Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

TERMS OF USE

Neither McGraw-Hill Education nor its licensors shall be liable to you or anyone else for any inaccuracy, error or omission, regardless of cause, in the work or for any damages resulting therefrom. McGraw-Hill Education has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill Education and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

Approach to the Surgical Patient

J. Englebert Dunphy, MD*
Lawrence W. Way, MD

1

The management of surgical disorders requires not only the application of technical skills and training in the basic sciences to the problems of diagnosis and treatment but also a genuine sympathy and indeed love for the patient. The surgeon must be a doctor in the old-fashioned sense, an applied scientist, an engineer, an artist, and a minister to his or her fellow human beings. Because life or death often depends upon the validity of surgical decisions, the surgeon's judgment must be matched by courage in action and by a high degree of technical proficiency.

THE HISTORY

At their first contact, the surgeon must gain the patient's confidence and convey the assurance that help is available and will be provided. The surgeon must demonstrate concern for the patient as a person who needs help and not just as a "case" to be processed. This is not always easy to do, and there are no rules of conduct except to be gentle and considerate. Most patients are eager to like and trust their doctors and respond gratefully to a sympathetic and understanding person. Some surgeons are able to establish a confident relationship with the first few words of greeting; others can only do so by means of a stylized and carefully acquired bedside manner. It does not matter how it is done, so long as an atmosphere of sympathy, personal interest, and understanding is created. Even under emergency circumstances, this subtle message of sympathetic concern must be conveyed.

Eventually, all histories must be formally structured, but much can be learned by letting the patient ramble a little. Discrepancies and omissions in the history are often due as much to overstructuring and leading questions as to the unreliability of the patient. The enthusiastic novice asks leading questions; the cooperative patient gives the answer

that seems to be wanted; and the interview concludes on a note of mutual satisfaction with the wrong answer thus developed.

BUILDING THE HISTORY

History taking is detective work. Preconceived ideas, snap judgments, and hasty conclusions have no place in this process. The diagnosis must be established by inductive reasoning. The interviewer must first determine the facts and then search for essential clues, realizing that the patient may conceal the most important symptom—for example, the passage of blood by rectum—in the hope (born of fear) that if it is not specifically inquired about or if nothing is found to account for it in the physical examination, it cannot be very serious.

Common symptoms of surgical conditions that require special emphasis in the history taking are discussed in the following paragraphs.

► Pain

A careful analysis of the nature of pain is one of the most important features of a surgical history. The examiner must first ascertain how the pain began. Was it explosive in onset, rapid, or gradual? What is the precise character of the pain? Is it so severe that it cannot be relieved by medication? Is it constant or intermittent? Are there classic associations, such as the rhythmic pattern of small bowel obstruction or the onset of pain preceding the limp of intermittent claudication?

One of the most important aspects of pain is the patient's reaction to it. The overreactor's description of pain is often obviously inappropriate, and so is a description of "excruciating" pain offered in a casual or jovial manner. A patient who shrieks and thrashes about is either grossly overreacting or suffering from renal or biliary colic. Very severe pain—due to infection, inflammation, or vascular disease—usually forces the patient to restrict all movement as much as possible.

*Deceased

Moderate pain is made agonizing by fear and anxiety. Reassurance of a sort calculated to restore the patient's confidence in the care being given is often a more effective analgesic than an injection of morphine.

► Vomiting

What did the patient vomit? How much? How often? What did the vomitus look like? Was vomiting projectile? It is especially helpful for the examiner to see the vomitus.

► Change in Bowel Habits

A change in bowel habits is a common complaint that is often of no significance. However, when a person who has always had regular evacuations notices a distinct change, particularly toward intermittent alternations of constipation and diarrhea; colon cancer must be suspected. Too much emphasis is placed upon the size and shape of the stool—for example, many patients who normally have well-formed stools may complain of irregular small stools when their routine is disturbed by travel or a change in diet.

► Hematemesis or Hematochezia

Bleeding from any orifice demands the most critical analysis and can never be dismissed as due to some immediately obvious cause. The most common error is to assume that bleeding from the rectum is attributable to hemorrhoids. The character of the blood can be of great significance. Does it clot? Is it bright or dark red? Is it changed in any way, as in the coffee-ground vomitus of slow gastric bleeding or the dark, tarry stool of upper gastrointestinal bleeding? The full details and variations cannot be included here but will be emphasized under separate headings elsewhere.

► Trauma

Trauma occurs so commonly that it is often difficult to establish a relationship between the chief complaint and an episode of trauma. Children in particular are subject to all kinds of minor trauma, and the family may attribute the onset of an illness to a specific recent injury. On the other hand, children may be subjected to severe trauma though their parents are unaware of it. The possibility of trauma having been inflicted by a parent must not be overlooked.

When there is a history of trauma, the details must be established as precisely as possible. What was the patient's position when the accident occurred? Was consciousness lost? Retrograde amnesia (inability to remember events just preceding the accident) always indicates some degree of cerebral damage. If a patient can remember every detail of an accident, has not lost consciousness, and has no evidence of external injury to the head, brain damage can be excluded.

In the case of gunshot wounds and stab wounds, knowing the nature of the weapon, its size and shape, the

probable trajectory, and the position of the patient when hit may be very helpful in evaluating the nature of the resultant injury.

The possibility that an accident might have been caused by preexisting disease such as epilepsy, diabetes, coronary artery disease, or hypoglycemia must be explored.

When all of the facts and essential clues have been gathered, the examiner is in a position to complete the study of the present illness. By this time, it may be possible to rule out (by inductive reasoning) all but a few diagnoses. A novice diagnostician asked to evaluate the causes of shoulder pain in a given patient might include ruptured ectopic pregnancy in the list of possibilities. The experienced physician will automatically exclude that possibility on the basis of gender or age.

► Family History

The family history is of great significance in a number of surgical conditions. Polyposis of the colon is a classic example, but diabetes, Peutz-Jeghers syndrome, chronic pancreatitis, multiglandular syndromes, other endocrine abnormalities, and cancer are often better understood and better evaluated in the light of a careful family history.

► Past History

The details of the past history may illuminate obscure areas of the present illness. It has been said that people who are well are almost never sick, and people who are sick are almost never well. It is true that a patient with a long and complicated history of diseases and injuries is likely to be a much poorer risk than even a very old patient experiencing a major surgical illness for the first time.

In order to make certain that important details of the past history will not be overlooked, the system review must be formalized and thorough. By always reviewing the past history in the same way, the experienced examiner never omits significant details. Many skilled examiners find it easy to review the past history by inquiring about each system as they perform the physical examination on that part of the body.

In reviewing the past history, it is important to consider the nutritional background of the patient. There is a clear awareness throughout the world that the underprivileged malnourished patient responds poorly to disease, injury, and operation. Malnourishment may not be obvious on physical examination and must be elicited by questioning.

Acute nutritional deficiencies, particularly fluid and electrolyte losses, can be understood only in the light of the total (including nutritional) history. For example, low serum sodium may be due to the use of diuretics or a sodium-restricted diet rather than to acute loss. In this connection, the use of any medications must be carefully recorded and interpreted.

A detailed history of acute losses by vomiting and diarrhea—and the nature of the losses—is helpful in estimating the probable trends in serum electrolytes. Thus, the patient who has been vomiting persistently with no evidence of bile in the vomitus is likely to have acute pyloric stenosis associated with benign ulcer, and hypochloremic alkalosis must be anticipated. Chronic vomiting without bile—and particularly with evidence of changed and previously digested food—is suggestive of chronic obstruction, and the possibility of carcinoma should be considered.

It is essential for the surgeon to think in terms of nutritional balance. It is often possible to begin therapy before the results of laboratory tests have been obtained, because the specific nature and probable extent of fluid and electrolyte losses can often be estimated on the basis of the history and the physician's clinical experience. Laboratory data should be obtained as soon as possible, but knowledge of the probable level of the obstruction and of the concentration of the electrolytes in the gastrointestinal fluids will provide sufficient grounds for the institution of appropriate immediate therapy.

► The Patient's Emotional Background

Psychiatric consultation is seldom required in the management of surgical patients, but there are times when it is of great help. Emotionally and mentally disturbed patients require surgical operations as often as others, and full cooperation between psychiatrist and surgeon is essential. Furthermore, either before or after an operation, a patient may develop a major psychotic disturbance that is beyond the ability of the surgeon to appraise or manage. Prognosis, drug therapy, and overall management require the participation of a psychiatrist.

On the other hand, there are many situations in which the surgeon can and should deal with the emotional aspects of the patient's illness rather than resorting to psychiatric assistance. Most psychiatrists prefer not to be brought in to deal with minor anxiety states. As long as the surgeon accepts the responsibility for the care of the whole patient, such services are superfluous.

This is particularly true in the care of patients with malignant disease or those who must undergo mutilating operations such as amputation of an extremity, ileostomy, or colostomy. In these situations, the patient can be supported far more effectively by the surgeon and the surgical team than by a consulting psychiatrist.

Surgeons are increasingly aware of the importance of psychosocial factors in surgical convalescence. Recovery from a major operation is greatly enhanced if the patient is not worn down with worry about emotional, social, and economic problems that have nothing to do with the illness itself. Incorporation of these factors into the record contributes to better total care of the surgical patient.

THE PHYSICAL EXAMINATION

The complete examination of the surgical patient includes the physical examination, certain special procedures such as gastroscopy and esophagoscopy, laboratory tests, x-ray examination, and follow-up examination. In some cases, all of these may be necessary; in others, special examinations and laboratory tests can be kept to a minimum. It is just as poor practice to insist on unnecessary thoroughness as it is to overlook procedures that may contribute to the diagnosis. Painful, inconvenient, and costly procedures should not be ordered unless there is a reasonable chance that the information gained will be useful in making clinical decisions.

THE ELECTIVE PHYSICAL EXAMINATION

The elective physical examination should be done in an orderly and detailed fashion. One should acquire the habit of performing a complete examination in exactly the same sequence, so that no step is omitted. When the routine must be modified, as in an emergency, the examiner recalls without conscious effort what must be done to complete the examination later. The regular performance of complete examinations has the added advantage of familiarizing the beginner with what is normal so that what is abnormal can be more readily recognized.

All patients are sensitive and somewhat embarrassed at being examined. It is both courteous and clinically useful to put the patient at ease. The examining room and table should be comfortable, and drapes should be used if the patient is required to strip for the examination. Most patients will relax if they are allowed to talk a bit during the examination, which is another reason for taking the past history while the examination is being done.

A useful rule is to first observe the patient's general physique and habitus and then to carefully inspect the hands. Many systemic diseases show themselves in the hands (cirrhosis of the liver, hyperthyroidism, Raynaud disease, pulmonary insufficiency, heart disease, and nutritional disorders).

Details of the examination cannot be included here. The beginner is urged to consult special texts.

Inspection, palpation, and auscultation are the time-honored essential steps in appraising both the normal and the abnormal. Comparison of the two sides of the body often suggests a specific abnormality. The slight droop of one eyelid characteristic of Horner syndrome can only be recognized by comparison with the opposite side. Inspection of the female breasts, particularly as the patient raises and lowers her arms, will often reveal slight dimpling indicative of an infiltrating carcinoma barely detectable on palpation.

Successful palpation requires skill and gentleness. Spasm, tension, and anxiety caused by painful examination procedures may make an adequate examination almost impossible, particularly in children.

Another important feature of palpation is the laying on of hands that has been called part of the ministry of medicine. A disappointed and critical patient often will say of a doctor, “He hardly touched me.” Careful, precise, and gentle palpation not only gives the physician the information being sought but also inspires confidence and trust.

When examining for areas of tenderness, it may be necessary to use only one finger in order to precisely localize the extent of the tenderness. This is of particular importance in examination of the acute abdomen.

Auscultation, once thought to be the exclusive province of the physician, is now more important in surgery than it is in medicine. Radiologic examinations, including cardiac catheterization, have relegated auscultation of the heart and lungs to the status of preliminary scanning procedures in medicine. In surgery, however, auscultation of the abdomen and peripheral vessels has become absolutely essential. The nature of ileus and the presence of a variety of vascular lesions are revealed by auscultation. Bizarre abdominal pain in a young woman can easily be ascribed to hysteria or anxiety on the basis of a negative physical examination and x-rays of the gastrointestinal tract. Auscultation of the epigastrium, however, may reveal a murmur due to obstruction of the celiac artery.

► Examination of the Body Orifices

Complete examination of the ears, mouth, rectum, and pelvis is accepted as part of a complete examination. Palpation of the mouth and tongue is as essential as inspection. Every surgeon should acquire familiarity with the use of the ophthalmoscope and sigmoidoscope and should use them regularly in doing complete physical examinations.

THE EMERGENCY PHYSICAL EXAMINATION

In an emergency, the routine of the physical examination must be altered to fit the circumstances. The history may be limited to a single sentence, or there may be no history if the patient is unconscious and there are no other informants. Although the details of an accident or injury may be very useful in the total appraisal of the patient, they must be left for later consideration. The primary considerations are the following: Is the patient breathing? Is the airway open? Is there a palpable pulse? Is the heart beating? Is massive bleeding occurring?

If the patient is not breathing, airway obstruction must be ruled out by thrusting the fingers into the mouth and pulling the tongue forward. If the patient is unconscious, the respiratory tract should be intubated and mouth-to-mouth respiration started. If there is no pulse or heartbeat, start cardiac resuscitation.

Serious external loss of blood from an extremity can be controlled by elevation and pressure. Tourniquets are rarely required.

Every victim of major blunt trauma should be suspected of having a vertebral injury capable of causing damage to the spinal cord unless rough handling is avoided.

Some injuries are so life threatening that action must be taken before even a limited physical examination is done. Penetrating wounds of the heart, large open sucking wounds of the chest, massive crush injuries with flail chest, and massive external bleeding all require emergency treatment before any further examination can be done.

In most emergencies, however, after it has been established that the airway is open, the heart is beating, and there is no massive external hemorrhage—and after antishock measures have been instituted, if necessary—a rapid survey examination must be done. Failure to perform such an examination can lead to serious mistakes in the care of the patient. It takes no more than 2 or 3 minutes to carefully examine the head, thorax, abdomen, extremities, genitalia (particularly in females), and back. If cervical cord damage has been ruled out, it is essential to turn the injured patient and carefully inspect the back, buttocks, and perineum.

Tension pneumothorax and cardiac tamponade may easily be overlooked if there are multiple injuries.

Upon completion of the survey examination, control of pain, splinting of fractured limbs, suturing of lacerations, and other types of emergency treatment can be started.

LABORATORY & OTHER EXAMINATIONS

► Laboratory Examination

Laboratory examinations in surgical patients have the following objectives:

1. Screening for asymptomatic disease that may affect the surgical result (eg, unsuspected anemia or diabetes)
2. Appraisal of diseases that may contraindicate elective surgery or require treatment before surgery (eg, diabetes, heart failure)
3. Diagnosis of disorders that require surgery (eg, hyperparathyroidism, pheochromocytoma)
4. Evaluation of the nature and extent of metabolic or septic complications

Patients undergoing major surgery, even though they seem to be in excellent health except for their surgical disease, should have age-appropriate laboratory examination. A history of renal, hepatic, or heart disease requires detailed studies. Medical consultation may be helpful in the total preoperative appraisal of the surgical patient. It is essential, however, that the surgeon not become totally dependent upon a medical consultant for the preoperative evaluation and management of the patient. The total management must be the surgeon's responsibility and is not to be delegated. Moreover, the surgeon is the only one with the experience

and background to interpret the meaning of laboratory tests in the light of other features of the case—particularly the history and physical findings.

► **Imaging Studies**

Modern patient care calls for a variety of critical radiologic examinations. The closest cooperation between the radiologist and the surgeon is essential if serious mistakes are to be avoided. This means that the surgeon must not refer the patient to the radiologist, requesting a particular examination, without providing an adequate account of the history and physical findings. Particularly in emergency situations, review of the films and consultation are needed.

When the radiologic diagnosis is not definitive, the examinations must be repeated in the light of the history

and physical examination. Despite the great accuracy of x-ray diagnosis, a negative gastrointestinal study still does not exclude either ulcer or a neoplasm; particularly in the right colon, small lesions are easily overlooked. At times, the history and physical findings are so clearly diagnostic that operation is justifiable despite negative imaging studies.

► **Special Examinations**

Special examinations such as cystoscopy, gastroscopy, esophagoscopy, colonoscopy, angiography, and bronchoscopy are often required in the diagnostic appraisal of surgical disorders. The surgeon must be familiar with the indications and limitations of these procedures and be prepared to consult with colleagues in medicine and the surgical specialties as required.

2

Training, Communication, Professionalism, & Systems-Based Practice

Gerard M. Doherty, MD

TRAINING

The process of medical education and surgical training in the United States is overseen by an interconnected group of organizations. Each of these organizations has their specific focus; however, the common theme is continuous process improvement encouraged by intermittent external review (Table 2-1). The ultimate goal is the provision of a consistent, qualified, and professional workforce for medical care in the United States.

► Medical Student Education

The Liaison Committee on Medical Education (LCME) is the group that provides accreditation for medical schools in the United States and Canada. *Accreditation* is the process of quality assurance in postsecondary education that assesses whether an institution meets established standards. Accreditation by the LCME is effectively necessary for schools to function in the United States. Without accreditation, the schools cannot receive federal grants for medical education or participate in federal loan programs. Graduation from an LCME-accredited school enables students to sit for medical licensing examinations (the USMLE) and to achieve licensure in most states around the country. Graduation from an LCME-accredited medical school is also necessary for acceptance into an ACGME-accredited residency program (see below) for graduates of US medical schools. The authority for the LCME to provide this accreditation is delegated by the United States Department of Education in the United States and the Committee on Accreditation of Canadian Medical Schools (CACMS) in Canada.

Each accredited medical school is reviewed annually for appropriateness of their function, structure, and performance. Formal site visits are conducted periodically with more in-depth review and reaccreditation at that time.

The usual period of full accreditation is 8 years. At the time of this in-depth accreditation visit, and in the intervals between, the LCME works to disseminate best practices and approve the overall quality of education leading to the MD degree.

► Graduate Medical Education

The Accreditation Council for Graduate Medical Education (ACGME) is responsible for the accreditation of post MD medical training programs within the United States. Accreditation is accomplished through a peer review process based on established standards and guidelines. The member organizations of the ACGME as an accrediting group are the American Board of Medical Specialties (ABMS), the American Hospital Association (AHA), the American Medical Association (AMA), the Association of American Medical Colleges (AAMC), and the Council of Medical Specialty Societies. The ACGME oversees a variety of graduate medical education programs in specific specialties. These ACGME-accredited residency programs must adhere to the ACGME common program requirements that apply to all residencies, as well as specific program requirements that apply to each training program. The ACGME also accredits institutions to house the residency training programs. There are thus also institutional requirements that must be met for overall accreditation of the institution to house training programs.

The ACGME has identified six general competency areas that must be addressed during every graduate residency training program (Table 2-2). The specific application of these competency areas varies widely among training programs. However, each rotation of each residency must include attention to, and assessment of, progress in fulfilling the general competency requirements.

The review and accreditation of specialty residency programs is undertaken by a committee specific for that field. In surgery, the group is the Residency Review Committee

Table 2-1. US organizations with medical education oversight.

Organization	Acronym and Website	Purpose
Liaison Committee on Medical Education	LCME www.LCME.org	Accreditation of medical schools in the United States and Canada
Accreditation Council for Graduate Medical Education	ACGME www.ACGME.org	Accreditation of post-MD training programs in some specialties
American Board of Surgery	ABS www.absurgery.org	Certifies and recertifies individual surgeons who have met standards of education, training, and knowledge
American College of Surgeons	ACS www.facs.org	Scientific and educational association of surgeons to improve the quality of care for the surgical patient

for Surgery (RRC-S). The RRC-S assesses program compliance with accreditation standards both at the common program requirement level, and at the program specific level. Programs are typically fully accredited on a five year cycle, with annual updates and questionnaires in the interim. Early site visits can be triggered by a variety of events including significant changes in the program or its leadership. The Residency Review Committees also control the number of positions that each program is accredited to have. This effectively sets the maximum number of graduates that can finish from a given training program in any given year.

► **American Board of Surgery**

The American Board of Surgery (ABS) is an independent, non-profit organization with the purpose of certifying individual surgeons who have met defined standards of education, training, and knowledge. The distinction between the ACGME and the ABS is that the ACGME accredits training programs, while the ABS certifies individuals. This distinction is similar for specialty boards in other disciplines as well. The ABS also recertifies practicing surgeons, and is making a fundamental philosophical change from periodic retesting for recertification to a more continuous maintenance of certification (MOC) plan.

The ACGME and the specialty boards interact. The success of individuals in achieving board certification is

considered an important measure of graduate medical education program success, and the measures that can be required of an individual for board certification must somehow also reflect the education that is offered to them through their graduate medical education. Thus though these entities have different purposes, they must, optimally, mesh their efforts constructively.

Board certification within a defined period after completing residency is necessary for privileging to perform surgery in many hospitals in the United States. Thus the most straightforward route into surgical practice in the United States includes graduation from an LCME-accredited medical school, completion of an ACGME-accredited residency training program, and satisfactory completion of the Qualifying Examination (written boards), and Certifying Examination (oral boards) of the American Board of Surgery.

There are other entry points into surgical practice in the United States, most prominently by physicians who have graduated from medical schools in countries outside the United States and Canada. These graduates can be certified by the Educational Commission for Foreign Medical Graduates (ECFMG). Once an individual graduate has been certified by the ECFMG, then he or she is eligible to train in an ACGME-approved residency training program, and can thus be eligible for board certification.

► **American College of Surgeons**

The American College of Surgeons (ACS) is a scientific and educational association of surgeons whose mission is to improve the quality of care for the surgical patient by setting high standards for surgical education and practice. The ACS has members, known as fellows, who are entitled to use the letters FACS after their name. Membership as a fellow implies that the surgeon has met standards of education, training, professional qualifications, surgical competence, and ethical conduct. However, despite these requirements, the ACS is a voluntary professional membership group,

Table 2-2. ACGME general competencies for graduate medical education.

General Competency
• Patient care
• Medical knowledge
• Interpersonal and communication skills
• Professionalism
• Practice-based learning
• Systems-based practice

and does not certify individuals for practice. The ACS does sponsor a wide variety of educational and professional support programs both for practicing surgeons and trainees. In addition, they have membership categories for surgeons in training (Resident Membership) and students (Medical Student Membership), and for those surgeons who have completed training but have not yet met all the requirements for fellowship (Associate Fellow). The ACS also engages in important advocacy roles on behalf of patients and the surgeon members.

COMMUNICATION

Efficient and effective communication skills are a critical resource for all clinicians including surgeons. A surgeon must be capable of establishing a rapport with the patient and family quickly and reliably. This mutual respect is critical to a therapeutic relationship. The patient and family must be confident of the competence of the surgeon in order to participate in the recommended management and recovery. Judgments about surgeon competence frequently come within the first few moments of interaction based on the surgeon's ability to communicate. In addition to communicating with patients, clinicians must communicate with referring and collaborating physicians, and also within their own health care teams.

► Communicating With Patients

Communication with patients requires attention to several aspects. First, the clinician must demonstrate respect for the patient as a person. Second, the clinician must display effective listening to the patient's message, followed by demonstrated empathy to their situation or concerns. Finally, the clinician must have clarity in the response. If any of these items are omitted, then the interaction will be less effective than it could be. Many surgeons try to jump straight to a very clear concise statement of the plan; however, unless the first three steps have occurred, the patient may not listen to the plan at all.

Respect

It is critically important to show respect for the patient and family as persons. The health care environment is often inconvenient and encountered during a time of stress. The patients are out of their normal venue and zone of comfort. They are often frightened by the prospect of what they may learn. Showing respect for their identity will place the patient at more ease and encourage their trusting communication with the clinician. Failing to show respect will have the contrary effect. Thus meeting an adult for the first time and addressing them by their first name can immediately put many patients on guard with respect to their personal independence and control. Similarly, referring to the mother

of a pediatric patient as "Mom" rather than using her name implies lack of attention to her as an individual worthy of learning her identity. On initial meetings, the clinician should use the patient's last name preceded by an honorific title (Mr. Smith, or Ms. Jones). If you are not certain if a woman prefers Mrs. or Ms, then ask her. In contemporary US society, a woman over 18 years of age is never referred to as Miss.

In addition, engaging in brief small talk regarding some aspect of a patient's life other than the medical matter at hand can additionally put them at ease ("It must be interesting to be a dog trainer. What is your favorite breed?"). These efforts will be rewarded by a more trusting patient and a more efficient interview, with a better therapeutic relationship over the long term.

Listening

Listening to the patient is critical to establishing a correct diagnosis and appropriate therapeutic plan for the individual. Every patient who comes to the medical system with a problem has a story that they have thought through and decided to tell. It is important to let them do so. Not only is the patient likely to reveal critical issues regarding the clinical matter, but they are also often determined to tell the story eventually, whether they are allowed to do so at the outset or not. Allowing, and in fact encouraging them, to tell the story at the beginning of the interview relieves them of this burden of information, and allows the clinician to move on to interpretation.

