City area resulted in thousands of cases. The index case was an unimmunized American child returning from Britain.

### RISK FACTORS

Factors that decrease or interrupt the flow of saliva:

- Dehydration
- Poor oral hygiene
- Oral trauma
- Xerostomia (dry mouth)
- Ductal obstruction (sialolithiasis)
- Drugs (anticholinergics, antihistamines, phenothiazines, iodide drugs)
- Chronic systemic diseases: Sjögren, diabetes mellitus, cystic fibrosis, chronic liver disease
- Malnutrition
- Neoplasms of oral cavity
- Exposure to ionizing radiation
- Tracheostomy
- Immunosuppression

### GENERAL PREVENTION

- Ensuring normal flow of saliva through the duct
- Routine immunization against mumps

### PATHOPHYSIOLOGY

- Mumps: Viral infection with parotid swelling as 1 of several symptoms
- Bacterial: Reduced salivary flow leads to ascending oral bacterial contamination of the parotid.
- Recurrent chronic parotitis:
  - Most commonly due to stones
  - Can lead to progressive acinar destruction with fibrous replacement and sialectasis (dilation of duct)
  - Destruction of normal architecture can lead to stasis of saliva and proliferation of bacteria.