Listening should be an active, engaged activity. The clinician should appear comfortable, settled, and upon as much of an even eye level with the patient as possible. It is important not to appear rushed, inattentive, or bored by their account. Interjecting questions for clarity or intermittent, brief verbal encouragements will let the patient know that the clinician is engaged with the problem.

It may be helpful at the outset of the listening phase to let the patient know what materials have been reviewed; for example, telling the patient that the clinician has reviewed the referral letter from the primary physician, the results of the last two operations, and their recent laboratory work may help the patient to be more concise in their discussion.

Empathy

Once the patient has recounted their history and the other aspects of examination and data review have been completed, it is important to review this material with the patient in a way that demonstrates empathy with their situation. A surgeon's understanding of the problem is important for the patient, but the problem is not confined to the medical issue, the problem must be understood in the context of the patient. For this reason demonstration of empathy is

important to the patient's trust of the physician. Establishing this connection with the patient is crucial to their engagement in the process of care.

Clarity

Having established respect for the patient, heard and understood their story, and empathized with their situation, the physician must speak clearly and in a vocabulary understood by the individual, about the recommendations for further evaluation or care. This portion of the conversation should include a clear distinction between what is known about the patient's diagnosis or condition and what is not known but might be anticipated. When appropriate, likelihoods of various outcomes should be estimated in a way that the patient can grasp. The recommended approach to next steps should be listed clearly, along with alternative approaches. Patients always have at least one alternative to the recommended choice, even if this is only to decide not to have further medical care. This portion of the conversation can be augmented with illustrations or models that may improve the patient's understanding. Often reviewing radiological studies directly with the patient or family at this time can help their understanding.

The risk taken by failing to establish this relationship with the patient is great. This can lead to errors in judgment about diagnosis or management. It also precludes the opportunity to engage the patient as an ally in his or her care. If things go badly, it also can make subsequent communication about problems or complications difficult or impossible. Finally, the surgeon who communicates poorly excludes him- or herself from enjoying a personally and professionally satisfying physician-patient relationship.

► Communication With Collaborating Physicians

Surgeons often work with other physicians in collaboration of care for patients. Communication in these settings is important to the overall patient outcome, particularly when the surgeon will be involved in the patient's care for some defined interval which has been preceded and will be followed by the ongoing care provided by the primary care physician. The communication in these settings can be separated into two basic types: routine and urgent. Routine communication can take place in a variety of ways depending on the health care setting. This communication is typically asynchronous and written. It may take the form of a note in the patient's electronic medical record, or a letter sent to the physician's office. This is an appropriate way to communicate reasonably expected information that does not need to be acted on urgently. For example, a patient who is referred to a surgeon for cholecystectomy and who has a plan made for cholecystectomy can have routine communication back to the referring physician.

Urgent communication should occur to the collaborating physicians when there are unexpected or adverse outcomes. Again, there are a variety of communication modes that may be utilized for this, but the communication is more often synchronous via a direct conversation either in person or by telephone. The communication is more than courtesy to the collaborating physician, as knowledge of these events allows them to participate constructively on behalf of the patient. Examples of situations that warrant more urgent communication include new diagnosis of significant cancers, life-altering complications from interventions, and certainly death of the patient.

Clarity in transfer of care responsibility is critical to the continuous optimal care of the patient. For that reason, any communication with the collaborating physicians should indicate either the ongoing role of the surgeon in the patient's care, or the deliberate transfer of responsibility for ongoing care issues back to other collaborating physicians.

► Communications Within Teams

Surgical care is often provided in a team setting. Current surgical teams typically include physicians, nonphysician mid-level providers (often physician assistants or nurse practitioners), and a variety of students. The student trainees may include students in medical school, physician assistant programs, or nursing school. These teams have become increasingly complex, and the information that they manipulate as a team to provide patient care is voluminous. In addition, the transfer of information from one provider to another as shifts or rotations change is recognized as a weak point in the patient care continuum.

With these complex teams and extensive information, the keys to efficient and effective team processes appear to be clarity of roles and designing processes that involve only writing things down once. The advent of electronic medical records has allowed the generation of electronic tools to transfer information from team member to team member. This may be useful to facilitate this process. Careful attention to transfers of care from one provider to another and explicit recognition that this is a potential time for errors is important.

PROFESSIONALISM

Professionalism denotes a series or group of behaviors that demonstrates that a person has achieved status as a professional. A *professional* in this context is implied to possess the specialized knowledge and have gone through long and intensive academic preparation for their vocation. These behaviors affect the interactions that professionals have both with patients and with other health care professionals. For optimal effectiveness, the surgeon should behave in a professional way both with patients and within their health

Table 2-3. AMA principles of medical ethics.

1. A physician shall be dedicated to providing competent medical care, with compassion and respect for human dignity and rights.
2. A physician shall uphold the standards of professionalism, be honest in all professional interactions, and strive to report physicians deficient in character or competence, or engaging in fraud or deception, to appropriate entities.
3. A physician shall respect the law and also recognize a responsibility to seek changes in those requirements which are contrary to the best interests of the patient.
4. A physician shall respect the rights of patients, colleagues, and other health professionals, and shall safeguard patient confidences and privacy within the constraints of the law.
5. A physician shall continue to study, apply, and advance scientific knowledge, maintain a commitment to medical education, make relevant information available to patients, colleagues, and the public, obtain consultation, and use the talents of other health professionals when indicated.
6. A physician shall, in the provision of appropriate patient care, except in emergencies, be free to choose whom to serve, with whom to associate, and the environment in which to provide medical care.
7. A physician shall recognize a responsibility to participate in activities contributing to the improvement of the community and the betterment of public health.
8. A physician shall, while caring for a patient, regard responsibility to the patient as paramount.
9. A physician shall support access to medical care for all people.

Available at <http://www.ama-assn.org/ama/pub/category/2512.html>

care institutions. The American Medical Association has promulgated a set of medical ethical principles that apply equally well to surgical practice, and that can help to guide professional behavior (Table 2-3).

The ethics of surgical practice are complex, and can be approached from a variety of theoretical frameworks. The most commonly applied framework for the evaluation of ethical dilemmas for individual patient decisions in medicine, known as “The Principles Approach,” involves four principles: Autonomy, Beneficence, Nonmaleficence, and Justice, as promulgated by Beauchamp and Childress (Table 2-4). A detailed analysis of these principles is beyond the scope here; however, the need for a code of medical ethics that is distinct from general societal ethics is the basis for medical professionalism. The following are five features of medical relationships that provide the moral imperatives underlying the profession and the requirement for a separate ethical code from other forms of business.

1. The inequality in medical knowledge, and attendant vulnerability, of the patient
2. The requirement for the patient to trust the physician, known as the fiduciary nature of the relationship

Table 2-4. Principles of medical ethics: “The Principles Approach.”

Principle	Definition
Autonomy	Deliberated self-rule; the patient has the right to choose or refuse their treatments; requires physicians to consult and obtain patient agreement before doing things to them
Beneficence	A practitioner should act in the best interest of the patient, without regard to physician’s self-interest
Nonmaleficence	Do no harm; the practitioner should avoid treatments that harm the patient
Justice	Rendering what is due to others; affects the distribution of medical care among patients and populations

3. The moral nature of medical decisions that encompass both the technical aspects of health management and the ultimate effect on the patient’s life
4. The nature of medical knowledge as a public property that physicians receive in order to apply to the practical improvement of patients’ lives
5. The moral complicity of the physician in the outcome of the prescribed care, in that no formal medical care can take place without the physician’s collusion

Because of these characteristics of the relationship between physicians and their patients, physicians must adhere to a set of ethical constraints specific to their profession.

While these imperatives are not generally understood explicitly by patients, patients can clearly grasp when these principles are in danger. They may even be suspicious that their physician or surgeon has competing motives to the patient’s best interest. One of the goals of the physician-patient interaction is to allay these fears, and construct a trusting relationship based on the patient’s needs, within the principles noted above.

► Interaction With Patients

The interactions with patients should be characterized by polite and possibly somewhat formal manners. These manners will aid the professional in their communication efforts as noted above. In order to meet the patient’s expectations of what the physician or surgeon should be, proper socially acceptable manners should be observed. The purpose of these manners is to put the patient at ease that the physician is an empathetic person with the self-awareness to recognize the way that he or she appears to other people. The manners that the physician projects affect the credibility of the subsequent interactions. These conventions extend to the type

of dress that is worn in a professional setting. The details of whether a physician wears a white coat or formal business clothing (suits, ties, pantsuits, blouses, skirts, etc) are best left to local custom and practice. However, the mode of dress in general should be neat, clean, and formal rather than casual, and not distracting to the interaction.

Another aspect to professionalism is the capability of the physician to do the right thing for the patient and the family even when that course is difficult or unpleasant. This includes such situations as frankly and openly disclosing errors made during care, or delivering bad news about new or unexpected diagnoses. While human nature can make these interactions difficult, the professional must rise to the task and perform it well. Avoiding the opportunity to do so not only obviates the professional's role as advisor on the issue at hand, but affects the physician's credibility in the remainder of that therapeutic relationship.

► Interactions With Health Care Personnel

Surgeons frequently work in complex, multilayered organizations. The behavior of the surgeon within this group should always remain productive and patient-centered. In any complex organization with multiple people and personalities, conflicts arise. In that context, it is not appropriate for the surgeon to necessarily shrink from the conflict, but rather the surgeon should take up the role of constructive evaluator and team builder to resolve the issue. At all times, the surgeon must avoid personal attacks on people based upon their personal characteristics, but may legitimately criticize behavior. Professional comportment in these matters will be rewarded with progress in resolving the issue.

Reputation is a fragile and valuable commodity. All health care professionals have a reputation, and it works either for or against them in achieving their patient care and professional goals. Careful adherence to professional behavior in dress, speech, manners, and conflict resolution will create the professional reputation that is most advantageous for the surgeon. With a positive reputation, the surgeon's behavior in ambiguous situations will be interpreted in a benevolent way. The reputation of any clinician is as valuable as their education or certification.

SYSTEMS-BASED PRACTICE

Systems-based practice is one of the core competencies defined by the ACGME as a necessary skill to be developed by graduate medical trainees. These residents must demonstrate an awareness of and responsiveness to the larger context and system of health care and the ability to effectively call on system resources to provide care that is of optimal value. The process of teaching and learning, systems-based practice has been in place for many years. This is what might be considered the practical part of graduate medical training.

However, it is only more recently that it has become a focus and metric for performance by training programs.

As a part of training then, residents must learn how different types of medical practice and health care delivery systems differ from one another, including methods that they use to control health care costs and allocate resources. They must use this knowledge to practice cost-effective health care and resource allocation that limits the compromise of quality of care. They must advocate for quality patient care and assist patients in dealing with complexities of the health care delivery system. They must also understand how to work with health care managers and other collaborating health care providers to assess, coordinate, and improve health care for patients.

In practice, this is easier to understand. The role of the resident in identifying both the health care needs of the patient and the capability of the system to meet those needs is well-established. Surgery residents in their senior years are often important resources for hospital systems by understanding how to manipulate the system to meet the needs of the patient. Medical students and surgical trainees must also recognize their role as a part of these complex systems.

MULTIPLE CHOICE QUESTIONS

- All of the following are true of the Principles of Medical Ethics, except
 - Beneficence and nonmaleficence are synonyms
 - Justice addresses the distribution of medical care among patients and populations
 - Autonomy includes the concept that the patient has the right to choose or refuse their treatments.
 - Beneficence asserts that a practitioner should act in the best interest of the patient, without regard to physician's self-interest
 - Autonomy requires physicians to consult and obtain patient agreement before doing things to them
- The LCME and the ACGME
 - Both accredit institutions to provide education or training
 - Provide diplomas and credentialing to individual practitioners
 - Conduct periodic reviews to ensure that institutions maintain their programs
 - Are units of the US Department of Commerce
 - Both A and C are true

3. ACGME general competencies include all of the following except
 - A. Interpersonal and communication skills
 - B. Professionalism
 - C. Technical skills
 - D. Practice-based learning
 - E. Systems-based practice
4. The American Board of Surgery and the American College of Surgeons
 - A. Are both part of the American Medical Association
 - B. Both report directly to the Surgery RRC of the ACGME
 - C. Work together to accredit individuals to practice general surgery
 - D. Are separate organizations that credential surgeons, and educate surgeons, respectively, as primary parts of their missions
 - E. A and C
5. Effective communication with patients requires
 - A. Demonstrated respect for the patient as a person
 - B. Effective listening to the patient's message
 - C. Clarity in the physician's response to the patient
 - D. Family members who can reinforce the messages
 - E. A, B, and C

Preoperative Preparation

David McAneny, MD

3

INTRODUCTION

The preoperative management of any patient is part of a continuum of care that extends from the surgeon's initial consultation through the patient's full recovery. While this ideally involves a multidisciplinary collaboration, surgeons lead the effort to assure that correct care is provided to all patients. This involves the establishment of a culture of quality care and patient safety with high, uniform standards. In addition, the surgeon is responsible for balancing the hazards of the natural history of the condition if left untreated versus the risks of an operation. A successful operation depends upon the surgeon's comprehension of the biology of the patient's disease and keen patient selection.

This chapter will consider preoperative preparation from the perspectives of the patient, the operating room facility and equipment, the operating room staff, and the surgeon.

PREPARATION OF THE PATIENT

► History & Physical Examination

The surgeon and team should obtain a proper history from each patient. The history of present illness includes details about the presenting condition, including establishing the acuity, urgency, or chronic nature of the problem. Inquiries will certainly focus on the specific disease and related organ system. Questions regarding pain can be guided by the acronym OPQRST, relating to Onset (sudden or gradual), Precipitant (eg, fatty foods, movement, etc), Quality (eg, sharp, dull, or cramps), Radiation (eg, to the back or shoulder), Stop (what offers relief?), and Temporal (eg, duration, frequency, crescendo-decrescendo, etc). The presence of fevers, sweats, or chills suggests the possibility of an acute infection, whereas significant weight loss may imply a chronic condition such as a tumor. The history of present illness is not necessarily confined to the patient interview. Family members or guardians provide useful information,

and outside records can be indispensable. Documents might include recent laboratory or imaging results that preclude the need for repetitive, costly testing. The surgeon should request CD-ROM disks of outside imaging, if appropriate. In the case of reoperative surgery, prior operative reports and pathology reports are essential (eg, when searching for a missing adenoma in recurrent primary hyperparathyroidism).

The past medical history should include prior operations, especially when germane to the current situation, medical conditions, prior venous thromboembolism (VTE) events such as deep vein thromboses (DVT) or pulmonary emboli (PE), bleeding diatheses, prolonged bleeding with prior operations or modest injuries (eg, epistaxis, gingival bleeding, or ecchymoses), and untoward events during surgery or anesthesia, including airway problems. One must secure a list of active medications, with dosages and schedule. Moreover, it is beneficial to inquire about corticosteroid usage within the past 6 months, even if not current, to avoid perioperative adrenal insufficiency. Medication allergies and adverse reactions should be elicited, although knowledge about environmental and food allergies is also valuable and should be recorded so that these exposures are avoided during the hospital stay. Some anesthesiologists are reluctant to use propofol in patients with egg allergies, and reactions to shellfish suggest the possibility of intolerance of intravenous iodinated contrast agents.

The social history classically involves inquiries into tobacco, alcohol, and illicit drug usage, but this moment also offers the opportunity to establish a personal relationship with patients (and their loved ones). It is fun and often stimulating to learn about patients' occupations, avocations, exercise, interests and accomplishments, fears and expectations, and family lives. Patients' regular activities offer insight into physiologic reserve; an elite athlete should tolerate nearly any major operation, whereas a frail, sedentary patient can be a poor candidate for even relatively minor operations.

A family history includes queries pertinent to the patient's presenting condition. For example, if a patient with a colorectal cancer has relatives with similar or other malignancies, genetic conditions such as familial adenomatous polyposis or hereditary nonpolyposis colorectal cancer could be indicated. This scenario would have screening implications for both the patient and family members. In addition, one should also elicit a family history of VTE complications, bleeding disorders, and anesthesia complications. For example, a sudden and unexpected death of a relatively young family member during an operation could suggest the possibility of a pheochromocytoma, particularly in the setting of a medullary cancer or related endocrine disorder. A strong family history of allergic reactions might imply hypersensitivity to medications.

A review of systems assesses the patient's cardiovascular, pulmonary, and neurologic status, including questions about exertional chest pain or dyspnea, palpitations, syncope, productive cough, or central nervous symptoms. It is also important to have a basic understanding of the patient's symptoms relative to other major organ systems. For example, while one might not necessarily expect an orthopedic surgeon to have an interest in a patient's gastrointestinal or genitourinary habits or problems, these issues may bear grave consequences if a patient experiences postoperative incontinence following joint replacement. Regardless of degree of specialization, surgeons and their designated teams are capable of identifying and investigating potentially confounding conditions.

A thorough physical examination is also an essential part of the patient assessment. Even if the surgeon already knows from imaging that there will be no pertinent physical findings, human touch and contact are fundamental to the development of a trusting physician-patient relationship. In addition to the traditional vital signs of pulse, blood pressure, respiratory rate, and temperature, for many operations it is also important to record the patient's baseline oxygen saturation on room air, weight, height, and body mass index (BMI). The physical examination includes an assessment of general fitness, exercise tolerance, cachexia, or obesity, as well as focusing on the patient's condition. Additional observations may detect findings such as cardiopulmonary abnormalities, bruits, absent peripheral pulses or bruits, adenopathy, skin integrity, incidental masses, hand dominance, neurologic deficits, or deformities. A thorough abdominal examination may include digital anorectal and pelvic examinations. The surgeon should also appreciate potential airway problems, particularly if general anesthesia is anticipated.

► Preoperative Testing

Laboratory and imaging investigations are tailored to the individual patient's presenting condition, as discussed in

later chapters. However, there should be no "routine" battery of preoperative laboratory studies for all patients. In fact, published data do not support an association between routine studies and outcome. In addition, laboratory tests are costly and may result in harm due to false-positive and fortuitous findings. Instead, tests should be selected based upon the patient's age, comorbidities, cardiac risk factors, medications, and general health, as well as the complexity of the underlying condition and proposed operation. For example, children uncommonly require preoperative laboratory tests for most operations. On the other hand, a complete blood count, chemistries, and an electrocardiogram are proper for high-risk patients before complex operations. Algorithms and grid matrices are available to individualize the selection of preoperative tests (Table 3-1). Importantly, each system should establish a practice for managing abnormal test results, whether germane to the patient's active condition or a serendipitous finding.

A complete blood cell count and basic chemistries are reasonable for some operations, but their likelihood of predicting abnormal or meaningful results should be considered. Coagulation factors such as prothrombin time (PT), international normalized ratio (INR), and partial thromboplastin time (PTT) are not routinely indicated but should be pursued when patients report prolonged bleeding or the usage of anticoagulants. Moreover, INR and PTT may be warranted for operations that have little threshold for intraoperative or postoperative bleeding, such as those on the brain, spine, or neck. Bile duct obstruction, malnutrition, or an absent terminal ileum can affect vitamin K absorption, and a preoperative assessment of INR is important in those instances as well. A pregnancy test (eg, urine beta-human chorionic gonadotropin [beta-HCG]) should be performed shortly before surgery on women with childbearing potential. Other laboratory testing will be dictated by specific conditions, including liver chemistries, tumor markers, and hormone levels. A blood bank specimen should be selectively submitted in advance of operations that are associated with significant hemorrhage or in the setting of anemia with prospects for further blood loss. The preparation of blood for transfusion is costly, so blood-typing alone may suffice without actual cross-matching.

Routine preoperative testing of blood glucose is an intriguing concept, given the relationship between elevated blood sugars and surgical site infections (SSIs), although hemoglobin A_{1C} levels have not correlated with postoperative infections. Some reckon that nondiabetic patients comprise 30%-50% of cases with perioperative hyperglycemia, perhaps constituting an argument for measuring preoperative glucose levels in all candidates for major operations. While it is accepted that diabetic patients require close monitoring of perioperative glucose levels, including immediately before the operation, the value of doing this for all patients is evolving and warrants thoughtful investigation.

Table 3–1. Sample preoperative testing grid.

	CBC	Basic Chemistries	INR or PT	PTT	Liver Chemistries	Urinalysis	EKG	CXR	Urine Pregnancy Test
Cardiac disease (MI, CHF, pacemaker/AICD, coronary stents)	X						X		
Pulmonary disease (COPD, active asthma)	X						X	X	
End-stage renal disease on dialysis	X	X					X		
Renal insufficiency	X	X							
Liver disease	X	X	X		X				
Hypertension							X		
Diabetes		X					X		
Vascular disease	X						X		
Symptoms of urinary tract infection						X			
Chemotherapy	X	X							
Diuretics		X							
Anticoagulants			X	X					
Major operation (eg, cardiac, thoracic, vascular, or abdominal)	X	X					X	X	
Menstruating women									X

AICD, automated implantable cardioverter-defibrillator; CBC, complete blood count; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; CXR, chest radiograph; EKG, electrocardiogram; INR, international normalized ratio; MI, myocardial infarction; PT, prothrombin time; PTT, partial thromboplastin time.

Some investigators have advocated routine nasal swab screening to identify carriers of *Staphylococcus aureus*. The results can guide decontamination measures such as intranasal application of antibiotic ointment (eg, mupirocin) and local hygiene with 2% chlorhexidine showers for 5 days before surgery. Patients with methicillin-resistant *S aureus* (MRSA) receive appropriate antibiotic prophylaxis and contact precautions. Although the issue of routine MRSA screening is not fully resolved, this practice may be ideal at least for immunocompromised patients and for those undergoing open cardiac operations and implantations of foreign bodies, particularly in orthopedics and neurosurgery. Prospective wound or abscess culture results should also influence decisions about perioperative antibiotics.

Electrocardiograms are not routinely performed but are justified for patients older than 50 years; those having vascular operations; and those with a history of hypertension, cardiac disease, significant respiratory disease, renal

dysfunction, and diabetes mellitus. Chest radiographs are no longer performed on a regular basis but are primarily reserved for patients with malignancies or perhaps with significant pulmonary disease. Further special tests are selectively obtained when clinically indicated and often with guidance from consultants; these tests may include echocardiography, cardiac stress testing, baseline arterial blood gases, and pulmonary function tests. Carotid ultrasonography may be valuable in patients with carotid bruits or histories of cerebrovascular accidents or transient ischemia attacks. Noninvasive venous studies may be considered in patients who have had prolonged immobility and/or hospital stays before surgery.

PREOPERATIVE PROCESS

At its simplest, the process of preparing a patient for an operation can involve a rapid assessment in the clinic or

emergency room followed by an expeditious trip to the operating room. However, like most care in the contemporary health care system, the process is more commonly complex and involves a formal series of integrated steps to assure best outcomes. It is incumbent upon the surgery team to create an efficient and cost-effective preoperative system and scheduling protocol that result in optimally prepared patients, rare cancellations of operations, and few disruptions of the operating room schedule. A systemic approach to patient preparation focuses upon risk assessment and reduction, as well as education of the patient and family. This effort begins during the first encounter with the surgeon and continues through the moments before the operation. Ideal preoperative systems assign risk based upon evaluations that are derived from sound published evidence and best practices and driven by standardized algorithms to identify and then modify hazards before operations.

► Risk Assessment & Reduction

Overview

The essence of preparing a patient for an operation regards considering whether the benefits of the operation justify the risks of doing harm, along with deciding how to minimize or eliminate those hazards. The American Society of Anesthesiologists (ASA) classification system (Table 3–2) stratifies the degree of perioperative risk for patients. While somewhat rudimentary, this system has faithfully served anesthesiologists and surgeons in predicting how well patients might tolerate operations, and the scores have been validated by several recent publications. The Acute Physiology and Chronic Health Evaluation (APACHE II and III) is an example of a severity of illness scoring system that may be applied to intensive care unit patients to predict mortality. The value of such assessments lies in numerically designating the severities of patients' conditions, permitting comparisons of outcomes.

The University Health Systems Consortium (UHC) analyses derive from inpatient administrative and financial datasets to predict risk-adjusted outcomes for mortality, lengths of stay, and cost of care. The vagaries of medical coding can result in discrepancies, and the UHC system does not monitor patients after hospital discharge. Nevertheless, UHC data can identify deficiencies in practice. Although clinical databases are more costly and challenging to implement than commercially available products such as the UHC program, they provide more robust risk-adjusted outcomes data. Examples of clinical databases include those from the Society of Thoracic Surgeons (STS) and the National Surgical Quality Improvement Program (NSQIP). In NSQIP, dedicated nurses prospectively collect and validate an established panel of defined patient variables, comorbidities, and outcomes, and they pursue surveillance for 30 days after hospital discharge. The NSQIP analysis considers patient

Table 3–2. American Society of Anesthesiologists (ASA) classification system.

ASA Classification	Preoperative Health Status	Example
ASA 1	Normal healthy patient	No organic, physiologic, or psychiatric disturbance; excludes the very young and very old; healthy with good exercise tolerance
ASA 2	Patients with mild systemic disease	No functional limitations; has a well-controlled disease of one body system; controlled hypertension or diabetes without systemic effects, cigarette smoking without chronic obstructive pulmonary disease (COPD); mild obesity, pregnancy
ASA 3	Patients with severe systemic disease	Some functional limitation; has a controlled disease of more than one body system or one major system; no immediate danger of death; controlled congestive heart failure (CHF), stable angina, former heart attack, poorly controlled hypertension, morbid obesity, chronic renal failure; bronchospastic disease with intermittent symptoms
ASA 4	Patients with severe systemic disease that is a constant threat to life	Has at least one severe disease that is poorly controlled or at end stage; possible risk of death; unstable angina, symptomatic COPD, symptomatic CHF, hepatorenal failure
ASA 5	Moribund patients who are not expected to survive without the operation	Not expected to survive > 24 h without surgery; imminent risk of death; multiorgan failure, sepsis syndrome with hemodynamic instability, hypothermia, poorly controlled coagulopathy
ASA 6	A declared brain-dead patient whose organs are being removed for donor purposes	

factors, effectiveness of care, and random variation, and logistic regression models calculate risk-adjusted 30-day morbidity and mortality. These data are reported as odds ratios for comparison with expected outcomes, allowing for the severity of the patients' illnesses. Immediate benefits of NSQIP present the ability to identify true risk-adjusted data and local opportunities for improvement. For example, Veterans Administration (VA) surgeons reduced postoperative mortality from 3.2% in 2003 to 1.7% in 2005, while the complication rate declined from 17% to 10% ($p < 0.0001$). This effort focuses upon systems of care, providing reliable data to assess and reduce risks associated with operations. When compared to UHC, NSQIP is much more likely to identify complications because of its surveillance of patients 30 days beyond their hospitalizations.

The NSQIP program has also generated a tremendous repository of data to develop "risk calculators" for a variety of operations and conditions, allowing preoperative risk assessments and hopefully facilitating significant reductions of preoperative hazards. Finally, NSQIP participants have fostered a culture of sharing best practices and processes, both within the published literature and through formal and personal collaborations.

Beyond the obvious physical and emotional implications of adverse outcomes for patients and their families, the financial costs of postoperative complications to the health care system are staggering. It has been postulated that a major postoperative complication adds over \$11,000 to the cost of the hospital care of an affected individual and significantly extends the duration of the inpatient confinement. In fact, the total cost of care increases by more than half when a complication develops. Notably, respiratory complications may increase the cost of care by more than \$52,000 per patient. Strikingly, data from NSQIP have demonstrated that the occurrence of a serious complication (excluding superficial wound infections) after major operations is an independent risk factor for decreased long-term survival. Therefore, it is crucial that efforts focus upon reducing and eliminating postoperative complications.

Well-designed, systematic preoperative assessment programs can prospectively identify predictors of various complications and drive the ability to attenuate risks and improve outcomes. The perspective of teams of surgeons, physicians, nurses, and others with expertise managing standardized, algorithm-driven preoperative evaluations, often with checklists, is a departure from traditional care that primarily involved solitary surgeons with disparate practices. The new paradigm recognizes that variability in practice is the enemy of efficiency.

The financial dividends appreciated from enhanced results and diminished death and complication rates more than compensate for the expenditures associated with quality improvement efforts and participation in auditing programs such as NSQIP. It is essential that surgeons monitor

their patients' outcomes, preferably in a risk-adjusted fashion, to understand their practices and to demonstrate opportunities for improvement.

Cardiovascular

In 1977, Goldman published a multifactorial index for assessing cardiac hazards among patients undergoing non-cardiac operations. The same group issued a Revised Cardiac Risk Index (RCRI) in 1999, reporting six independent predictors of cardiac complications. These include a history of ischemic heart disease, congestive heart failure, cerebrovascular disease, a high-risk operation, preoperative treatment with insulin, and a preoperative serum creatinine greater than 2.0 mg/dL. The likelihood of major cardiac complications increases incrementally with the number of factors present. Contemporary NSQIP data have led to the development of a risk calculator to predict postoperative cardiac complications. A multivariate logistic regression analysis demonstrated five prognostic factors for perioperative myocardial infarction (MI) or cardiac arrest: the type of operation, dependent functional status, abnormal creatinine, ASA class, and increasing age. The analysis has been validated and has led to the composition of an interactive risk calculator. Another multivariate model demonstrated criteria that predict adverse cardiac events among patients who have had elective vascular operations, and it also suggests improved predictive accuracy among these patients compared to the RCRI. Independent hazards include increasing age, smoking, insulin-dependent diabetes, coronary artery disease, congestive heart failure (CHF), abnormal cardiac stress test, long-term beta-blocker therapy, chronic obstructive pulmonary disease, and creatinine ≥ 1.8 mg/dL. Conversely, the analysis demonstrated a beneficial effect of prior cardiac revascularization. There is obviously overlap among the factors identified in these models.

The determination of an increased chance of a patient developing postoperative cardiac complications will certainly influence the tenor of preoperative discussions with patients and their family members, especially if the surgeon can present validated data regarding the actual likelihood of a cardiac complication or death. In addition, correctable hazards may be addressed, including smoking cessation, optimal control of diabetes, hypertension, and fluid status, and assurance of compliance with medical measures. Finally, formal risk assessments guide cardiologists with respect to cardiac stress testing, echocardiography, and coronary catheterization among higher-risk patients. Selected patients may be candidates for preoperative revascularization, either with coronary artery stent placement or surgical bypass.

The American College of Cardiology (ACC) Foundation and the American Heart Association (AHA) periodically issue joint recommendations about the cardiac evaluation and preparation of patients in advance of noncardiac

operations. These guidelines are evidence based, include an explanation of the quality of the data, and provide comprehensive algorithms for the propriety of testing, medications, and revascularization to assure cardiac fitness for operations. As important as preoperative cardiac risk stratification is, a cardiology consultation also lays the groundwork for postoperative risk assessment and later modifications of coronary risk factors.

Noninvasive and invasive preoperative testing should be performed only when the results will influence patient care. Noninvasive stress testing before noncardiac operations is indicated in patients with active cardiac conditions (eg, unstable angina, recent MI, significant arrhythmias, or severe valvular disease), or in patients who require vascular operations and have clinical risk factors and poor functional capacity. Good data support coronary revascularization before noncardiac operations in patients who have significant left main coronary artery stenosis, stable angina with three-vessel coronary disease, stable angina with two-vessel disease and significant proximal left anterior descending coronary artery stenosis with either an ejection fraction < 50% or ischemia on noninvasive testing, high-risk unstable angina or non-ST-segment elevation MI, or acute ST-elevation MI. However, current data do not support routine preoperative percutaneous revascularization among patients with asymptomatic coronary ischemia or stable angina.

The role of beta-blockers for cardiac protection is evolving, and these agents are no longer empirically advised for all high-risk patients due to potential adverse consequences. Beta-blockers should be continued perioperatively among those patients who are already taking them and among those having vascular operations and at high cardiac risk, including known coronary heart disease or the presence of ischemia on preoperative testing. The role of beta-blockers is uncertain for patients with just a single clinical risk factor for coronary artery disease. Cardiac complication risk calculators may become beneficial in the stratification of patients who should receive beta-blockers to reduce perioperative cardiac complications.

Preoperative aspirin usage should continue among patients at moderate to high risk for coronary artery disease, unless the risk of resultant hemorrhage definitely outweighs the likelihood of an atherothrombotic event. Thienopyridines, such as ticlopidine or clopidogrel, are administered in concert with aspirin as dual antiplatelet therapy following placement of coronary artery stents. They are intended to inhibit platelet aggregation and resultant stent thrombosis, although they certainly increase the risk of hemorrhage. Therefore, if an operation can be anticipated, the surgeon and cardiologist must coordinate efforts regarding the sequence of the proposed operation and coronary stenting, weighing the hazards of operative bleeding while on antiplatelet therapy for a stent versus potential postoperative coronary ischemia. Elective operations with a significant

risk of bleeding should be delayed 12 months before the discontinuation of the thienopyridine in the presence of a drug-eluting stent, at least 4-6 weeks for bare-metal stents, and 4 weeks after balloon angioplasty. Therefore, if a patient requires percutaneous coronary artery intervention prior to noncardiac surgery, bare-metal stents or balloon angioplasty should be employed rather than drug-eluting stents. Even when thienopyridines are withheld, aspirin should be continued, and the thienopyridine is to be resumed as soon as possible after the operation. In circumstances such as cardiovascular surgery, the dual antiplatelet agents are continued throughout the perioperative course to minimize the likelihood of vascular thrombosis.

Pulmonary

Postoperative pulmonary complications (PPC), such as the development of pneumonia and ventilator dependency, are debilitating and costly. They are associated with prolonged lengths of hospital stay, an increased likelihood of readmission, and increased 30-day mortality. Therefore, it is critical to identify patients at greatest risk for PPC. Established risk factors for PPC include advanced age, elevated ASA class, congestive heart failure, functional dependence, known chronic obstructive pulmonary disease, and perhaps malnutrition, alcohol abuse, and altered mental status. In addition, hazards are greater for certain operations (eg, aortic aneurysm repair, thoracic or abdominal, neurosurgery, head and neck, and vascular), prolonged or emergency operations, and those done under general anesthesia. A risk calculator was devised to predict the likelihood of PPC occurrence, indicating seven independent risk factors. These include low preoperative arterial oxygen saturation, recent acute respiratory infection, age, preoperative anemia, upper abdominal or thoracic operations, duration of operation over 2 hours, and emergency surgery.

A multivariable logistic regression has affirmed that active smoking is significantly associated with postoperative pneumonia, SSI, and death, when compared to nonsmokers or those who have quit smoking. Moreover, this is a dose-dependent phenomenon, predicated upon the volume and duration of tobacco consumption. The benefits of preoperative smoking cessation seem to be conferred after an interval of at least 4 weeks. Conversely, the risk of developing PPC is the same for current smokers versus those who quit smoking for less than 4 weeks before an operation. Smoking cessation also confers favorable effects on wound healing. Therefore, patients should be encouraged to stop smoking at least 1 month before operations, ideally with programmatic support through formal counseling programs and possibly smoking cessation aids such as varenicline or transdermal nicotine.

A recent analysis of patients having general surgery and orthopedic operations demonstrated that sleep apnea

is an independent risk factor for the development of PPC. A simple “STOP BANG” questionnaire can screen patients for sleep apnea. The acronym queries Snoring, Tired during day, Obstructed breathing pattern during sleep, high blood Pressure, BMI, Age over 50 years, Neck circumference, and male Gender. Patients with sleep apnea may be managed with continuous positive pressure (CPAP) or bilevel positive airway pressure (BiPAP) devices, both before and after operations. The presence of sleep apnea may also influence anesthesia techniques.

Patients identified as being at highest risk for the development of PPC may benefit from preoperative consultations with respiratory therapy and pulmonary medicine experts. Pulmonary function tests and baseline arterial blood gas tests guide the care of select patients, especially those anticipating lung resections. In addition to smoking cessation, asthma should be medically controlled. Patient education focuses upon inspiratory muscle training (including the usage of incentive spirometry), the concepts of postoperative mobilization, deep inspiration, and coughing, along with oral hygiene (tooth brushing and mouth washes). Respiratory therapists can provide expertise with CPAP and BiPAP systems for patients with sleep apnea. Surgeons and anesthesiologists should collaborate regarding plans for neuromuscular blocking agents and strategies to reduce pain, including the administration of epidural analgesics and the consideration of minimally invasive techniques to avoid large abdominal or thoracic incisions. Finally, formal intensive care unit protocols can promote liberation from ventilator support.

Venous Thromboembolism

Venous thromboembolism (VTE) events such as DVT or PE are major complications that can lead to death or serious long-term morbidity, including chronic pulmonary hypertension and postthrombotic limb sequelae. Scoring systems stratify patients by their probability of developing a postoperative VTE to guide preventative measures. In the 2012 American College of Chest Physicians (ACCP) recommendations, the patient’s score selects the alternatives of early ambulation alone (very low risk), mechanical prophylaxis with intermittent pneumatic compression (IPC) devices (low risk), options of low-molecular-weight heparin (LMWH) or low-dose unfractionated heparin or IPC (moderate risk), and IPC in addition to either LMWH or low-dose heparin (high risk). Furthermore, an extended course (4 weeks) of LMWH may be indicated among patients undergoing resections of abdominal or pelvic malignancies. Of course, the surgeon must entertain the hazards of pharmacologic prophylaxis when bleeding poses even greater harm than VTE, in which case IPC alone may suffice. Heparin prophylaxis is associated with a 4%-5% chance of wound hematomas, 2%-3% incidence of mucosal bleeding and the need to stop

the anticoagulation, and a 1%-2% risk of reoperation. The ACCP 2012 guidelines do not advocate routine vein surveillance with ultrasonography or the insertion of inferior vena cava filters for primary VTE prevention. Notably, antiembolism graduated compression stockings (GCS) do not promote venous blood flow from the leg and can violate skin integrity and result in the accumulation of edema. The efficacy of stocking for VTE prevention is unproven.

Caprini has developed a more elaborate risk calculation that has been validated in a variety of clinical settings and specialties, and is adaptable to standardized order sets (Figure 3–1). This scoring system acknowledges the gravity of individual hazards, including personal and family histories of VTE, the diagnosis of a malignancy, a history of obstetrical complications or known procoagulants, and prolonged operations, among several other factors. It also identifies patients who may either entirely avoid anticoagulation or benefit from an extended duration of LMWH. There is no doubt that the cumulative incidence of VTE extends many weeks after operations, particularly for malignancies and in an era when the duration of hospital stays (and inpatient prophylaxis) has declined. In fact, about one-third to half of patients who manifest a postoperative VTE after cancer surgery do so following hospital discharge. Therefore, regimens of pharmacologic prophylaxis should be maintained after the discharge of patients who have elevated risk scores. The ACCP and Caprini systems are two among several VTE risk assessment tools, each of which has advantages and disadvantages. The system adopted in any hospital or surgery center will be a function of local resources and culture, but it is ideal that surgeons develop and maintain a local standard to minimize the threat of postoperative VTE.

Diabetes Mellitus

Patients with diabetes mellitus are more likely to undergo operations than are those without diabetes, and their care is associated with longer lengths of hospital stay, increased rates of postoperative death and complications, and relatively greater utilization of health care resources. It has been established that elevated postoperative blood glucose levels in diabetic patients translate to progressively greater chances of SSIs following cardiac operations, as well as a greater likelihood of postoperative infections and prolonged hospital stays in patients with noncardiac operations. In fact, increased perioperative glucose levels have correlated with a higher risk of SSIs in general surgery, cardiac surgery, colorectal surgery, vascular surgery, breast surgery, hepatobiliary and pancreas surgery, orthopedic surgery, and trauma surgery. The relative risk of an SSI seems to incrementally increase in a linear pattern with the degree of hyperglycemia, with levels greater than 140 mg/dL being the sole predictor of SSI upon multivariate analysis. In one study, the likelihood of an adverse postoperative outcome increased by

Venous Thromboembolism (VTE) Risk Factor Assessment

Assessments in Last 30 Days: Assessment #1: 10/3/2012 LOC: E8EOF-1 Score: 3 Moderate Risk

Previously Selected Safety Considerations: Patient taking oral anticoagulants, platelet inhibitors (eg, NSAIDs, Clopidogrel, Salicylates)

Previously Selected Risk Factors: Age 40-59 years, Major surgery (>45 minutes)*

Today's Assessment Date: 10/3/2012 Location: E8EOF-1 Score: 3 Level: Moderate Risk MRN: [REDACTED]

Anticoagulants: Factors Associated with Increased Bleeding

- Patient is experiencing active bleeding
- Patient has (or has had history of) heparin-induced thrombocytopenia
- Patient's platelet count <100,000/mm³
- Patient taking oral anticoagulants, platelet inhibitors (eg, NSAIDs, Clopidogrel, Salicylates)
- Patient's creatinine clearance is abnormal. Value: _____

Potential contraindications to Intermittent Pneumatic Compression (IPC)

- Patient has severe peripheral Arterial disease
- Patient has congestive heart failure
- Patient has an acute superficial/deep vein thrombosis

A1: Each Risk Factor Represents 1 Point

- Age 40-59 years
- Minor surgery planned*
- History of prior major surgery (<1 month)
- Varicose veins
- History of inflammatory bowel disease
- Swollen legs (current)
- Obesity (BMI > 30)
- Acute myocardial infarction (<1 month)
- Congestive heart failure (<1 month)
- Sepsis (<1 month)
- Serious acute lung disease incl. pneumonia (<1 month)
- Abnormal pulmonary function (chronic obstructive pulmonary disease)
- Medical patient currently at bed rest

A2: For Women Only (Each Represents 1 Point)

- Oral contraceptives or hormone replacement therapy
- Pregnancy or postpartum (< 1 month)
- History of unexplained stillborn infant, recurrent spontaneous abortion (≥ 3), premature birth with toxemia of pregnancy or growth restricted infant

B: Each Risk Factor Represents 2 Points

- Age 60-74 years
- Major surgery (>45 minutes)*
- Arthroscopic surgery*
- Laparoscopic surgery (>45 minutes)*
- Leg plaster cast or brace
- Central Venous access
- Prior cancer (except non-melanoma skin)
- Present Cancer (except breast or thyroid)
- Patient confined to bed (>72 hrs)

C: Each Risk Factor Represents 3 Points

- Age 75 years or more
- History of DVT/PE
- Family History of DVT/PE
- Present chemotherapy
- Positive Factor V Leiden
- Positive Prothrombin 20210A
- Elevated serum homocysteine
- Positive Lupus anticoagulant
- Elevated anticardiolipin antibodies
- Heparin-induced thrombocytopenia (HIT)
- Other thrombophilia-Type _____

D: Each Risk Factor Represents 5 Points

- Major Surgery lasting over 6 hours*
- Elective major lower extremity arthroplasty
- Hip, pelvis or leg fracture (<1 month)
- Stroke (<1 month)
- Multiple trauma (<1 month)
- Acute spinal cord injury (paralysis) (<1 month)

30% for every 20 mg/dL increase in the mean intraoperative glucose level. Interestingly, about one-third of patients with perioperative hyperglycemia are not diabetics. Furthermore, the risk of death relative to perioperative hyperglycemia among patients undergoing noncardiac operations has been shown to be greater for those without a history of diabetes than for those with known diabetes. Nevertheless, these data pertain to intraoperative and postoperative blood sugars, not preoperative values.

Current recommendations for desirable glucose ranges in critically ill patients are commonly about 120-180 mg/dL, but the best range for perioperative glucose levels is not yet established, and low levels may result in harm when clinicians try to achieve “tight” control of blood sugars. In fact, trials and meta-analyses have failed to prove a clinical benefit of maintaining glucose levels in the normal laboratory reference range (80-110 mg/dL). Although preoperative blood sugar and hemoglobin A_{1C} levels have not clearly

correlated with adverse outcomes, good control of glucose before operations likely facilitates blood sugar management during and after operations. An abundance of data support postoperative glucose control as a major determinant of postoperative complications, with emerging data also indicating an adverse effect of intraoperative hyperglycemia. Interestingly, surgeons may actually be more influential than are patients’ primary care physicians in terms of encouraging preoperative compliance with diabetes medications, at least in the short term. Patients are commonly motivated to attend to medical conditions such as diabetes to enhance chances of postoperative success.

Patients having operations that require fasting status are advised about oral antihyperglycemic medications on the day of surgery in accordance to Table 3-3. Injectable medications such as exenatide and pramlintide are not administered on the day of surgery, and insulin therapy is determined by the duration of action of the particular

Table 3–3. Instructions for preoperative management of oral antihyperglycemic medications.

Medication	Prior to Procedure	After Procedure
Short-acting sulfonylureas: Glipizide (Glucotrol), glyburide (DiaBeta, Glynase, Micronase)	Do not take the morning of procedure	Resume when eating
Long-acting sulfonylureas: <i>f</i> Glimepiride (Amaryl), glipizide XL (Glucotrol XL)	Do not take the evening prior to or the morning of procedure	Resume when eating
Biguanides: <i>f</i> Metformin (Glucophage), metformin ER (Glucophage XL)	Do not take the morning of procedure; do not take the day prior to procedure if receiving contrast dye	Resume when eating. After contrast dye wait 48 h and repeat creatinine prior to restarting
Thiazolidinediones: <i>f</i> Pioglitazone (Actos), rosiglitazone (Avandia)	Do not take the morning of procedure	Resume when eating
Alpha-glucosidase inhibitors: Acarbose (Precose), miglitol (Glyset)	Do not take the morning of procedure	Resume when eating
DPP-4 Inhibitors: <i>f</i> Sitagliptin (Januvia)	Do not take the morning of procedure	Resume when eating
Meglitinides: <i>f</i> Nateglinide (Starlix), repaglinide (Prandin)	Do not take the morning of procedure	Resume when eating

preparation, as outlined in Table 3–4. Patients with type 1 diabetes require basal insulin at all times. Patients with insulin pumps may continue their usual basal rates.

Multidisciplinary teams, including endocrinologists, surgeons, anesthesiologists, nurses, pharmacists, information technology experts, and others, have developed formal protocols and algorithms for perioperative glycemic control, and an example of a preoperative order set is illustrated in Table 3–5. A typical protocol is nurse-driven and involves checking glucose levels on all diabetic patients in the holding area shortly before an operation. As an example of one protocol, glucose values ≤180 mg/dL are satisfactory and require no treatment. Glucose levels of 181–300 mg/dL prompt the nurse to begin an infusion of intravenous (IV) insulin before

Table 3–4. Instructions for preoperative management of injectable antihyperglycemic medications and insulin.

Medication	Prior to Procedure	After Procedure
Injectable Medications		
Exenatide (Byetta)	Do not take the morning of procedure	Resume when eating
Symlin (Pramlintide)	Do not take the morning of procedure	Resume when eating
Insulins		
Glargine (Lantus)	Take usual dose the night before or the morning of procedure	Resume usual schedule after procedure
Detemir (Levemir)	Take usual dose the night before or the morning of procedure	Resume usual schedule after procedure
NPH (Humulin N, Novolin N)	Take ½ of usual dose the morning of procedure	Resume usual schedule when eating, ½ dose while NPO
Humalog mix 70/30, 75/25, Humulin 70/30, 50/50, Novolin 70/30 (all mixed insulins)	Do not take the morning of procedure	Resume usual schedule when eating
Regular insulin (Humulin R, Novolin R)	Do not take the morning of procedure	Resume when eating
Lispro (Humalog), Aspart (Novolog), Glulisine (Apidra)	Do not take the morning of procedure	Resume when eating
Subcutaneous insulin infusion pumps	Requires tailored recommendations. In general, most patients may continue their usual basal rate and correction doses, and resume meal-time boluses when eating again

the operation, along with a 5% dextrose solution to minimize the chances of hypoglycemia. Endocrinologists are automatically consulted to assist with postoperative insulin management in these patients and in those with insulin pumps. In general, insulin pump therapy is continued along with the infusion of a dextrose solution. Patients with pumps may also require the addition of IV insulin, as per the protocol.

Patients with glucose levels > 300 mg/dL are assessed for ketones or for acidosis prior to starting an insulin infusion.

Table 3–5. Example of adult perioperative glycemic control protocol.

Adult 120-180 mg/dL Perioperative Insulin Infusion Guideline *** Not to be used in patients with acute diabetic ketoacidosis or hyperglycemic hyperosmolar syndrome *** Goal: The goal is to maintain whole blood glucose levels and/or fingersticks between 120 and 180 mg/dL.									
Glucose Level	Below Desired Range			Desired Range			Above Desired Range		
	< 80 mg/dL	80-99 mg/dL	100-119 ^b mg/dL	120-180 mg/dL ^b	181-220 ^b mg/dL	221-250 mg/dL	251-300 mg/dL	301-350 mg/dL	> 350 mg/dL
Infusion rate of 1 U/h	Stop insulin infusion: give 25 mL of D50 IVP, maintain continuous dextrose source	Stop insulin infusion. Maintain continuous dextrose source		Once in range If glucose ↑ over 2 consecutive checks, ↑ infusion by 0.5 U/h ^a	↑ infusion by 1 U/h	Give 2 units insulin IVP and ↑ infusion by 1 U/h.	Give 3 units insulin IVP and ↑ infusion by 1 U/h	Give 4 units insulin IVP and ↑ infusion by 1 U/h	Give 5 units insulin IVP and ↑ infusion by 1 U/h

Infusion rate of 6-10 U/h	Glucose level in 15 min. If > 120 mg/dL, restart at ½ previous rate	glucose level in 15 min. If > 120 mg/dL, restart at ½ previous rate	Decrease infusion rate by 50%	Once in range If glucose ↑ over 2 consecutive checks, ↑ infusion by 1 U/h	↑ infusion by 1.5 U/h	Give 2 units insulin IVP and ↑ infusion by 2 U/h	Give 3 units insulin IVP and ↑ infusion by 2 U/h	Give 6 units insulin IVP and ↑ infusion by 2 U/h	Give 8 units insulin IVP and ↑ infusion by 2 U/h
Infusion rate of 11-16 U/h	Resume fingersticks every hour until stable. Restart drip as above any time glucose is > 120	Resume fingersticks every hour until stable. Restart drip as above any time glucose is > 120		Once in range If glucose ↑ over 2 consecutive checks, ↑ infusion by 2 U/h ^a	↑ infusion by 2 U/h	Give 2 units insulin IVP and ↑ infusion by 3 U/h	Give 3 units insulin IVP and ↑ infusion by 3 U/h	Give 6 units insulin IVP and ↑ infusion by 3 U/h	Give 8 units insulin IVP and ↑ infusion by 3 U/h
Infusion rate of > 16 U/h					Call MD				

Monitoring: Check glucose every hour.

^a"Once in range" example:

Glucose	190	140 (in range now)	130 (drop 1)	120 (drop 2)	130
U	4	4	4	↑3.5	3.5

^bIf the glucose drops by > 100 mg/dL/h, consider decreasing infusion rate or discontinuing infusion if BG is declining rapidly and < 150 mg/dL.

© Boston Medical Center Corporation 2012.

Markedly elevated preoperative blood sugars warrant special deliberation by all involved. Matters to be considered include the urgency of the operation, whether the underlying condition itself may be contributing to hyperglycemia, metabolic consequences such as the presence of ketoacidosis, the risks of proceeding with an operation at that moment, the likelihood of establishing better control at a later date, and the dangers imposed by postponing the operation. Dramatic elevations (eg, > 300 mg/dL) are typically indicative of chronic poor glucose control, but the clinician often does not have the luxury of perfectly managing diabetes before operations.

Intravenous insulin is best for perioperative glucose control due to its rapid onset of action, short half-life, and immediate availability (as opposed to subcutaneous absorption). Insulin may be administered with an IV bolus technique or via continuous IV infusion, but regular glucose monitoring (eg, hourly for continuous insulin infusions) is necessary in either system to assure adequate control and to avoid hypoglycemia. The insulin administration method before, during, and after an operation (infusion vs bolus) is a function of local resources (eg, glucose meters, blood sample processing, and staffing), as well as the patient's individual circumstances. After the operation, a patient should be assessed for an insulin infusion regimen if being transferred to a critical care setting, a basal-bolus insulin program, or the resumption of the patient's usual diabetes medications.

Surgical Site Infection

Surgical site infections (SSIs) are major contributors to postoperative morbidity and can be monitored and reduced by multiple complex interventions that are institution-specific. Excellent surgical technique is obviously a major factor in eliminating SSIs, and this involves limiting wound contamination, blood loss, the duration of the operation, and local tissue trauma and ischemia (eg, using sharp dissection rather than excessive electrocoagulation). However, a variety of adjuvant preoperative measures, beyond glycemic control described above, also contribute to the prevention of SSIs. Antibiotics should be administered within the 1-hour period before incision for certain clean operations and for all clean-contaminated, contaminated, and dirty operations. In addition, further dosages of the antibiotics should be infused about every two half-lives during the operation (eg, every 4 hours for cefazolin). Correct antibiotic selection is determined by several factors, such as the bacterial flora that are most likely to cause an infection, local bacterial sensitivities, medication allergies, the presence of MRSA, and the patient's overall health and ability to tolerate an infection. In clean operations with low rates of infections, the surgeon should contrast the cost and hazards of antibiotics with the likelihood, cost, and morbidity of a postoperative infection. Antibiotic choices for prophylaxis against SSIs are cited in

Table 3–6 for a variety of operations. Operations that involve bacteroides should prompt the addition of metronidazole to the regimen, and operations with a dirty wound classification may be guided by culture results and hospital-specific bacteria sensitivities. When antibiotics are administered for SSI prophylaxis rather than for treatment of an established or suspected infection, they are typically not continued after surgery, except in special circumstances such as vascular grafts, cardiac surgery, or joint replacements. Even then, prophylaxis should expire within one to two days. Order sets, automated reminders, and team vigilance are essential to assure the consistent usage of the correct antibiotics at the right time and for the proper duration.

Wound perfusion and oxygenation are also essential to minimize the likelihood of SSIs. A sufficient intravascular blood volume provides end-organ perfusion and oxygen delivery to the surgical site. The maintenance of perioperative normothermia also has salutary effects on wound oxygen tension levels and can consequently reduce the incidence of SSIs. Therefore, the application of warming blankets immediately prior to the operation may support the patient's temperature in the operating room, especially for high-risk operations such as bowel resections that often involved a prolonged interval of positioning and preparation when a broad surface area is exposed to room air. Similarly, some data support hyperoxygenation with $\text{FiO}_2 \geq 80\%$ during the first 2 hours after a major colorectal operation.

Several other adjuvant measures are employed at the surgical site to reduce the incidence of SSIs. Protocols with mupirocin nasal ointment application and chlorhexidine soap showers have reduced the incidence of SSIs among patients colonized with methicillin-sensitive *S aureus*. During an operation, wound protectors may be deployed to minimize the chances of a superficial or deep SSI developing. Some surgeons (and their teams) change gloves and gowns, and may use a separate set of instruments (that have not come into contact with potential contaminants) for wound closure.

► Fluid & Blood Volume

Likely out of concerns about incurring renal insult, surgeons and anesthesiologists have traditionally advocated liberal perioperative fluid resuscitation during recent decades, often overestimating insensible and “third space” fluid losses. As a result, patients can develop significant volume overload that is associated with serious complications. Recent data instead support goal-directed (or protocol-based) fluid restriction as likely resulting in a decreased incidence of cardiac and renal events, pneumonia, pulmonary edema, ileus, wound infections, and anastomosis and wound healing problems, as well as shorter durations of hospital stay. Unfortunately, traditional vital signs, including even central venous pressure, do not reliably correlate with intravascular volume or

Table 3–6. Examples of prophylactic antibiotic selections for various operations.^a

Operation	Standard Selection	Penicillin Allergy	MRSA Colonization
Clean			
Adrenalectomy	Cefazolin	Vancomycin	Vancomycin
Breast	Cefazolin	Vancomycin	Vancomycin

^a These recommendations differ depending on local antibiotic resistance patterns.

cardiac output. Moreover, pulmonary artery catheterization has actually been associated with increased mortality, and its implementation for the optimization of hemodynamic status is rarely required. Pulmonary artery catheterization is valuable for few, highly selected patients who exhibit clinical cardiac instability along with multiple comorbid conditions. Newer, minimally invasive modalities for monitoring cardiac output offer promise to determine optimal preload volume and tissue oxygen delivery before and during operations, including esophageal Doppler and analyses of stroke volume variation and pulse pressure variation. The precise standards of goal-directed volume resuscitation remain elusive, but surgeons and anesthesiologists should prospectively collaborate regarding plans for both volume resuscitation and the selection of the type of anesthesia. This is especially so during the management of challenging problems such as pheochromocytomas, when patients require preoperative vasodilatation and then intravascular volume expansion. Another clinical dilemma involves patients with end-stage renal failure. Dialysis should be performed within about 24-36 hours before an operation to avoid electrolyte disturbances, but the surgeon should confer with the nephrologist to minimize intravascular blood volume depletion.

Blood transfusions may be necessary before operations, especially in the setting of active hemorrhage or profound anemia. However, transfusions have been associated with increased operative mortality and morbidity, decreased long-term survival, greater lengths of hospital stay, and higher chances of tumor recurrence due to immunosuppressive effects imparted by transfused blood. The benefits of transfusions must be balanced against their hazards. Of course, bleeding diatheses require preoperative correction, including transfusions of blood products such as fresh frozen plasma, specific clotting factors, or platelets. Hematology consultations are invaluable when blood incompatibilities or unusual factor deficiencies are present.

► Nutrition

Preoperative nutritional status bears a major impact on outcome, especially with respect to wound healing and immune status. A multivariate analysis recognizes hypoalbuminemia (albumin < 3.0 mg/dL) as an independent risk factor for the development of SSIs, with a fivefold increased incidence versus patients with normal albumin levels, corroborating the results of previous studies. Among moderately to severely malnourished patients, efforts may be focused upon preoperative feedings, ideally via the gut, although at least 1 week of the regimen is necessary to confer benefit. Total parenteral nutrition is an option for select patients in whom the gut cannot be used, but it conveys potential hazards. Immune modulating nutrition (IMN), with agents such as L-arginine, L-glutamine, ω -3 fatty acids, and nucleotides, can enhance immune and inflammatory responses. A recent

meta-analysis of randomized controlled trials suggests that perioperative IMN with open, elective gastrointestinal operations is associated with fewer postoperative complications and shorter lengths of hospital stay compared to results for patients with standard enteral nutrition. However, the value of preoperative IMN is not firmly established.

At the other end of the spectrum, investigators have demonstrated that severe obesity is associated with increased rates of postoperative mortality, wound complications, renal failure, and pulmonary insufficiency, as well as greater durations of operative time and hospital stays. The AHA has issued guidelines for the assessment and management of morbidly obese patients, including an obesity surgery mortality score for gastric bypass. Unfavorable prognostic elements include BMI ≥ 50 kg/m², male sex, hypertension, PE risks (eg, presence of a VTE event, prior inferior vena cava filter placement, history of right heart failure or pulmonary hypertension, findings of venous stasis disease), and age ≥ 45 years. Bariatric surgeons typically enforce a preoperative regimen of weight reduction before proceeding with surgery to enhance outcomes and to assure the patient's commitment to the process.

► Endocrine

Endocrine deficiencies pose special problems. Patients may have either primary adrenal insufficiency or chronic adrenal suppression from chronic corticosteroid usage. Inadequate amounts of perioperative steroids can result in an Addisonian crisis, with hemodynamic instability and even death. The need for perioperative "stress" steroid administration is a function of the duration of steroid therapy and the degree of the physiologic stress imposed by the operation. Supplemental corticosteroids should definitely be administered for established primary or secondary adrenal insufficiency, for a current regimen of more than the daily equivalent of 20 mg of prednisone, or for those with a history of chronic steroid usage and a Cushingoid appearance. Perioperative steroids should be considered if the current regimen is 5 to 20 mg of prednisone for 3 weeks or longer, for a history of more than a 3-week course of at least 20 mg of prednisone during the past year, for chronic usage of oral and rectal steroid therapy for inflammatory bowel disease, or for a significant history of chronic topical steroid usage (> 2 g daily) on large areas of affected skin. Increased amounts of corticosteroids are not necessary for patients who have received less than a 3-week course of steroids. Patients having operations of moderate (eg, lower extremity revascularization or total joint replacement) and major (eg, cardiothoracic, abdominal, central nervous system) stress should receive additional corticosteroids as outlined in Table 3-7. Minor or ambulatory operations, including those under local anesthesia, do not require supplemental steroids. Excessive amounts of steroids can have adverse

Table 3–7. Recommendations for perioperative corticosteroid management.

Type of Operation	Corticosteroid Administration
Minor/ambulatory operation ^a Example: inguinal hernia repair or operation under local anesthesia	Take usual morning steroid dose; no supplementary steroids are needed.
Moderate surgical stress ^a Example: lower extremity revascularization, total joint replacement	Day of surgery: Take usual morning steroid dose. Just before induction of anesthesia: Hydrocortisone 50 mg IV, then hydrocortisone 25 mg IV every 8 h × 6 doses (or until able to take oral steroids). When able to take oral steroids, change to daily oral prednisone equivalent of hydrocortisone, or preoperative steroid dose if that dose was higher. On the second postoperative day: Resume prior outpatient dose, assuming the patient is in stable condition. ^a
Major surgical stress ^a Example: major cardiac, brain, abdominal, or thoracic surgery Inflammatory bowel disease ^b	Day of surgery: Take usual morning steroid dose. Just before induction of anesthesia: Hydrocortisone 100 mg IV, then hydrocortisone 50 mg every 8 h × 6 doses (or until able to take oral steroids). On the second postoperative day: Reduce to hydrocortisone 25 mg q8h if still fasting, or oral prednisone 15 mg daily (or preoperative steroid dose if that was higher). Postoperative day 3 or 4: Resume preoperative steroid dose if the patient is in stable condition. ^a

^aFor patients who have a complicated postoperative course or a prolonged illness, consider endocrinology consultation for dosing recommendations. If the steroid-requiring disease *may directly impact* the postoperative course (eg, autoimmune thrombocytopenia [ITP] or hemolytic anemia), specific dosing programs and tapers should be advised prior to surgery and in consultation with the appropriate service (eg, hematology for ITP patients) during hospital stay.

^bFor patients with inflammatory bowel disease in whom all affected bowel was resected, taper to prednisone 10 mg daily (or IV equivalent) by discharge (or no later than postoperative day 7), followed by an outpatient taper over the next 1–3 months, depending on the duration of prior steroid usage and assuming that there are no concurrent indications for steroids (eg, COPD). © Boston Medical Center Corporation 2012.

consequences, including increased rates of SSIs, so hydrocortisone should not be indiscriminately prescribed. Of course, glucose levels should be closely monitored while patients receive steroids. Conversely, patients with advanced Cushing syndrome require expeditious medical and perhaps surgical treatment due to the potential for rapid deterioration, including fungal sepsis. Cushing syndrome and pheochromocytomas are separately addressed in Chapter 33.

Thyrotoxicosis must be corrected to avoid perioperative thyroid storm. Management includes antithyroid medications (eg, methimazole or propylthiouracil) and beta-blockers; saturated solution of potassium iodide controls hyperthyroidism and reduces the vascularity of the gland in patients with Graves disease. On the other hand, significant hypothyroidism can progress to perioperative hypothermia and hemodynamic collapse and thus requires preoperative hormone replacement. This is normally accomplished with daily oral levothyroxine, but greater doses of IV thyroid hormone may be necessary to acutely reverse a significant deficit. Large goiters can affect the airway and require collaboration between surgeon and anesthesiologist, possibly including a review of imaging to demonstrate the extent and location (eg, substernal) of the goiter. When possible, computed tomography contrast should be avoided in patients with significant goiters as the iodine load may provoke thyrotoxicosis.

► Geriatric Patients

As the elderly demographic expands, surgeons are confronted with increasingly frail patients who have multiple comorbidities. Simple, noninvasive, yet focused elements from the patient's history and physical examination serve as prognostic factors based upon the patient's well-being or frailty. Makary has reported graded scores (allowing for BMI, height, and gender) that are predicated upon degree of weight loss, diminished dominant grip strength, self-reported description of exhaustion levels, and weekly energy expenditure in the course of routine activities, along with walking speed. Preoperative frailty is predictive of an increased chance of postoperative complications, prolonged lengths of hospital stay, and discharge to a skilled or assisted-living facility after having previously lived at home. A recent multivariate analysis demonstrated that among more than 58,000 patients undergoing colon resection, independent predictors of major complications were an elevated frailty index, an open (vs laparoscopic) operation, and ASA Class 4 or 5, but interestingly not wound classification or emergency status. The care of the elderly requires thoughtful considerations of their diminished physiologic reserve and tolerance of the insult of an operation. Interventions may include preoperative and early postoperative physical therapy, prospective discharge planning, and the introduction of elder-specific order sets. Simple scoring systems can

provide valuable information for the surgeon to present to the patient and family so that they can anticipate the nature of the postoperative care and recovery, including potential transfer to a rehabilitation facility and long-term debility.

► Illicit Drug & Alcohol Usage

The value of routine testing for the presence of illicit drugs, at least among patients with suggestive histories, is uncertain. The presence of drugs in blood or urine might result in a cancellation of an operation, particularly if it is not immediately required. Conversely, some clinicians are not concerned about proving recent drug usage as long as the patient does not exhibit current evidence of toxicity or a hypermetabolic state. The confirmation of illicit drug usage obviously heightens awareness about the possibility of postoperative withdrawal. In general, patients should be advised to refrain from taking illicit drugs for at least a couple of weeks before an operation. Similarly, a history of heavy alcohol consumption raises the possibility of a postoperative withdrawal syndrome, which can be associated with significant morbidity and even death. It is ideal if patients can cease drinking alcohol for at least one week before an operation. Regardless of whether the patient can suspend alcohol consumption, the surgeon must closely monitor for symptoms of withdrawal among these patients and consider the regular administration of a benzodiazepine during recovery to prevent or treat acute withdrawal.

► Cancer Therapy

Many patients undergo neoadjuvant therapy for malignancies involving the breast, esophagus, stomach, pancreas, rectum, soft tissues, and other sites. The surgeon is responsible for restaging the tumor before proceeding with a resection. In general, the interval between the completion of the external beam radiation and the operation is commensurate with the duration of the radiation therapy. Similarly, a reasonable amount of time should elapse after systemic therapy to permit restoration of bone marrow capacity and nutrition, to the extent possible. Angiogenesis inhibitors such as bevacizumab disrupt normal wound perfusion and healing. The duration of time between biological therapy and an operation is not firmly established. However, it is probably best to allow 4 to 6 weeks to elapse after treating with bevacizumab before proceeding with an operation, and the therapy should not be resumed until the wound is fully healed, perhaps 1 month later.

► Emergency Operations

Emergency operations generally permit little time for risk reduction, although fluid and blood resuscitation can be instituted and antibiotics administered. Emergency operations among patients who have undergone chemotherapy

within the past month are associated with increased rates of major complications and death. In patients with profound neutropenia, operations should be deferred to the extent possible due to severely impaired wound healing and the likelihood of irreversible postoperative sepsis.

INFORMED CONSENT

The informed consent process is far more than a signed document or “permission slip.” Consent involves a conversation between the surgeon and patient (and perhaps family members or a legal guardian) that extends from the initial consultation through subsequent clinic visits or correspondence and into the preoperative holding area. The discussion addresses indications for the operation and its expected outcome, alternative treatments, the natural history of the underlying condition without intervention, the basic mechanics and details of the operation, potential risks, the impact of the operation on the patient’s health and quality of life, the extent of hospitalization and recuperation (including possible rehabilitation care), the timing of resumption of normal activities, and residual effects. The informed consent process may also indicate that a resident will participate in the patient’s care, under the supervision of the teaching surgeon and with the appropriate level of competence. Spouses and other family members should be included in the consent process for major operations that present chances of death or major debilitation.

In some circumstances, the patient may not be able to provide consent and no family members or guardians may be available. The surgeon should consider the acuity of the patient’s condition and whether it requires an immediate operation. If emergency surgery is indicated, the surgeon should document the situation and advise a hospital administrator, if possible. Some unusual, nonacute scenarios may require seeking legal consent for an operation through the judicial process.

PREOPERATIVE INSTRUCTIONS

In some settings, all preoperative preparation is conducted through surgeons and their office staffs. Conversely, more robust systems may employ an elaborate process to prepare patients for operations. Regardless of the preoperative process, education constitutes a major component. In addition to learning about the actual operation, patients (and family members or caretakers) need to understand both preparation for and recovery from the operation.

Consistent information should be provided about how long a patient should fast and what medications are to be taken on the morning of the operation. The ASA has issued guidelines about preoperative fasting. To minimize retained gastric volume and maximize gastric pH, anesthesiologists advise adults and children to refrain from drinking clear

liquids for at least 2 hours before general anesthesia, regional anesthesia, or sedation/analgesia (vs 4 hours for infants taking breast milk, or 6 hours for infant formula). Patients should avoid eating light meals for at least 6 hours and fatty meals for 8 hours before receiving anesthetics or sedatives.

In general, it is ideal for patients to continue to take their usual critical medications with a sip of water on the morning of an operation, including beta-blockers, calcium channel blockers, nitrates, and other hypertension control agents, alpha agonists or alpha antagonists, statins, hormones such as levothyroxine, psychotropic agents, oral contraceptives, and medications for cardiac rhythm problems, chronic obstructive pulmonary disease, gastroesophageal reflux, peptic diatheses, and neurologic disorders. Some surgeons and anesthesiologists advise patients to not take angiotensin-converting enzyme (ACE) inhibitors on the day of surgery due to the possibility of patients developing refractory hypotension during general anesthesia, although ACE inhibitors should be resumed shortly after the operation. Similarly, diuretics are commonly withheld on the morning of operations that involve potentially significant amounts of fluid losses and resuscitation. Of course, these recommendations are tempered by individual circumstances and clinical judgment; for example, patients probably should take their ACE inhibitors and diuretics before operations that do not require general anesthesia or involve much intravenous fluid, and when inadequately controlled hypertension could postpone the operation. Glucose and corticosteroid management have already been addressed.

Chronic narcotics (eg, methadone) are continued on the day of surgery to avoid possible withdrawal. Monoamine oxidase (MAO) inhibitors are associated with drug interactions with indirect sympathomimetics such as ephedrine (resulting in severe hypertension) or with phenylpiperidine opioids such as meperidine, tramadol, methadone, dextromethorphan, and propoxyphene (causing a serotonin syndrome with potential coma, seizures, or even death). Acute withdrawal of MAO inhibitors can provoke major depression, so they can be continued preoperatively, but without the concomitant usage of confounding medications.

The management of aspirin and thienopyridines for active coronary (or cerebrovascular) disease was reviewed earlier. Aspirin taken for other reasons, nonsteroidal anti-inflammatory agents, herbal preparations, and vitamin E can disrupt normal coagulation and should be stopped one week before an operation. Epoprostenol is a prostaglandin that is used to treat pulmonary hypertension; it also inhibits platelet aggregation and behaves like “liquid aspirin.” The discontinuation of epoprostenol will provoke pulmonary hypertension, so it is best to continue the infusion, accepting possible oozing from surgical sites that can be controlled with standard measures. Estrogen receptor antagonists (eg, tamoxifen) can be associated with an increased risk of VTE. Therefore, the surgeon should consider stopping such

medications 2-4 weeks before an operation and resuming them after a similar postoperative interval, especially in patients at a heightened risk of developing VTE.

Patients receiving anticoagulants require consideration of the indication for this therapy, the potential hazards of thrombosis developing while the anticoagulation is suspended, and the dangers of perioperative hemorrhage. Stopping warfarin 5 days before the operation will ordinarily allow normalization of INR, and the surgeon will determine if a “bridge” of a quickly reversible infusion of unfractionated heparin or LMWH injections is necessary to minimize the duration of time during which anticoagulation is withheld.

Patients should bring asthma inhalers to the hospital for usage shortly before being anesthetized. Similarly, eye drops, particularly those with beta-blockade properties, should be taken in accordance with their usual schedule.

Additional preoperative instructions include skin hygiene (eg, preoperative chlorhexidine showers, although their benefit is not absolutely proven), local care of preexisting wounds or ulcers, and discussions about tobacco, drug, or alcohol cessation, glucose management, and nutrition. Nurses may mark potential sites for bowel stomae. Some patients will require vaccinations when a splenectomy is possible.

Education also addresses what patients can expect during convalescence. This includes the importance of early postoperative mobilization and ambulation, pulmonary toilet, oral care, wound care, diet, physical therapy, rehabilitation, later adjuvant care, and even complementary or alternative options. Patients may be shown videos or provided brochures, which can be available in multiple languages. The team should definitely provide details about the logistics of the operation, including when and where the patient will report for preoperative visits and tests and for the operation itself. Finally, patients should know whom to contact with questions.

PREOPERATIVE HOLDING AREA

The time in the preoperative holding unit offers a final opportunity to educate the patient and family and to coordinate care before proceeding into the operating room. Patients (and their loved ones) are often anxious before operations and will be reassured by an organized, professional, and collegial environment. Members of the surgery team should introduce themselves and discuss the proposed operation and the anticipated postoperative care and recovery, including the possibilities of transfer to an intensive care unit or later to a rehabilitation facility. Traditional vital signs are recorded, ideally including baseline oxygen saturation. Special instructions address postoperative mobilization and pulmonary care for those patients undergoing general anesthesia or at high risk for PPC and might involve breathing

exercises with incentive spirometry. This setting is definitely a good moment to formally mark the correct site and laterality of the operation, when pertinent, and to confirm fasting status, medications taken during the past 24 hours (especially beta-blockers), allergies, recent corticosteroid usage, and pregnancy status. Checklists (Figure 3–2) have become an important mechanism to assure the application of standard practices, and a section can be devoted to the preoperative unit. In addition, order sets greatly contribute to the delivery of consistent and correct care, including the administration of prophylactic antibiotics, adequate VTE prophylaxis (including the application of compression boots), and hydrocortisone for those patients with a recent history of significant corticosteroid usage. The infusion of antibiotics is not necessarily begun in the holding area, as it may still be more than 1 hour before the actual incision, but antibiotics can be secured for delivery to the operating room with the patient. Glycemic control protocols are begun in the holding area, as outlined earlier. For patients having bowel resections, the effectiveness of the mechanical prep may be investigated, and warming blankets can be applied. Finally, surgeons and anesthesiologists have the chance to discuss blood volume status and strategies for fluid administration, which may begin in the holding area.

OPERATING ROOM

Preparation of the patient continues in the operating room, up to the moment of the incision. When local hair removal is necessary for exposure, this should be done immediately before the operation, with electric clippers. Razors traumatize skin and have been associated with a greater chance of infection. Most surgical site skin preparations contain iodine-based compounds or chlorhexidine, but the addition of isopropyl alcohol to either of these agents seems to confer the best outcomes. Regardless of the agent selected, it is important that the skin prep be applied in a standard fashion—ideally by an assigned, trained individual to assure consistency—and that it dries prior to the application of the sterile drapes. Iodine-impregnated adherent drapes can also be used to cover the skin surrounding the surgical site. The role of mechanical bowel preparations and antibiotic prophylaxis (oral and/or parenteral) in colorectal operations is addressed in another chapter. The placement of urinary catheters in the operating room merits special comment. Urinary tract infections (UTI) are costly and can be reduced in frequency by sterile placement and prompt postoperative removal. The routine practice of two people (one for exposure and one for insertion) catheterizing obese women can decrease the incidence of UTI.

Proper positioning of the patient for an operation is critical to enhance exposure, to protect potential pressure points or muscle compartments, and to avoid traction injuries to nerves. Surgeons, nurses, and anesthesia staff share

responsibility for patient safety during operations and should concur about how the patient is situated on the operating room table.

PREPARATION OF THE OPERATING ROOM FACILITY

Beyond the hazards for SSIs discussed earlier, wound sepsis is also related to the bacteriologic status of both the hospital setting in general and the operating room in particular. The entire hospital environment must be protected from undue contamination to avoid colonization and cross-infection of patients with virulent strains of microorganisms that could invade surgical sites despite the practice of asepsis, antisepsis, and sterile surgical technique. All staff should diligently wash their hands before and after contact with patients, regardless of location (ie, in the operating room or elsewhere in the facility). Patients with especially dangerous or resistant organisms (eg, *Clostridium difficile*, MRSA, and vancomycin-resistant *Enterococcus*) may warrant special precautions such as isolation and staff wearing gowns and gloves during direct contact with the patient and secretions. Notably, alcohol-based hand sanitizers are not effective against *C difficile*.

In the United States, it is standard for members of the operating room team to wear issued “scrub” clothes, caps, shoe covers, and masks, although this practice is less dogmatic in other countries. Surgeons and staff who perform the operation and handle sterile instruments wear sterile gowns, protective eye gear, and gloves. “Universal precautions” are practiced for the safety of the team, under the presumption that any patient’s blood or fluids can convey communicable diseases such as human immunodeficiency virus (HIV) or hepatitis. Formal procedures and policies should be developed locally for injured staff or those exposed to blood or other potential hazards during operations.

► Sterilization

Items used during an operation are sterilized to destroy microorganisms on the surface of the instrument or in a fluid. Current sterilization methods include steam autoclave, hydrogen peroxide gas plasma, gamma irradiation, ethylene oxide gas, and dry heat. An autoclave system uses saturated steam under pressure. This is the most widely used method due to its ability to rapidly sterilize devices while being relatively inexpensive and nontoxic. The two most common types of steam autoclaves are gravity displacement, which must reach temperatures of 121°C, and prevacuum sterilizers, which must reach temperatures of 132°C. Minimum exposure periods for wrapped devices are 30 minutes for the former technique and 4 minutes for the latter system. Of course, the implementation of steam is limited by its corrosive effect on heat-sensitive items.

▲ **FIGURE 3–2.** Sample of Universal Checklist for perioperative care. © Boston Medical Center Corporation 2012.

Liquid hydrogen peroxide is a nontoxic sterilizing agent that initiates the inactivation of microorganisms on a heat-sensitive device within 75 minutes. Liquid hydrogen peroxide is vaporized and diffused through the sterilization chamber to contact the surfaces of the device. An electrical field is created within the chamber, changing the vapor to gas plasma. Microbicidal free radicals are generated in the plasma, rendering the device sterile.

Gamma sterilization utilizes Cobalt-60 radiation to inactivate microorganisms on single-use medical supplies, pharmaceuticals, and biological-based products, although the US Food and Drug Administration does not approve gamma irradiation in health care facilities. Liquid and gaseous ethylene oxide is a toxic, flammable sterilizing agent that initiates the inactivation of microorganisms on a heat-sensitive device within 1-6 hours, with 8-12 hours required for aeration. Ethylene oxide gas is diffused through the sterilization chamber at temperatures between 37°C and 63°C and a relative humidity of 40%-80%. The gas bonds with water molecules to reach the device surfaces and render the device sterile. Due to the extended aeration time requirement and high level of toxicity, ethylene oxide gas sterilization is being replaced with nontoxic processes that have shorter process times.

Dry heat sterilization utilizes heating coils to raise the temperature of the air inside the sterilization chamber to sterilize surfaces of devices. It is appropriate only for items that have a low moist heat tolerance but high temperature tolerance. The most common time-temperature relationships for dry heat sterilization are 170°C for 1 hour, 160°C for 2 hours, and 150°C for 2.5 hours.

► Operating Room Plans

Surgeons should prospectively communicate with the operating room staff about what operation will be performed, including its anticipated duration and all necessary items, to enhance efficiency and avoid delays. “Case cards” contain information about standard equipment, devices, and sutures. Surgeons must also anticipate special needs such as unusual instruments or hardware, prosthetic materials for implantation, coagulation devices (eg, electrocautery, ultrasound or radiofrequency energy devices, lasers), intraoperative laboratory testing (eg, glucose, hematocrit, parathyroid hormone), imaging (eg, fluoroscopy, ultrasonography), nerve monitoring, and any other details specific to the operation. The primary surgeon is responsible for coordinating surgery teams when multiple consultants and allied professionals collaborate in a patient’s care, including surgeons, anesthesiologists, nurses, technicians, and others. A checklist hopefully promotes communication about these matters to assure that it is safe to proceed with an operation.

Preparations also include the development of contingency plans for a variety of dangerous scenarios. These

could include environmental problems in the operating room (eg, a fire, the loss of humidity control or power, or computer failure), or threatening clinical conditions (eg, massive hemorrhage, cardiac arrest, air embolus, malignant hyperthermia, etc). Plans can be composed as algorithms and documented on paper or online and even projected on monitors for the entire team to review.

► Preparation of the Surgery Team

Attention is being increasingly focused upon the development of teams in the operating room. Much of this work has been modeled upon the concepts of crew resource management (CRM), as promulgated by the aviation profession. Psychologists analyzed behaviors of flight crews in the 1970s and proposed measures to improve safety, including reducing the hierarchy of that time, empowering junior team members to express concerns about potential problems, and training senior crew members to listen to the perspectives of other team members while accepting questions as honest communication rather than insubordination. This approach encourages the crew to participate in the enterprise and offer their expertise and talents, while the captain remains the ultimate authority.

As in the airline industry, the implementation of CRM in the operating room is supported by a series of activities before the main event. The ideal preoperative briefing establishes the team leader, facilitates communication, outlines the team’s work, and specifies protocols, responsibilities, expectations, and contingency plans. This collaboration can result in improved outcomes, greater patient satisfaction, and better morale among team members. Checklists should not merely be perfunctory recitations of goals; they should promote a culture of teamwork. These checklists can be modified to suit local circumstances, resources, and cultures, and they codify critical steps, such as having necessary materials and medications on hand as well as indicating the appropriate location and side of the operation in instances when wrong-site mistakes could be made. Simulation training is also becoming more readily available, particularly regarding rare, complex, or high-risk scenarios, as well as the introduction of new members to teams.

► Preparation of the Surgeon

The professional development of a surgeon is a privilege and an enduring pursuit involving emotional and intellectual growth, discipline, creativity, dedication, equanimity, technical talent, and formal education. College, postgraduate, and medical school curricula are certainly preludes to accredited surgery residencies and fellowships. That certain personalities are drawn to different surgical specialties is part of the joy and diversity of the profession.

Board certification confirms that a surgeon has completed the requisite years of residency and passed a rigorous

examination to indicate competence. Learning continues well beyond formal training, as exemplified by specialty board certification and the recent Maintenance of Certification program, instituted by the American Board of Surgery and 23 other member boards of the American Board of Medical Specialties to assure lifelong professional development. The surgeon must be familiar with contemporary literature and adapt to emerging technologies and operative techniques, building upon established knowledge and skills. Moreover, the surgeon critically assesses data to decide the wisdom and value of new developments for the individual patient, the surgeon, and the prevailing health care system. Fellowship in the American College of Surgeons (or comparable organizations outside the United States and Canada) endorses that the surgeon has successfully completed a thorough evaluation of professional competence and ethical fitness. The qualifications include board certification, commitment to the welfare of patients above all else, and pledges regarding appropriate compensation and the avoidance of unjustified operations.

The surgeon must also be versed in and a leader of quality improvement within the process of caring for patients. Naturally, the proficiency provided by performing large numbers of certain high-risk operations results in improved outcomes. This is a matter of designing excellent systems that support surgical care, rather than the exclusive talents of a solitary surgeon. Ideal care involves a coordinated series of steps and collaborations—bundles of care—among teams of professionals so that the system and culture are sustained despite the loss of any individual, and the surgeon is the leader of that team. Crew Resource Management, as described earlier, has defined seven characteristics of leaders of high-performance teams:

1. **Command:** One person retains the ultimate authority and responsibility for the team and outcomes.
2. **Leadership:** The leader establishes a culture of open communication, accountability, and teamwork, serves as a mentor, manages conflict, and establishes high standards of excellence and professionalism. An effective leader inspires the team with strength and humanity.
3. **Communication:** A work environment thrives upon an effective and timely exchange of ideas among professionals to create the essential bond within the team. Members of the team should be empowered to raise concerns and to ask questions, particularly when doing so might prevent harm to a patient.
4. **Situational Awareness:** This involves a comprehension of the present circumstances through active communication with team members and knowledge of preceding events.
5. **Workload Management:** Tasks are delegated among team members commensurate with their skills and

training so that everybody is doing the right job in synergy with others.

6. **Resource Management:** This trait prospectively identifies the local resources to result in optimal outcomes.
7. **Decision Making:** This process includes collecting data from the environment and soliciting opinions from team members to permit informed judgments.

Leadership traits are not necessarily intuitive, and they require introspection, training, and practice. The surgeon remains the proverbial captain of the ship regarding the care of patients having operations, but as a consultative leader among trusted colleagues.

- C. Can be used to determine who not to operate on, for example, no ASA 5 patients should undergo operation
 - D. Includes categories ASA 1 through ASA 5
 - E. Both A and C are true
2. The perioperative process, including the workup regarding safety for anesthetic, after the decision to operate has been made
 - A. Is the sole province of the anesthesiology specialists
 - B. Should not take into account the planned operation
 - C. Is best performed by specialists not directly invested in the planned operation
 - D. Should include a pain assessment to aid in the management of postoperative pain
 - E. Both A and C are true
 3. Venous thromboembolism (VTE) risk
 - A. Has no relationship to the family history
 - B. Is assessed using the RCRI score
 - C. Can be modified by risk-based interventions
 - D. Has few long-term consequences as long as a pulmonary embolus is not fatal
 - E. Frequently should be modified by placement of an inferior vena cava filter preoperatively
 4. Patients with diabetes mellitus require more operations than their nonaffected counterparts, and if diabetes mellitus is not carefully controlled, they have increased risk of
 - A. Surgical site infection (SSI)
 - B. Perioperative adrenal insufficiency
 - C. Perioperative hypoglycemia
 - D. A, B, and C are all true
 - E. Both A and C are true
 5. Geriatric patients
 - A. Are a limited portion of a general surgery practice now and in the future
 - B. Can have their perioperative risk very closely estimated by their chronological age
 - C. Can have frailty measured by a variety of means that predict the risk of complications
 - D. Require limited special assessment other than modification of drug dosages
 - E. Both A and C are true

MULTIPLE CHOICE QUESTIONS

1. The American Society of Anesthesiologists (ASA) patient classification system
 - A. Is an approach to categorizing patients preoperatively to assess their risk for an operative procedure
 - B. Requires specific measures of certain laboratory values in order to complete the scoring system

4

Postoperative Care

Jennifer E. Rosen, MD

The modern surgeon is involved with the management of a patient from preoperative evaluation, through the conduct of the operation into the postoperative care period and often into generating a long-term plan. As the operating surgeon, he/she is best situated to apply evidence-based scientific knowledge and a deep understanding of potential complications to that patient's care. The recovery from major surgery can be divided into three phases:

1. An immediate, or postanesthetic phase
2. An intermediate phase, encompassing the hospitalization period
3. A convalescent phase

During the first two phases, care is principally directed at maintenance of homeostasis, treatment of pain, and prevention and early detection of complications. The convalescent phase is a transition period from the time of hospital discharge to full recovery. The trend toward earlier postoperative discharge after major surgery has shifted the venue of this period.

THE IMMEDIATE POSTOPERATIVE PERIOD

The primary causes of early complications and death following major surgery are acute pulmonary, cardiovascular, and fluid derangements. The postanesthesia care unit (PACU) is staffed by specially trained personnel and provided with equipment for early detection and treatment of these problems. All patients should be monitored in this specialized unit initially following major procedures unless they are transported directly to an intensive care unit. While en route from the operating room to the PACU, the patient should be accompanied by a physician and other qualified attendants. In the PACU, the anesthesiology service generally exercises primary responsibility for cardiopulmonary function. The surgeon is responsible for the operative site

and all other aspects of the care not directly related to the effects of anesthesia. The patient can be discharged from the recovery room when cardiovascular, pulmonary, and neurologic functions have returned to baseline, which usually occurs 1-3 hours following operation. Patients who require continuing ventilatory or circulatory support or who have other conditions that require frequent monitoring are transferred to an intensive care unit. In this setting, nursing personnel specially trained in the management of respiratory and cardiovascular emergencies are available, and the staff-to-patient ratio is higher than it is on the wards. Monitoring equipment is available to enable early detection of cardiorepiratory derangements.

► Postoperative Orders

Detailed treatment orders are necessary to direct postoperative care. The transfer of the patient from OR to PACU requires reiteration of any patient care orders. Unusual or particularly important orders should also be communicated to the nursing team orally. The nursing team must also be advised of the nature of the operation and the patient's condition. Errors in postoperative orders, including medication errors and omission of important orders, are diminished by electronic order entry systems that can contain postoperative order sets. Careful review of order sets is still warranted, as individual patients require specialized attention. Postoperative orders should cover the following.

A. Monitoring

1. Vital signs—Blood pressure, pulse, and respiration should be recorded frequently until stable and then regularly until the patient is discharged from the recovery room. The frequency of vital sign measurements thereafter depends upon the nature of the operation and the course in the PACU. When an arterial catheter is in place, blood pressure and

pulse should be monitored continuously. Continuous electrocardiographic monitoring is indicated for most patients in the PACU. Any major changes in vital signs should be communicated to the anesthesiologist and attending surgeon immediately.

2. Central venous pressure—Central venous pressure should be recorded periodically in the early postoperative period if the operation has entailed large blood losses or fluid shifts, and invasive monitoring is available. A Swan-Ganz catheter for measurement of pulmonary artery wedge pressure is indicated under these conditions if the patient has compromised cardiac or respiratory function.

3. Fluid balance—The anesthetic record includes all fluid administered as well as blood loss and urine output during the operation. This record should be continued in the postoperative period and should also include fluid losses from drains and stomas. This aids in assessing hydration and helps to guide intravenous fluid replacement. A bladder catheter can be placed for frequent measurement of urine output. In the absence of a bladder catheter, the surgeon should be notified if the patient is unable to void within 6-8 hours after operation to determine whether intermittent catheterization may be warranted.

4. Other types of monitoring—Depending on the nature of the operation and the patient's preexisting conditions, other types of monitoring may be necessary. Examples include measurement of intracranial pressure and level of consciousness following cranial surgery and monitoring of distal pulses following vascular surgery or in patients with casts, evaluating for expanding hematoma in patients after thyroid surgery et cetera.

5. The "postoperative check"—Most patients who remain in the hospital beyond the immediate postoperative period require an evaluation by a physician or adjunct during the 4-6 hours following surgery. This evaluation should include a review of the patient's overall subjective status, any objective alterations during that time period, an assessment of whether the postoperative orders are appropriate and adequate and if the patient has developed any signs or symptoms indicative of a complication related to their particular procedure or the anesthesia and medications administered since that time. A thorough understanding of the patient's history and surgical course will help in anticipating, preventing, and identifying any complications. Any worrisome findings should be directly and quickly communicated to the attending surgeon, who is in the best position to determine if an intervention is warranted.

B. Respiratory Care

In the early postoperative period, the patient may remain mechanically ventilated or be treated with supplemental

oxygen by mask or nasal prongs, preferably with humidification. These orders should be specified. For intubated patients, tracheal suctioning or other forms of respiratory therapy must be specified as required. Patients who are not intubated should be instructed on how to cough and do deep breathing exercises frequently to prevent atelectasis.

C. Position in Bed and Mobilization

The postoperative orders should describe any required special positioning of the patient. Unless doing so is contraindicated, the patient should be turned from side to side every 30 minutes until conscious and then hourly for the first 8-12 hours to minimize atelectasis. Early ambulation is encouraged to reduce venous stasis; the upright position helps to increase diaphragmatic excursion. Venous stasis may also be minimized by intermittent compression of the calf by pneumatic stockings. Safety considerations are paramount, including special alerts to fall risk (such as using red socks and bed rails), one-on-one monitoring, and assistance with all transfers. Support under the knees and heels can help reduce back pain and tension from immobility during surgery.

D. Diet

Patients at risk for emesis and pulmonary aspiration should have nothing by mouth until some gastrointestinal function has returned (usually within 4 days). Most patients can tolerate liquids by mouth shortly after return to full consciousness.

E. Administration of Fluid and Electrolytes

Orders for postoperative intravenous fluids should be based on maintenance needs, operative losses, and the replacement of gastrointestinal losses from drains, fistulas, or stomas.

F. Drainage Tubes

Drain care instructions should be included in the postoperative orders. Details such as type and pressure of suction, irrigation fluid and frequency, skin exit site care and support during ambulation or showering should be specified. The surgeon should examine drains frequently, since the character or quantity of drain output may herald the development of postoperative complications such as bleeding or fistulas. Careful positioning and reinforcement of anchors can prevent the dreaded early loss of key placement of nasogastric tubes, chest tubes, and drains.

G. Medications

Orders should be written for antibiotics, analgesics, gastric acid suppression, deep vein thrombosis prophylaxis, and sedatives. If appropriate, preoperative medications should

be reinstated. Medication reconciliation is important, as interactions are possible and potentially harmful. Route of administration of medications and medication substitution should be discussed with the pharmacy when necessary. Careful attention should be paid to replacement of corticosteroids in patients at risk, since postoperative adrenal insufficiency may be life threatening, but over-supplementation can affect wound healing. Other medications such as antipyretics, laxatives, and stool softeners should be used selectively as indicated. Prophylaxis for postoperative nausea and vomiting can be useful; the type and route of medication remains controversial and should be tailored to the patient.

H. Laboratory Examinations and Imaging

Postoperative laboratory and radiographic examinations should be used to detect specific abnormalities in high-risk groups. The routine use of daily chest radiographs, blood counts, electrolytes, and renal or liver function panels is not useful. Identification and treatment of hyperglycemia should be instituted in patients who require management.

THE INTERMEDIATE POSTOPERATIVE PERIOD

The intermediate phase begins with complete recovery from anesthesia and lasts for the rest of the hospital stay. During this time, the patient recovers most basic functions and becomes self-sufficient and ready to continue convalescence at home. Transfer from the PACU/SICU to a less monitored setting usually occurs at the start of this period. Communication within the care team is important during this transition; this team can include surgeons, nurses, nutritionists, social workers and case managers, respiratory, physical and occupational therapists, residents and consulting physicians. Isolation and specialized management of patients colonized or infected with drug-resistant organisms or highly contagious infectious agents continues from the OR through stay in the PACU and then with appropriate barrier devices and room determination throughout the hospital stay.

► Care of the Wound

Within hours after a wound is closed, the wound space fills with an inflammatory exudate. Epidermal cells at the edges of the wound begin to divide and migrate across the wound surface. By 48 hours after closure, deeper structures are completely sealed off from the external environment. Sterile dressings applied in the operating room provide protection during this period.

Removal of the dressing and handling of the wound during the first 24 hours should be done with aseptic technique. Medical personnel should wash their hands before and after caring for any surgical wound. Gloves should always be used when there is contact with open wounds or fresh wounds.

Dressings over closed wounds should be removed by the third or fourth postoperative day. If the wound is dry, dressings need not be reapplied; this simplifies periodic inspection. Dressings should be removed earlier if they are wet or placed in a contaminated setting, because soaked dressings increase bacterial contamination of the wound. Dressings should also be removed if the patient has new manifestations of infection (such as fever or increasing wound pain). The wound should then be inspected and the adjacent area gently compressed. Any drainage from the wound should be examined by culture and Gram-stained smear.

Vacuum dressings should usually be replaced within 24-72 hours. Pain management around the time of dressing change is important to consider, as proper prophylaxis can make the procedure less difficult for both the patient and the surgical team.

Generally, skin sutures or skin staples may be removed by the fifth postoperative day and replaced by tapes. Sutures should be left in longer (eg, for 2 weeks) for incisions that cross creases (eg, groin, popliteal area), for incisions closed under tension, for some incisions in the extremities (eg, the hand), and for incisions of any kind in debilitated patients. Sutures should be removed if suture tracts show signs of infection. If the incision is healing normally, the patient may be allowed to shower or bathe by the seventh postoperative day (and often sooner, depending on the incision).

► Management of Drains

Drains are used either to prevent or to treat an unwanted accumulation of fluid such as pus, blood, or serum. Drains are also used to evacuate air from the pleural cavity so that the lungs can re-expand. When used prophylactically, drains are usually placed in a sterile location. Strict precautions must be taken to prevent bacteria from entering the body through the drainage tract in these situations. The external portion of the drain must be handled with aseptic technique, and the drain must be removed as soon as it is no longer useful. When drains have been placed in an infected area, there is a smaller risk of retrograde infection of the peritoneal cavity, since the infected area is usually walled off. Drains should usually be brought out through a separate incision, because drains through the operative wound increase the risk of wound infection. Closed drains connected to suction devices (Jackson-Pratt or Blake drains are two examples) are preferable to open drains (such as Penrose) that predispose to wound contamination. The quantity and quality of drainage should be recorded and contamination minimized. When drains are no longer needed, they may be withdrawn entirely at one time if there has been little or no drainage or may be progressively withdrawn over a period of a few days.

Sump drains (such as Davol drains) have an airflow system that keeps the lumen of the drain open when fluid is not passing through it, and they must be attached to a continuous

suction device. Sump drains are especially useful when the amount of drainage is large or when drainage is likely to plug other kinds of drains. Some sump drains have an extra lumen through which saline solution can be infused to aid in keeping the tube clear. After infection has been controlled and the discharge is no longer purulent, the large-bore catheter may be progressively replaced with smaller catheters as the cavity closes.

Drains that have clot or thick material within them or that have lost their drainage capacity can be stripped or flushed to restore function; this should be performed only under the supervision and approval of the attending surgeon as doing so could disrupt the operative bed in some circumstances.

► Postoperative Pulmonary Care

The changes in pulmonary function observed following anesthesia and surgery are principally the result of decreased vital capacity, functional residual capacity (FRC), and pulmonary edema. Vital capacity decreases to about 40% of the preoperative level within 1-4 hours after major intra-abdominal surgery. It remains at this level for 12-14 hours, slowly increases to 60%-70% of the preoperative value by 7 days, and returns to the baseline level during the ensuing week. FRC is affected to a lesser extent. Immediately after surgery, FRC is near the preoperative level, but by 24 hours postoperatively, it has decreased to about 70% of the preoperative level. It remains depressed for several days and then gradually returns to its preoperative value by the tenth day. These changes are accentuated in patients who are obese, who smoke heavily, or who have preexisting lung disease. Elderly patients are particularly vulnerable because they have decreased compliance, increased closing volume, increased residual volume, and increased dead space, all of which enhance the risk of postoperative atelectasis. In addition, reduced forced expiratory volume in 1 second (FEV_1) impairs the aged patient's ability to clear secretions and increases the chance of infection postoperatively.

The postoperative decrease in FRC is caused by a breathing pattern consisting of shallow tidal breaths without periodic maximal inflation. Normal human respiration includes inspiration to total lung capacity several times each hour. If these maximal inflations are eliminated, alveolar collapse begins to occur within a few hours, and atelectasis with transpulmonary shunting is evident shortly thereafter. Pain is thought to be one of the main causes of shallow breathing postoperatively. Complete abolition of pain, however, does not completely restore pulmonary function. Neural reflexes, abdominal distention, obesity, and other factors that limit diaphragmatic excursion appear to be as important.

The principal means of minimizing atelectasis is deep inspiration and cough. Using an incentive spirometer can facilitate periodic hyperinflation. This is particularly useful

in patients with a higher risk of pulmonary complications (eg, elderly, debilitated, or markedly obese patients). Early mobilization, encouragement to take deep breaths (especially when standing), and good coaching by the nursing staff suffice for most patients.

Postoperative pulmonary edema is caused by high hydrostatic pressures (due to left ventricular failure, fluid overload, decreased oncotic pressure, etc), increased capillary permeability, or both. Edema of the lung parenchyma narrows small bronchi and increases resistance in the pulmonary vasculature. In addition, pulmonary edema may increase the risk of pulmonary infection. Adequate management of fluids postoperatively and early treatment of cardiac failure are important preventive measures.

Systemic sepsis increases capillary permeability and can lead to pulmonary edema. In the absence of deranged cardiac function or fluid overload, the development of pulmonary edema postoperatively should be regarded as evidence of sepsis. Signs and symptoms of pulmonary complications include fever, tachypnea, tachycardia, and an alteration in mental status. Development of atrial fibrillation or an abnormal cardiac rhythm can often precede identification of pulmonary complications.

Patients who smoked tobacco up until the time of surgery should be considered at higher risk for postoperative pulmonary complications. Symptoms of withdrawal from nicotine can be managed with a nicotine patch or gum.

Many patients undergoing surgery are offered vaccination against pneumococcal or influenza infection during their hospital stay; these should be considered where there are no contraindications.

RESPIRATORY FAILURE

Most patients tolerate the postoperative changes in pulmonary function described above and recover from them without difficulty. Patients who have marginal preoperative pulmonary function may be unable to maintain adequate ventilation in the immediate postoperative period and may develop respiratory failure. In these patients, the operative trauma and the effects of anesthesia reduce respiratory reserve below levels that can provide adequate gas exchange. In contrast to acute respiratory distress syndrome (see Chapter 12), early postoperative respiratory failure (which develops within 48 hours after the operation) is usually only a mechanical problem; that is, there are minimal alterations of the lung parenchyma. However, this problem is life threatening and requires immediate attention.

Early respiratory failure develops most commonly in association with major operations (especially on the chest or upper abdomen), severe trauma, and preexisting lung disease. In most of these patients, respiratory failure develops over a short period (minutes to 1-2 hours) without evidence of a precipitating cause. By contrast, late postoperative

respiratory failure (which develops beyond 48 hours after the operation) is usually triggered by an intercurrent event such as pulmonary embolism, abdominal distention, or opioid overdose.

Respiratory failure is manifested by tachypnea of 25-30 breaths per minute with a low tidal volume of less than 4 mL/kg. Laboratory indications are acute elevation of PCO_2 above 45 mm Hg, depression of PO_2 below 60 mm Hg, or evidence of low cardiac output. Treatment consists of immediate endotracheal intubation and ventilatory support to ensure adequate alveolar ventilation. As soon as the patient is intubated, it is important to determine whether there are any associated pulmonary problems such as atelectasis, pneumonia, or pneumothorax that require immediate treatment.

Prevention of respiratory failure requires careful postoperative pulmonary care. Atelectasis must be minimized using the techniques described above. Patients with preexisting pulmonary disease must be hydrated carefully to avoid hypovolemia or hypervolemia. These patients must hyperventilate in order to compensate for the inefficiency of the lungs. This extra work causes greater evaporation of water and dehydration. Hypovolemia leads to dry secretions and thick sputum, which are difficult to clear from the airway. High fraction of inspired oxygen (FI_{O_2}) in these patients removes the stabilizing gas nitrogen from the alveoli, predisposing to alveolar collapse. In addition, it may impair the function of the respiratory center, which is driven by the relative hypoxemia, and thus further decrease ventilation. The use of epidural blocks or other methods of local analgesia in patients with chronic obstructive pulmonary disease (COPD) may prevent respiratory failure by relieving pain and permitting effective respiratory muscle function.

► Postoperative Fluid & Electrolyte Management

Postoperative fluid replacement should be based on the following considerations:

1. Maintenance requirements
2. Extra needs resulting from systemic factors (eg, fever, burns, loss during surgery)
3. Losses from drains
4. Requirements resulting from tissue edema and ileus (third space losses)

Daily maintenance requirements for sensible and insensible loss in the adult are about 1500-2500 mL depending on the patient's age, gender, weight, and body surface area. A rough estimate can be obtained by multiplying the patient's weight in kilograms times 30 (eg, 1800 mL/24 h in a 60-kg patient). Maintenance requirements are increased by fever, hyperventilation, and conditions that increase the catabolic rate.

For patients requiring intravenous fluid replacement for a short period (most postoperative patients), it is not necessary to measure serum electrolytes at any time during the postoperative period, but measurement is indicated in patients with extra fluid losses, sepsis, preexisting electrolyte abnormalities, renal insufficiency or other factors. Assessment of the status of fluid balance requires accurate records of fluid intake and output and is aided by obtaining the patient's body weight prior to surgery and weighing the patient daily.

As a rule, 2000-2500 mL of 5% dextrose in normal saline or in lactated Ringer solution is delivered daily (Table 4-1). Potassium should usually not be added during the first 24 hours after surgery, because increased amounts of potassium enter the circulation during this time as a result of operative trauma and increased aldosterone activity.

In most patients, fluid loss through a nasogastric tube is less than 500 mL/d and can be replaced by increasing the infusion used for maintenance by a similar amount. About 20 mEq of potassium should be added to every liter of fluid used to replace these losses. However, with the exception of urine, body fluids are isosmolar, and if large volumes of gastric or intestinal juice are replaced with normal saline solution, electrolyte imbalance will eventually result. Whenever external losses from any site amount to 1500 mL/d or more, electrolyte concentrations in the fluid should be measured periodically, and the amount of replacement fluids should be adjusted to equal the amount lost. Table 4-1 lists the compositions of the most frequently used solutions.

Losses that result from fluid sequestration at the operative site are usually adequately replaced during operation, but in a patient with a large retroperitoneal dissection, severe pancreatitis, etc, third space losses may be substantial and should be considered when postoperative fluid needs are assessed.

Fluid requirements must be evaluated frequently. Intravenous orders should be evaluated every 24 hours or more often if indicated by special circumstances. Following an extensive operation, fluid needs on the first day should be reevaluated every 4-6 hours. Potassium administration can be added to the intravenous infusion only if the patient has good urine flow, has a demonstrated deficiency after significant pathologic fluid losses, and is not anticipated to start enteral feedings shortly. Postoperative ionized serum calcium in patients who have undergone thyroid or parathyroid surgery should be monitored and replaced as per the operating surgeon.

► Postoperative Care of the Gastrointestinal Tract

Following laparotomy, gastrointestinal peristalsis temporarily decreases. Peristalsis returns in the small intestine within 24 hours, but gastric peristalsis may return more slowly.

Table 4-1 Composition of frequently used intravenous solutions.

Solution	Glucose (g/dL)	Na ⁺ (mEq/L)	Cl ⁻ (mEq/L)	HCO ₃ ⁻ (mEq/L)	K ⁺ (mEq/L)
Dextrose 5% in water	50
Dextrose 5% and sodium chloride 0.45%	50	77	77
Sodium chloride 0.9%	...	154	154
Sodium chloride 0.45%	...	77	77
Lactated Ringer solution	...	130	109	28	4
Sodium chloride 3%	...	513	513

Function returns in the right colon by 48 hours and in the left colon by 72 hours. After operations on the stomach and upper intestine, propulsive activity of the upper gut can remain disorganized for 3-4 days. In the immediate postoperative period, the stomach may be decompressed with a nasogastric tube. Nasogastric intubation was once used in almost all patients undergoing laparotomy to avoid gastric distention and vomiting, but it is now recognized that routine nasogastric intubation is unnecessary and may contribute to the occurrence of postoperative atelectasis and pneumonia. For example, following cholecystectomy, pelvic operations, and colonic resections, nasogastric intubation is not needed in the average patient, and it is probably of marginal benefit following operations on the small bowel. On the other hand, nasogastric intubation is probably useful after esophageal and gastric resections and should always be used in patients with marked ileus or a very low level of consciousness (to avoid aspiration) and in patients who manifest acute gastric distention or vomiting postoperatively.

The nasogastric tube should be connected to low intermittent suction and assessed frequently to ensure patency. The tube should be left in place for 2-3 days or until there is evidence that normal peristalsis has returned (eg, return of appetite, audible peristalsis, or passage of flatus). Suture placement is usually unnecessary but careful placement of the tube and tape fixation in a natural curve can enable the patient to move their head without risk of inadvertent removal. The nasogastric tube enhances gastroesophageal reflux, and if it is clamped for a period to assess residual volume, there is a slight risk of aspiration. Most tubes are used as a "sump" where one port is for suction and the other left open to air to allow for continuous flow. This sump port should not be clamped, tied, or flushed with saline unless clogged with material.

Once the nasogastric tube has been withdrawn, fasting is usually continued for another 24 hours, and the patient is then started on a liquid diet. Opioids may interfere with gastric motility and should be limited if possible for patients

who have slow gastric emptying beyond the first postoperative week. Routine use of promotility agents or chewing gum has not demonstrated benefit in terms of quicker return to GI function.

Gastrostomy and jejunostomy tubes should be connected to low intermittent suction or dependent drainage for the first 24 hours after surgery. Absorption of nutrients and fluids by the small intestine is not affected by laparotomy, and enteral nutrition through a jejunostomy feeding tube may be started on the second postoperative day even if motility is not entirely normal. Gastrostomy or jejunostomy tubes should not be removed before the third postoperative week once firm adhesions have developed between the viscera and the parietal peritoneum. The length of tube from its point of entry into the abdominal cavity should be measured and similar between the time of insertion and the time of use; dislodgement of the tubes can be catastrophic if unrecognized before use. Any pills or medication used through the tube should be crushed (and crushable) and flushed carefully to ensure that the tube is not clogged and rendered unusable.

After most operations in areas other than the peritoneal cavity, the patient may be allowed to resume a regular diet as soon as the effects of anesthesia have completely resolved. Short-term use of parenteral nutrition in patients with good preoperative nitrogen balance and caloric intake is ill-advised; patients with preoperative catabolic states may benefit from longer-term nutritional support.

IDENTIFICATION & MANAGEMENT OF PERIOPERATIVE HYPERGLYCEMIA

Patients should be assessed at admission for history of diabetes and should undergo blood glucose testing on admission. Point of care assessment should be made in cases of elevated blood glucose for patients with known diabetes regarding monitoring, testing schedules, and glycemic targets to allow for careful coordination of blood glucose control and return to reinstitution of preadmission regimens. For patients not

previously known to have diabetes or those who may have new glucocorticoid- or surgery-induced diabetes, discharge planning may need to include management of this new diagnosis.

TRANSFUSION THERAPY

Determination of the need for transfusion and what type of transfusion is necessary can do much to improve patient outcome or can obfuscate a complication when performed without consideration of the underlying etiology of the patient's need. Knowledge of the patient's preoperative status, the course of the operation and any complications, and proper preparation for potential complications should help the physician who is considering transfusion. Restrictive transfusion thresholds may minimize patient exposure to adverse outcomes. Ultimately, the attending surgeon should determine the need for transfusion, as patients can have deficits even when laboratory values appear transiently normal.

▶ Whole Blood

Whole blood is composed of 450-500 mL of donor blood, containing RBCs (hematocrit, 35%-45%), plasma, clotting factors (reduced levels of labile factors V and VIII), and anticoagulant. Platelets and granulocytes are not functional. It is indicated for red cell replacement in massive blood loss with pronounced hypovolemia. However, whole blood for transfusion is not routinely available.

▶ Red Blood Cells

Red blood cells (RBCs) are obtained by apheresis collection or prepared from whole blood by centrifugation and removal of plasma, followed by supplementation with 100 mL of adenine-containing red cell nutrient solution. The hematocrit is 55%-60%, and the volume is 300-350 mL. RBCs collected in CPDA-1 anticoagulant have a hematocrit of 65%-80% and a storage volume of 250-300 mL. RBC transfusions are indicated to increase oxygen-carrying capacity in anemic patients. Hemoglobin levels of 7-9 g/dL are well tolerated by most asymptomatic patients. A transfusion trigger of 7 g/dL is commonly used in most stable patients. Symptomatic patients with cardiac, pulmonary, or cerebrovascular disease may require RBC transfusions to achieve higher hemoglobin levels. In a nonbleeding 70-kg recipient, transfusion of 1 unit of RBCs should increase hemoglobin level by 1 g/dL and the hematocrit by 3%. Patients can donate autologous blood in the month before surgery when appropriate; directed donors do not necessarily reduce the risk of transfusion or transfusion reaction.

▶ Washed Red Blood Cells

RBCs are washed with saline to remove more than 98% of plasma proteins and resuspended in approximately 180 mL

of saline, at an approximate hematocrit of 75%. Anemic patients with recurrent or severe allergic reactions benefit from washed RBCs. Patients with severe IgA deficiency who test positive for anti-IgA antibodies should receive RBCs washed with 2-3 L of saline or receive blood collected from IgA-deficient donors.

▶ Leukocyte-Reduced Red Blood Cells

Third-generation leukocyte reduction filters remove more than 99.9% of the contaminating leukocytes, leaving less than 5×10^6 white blood cells (WBCs) per unit. Filtration done soon after collection (prestorage leukoreduction) is more effective than bedside filtration. Patients experiencing recurrent febrile nonhemolytic transfusion reactions (FNHTRs) to RBCs or platelets should receive leukocyte-reduced products. The prophylactic use of leukoreduced RBCs and platelets in patients with long-term transfusion needs decreases the likelihood of human leukocyte antigens (HLA) alloimmunization and protects from immune platelet refractoriness and recurrent FNHTRs. Leukoreduction also decreases the risk of transmission of cytomegalovirus (CMV) infection in immunosuppressed CMV-seronegative patients.

▶ Irradiated Red Blood Cells

RBCs are irradiated with 25 Gy of gamma irradiation. All cellular products should be irradiated for patients who are at risk for transfusion-associated graft-versus-host disease (TA-GVHD). Adult patients at risk for TA-GVHD include, but are not limited to, the following: those with congenital severe immunodeficiency, hematological malignancy receiving intensive chemoradiotherapy, Hodgkin and non-Hodgkin lymphoma, certain solid tumors (neuroblastoma and sarcoma), peripheral blood stem cell and marrow transplants, or recipients of fludarabine-based chemotherapy, and those receiving directed donations from blood relatives or HLA-matched platelets. Acellular products such as fresh frozen plasma (FFP) and cryoprecipitate are not irradiated. Leukoreduction is not an acceptable substitute for irradiation.

▶ Frozen-Deglycerolized Red Blood Cells

RBCs frozen in glycerol are washed extensively in normal saline to remove the cryoprotectant and then resuspended in saline at a hematocrit of approximately 75%. More than 99.9% of the plasma is removed, and few leukocytes remain in the product. Patients who are alloimmunized to multiple antigens or those with antibodies against high-frequency antigens are supported with blood collected from donors with rare phenotypes. Most patients with severe IgA deficiency can safely receive RBCs washed with 2 L or more of saline. Frozen-deglycerolized RBCs are an equally safe and effective, albeit more cumbersome, alternative for

these patients. Rarely, patients may require RBCs collected from IgA-deficient donors. A national rare donor program facilitates the collection and storage of rare blood types.

► Platelets

Apheresis platelets are collected from single donors by apheresis and contain at least 3×10^{11} platelets in 250-300 mL plasma. Random-donor platelets (RDP) are platelet concentrates prepared from whole blood and contain 5.5×10^{10} platelets suspended in approximately 50 mL of plasma. To provide an adult dose, 5-6 units of RDP are pooled into a single pack. Platelet transfusions are indicated for the management of active bleeding in thrombocytopenic patients. Nonthrombocytopenic patients with congenital or acquired disorders of platelet function may also require platelets to stop bleeding. Platelet transfusions are also indicated prophylactically in patients requiring line placement or minor surgery when the platelet counts are less than 50,000/ μ L and in patients undergoing major surgical procedures when the count falls below 50-75,000/ μ L. Patients scheduled for ophthalmic, upper airway, or neurosurgical procedures should have platelet counts above 100,000/ μ L. Platelets are not usually recommended for the correction of thrombocytopenia in patients with heparin-induced thrombocytopenia (HIT), type IIB von Willebrand disease (vWD), idiopathic thrombocytopenic purpura (ITP), or thrombotic thrombocytopenic purpura (TTP). The clinical indications for the use of washed, irradiated, and leukoreduced platelets are analogous to those described in the section on RBCs. Patients with platelet refractoriness secondary to HLA alloimmunization should be supported with HLA-matched platelets.

► Fresh Frozen Plasma

Fresh frozen plasma (FFP) is obtained by apheresis or prepared by centrifugation of whole blood and frozen within 8 hours of collection. It contains normal levels of all clotting factors, albumin, and fibrinogen. FFP is indicated for the replacement of coagulation factors in patients with deficiencies of multiple clotting factors as occurs in the coagulopathy of liver disease, disseminated intravascular coagulation (DIC), warfarin overdose, and massive transfusions. One mL of FFP contains 1 unit of coagulation factor activity; soon after the infusion of a 10-15 mL/kg dose, the activity of all coagulation factors is increased by 20%-30%. Coagulation tests should be monitored to determine efficacy and appropriate dosing intervals. FFP should be used only if the INR is greater than 1.5 or the PT/aPTT are elevated more than 1.5 times the normal. Patients with liver disease who have minimally altered PT/aPTT and nominal bleeding should initially be managed with vitamin K replacement. Similarly, most patients with warfarin overdose can be managed by stopping warfarin for 48 hours and monitoring coagulation tests until they return to baseline levels. FFP is indicated only

for active bleeding or if there is a risk for bleeding from an emergent procedure. FFP is the only replacement product currently available for patients with rare disorders such as isolated factor deficiencies (V, X, XI) or C-1 esterase inhibitor deficiency. Patients with severe IgA deficiency should be supported with IgA-deficient plasma. FFP is the first choice for fluid replacement in patients with TTP undergoing therapeutic plasma exchange. FFP is not indicated for volume replacement, nutritional support, or replacement of immunoglobulins.

► Cryoprecipitate

Cryoprecipitate is the cold-insoluble precipitate formed when FFP is thawed at 1-6°C. This is then resuspended in 10-15 mL plasma. It contains 150 mg or more of fibrinogen, 80 IU or more of factor VIII, 40%-70% of vWF and 20%-30% of factor XIII present in the initial unit of FFP, and 30-60 mg of fibronectin. Each unit (bag) of cryoprecipitate increases fibrinogen level by 5-10 mg/dL. Eight to 10 bags are pooled and infused as a single dose in a 70-kg adult. Cryoprecipitate is indicated for the correction of hypofibrinogenemia in dilutional coagulopathy and the hypofibrinogenemia/dysfibrinogenemias of liver disease and DIC. Cryoprecipitate improves platelet aggregation and adhesion and decreases bleeding in uremic patients. It has been used for the correction of factor XIII deficiency, and it is the source of fibrinogen in the two-component fibrin sealant (Tisseel). Cryoprecipitate is no longer used to treat patients with hemophilia A or vWD.

► Granulocyte Transfusions

Granulocytes are collected by leukapheresis from donors stimulated with granulocyte colony-stimulating factor (G-CSF) and steroids to mobilize neutrophils from the marrow storage pool into peripheral blood. On average they contain 1×10^{10} or more granulocytes suspended in 200-300 mL plasma. About $1-3 \times 10^{11}$ platelets and 10-30 mL RBCs are also present in the product. Granulocyte transfusions are indicated in severely neutropenic (absolute neutrophil count $< 0.5 \times 10^3$ / μ L) patients with bacterial sepsis who have not responded to optimum antibiotic therapy after 48-72 hours, provided there is a reasonable expectation of recovery of bone marrow function. Transfusions are given daily until clinical improvement or neutrophil recovery occurs.

► Erythropoietin Stimulating Agents & Other Blood Substitutes

Routine use of erythropoietin stimulating agents for patients undergoing surgery is not recommended. Selective use in patients with anemia undergoing major elective surgery is under investigation. Likewise, the effectiveness of recombinant human factor VIIa and other coagulation factor

replacement for routine prophylactic use in general surgery in patients without hemophilia remains unproven.

POSTOPERATIVE PAIN

Severe pain is a common sequela of intrathoracic, intra-abdominal, and major bone or joint procedures. About 60% of such patients perceive their pain to be severe, 25% moderate, and 15% mild. In contrast, following superficial operations on the head and neck, limbs, or abdominal wall, less than 15% of patients characterize their pain as severe. The factors responsible for these differences include duration of operation, degree of operative trauma, type of incision, and magnitude of intraoperative retraction. Gentle handling of tissues, expedient operations, and good muscle relaxation help lessen the severity of postoperative pain. Objective measures of pain remain elusive.

While factors related to the nature of the operation influence postoperative pain, it is also true that the same operation produces different amounts of pain in different patients. This varies according to individual physical, emotional, and cultural characteristics. Much of the emotional aspect of pain can be traced to anxiety. Feelings such as helplessness, fear, and uncertainty contribute to anxiety and may heighten the patient's perception of pain.

It was once thought that anesthesia and analgesia in neonates and infants was too risky and that these young patients did not perceive pain. It is now known that reduction of pain with appropriate techniques actually decreases morbidity from major surgery in this age group.

The physiology of postoperative pain involves transmission of pain impulses via splanchnic (not vagal) afferent fibers to the central nervous system, where they initiate spinal, brain stem, and cortical reflexes. Spinal responses result from stimulation of neurons in the anterior horn, resulting in skeletal muscle spasm, vasospasm, and gastrointestinal ileus. Brain stem responses to pain include alterations in ventilation, blood pressure, and endocrine function. Cortical responses include voluntary movements and psychologic changes, such as fear and apprehension. These emotional responses facilitate nociceptive spinal transmission, lower the threshold for pain perception, and perpetuate the pain experience.

Postoperative pain serves no useful purpose and may cause alterations in pulmonary, circulatory, gastrointestinal, and skeletal muscle function that contribute to postoperative complications. Pain following thoracic and upper abdominal operations, for example, causes voluntary and involuntary splinting of thoracic and abdominal muscles and the diaphragm. The patient may be reluctant to breathe deeply, promoting atelectasis. The limitation in motion due to pain predisposes to venous stasis, thrombosis, and embolism. Release of catecholamines and other stress hormones by postoperative pain causes vasospasm and hypertension,

which may in turn lead to complications such as stroke, myocardial infarction, and bleeding. Prevention of postoperative pain is thus important for reasons other than the pain itself. Effective pain control may improve the outcome of major operations.

▶ A. Communication

Close attention to the patient's needs, frequent reassurance, and genuine concern help to minimize postoperative pain. Spending a few minutes with the patient every day in frank discussions of progress and any complications does more to relieve pain than many physicians realize. Patients with preoperative drug and substance abuse still have postoperative pain needs and may require more medication than others. Communication among the patient care team can help in the understanding of specific pain-control needs.

▶ B. Parenteral Opioids

Opioids are the mainstay of therapy for postoperative pain. Their analgesic effect is via two mechanisms:

1. A direct effect on opioid receptors
2. Stimulation of a descending brain stem system that contributes to pain inhibition

Although substantial relief of pain may be achieved with opioids, they do not modify reflex phenomena associated with pain, such as muscle spasm. Opioids administered intramuscularly, while convenient, result in wide variations in plasma concentrations. This, as well as the wide variations in dosage required for analgesia among patients, reduces analgesic efficacy. Physician and nurse attitudes reflect a persistent misunderstanding of the pharmacology and psychology of pain control. Frequently, the dose of opioid prescribed or administered is too small and too infrequent. When opioid usage is limited to temporary treatment of postoperative pain, drug addiction is extremely rare.

Morphine is the most widely used opioid for treatment of postoperative pain. Morphine may be administered intravenously, either intermittently or continuously. Except as discussed below in the section on patient-controlled analgesia (PCA), continuous intravenous administration requires close supervision and is impractical except in the PACU or intensive care unit. Side effects of morphine include respiratory depression, nausea and vomiting, and clouded sensorium. In the setting of severe postoperative pain, however, respiratory depression is rare, because pain itself is a powerful respiratory stimulant.

Meperidine is an opioid with about one-eighth the potency of morphine. It provides a similar quality of pain control with similar side effects. The duration of pain relief is somewhat shorter than with morphine. Like morphine, meperidine may be given intravenously, but the same requirements for monitoring apply.

Other opioids useful for postoperative analgesia include hydromorphone and methadone. Hydromorphone is usually administered in a dose of 1-2 mg intramuscularly every 2-3 hours. Methadone is given intramuscularly or orally in an average dose of 10 mg every 4-6 hours. The main advantage of methadone is its long half-life (6-10 hours) and its ability to prevent withdrawal symptoms in patients with morphine dependence. Patients who use methadone preoperatively should be continued postoperatively on their usual dose to avoid withdrawal; most clinics maintain records on their patients and should be consulted to confirm the appropriate replacement.

▶ C. Nonopioid Parenteral Analgesics

Ketorolac tromethamine is a nonsteroidal anti-inflammatory drug (NSAID) with potent analgesic and moderate anti-inflammatory activities. It is available in injectable form suitable for postoperative use. In controlled trials, ketorolac (30 mg) demonstrated analgesic efficacy roughly equivalent to that of morphine (10 mg). A potential advantage over morphine is its lack of respiratory depression. Gastrointestinal ulceration, impaired coagulation, and reduced renal function—all potential complications of NSAID use—have not yet been reported with short-term perioperative use of ketorolac.

▶ D. Oral Analgesics

Within several days following most abdominal surgical procedures, the severity of pain decreases and oral analgesics suffice for control. Aspirin is often avoided as an analgesic postoperatively, since it interferes with platelet function, prolongs bleeding time, and interferes with the effects of anticoagulants; however, in some settings aspirin is used to diminish the risk of cardiovascular complications by these mechanisms. For most patients, a combination of acetaminophen with codeine (eg, Tylenol No. 3) or propoxyphene (Darvocet-N 50 or -N 100) suffices. Hydrocodone with acetaminophen (Vicodin) is a synthetic opioid with properties similar to those of codeine. For more severe pain, oxycodone is available in combination with aspirin (Percodan) or acetaminophen (Percocet, Tylox). Oxycodone is an opioid with slightly less potency than morphine. As with all opioids, tolerance develops with long-term use.

▶ E. Patient-Controlled Analgesia

Patient-controlled analgesia puts the frequency of analgesic administration under the patient's control but within safe limits. A device containing a timing unit, a pump, and the analgesic medication is connected to an intravenous line. By pressing a button, the patient delivers a predetermined dose of analgesic (usually morphine, 1-3 mg). The timing unit prevents overdosage by interposing an inactivation period

(usually 6-8 minutes) between patient-initiated doses. The possibility of overdosage is also limited by the fact that the patient must be awake in order to search for and push the button that delivers the morphine. The dose and timing can be changed by medical personnel to accommodate the needs of the patient. This method appears to improve pain control and even reduces the total dose of opioid given in a 24-hour period. The addition of a background continuous infusion to the patient-directed administration of analgesic appears to offer no advantage over PCA alone.

▶ F. Continuous Epidural Analgesia

Opioids are also effective when administered directly into the epidural space. Topical morphine does not depress proprioceptive pathways in the dorsal horn, but it does affect nociceptive pathways by interacting with opioid receptors. Therefore, epidural opioids produce intense, prolonged segmental analgesia with relatively less respiratory depression or sympathetic, motor, or other sensory disturbances. In comparison with parenteral administration, epidural administration requires similar dosage for control of pain, has a slightly delayed onset of action, provides substantially longer pain relief, and is associated with better preservation of pulmonary function. Epidural morphine is usually administered as a continuous infusion at a rate of 0.2-0.8 mg/h with or without the addition of 0.25% bupivacaine. Analgesia produced by this technique is superior to that of intravenous or intramuscular opioids. Patients managed in this way are more alert and have better gastrointestinal function. Side effects of continuous epidural administration of morphine include pruritus, nausea, and urinary retention. Respiratory depression may occur.

▶ G. Intercostal Block

Intercostal block may be used to decrease pain following thoracic and abdominal operations. Since the block does not include the visceral afferent nerve fibers, it does not relieve pain completely, but it does eliminate muscle spasm induced by cutaneous pain and helps to restore respiratory function. It does not carry the risk of hypotension—as does continuous epidural analgesia—and it produces analgesia for periods of 3-12 hours. The main disadvantage of intercostal blocks is the risk of pneumothorax and the need for repeated injections. These problems can be minimized by placing a catheter in the intercostal space or in the pleura through which a continuous infusion of bupivacaine 0.5% is delivered at a rate of 3-8 mL/h.

▶ H. Direct Infiltration

Direct administration of a combination of short- and long-acting local anesthetics can help significantly in management of postoperative pain in a variety of settings. Optimally,

wound infiltration or local nerve block should occur following the induction of intravenous anesthesia and prior to skin incision but may still be beneficial after incision.

► Special Considerations

Patients at the extreme of ages, who underwent acute/emergency surgery or had a poor preoperative functional and nutritional status require special postoperative consideration.

Infants and children can be both more easily taken out of equilibrium and yet can return to health more quickly. Reassessment should occur more frequently with calculation of fluid needs tailored to their body surface area and losses. The nursing ratio is expected to be higher for more critically ill children. Elderly patients tend to have more complex preoperative medical issues, require a careful preoperative functional assessment of their nutritional reserve, and may have a more sensitive response to sedatives and other medications with a prolonged return to full mental function. Careful attention to even small changes in status should trigger thoughtful appraisal of the patient.

THE CONVALESCENT PHASE

Determination and planning for discharge should start even before the operation and should be modified accordingly. It is not uncommon for patients to be discharged to a setting other than home; emergency or acute care surgery is more likely to lend itself to a change in disposition of the patient. Plans should be made early for home assistance in the activities of daily living and in assisting recovery from surgery including education on the care of ostomies, new tubes/drains, intravenous or intramuscular medications.

Daily rounds should include a plan for discontinuation of drains, supplemental oxygen, nasogastric tubes, indwelling urinary catheters, medications including antibiotics, and the need for ongoing antithrombotic therapy. Transition of medication to oral route where possible should occur early; otherwise, preparation for home administration of IV or SQ/IM medication should be made.

MULTIPLE CHOICE QUESTIONS

1. A 65-year-old woman undergoes a thyroid lobectomy for a follicular neoplasm. She has a history of coronary artery disease, hypertension, insulin-dependent diabetes, and stroke. The procedure lasted 2 hours during which the patient required occasional Neo-Synephrine for brief interoperative hypotension. Two hours after the procedure, the nurse calls from the PACU to report that the patient is agitated and hypertensive. Which of the following is unlikely to be the cause for her agitation?
 - A. Hypoxia
 - B. Stroke
 - C. "Unmasking" of cognitive dysfunction
 - D. Hyperglycemia
 - E. Hypocalcemia
2. A 43-year-old man with a distant history of intravenous drug use is now status post a right inguinal hernia

- repair and is complaining of severe groin pain on the side of the operation. All of the following are appropriate maneuvers except
- Evaluate the patient for necrotizing fasciitis
 - Reassure the patient that his use of preoperative suboxone that morning may have blocked his postoperative response to narcotics
 - Allow the nurse to administer a postoperative parenteral nonopioid analgesic
 - Discharge the patient with a prescription for pain medication and a plan for follow-up in 2 weeks
 - Perform a nerve block with local anesthetics
3. A 56-year-old woman is being prepared for an elective ventral hernia repair in the preoperative care unit. She is overweight, with a history of non-insulin-dependent diabetes, hypertension, and smoking. Her fingerstick glucose is 326, and you note that her most recent HgA_{1C} is 8.4%. She wants to proceed with the operation and has traveled a long distance to see you and has taken the day off from work. The most appropriate choice of management is
- Proceed with the operation and plan for an intraoperative insulin drip
 - Repeat the fingerstick after insulin administration and proceed with the operation if the glucose is improved with the plan for consultation of the diabetes team postoperatively for management
 - Cancel the operation with the plan for improved preoperative preparation
 - Admit the patient for preoperative glucose management and reschedule the operation for several days from now
4. Which of the following are routine components of the first 24-hour postoperative check in patients who have undergone colon resection?
- Vital signs including heart rate, blood pressure, oxygen saturation
 - Wound evaluation including assessment of drain output and content
 - Assessment of the adequacy of pain management
 - Plan for removal of the nasogastric tube, Foley catheter, and advancement of diet
 - All of the above except for D
5. A 72-year-old man underwent resection of hepatic segments 5/6 for a hepatoma in the setting of hepatocellular carcinoma 2 days ago and was recently discharged to the floor. Perioperatively, he required a large volume of fluid resuscitation. He now has bloody output from his two Jackson-Pratt drains that are seated in the liver bed, his hematocrit has fallen 7 points to 23 and his INR is 2.7, and he is febrile to 102.8°F and confused. Which of the following is the most appropriate order and choice of management?
- Evaluation of the patient, transfer to higher level of care, transfusion with 2 units of unmatched packed RBCs, return to the operating room for surgical control of bleeding
 - Evaluation of the patient, transfusion with two packs of FFP and 2 units of matched packed RBCs, computed tomography with angiography for possible embolization
 - Evaluation of the patient, intubation for protection of airway, transfer to higher level of care, transfusion with cryoprecipitate, antibiotic administration, return to the operating room for surgical control of bleeding.
 - Evaluation of the patient, intubation for protection of airway, transfer to a higher level of care, transfusion with 2 units of FFP and 2 units of matched packed RBCs, antibiotic administration, and computed tomography of the abdomen.

Postoperative Complications

Daniel I. Chu, MD
Suresh Agarwal, MD

INTRODUCTION

Complications occur after operations and surgeons must be versed in anticipating, recognizing, and managing them. The spectrum of these complications ranges from the relatively minor, such as a small postoperative seroma, to the catastrophic, such as postoperative myocardial infarction or anastomotic leak. The management of these complications also spans a spectrum from nonoperative strategies to those requiring an emergent return to the operating room.

When considering postoperative complications, it is helpful to categorize them in a system-based method that has additional usefulness in clinical research.

MECHANICAL COMPLICATIONS

Mechanical complications are defined as those that occur as a direct result of technical failure from a procedure or operation. These complications include postoperative hematoma and hemoperitoneum, seroma, wound dehiscence, anastomotic leak, and those related to lines, drains, and retained foreign bodies.

► Hematoma

Wound hematoma, a collection of blood and clot in the wound, is a common wound complication and is usually caused by inadequate hemostasis. The risk is much higher in patients who have been systemically anticoagulated and in those with preexisting coagulopathies. However, patients receiving aspirin or low-dose heparin also have a slightly higher risk of developing this complication. Vigorous coughing or marked arterial hypertension immediately after surgery may contribute to the formation of a wound hematoma.

Hematoma produces elevation and discoloration of the wound edges, discomfort, and swelling. Blood sometimes leaks between skin sutures. Neck hematoma following operation on the thyroid, parathyroid, or carotid artery are particularly

dangerous, because it may expand rapidly and compromise the airway. Small hematomas may resorb, but they increase the incidence of wound infection. Treatment in most cases consists of evacuation of the clot under sterile conditions, ligation of bleeding vessels, and reclosure of the wound.

► Hemoperitoneum

Bleeding is the most common cause of shock in the first 24 hours after abdominal surgery. Postoperative hemoperitoneum—a rapidly evolving, life-threatening complication—is usually the result of a technical problem with hemostasis, but coagulation disorders may play a role. Causes of coagulopathy, such as dilution of hemostatic factors after massive blood loss and resuscitation, mismatched transfusion, or administration of heparin, should also be considered. In these cases, bleeding tends to be more generalized, occurring in the wound, venipuncture sites, etc.

Hemoperitoneum usually becomes apparent within 24 hours after the operation. It manifests as intravascular hypovolemia: tachycardia, hypotension, decreased urine output, and peripheral vasoconstriction. If bleeding continues, abdominal girth may increase and intra-abdominal hypertension or abdominal compartment syndrome may ensue. Changes in the hematocrit are usually not obvious for 4-6 hours and are of limited diagnostic help in patients who sustain rapid blood loss.

Manifestations may be so subtle that the diagnosis is initially overlooked. Only a high index of suspicion, frequent examination of patients at risk, and systematic investigation of patients with postoperative hypotension will reliably result in early recognition. Preexisting disease and drugs taken before surgery as well as those administered during the operation may cause hypotension. The differential diagnosis of immediate postoperative circulatory collapse also includes pulmonary embolism, cardiac dysrhythmias, pneumothorax, myocardial infarction, and

severe allergic reactions. Infusions to expand the intravascular volume should be started as soon as other diseases have been ruled out. If hypotension or other signs of hypovolemia persist, one usually must reoperate promptly. At operation, bleeding should be stopped, clots evacuated, and the peritoneal cavity rinsed with saline solution.

► Seroma

A seroma is a fluid collection in the wound other than pus or blood. Seromas often follow operations that involve elevation of skin flaps and transection of numerous lymphatic channels (eg, mastectomy, operations in the groin). Seromas delay healing and increase the risk of wound infection. Those located under skin flaps can usually be evacuated by needle aspiration if necessary. Compression dressings can then occlude lymphatic leaks and limit reaccumulation. Small seromas that recur may be treated by repeated evacuation. Seromas of the groin, which are common after vascular operations, are best left to resorb without aspiration, since the risks of introducing a needle (infection, disruption of vascular structures, etc) are greater than the risk associated with the seroma itself. If seromas persist—or if they leak through the wound—the wound should be explored in the operating room and the draining sites oversewn. Open wounds with persistent lymph leaks can be treated with wound vacuum devices.

► Wound Dehiscence

Wound dehiscence is partial or total disruption of any or all layers of the operative wound. Rupture of all layers of the abdominal wall and extrusion of abdominal viscera is evisceration. Wound dehiscence occurs in 1%-3% of abdominal surgical procedures. Systemic and local factors contribute to the development of this complication.

Systemic Risk Factors

Dehiscence after laparotomy is rare in patients younger than 30 years but affects about 5% of patients older than 60 years. It is more common in patients with diabetes mellitus, uremia, immunosuppression, jaundice, sepsis, hypoalbuminemia, cancer, obesity, and in those receiving corticosteroids.

Local Risk Factors

The three most important local factors predisposing to wound dehiscence are inadequate closure, increased intra-abdominal pressure, and deficient wound healing. Dehiscence often results from a combination of these factors rather than from a single one. The type of incision (transverse, midline, etc) does not influence the incidence of dehiscence.

1. Closure—This is the single most important factor. The fascial layers give strength to a closure, and when fascia disrupts, the wound separates. Accurate approximation of anatomic layers is essential for adequate wound closure.

Most wounds that dehisce do so because the sutures tear through the fascia. Prevention of this problem includes performing a neat incision, avoiding devitalization of the fascial edges by careful handling of tissues during the operation, placing and tying sutures correctly, and selecting the proper suture material. Sutures must be placed 2-3 cm from the wound edge and about 1 cm apart. *Dehiscence is often the result of using too few stitches and placing them too close to the edge of the fascia.* It is unusual for dehiscence to recur following reclosure, implying that adequate closure was technically possible at the initial procedure. In patients with risk factors for dehiscence, the surgeon should “do the second closure at the first operation”; that is, take extra care to prevent dehiscence. Modern synthetic suture materials (polyglycolic acid, polypropylene, and others) are clearly superior to catgut for fascial closure. In infected wounds, polypropylene sutures are more resistant to degradation than polyglycolic acid sutures and have lower rates of wound disruption. Wound complications are decreased by obliteration of dead space. Stomas and drains should be brought out through separate incisions to reduce the rate of wound infection and disruption.

2. Intra-abdominal pressure—After most intra-abdominal operations, some degree of ileus exists, which may increase pressure by causing distention of the bowel. High abdominal pressure can also occur in patients with chronic obstructive pulmonary disease who use their abdominal muscles as accessory muscles of respiration. In addition, coughing produces sudden increases in intra-abdominal pressure. Other factors contributing to increased abdominal pressure are postoperative bowel obstruction, obesity, and cirrhosis with ascites formation. Extra precautions are necessary to avoid dehiscence in such patients.

3. Poor wound healing—Infection is an associated factor in more than half of wounds that rupture. The presence of drains, seromas, and wound hematomas also delays healing. Normally, a “healing ridge” (a palpable thickening extending about 0.5 cm on each side of the incision) appears near the end of the first week after operation. The presence of this ridge is clinical evidence that healing is adequate, and it is invariably absent from wounds that rupture.

Diagnosis and Management

Although wound dehiscence may occur at any time following wound closure, it is most commonly observed between the fifth and eighth postoperative days, when the strength of the wound is at a minimum. Wound dehiscence may occasionally be the first manifestation of intra-abdominal sepsis. The earliest sign of dehiscence is often discharge of serosanguineous fluid from the wound or, in some cases, sudden evisceration. The patient may describe a popping sensation associated with severe coughing or retching.

Thoracic wounds, with the exception of sternal wounds, are much less prone to dehiscence than are abdominal wounds.

When a thoracotomy closure ruptures, it is heralded by leakage of pleural fluid or air and paradoxical motion of the chest wall. Sternal dehiscence, which is almost always associated with infection, produces an unstable chest and requires early treatment. If infection is not overwhelming and there is minimal osteomyelitis of the adjacent sternum, the patient may be returned to the operating room for reclosure. Continuous mediastinal irrigation through small tubes left at the time of closure appears to reduce the failure rate. In cases of overwhelming infection, the wound is best treated by debridement and closure with a pectoralis major muscle flap, which resists further infection by increasing vascular supply to the area.

Patients with dehiscence of a laparotomy wound and evisceration should be returned to bed and the wound covered with moist towels. With the patient under general anesthesia, any exposed bowel or omentum should be rinsed with lactated Ringer solution containing antibiotics and then returned to the abdomen. After mechanical cleansing and copious irrigation of the wound, the previous sutures should be removed and the wound reclosed using additional measures to prevent recurrent dehiscence, such as full-thickness retention sutures of no. 22 wire or heavy nylon. Evisceration carries a 10% mortality rate due both to contributing factors (eg, sepsis and cancer) and to resulting local infection.

Wound dehiscence without evisceration is best managed by prompt elective reclosure of the incision. If a partial disruption is stable and the patient is a poor operative risk, treatment may be delayed and the resulting incisional hernia accepted. It is important in these patients that skin stitches, if present, not be removed before the end of the second postoperative week and that the abdomen be wrapped with a binder or corset to limit further enlargement of the fascial defect or sudden disruption of the covering skin. When partial dehiscence is discovered during treatment of a wound infection, repair should be delayed if possible until the infection has been controlled, the wound has healed, and 6-7 months have elapsed. In these cases, antibiotics specific for the organisms isolated from the previous wound infection must be given at the time of hernia repair.

Recurrence of evisceration after reclosure of disrupted wounds is rare, though incisional hernias are later found in about 20% of such patients—usually those with wound infection in addition to dehiscence.

Of special circumstance, patients with ascites are at risk of fluid leak through the wound. Left untreated, ascitic leaks increase the incidence of wound infection and, through retrograde contamination, may result in peritonitis. Prevention in susceptible patients involves closing at least one layer of the wound with a continuous suture and taking measures to avoid the accumulation of ascites postoperatively. If an ascitic leak develops, the wound should be explored and the fascial defect closed. The rest of the wound, including the skin, should also be closed.

In patients at high risk for wound dehiscence, placement of retention stitches at the initial operation should be considered. Although these do not prevent dehiscence, they may prevent evisceration and the morbidity and mortality that are associated with it.

► Anastomotic Leak

Anastomotic leaks are reported in 1%-24% of anastomoses with higher frequencies in low pelvic anastomoses compared to more proximal ones. The morbidity and mortality for a patient with an anastomotic leak is significantly increased with a reportedly threefold increase in mortality.

Anastomotic healing follows the same principles of normal wound healing, and the risk factors for developing an anastomotic leak are identical to those that predict wound dehiscence. Systemic risk factors include age, malnutrition, vitamin deficiencies, and comorbid conditions such as diabetes, smoking, inflammatory bowel disease such as regional enteritis, previous radiation/chemotherapy and anemia. Local risk factors include tension, poor blood flow, hypotension, radiation, and contamination.

Technical considerations such as hand-sewn versus stapled anastomoses, continuous versus interrupted sutures, and single versus double-layer hand-sewn anastomoses have been extensively studied. While such topics generate much discussion and controversy, the technique chosen has less to do with anastomotic leaks than systemic and local factors. Stapled end-to-end anastomoses, however, may lead to higher rates of anastomotic strictures in long-term follow-up.

The diagnosis of an anastomotic leak can be made clinically, radiographically, and intraoperatively. Clinical signs include pain, fever, peritonitis, and drainage of purulent material, bilious succus, or fecal material. Radiographic signs include fluid and gas-containing collections tracking to an anastomosis. Intraoperative findings include gross contamination from gastrointestinal contents and evidence of anastomotic disruption.

The management of an anastomotic leak depends on several factors, including the patient's clinical status, the time from initial operation, and the location and severity of the leak. The management strategies can range from nonoperative (observation, bowel rest, antibiotics, and percutaneous drainage of abscesses) to the operative (open drainage, proximal diversion, and revision of anastomosis).

► Complications of Lines, Drains, & Retained Foreign Bodies

Lines

Complications due to central line placement and maintenance are preventable with adequate experience, preparation, and technique. Choice of site, utilization of ultrasound,

and assiduous adherence to sterile technique decrease infection, as well as mechanical complications such as pneumothorax and arterial injury.

Phlebitis—A needle or a catheter inserted into a vein and left in place will in time cause inflammation at the entry site. When this process involves the vein wall, it is called *phlebitis*. Factors determining the degree of inflammation are the nature of the cannula, the solution infused, bacterial infection, and venous thrombosis. Phlebitis is one of the most common causes of fever after the third postoperative day. The symptomatic triad of induration, edema, and tenderness is characteristic. Visible signs may be minimal. Prevention of phlebitis is best accomplished by observance of aseptic techniques during insertion of venous catheters, frequent change of tubing (ie, every 48-72 hours), and rotation of insertion sites (ie, every 4 days). Silastic catheters, which are the least reactive, should be used when the line must be left in for a long time. Hypertonic solutions should be infused only into veins with substantial flow, such as the subclavian, jugular, or vena cava. Venous catheters should be removed at the first sign of redness, induration, or edema. Because phlebitis is most frequent with cannulation of veins in the lower extremities, this route should be used only when upper extremity veins are unavailable. Removal of the catheter is adequate treatment.

Suppurative phlebitis—Suppurative phlebitis may result from the presence of an infected thrombus around the indwelling catheter. Staphylococci are the most common causative organisms. Local signs of inflammation are present, and pus may be expressed from the venipuncture site. High fever and positive blood cultures are common. Treatment consists of excising the affected vein, extending the incision proximally to the first open collateral, and leaving the wound open.

Cardiopulmonary complications—Pneumothorax after placement of a central catheter into either the subclavian or internal jugular veins occurs with an incidence approaching 1%. Chances for occurrence may be minimized by proper positioning, use of ultrasound, and experience. Ultrasound, in general, has markedly decreased the complication rate of central line placement. By adequately imaging the vein prior to venipuncture, the rate of arterial injury has markedly decreased. Injury to arteries can lead to pseudoaneurysm formation, continuous bleeding, or stroke, depending upon the vessel injured, size of arteriotomy, and presence of coagulopathy. Perforation of the right atrium with cardiac tamponade can occur due to central venous lines. This complication can be avoided by checking the position of the tip of the line, which should be in the superior vena cava, not the right atrium. Complications associated with the use of the flow-directed balloon-tipped (Swan-Ganz) catheter include cardiac perforation (usually of the right atrium),

intracardiac knotting of the catheter, and cardiac dysrhythmias. Pulmonary hemorrhage may result from disruption of a branch of the pulmonary artery during balloon inflation and may be fatal in patients with pulmonary hypertension. Steps in prevention include careful placement, advancement under continuous pressure monitoring, and checking the position of the tip before inflating the balloon.

Air embolism—Air embolism may occur during or after insertion of a venous catheter or as a result of accidental introduction of air into the line. Intravenous air lodges in the right atrium, preventing adequate filling of the right heart. This is manifested by hypotension, jugular venous distention, and tachycardia. This complication can be avoided by placing the patient in the Trendelenburg position when a central venous line is inserted. Emergency treatment consists of aspiration of the air with a syringe. If this is unsuccessful, the patient should be positioned right side up and head down, which will help dislodge the air from the right atrium and return circulatory dynamics to normal.

Ischemic necrosis of the finger—Continuous monitoring of arterial blood pressure during the operation and in the intensive care unit requires insertion of a radial or femoral arterial line. The hand receives its blood supply from the radial and ulnar arteries, and because of the anatomy of the palmar arches, patency of one of these vessels is usually enough to provide adequate blood flow through the hand. Occasionally, ischemic necrosis of the finger follows use of an indwelling catheter in the radial artery. This serious complication may be limited by evaluating the patency of the ulnar artery (Allen test) before establishing the radial line and by changing arterial line sites every 3-4 days. After an arterial catheter is withdrawn, a pressure dressing should be applied to avoid formation of an arterial pseudoaneurysm.

Drains

Postoperative drainage of the peritoneal cavity is indicated to prevent accumulation of fluid such as bile or pancreatic fluid, or to treat established abscess. Drains may be left to evacuate small amounts of blood, but drain output cannot be used to provide a reliable estimate of the rate of bleeding. The use of drains in operations not expected to have fluid leak (such as cholecystectomy, splenectomy, and colectomy) increases the rate of postoperative intra-abdominal and wound infection. Latex Penrose drains, which were used frequently in the past, should generally be avoided because of the risk of introducing infection. Large rigid drains may erode into adjacent viscera or vessels and cause fistula formation or bleeding. This risk is lessened with the use of softer Silastic drains, and removing them as early as possible. Drains should not be left in contact with intestinal anastomoses, as they may promote anastomotic leakage and fistula formation.

Retained Foreign Bodies

Studies based on hospital claims data estimate that cases of retained objects, which include sponges and instruments, occur at least once a year in those hospitals where 8000 to 18,000 major procedures are performed annually. While mortality is low, the morbidity is high due to the almost universal need for reoperation. The most common body cavity involved is the abdomen followed by the thoracic cavity. Improving communication within the operating room, formal sponge and instrument counts, and appropriate use of radiography all contribute to a decrease in this complication.

NEUROLOGICAL COMPLICATIONS

► Postoperative Cerebrovascular Accidents

Postoperative cerebrovascular accidents are almost always the result of ischemic neural damage due to poor perfusion. These often occur in elderly patients with atherosclerosis who become hypotensive during or after surgery (from sepsis, bleeding, cardiac arrest, or anesthetic effects). Normal regulatory mechanisms of the cerebral vasculature can maintain blood flow over a wide range of blood pressures down to a mean pressure of about 55 mm Hg. Abrupt hypotension, however, is less well tolerated than a more gradual pressure change. Irreversible brain damage occurs after about 4 minutes of total cerebral ischemia.

Strokes occur in 1%-5% of patients after carotid endarterectomy and other reconstructive operations of the extracranial portion of the carotid system. Rates of cerebrovascular accidents vary depending upon patient symptomatology, plaque anatomy, and degree of stenosis. Causative factors such as embolization from atherosclerotic plaques, ischemia during carotid clamping, postoperative thrombosis at the site of the arteriotomy, or intimal flap development are usually responsible. Aspirin, which inhibits platelet aggregation, may prevent immediate postoperative thrombosis.

Open heart surgery using extracorporeal circulation or deep cooling is also occasionally followed by stroke. The pathogenesis of stroke may be related to hypoxemia, emboli, or poor perfusion. The presence of a carotid bruit preoperatively increases the risk of postoperative stroke after coronary bypass by a factor of 4. Previous stroke or transient ischemic attacks and postoperative atrial fibrillation also increase the risk. For patients undergoing noncardiac, noncarotid surgery, the risk of stroke is about 0.2%. Predictors of risk in these patients are the presence of cerebrovascular, cardiac, or peripheral vascular disease and arterial hypertension.

► Seizures

Epilepsy, metabolic derangements, and medications may lead to seizures in the postoperative period. For unknown reasons, patients with ulcerative colitis and Crohn disease

are peculiarly susceptible to seizures with loss of consciousness after surgery. Seizures should be treated rapidly to minimize their harmful effects.

PSYCHIATRIC COMPLICATIONS

Anxiety and fear are normal in patients undergoing surgery. The degree to which these emotions are experienced depends upon diverse cultural and psychological variables. Underlying depression or a history of chronic pain may serve to exaggerate the patient's response to surgery. The boundary between the normal manifestations of stress and postoperative psychosis is difficult to establish, since the latter is not really a distinct clinical entity.

Postoperative psychosis develops in about 0.5% of patients having abdominal operations. It is more common after thoracic surgery, in the elderly, and in those with chronic disease. About half of these patients suffer from mood disturbances (usually severe depression). Twenty percent have delirium. Drugs given in the postoperative period may play a role in the development of psychosis; meperidine, cimetidine, and corticosteroids are most commonly implicated. Patients who develop postoperative psychosis have higher plasma levels of β -endorphin and cortisol than those who do not. These patients also lose, temporarily, the normal circadian rhythms of β -endorphin and cortisol. Specific psychiatric syndromes may follow specific procedures, such as visual hallucinations and the "black patch syndrome" after ophthalmic surgery. Preexisting psychiatric disorders not apparent before the operation sometimes contribute to the motivation for surgery (eg, circumcision or cosmetic operations in schizophrenic patients).

Clinical manifestations are rare on the first postoperative day. During this period, patients appear emotionless and unconcerned about changes in the environment or in themselves. Most overt psychiatric derangements are observed after the third postoperative day. The symptoms are variable but often include confusion, fear, and disorientation as to time and place. Delirium presents as altered consciousness with cognitive impairment. These symptoms may not be readily apparent to the surgeon, as this problem usually occurs in sick patients whose other problems may mask the manifestations of psychosis. Early psychiatric consultation should be obtained when psychosis is suspected so that adequate and prompt assessment of consciousness and cognitive function can be done and treatment instituted. The earlier the psychosis is recognized, the easier it is to correct. Metabolic derangements or early sepsis (especially in burn patients) must be evaluated and treated if present. Severe postoperative emotional disturbances may be avoided by appropriate preoperative counseling of the patient by the surgeon. This includes a thorough discussion of the operation and the expected outcome, acquainting the patient with the intensive care unit, etc. Postoperatively, the surgeon must attend to the patient's emotional needs, offering frequent reassurance,

explaining the postoperative course, and discussing the prognosis and the outcome of the operation.

► Special Psychiatric Problems

The ICU Syndrome

The continuous internal vigilance that results from pain and fear and the sleep deprivation from bright lights, monitoring equipment, and continuous noise can cause a psychologic disorganization known as ICU psychosis. The patient whose level of consciousness is already decreased by illness and drugs is more susceptible than a normal individual, and the result is decreased ability to think, perceive, and remember. When the cognitive processes are thoroughly disorganized, delirium occurs. The manifestations include distorted visual, auditory, and tactile perception; confusion and restlessness; and inability to differentiate reality from fantasy. Prevention includes isolation from the environment, decreased noise levels, adequate sleep, and removal from the intensive care unit as soon as possible.

Postcardiotomy Delirium

Mental changes that occasionally follow open heart surgery include impairment of memory, attention, cognition, and perception and occasionally hysteria, depressive reaction, and anxiety crisis. The symptoms most often appear after the third postoperative day. The type of operation, the presence of organic brain disease, prolonged medical illness, and the length of time on extracorporeal circulation are related to the development of postcardiotomy psychosis. Mild sedation and measures to prevent the ICU syndrome may prevent this complication. In more severe cases, haloperidol (Haldol) in doses of 1-5 mg given orally, intramuscularly, or intravenously may be required. Haloperidol is preferred over phenothiazines in these patients because it is associated with a lower incidence of cardiovascular side effects.

Delirium Tremens

Delirium tremens occurs in alcoholics who stop drinking suddenly. Hyperventilation and metabolic alkalosis contribute to the development of the full-blown syndrome. Hypomagnesemia and hypokalemia secondary to alkalosis or nutritional deficits may precipitate seizures. Readaptation to ethanol-free metabolism requires about 2 weeks, and it is during this period that alcoholics are at greatest risk of developing delirium tremens.

The prodrome includes personality changes, anxiety, and tremor. The complete syndrome is characterized by agitation, hallucinations, restlessness, confusion, overactivity, and occasionally seizures and hyperthermia. The syndrome also causes a hyperdynamic cardiorespiratory and metabolic state. For example, cardiac index, oxygen delivery, and oxygen consumption double during delirium tremens and

return to normal 24-48 hours after resolution. The wild behavior may precipitate dehiscence of a fresh laparotomy incision. Diaphoresis and dehydration are common, and exhaustion may herald death.

Withdrawal symptoms may be prevented by giving small amounts of alcohol, but benzodiazepines are the treatment of choice. Vitamin B₁ (thiamine) and magnesium sulfate should also be given.

The aims of treatment are to reduce agitation and anxiety as soon as possible and to prevent the development of other complications (eg, seizures, aspiration pneumonia). General measures should include frequent assessment of vital signs, restoration of nutrition, administration of vitamin B, correction of electrolyte imbalance or other metabolic derangements, and adequate hydration. Physical restraint, though necessary for seriously violent behavior, should be as limited as possible. With proper care, most patients improve within 72 hours.

SEXUAL DYSFUNCTION

Sexual problems commonly occur after certain kinds of operations, such as prostatectomy, heart surgery, and aortic reconstruction. The pathogenesis can be due to injury to nerves necessary for sexual function, though in other cases the etiology is unclear. After abdominoperineal resection, severance of the peripheral branches of the sacral plexus may cause impotence. It is important to discuss this possibility with the patient before any operation with a risk of impotence is performed. When sexual dysfunction is psychogenic, reassurance is usually all that is needed. If impotence persists beyond 4-6 weeks, appropriate consultation is indicated.

CARDIAC COMPLICATIONS

Cardiac complications following surgery may be life threatening. Their incidence is reduced by appropriate preoperative preparation.

Dysrhythmias, unstable angina, heart failure, or severe hypertension should be corrected before surgery whenever possible. Valvular disease—especially aortic stenosis—limits the ability of the heart to respond to increased demand during operation or in the immediate postoperative period. When aortic stenosis is recognized preoperatively—and assuming that the patient is monitored adequately—the incidence of major perioperative complications is small. Patients with preexisting heart disease should be evaluated by a cardiologist preoperatively. Determination of cardiac function, including indirect evaluation of the left ventricular ejection fraction, identifies patients at higher risk for cardiac complications. Continuous electrocardiographic monitoring during the first 3-4 postoperative days detects episodes of ischemia or dysrhythmia in about a third of these patients. Oral anticoagulant drugs should be stopped 3-5 days before surgery, and the prothrombin time should be allowed to

return to normal. Patients at high risk of thromboembolic disease should receive heparin until approximately 6 hours before the operation, when heparin should be stopped. If needed, heparin can be restarted 36-48 hours after surgery along with oral anticoagulation.

General anesthesia depresses the myocardium, and some anesthetic agents predispose to dysrhythmias by sensitizing the myocardium to catecholamines. Monitoring of cardiac activity and blood pressure during the operation detects dysrhythmias and hypotension early. In patients with a high cardiac risk, regional anesthesia may be safer than general anesthesia for procedures below the umbilicus.

The duration and urgency of the operation and uncontrolled bleeding with hypotension have been individually shown to correlate positively with the development of serious postoperative cardiac problems. In patients with pacemakers, the electrocautery current may be sensed by the intracardiac electrode, causing inappropriate pacemaker function.

Noncardiac complications may affect the development of cardiac complications by increasing cardiac demands in patients with a limited reserve. Postoperative sepsis and hypoxemia are foremost. Fluid overload can produce acute left ventricular failure. Patients with coronary artery disease, dysrhythmias, or low cardiac output should be monitored postoperatively in an intensive care unit.

► Dysrhythmias

Most dysrhythmias appear during the operation or within the first 3 postoperative days. They are especially likely to occur after thoracic procedures.

Intraoperative Dysrhythmias

The overall incidence of intraoperative cardiac dysrhythmias is 20%; most are self-limited. The incidence is higher in patients with preexisting dysrhythmias and in those with known heart disease (35%). About one-third of dysrhythmias occur during induction of anesthesia. These dysrhythmias are usually related to anesthetic agents (eg, halothane, cyclopropane), sympathomimetic drugs, digitalis toxicity, and hypercapnia.

Postoperative Dysrhythmias

These dysrhythmias are generally related to reversible factors such as hypokalemia, hypoxemia, alkalosis, digitalis toxicity, and stress during emergence from anesthesia. Occasionally, postoperative dysrhythmias may be the first sign of myocardial infarction. Most postoperative dysrhythmias are asymptomatic, but occasionally the patient complains of chest pain, palpitations, or dyspnea.

Supraventricular dysrhythmias usually have few serious consequences but may decrease cardiac output and coronary

blood flow. Patients with atrial flutter or fibrillation with a rapid ventricular response and who are in shock require cardioversion. If they are hemodynamically stable, they should have the heart rate controlled with digitalis, beta-blockers, or calcium channel blockers. Associated hypokalemia should be treated promptly.

Ventricular premature beats are often precipitated by hypercapnia, hypoxemia, pain, or fluid overload. They should be treated with oxygen, sedation, analgesia, and correction of fluid losses or electrolyte abnormalities. Ventricular dysrhythmias have a more profound effect on cardiac function than supraventricular dysrhythmias and may lead to fatal ventricular fibrillation. Immediate treatment is with lidocaine, 1 mg/kg intravenously as a bolus, repeated as necessary to a total dose of 250 mg, followed by a slow intravenous infusion at a rate of 1-2 mg/min. Higher doses of lidocaine may cause seizures.

Postoperative complete heart block is usually due to serious cardiac disease and calls for the immediate insertion of a pacemaker. First- or second-degree heart block is usually well tolerated.

► Postoperative Myocardial Infarction

Approximately 0.4% of all patients undergoing an operation in the United States experience a postoperative myocardial infarction. The incidence increases to 5%-12% in patients undergoing operations for other manifestations of atherosclerosis (eg, carotid endarterectomy, aortoiliac graft). Other important risk factors include preoperative congestive heart failure, ischemia identified on dipyridamole-thallium scan or treadmill exercise test, and age over 70 years. In selected patients with angina, consideration should be given to coronary revascularization before proceeding with a major elective operation on another organ.

Postoperative myocardial infarction may be precipitated by factors such as hypotension or hypoxemia. Clinical manifestations include chest pain, hypotension, and cardiac dysrhythmias. Over half of postoperative myocardial infarctions, however, are asymptomatic. The absence of symptoms is thought to be due to the residual effects of anesthesia and to analgesics administered postoperatively.

Diagnosis is substantiated by electrocardiographic changes, elevated serum creatine kinase levels—especially the MB isoenzyme—and serum troponin I levels. The mortality rate of postoperative myocardial infarction is as high as 67% in high-risk groups. The prognosis is better if it is the first infarction and worse if there have been previous infarctions. Prevention of this complication includes postponing elective operations for 3 months or preferably 6 months after myocardial infarction, treating congestive heart failure preoperatively, and controlling hypertension perioperatively.

Patients with postoperative myocardial infarction should be monitored in the intensive care unit and provided with adequate oxygenation and precise fluid and electrolyte

replacement. Anticoagulation, though not always feasible after major surgery, limits the risk of mural thrombosis development and arterial embolism after myocardial infarction. Congestive heart failure should be treated with positive pressure ventilation, diuretics, and vasodilators as needed. Chronic management of congestive heart failure includes ACE inhibitors, diuretics, beta-blockers, and, in severe cases, ventricular assist devices and transplantation.

► Postoperative Cardiac Failure

Left ventricular failure and pulmonary edema appear in 4% of patients over age 40 undergoing general surgical procedures with general anesthesia. Fluid overload in patients with limited myocardial reserve is the most common cause. Postoperative myocardial infarction and dysrhythmias producing a high ventricular rate are other causes. Clinical manifestations are progressive dyspnea, hypoxemia with normal CO₂ tension, and diffuse congestion on chest x-ray.

Clinically unapparent ventricular failure is frequent, especially when other factors predisposing to pulmonary edema are present (massive trauma, multiple transfusions, sepsis, etc). The diagnosis may be suspected from a decreased Pao₂, abnormal chest x-ray, or elevated pulmonary artery wedge pressure. The treatment of left ventricular failure depends on the hemodynamic state of the patient. Those who are in shock require transfer to the intensive care unit, placement of a pulmonary artery line, monitoring of filling pressures, and immediate preload and afterload reduction. Preload reduction is achieved by diuretics (and nitroglycerin if needed); afterload reduction, by administration of sodium nitroprusside. ACE inhibitors and beta-blockers have been demonstrated to reduce mortality. Fluids should be restricted, and diuretics may be given. Respiratory insufficiency calls for ventilatory support either with noninvasive positive pressure ventilation or with endotracheal intubation and a mechanical respirator. Although pulmonary function may improve with the use of positive end-expiratory pressure, hemodynamic derangements and decreased myocardial reserve preclude it in most cases.

PULMONARY COMPLICATIONS

Respiratory complications are the most common single cause of morbidity after major surgical procedures and the second most common cause of postoperative deaths in patients older than 60 years. Patients undergoing chest and upper abdominal operations are particularly prone to pulmonary complications. The incidence is lower after pelvic surgery and even lower after extremity or head and neck procedures. Pulmonary complications are more common after emergency operations. Special hazards are posed by preexisting chronic obstructive pulmonary disease (chronic bronchitis, emphysema, asthma, pulmonary fibrosis). Elderly patients are at much higher risk because they have decreased compliance,

increased closing and residual volumes, and increased dead space, all of which predispose to atelectasis.

► Atelectasis

Atelectasis, the most common pulmonary complication, affects 25% of patients who have abdominal surgery. It is more common in patients who are elderly or overweight and in those who smoke or have symptoms of respiratory disease. It appears most frequently in the first 48 hours after operation and is responsible for over 90% of febrile episodes during that period. In most cases, the course is self-limited and recovery uneventful.

The pathogenesis of atelectasis involves obstructive and nonobstructive factors. Obstruction may be caused by secretions resulting from chronic obstructive pulmonary disease, intubation, or anesthetic agents. Occasional cases may be due to blood clots or malposition of the endotracheal tube. In most instances, however, the cause is not obstruction but closure of the bronchioles. Small bronchioles (≤ 1 mm) are prone to close when lung volume reaches a critical point ("closing volume"). Portions of the lung that are dependent or compressed are the first to experience bronchiole closure, since their regional volume is less than that of nondependent portions. Shallow breathing and failure to periodically hyperinflate the lung result in small alveolar size and decreased volume. The closing volume is higher in older patients and in smokers owing to the loss of elastic recoil of the lung. Other nonobstructive factors contributing to atelectasis include decreased functional residual capacity and loss of pulmonary surfactant.

The air in the atelectatic portion of the lung is absorbed, and since there is minimal change in perfusion, a ventilation/perfusion mismatch results. The immediate effect of atelectasis is decreased oxygenation of blood; its clinical significance depends on the respiratory and cardiac reserve of the patient. A later effect is the propensity of the atelectatic segment to become infected. In general, if a pulmonary segment remains atelectatic for over 72 hours, pneumonia is almost certain to occur.

Atelectasis is usually manifested by fever (pathogenesis unknown), tachypnea, and tachycardia. Physical examination may show elevation of the diaphragm, scattered rales, and decreased breath sounds, but it is often normal. Postoperative atelectasis can be largely prevented by early mobilization, frequent changes in position, encouragement to cough, and use of an incentive spirometer. Preoperative teaching of respiratory exercises and postoperative execution of these exercises prevent atelectasis in patients without preexisting lung disease. Intermittent positive pressure breathing is expensive and less effective than these simpler exercises.

Treatment consists of clearing the airway by chest percussion, coughing, or nasotracheal suction. Bronchodilators and

mucolytic agents given by nebulizer may help in patients with severe chronic obstructive pulmonary disease. Atelectasis from obstruction of a major airway may require intrabronchial suction through an endoscope, a procedure that can usually be performed at the bedside with mild sedation.

► Pulmonary Aspiration

Aspiration of oropharyngeal and gastric contents is normally prevented by the gastroesophageal and pharyngoesophageal sphincters. Insertion of nasogastric and endotracheal tubes and depression of the central nervous system by drugs interfere with these defenses and predispose to aspiration. Other factors, such as gastroesophageal reflux, food in the stomach, or position of the patient, may play a role. Trauma victims are particularly likely to aspirate regurgitated gastric contents when consciousness is depressed. Patients with intestinal obstruction and pregnant women—who have increased intra-abdominal pressure and decreased gastric motility—are also at high risk of aspiration. Two-thirds of cases of aspiration follow thoracic or abdominal surgery, and of these, one-half result in pneumonia. The death rate for grossly evident aspiration and subsequent pneumonia is about 50%.

Minor amounts of aspiration are frequent during surgery and are apparently well tolerated. Methylene blue placed in the stomach of patients undergoing abdominal operations can be found in the trachea at completion of the procedure in 15% of cases. Radionuclide techniques have shown aspiration of gastric contents in 45% of normal volunteers during sleep.

The magnitude of pulmonary injury produced by aspiration of fluid, usually from gastric contents, is determined by the volume aspirated, its pH, and the frequency of the event. If the aspirate has a pH of 2.5 or less, it causes immediate chemical pneumonitis, which results in local edema and inflammation, changes that increase the risk of secondary infection. Aspiration of solid matter can produce airway obstruction. Obstruction of distal bronchi, though well tolerated initially, can lead to atelectasis and pulmonary abscess formation. The basal segments are affected most often. Tachypnea, rales, and hypoxia are usually present within hours; less frequently, cyanosis, wheezing, and apnea may appear. In patients with massive aspiration, hypovolemia caused by excessive fluid and colloid loss into the injured lung may lead to hypotension and shock.

Aspiration has been found in 80% of patients with tracheostomies and may account for the predisposition to pulmonary infection in this group. Patients who must remain intubated for long periods should have a low-pressure, high-volume cuff on their tube, which helps prevent aspiration and limits the risk of pressure necrosis of the trachea.

Aspiration can be limited by preoperative fasting, proper positioning of the patient, and careful intubation. A single

dose of H₂-blocker or proton pump inhibitor before induction of anesthesia may have value when the risk of aspiration is high. Treatment of tracheobronchial aspiration involves reestablishing patency of the airway and preventing further damage to the lung. Endotracheal suction should be performed immediately, as this procedure confirms the diagnosis and stimulates coughing, which helps to clear the airway. Bronchoscopy may be required to remove solid matter. Fluid resuscitation should be undertaken concomitantly. Antibiotics are used initially when the aspirate is heavily contaminated; they are used later to treat pneumonia.

► Postoperative Pneumonia

Pneumonia is the most common pulmonary complication among patients who die after surgery. It is directly responsible for death—or is a contributory factor—in more than half of these patients. Patients with peritoneal infection and those requiring prolonged ventilatory support are at highest risk for developing postoperative pneumonia. Atelectasis, aspiration, and copious secretions are important predisposing factors.

Host defenses against pneumonitis include the cough reflex, the mucociliary system, and the activity of alveolar macrophages. After surgery, cough is usually weak and may not effectively clear the bronchial tree. The mucociliary transport mechanism is damaged by endotracheal intubation, and the functional ability of the alveolar macrophage is compromised by a number of factors that may be present during and after surgery (oxygenation, pulmonary edema, tracheobronchial aspiration, corticosteroid therapy, etc). In addition, squamous metaplasia and loss of ciliary coordination further hamper antibacterial defenses. More than half of the pulmonary infections that follow surgery are caused by gram-negative bacilli. They are frequently polymicrobial and usually acquired by aspiration of oropharyngeal secretions. Although colonization of the oropharynx with gram-negative bacteria occurs in only 20% of normal individuals, it is frequent after major surgery as a result of impaired oropharyngeal clearing mechanisms. Aggravating factors are azotemia, prolonged endotracheal intubation, and severe associated infection.

Occasionally, infecting bacteria reach the lung by inhalation—for example, from respirators. *Pseudomonas aeruginosa* and *Klebsiella* can survive in the moist reservoirs of these machines, and these pathogens have been the source of epidemic infections in intensive care units. Rarely, contamination of the lung may result from direct hematogenous spread from distant septic foci.

The clinical manifestations of postoperative pneumonia are fever, tachypnea, increased secretions, and physical changes suggestive of pulmonary consolidation. A chest x-ray usually shows localized parenchymal consolidation. Overall mortality rates for postoperative pneumonia vary

from 20% to 40%. Rates are higher when pneumonia develops in patients who had emergency operations, are on respirators, or develop remote organ failure, positive blood cultures, or infection of the second lung.

Maintaining the airway clear of secretions is of paramount concern in the prevention of postoperative pneumonia. Respiratory exercises, deep breathing, and coughing help prevent atelectasis, which is a precursor of pneumonia. Although postoperative pain is thought to contribute to shallow breathing, neither intercostal blocks nor epidural narcotics prevent atelectasis and pneumonia when compared with traditional methods of postoperative pain control. The prophylactic use of antibiotics does not decrease the incidence of gram-negative colonization of the oropharynx or that of pneumonia. Treatment consists of measures to aid the clearing of secretions and administration of antibiotics. Sputum obtained directly from the trachea, usually by endotracheal suctioning, is required for specific identification of the infecting organism.

► Postoperative Pleural Effusion & Pneumothorax

Formation of a very small pleural effusion is fairly common immediately after upper abdominal operations and is of no clinical significance. Patients with free peritoneal fluid at the time of surgery and those with postoperative atelectasis are more prone to develop effusions. In the absence of cardiac failure or a pulmonary lesion, appearance of a pleural effusion late in the postoperative course suggests the presence of subdiaphragmatic inflammation (subphrenic abscess, acute pancreatitis, etc). Effusions that do not compromise respiratory function should be left undisturbed. If there is a suspicion of infection, the effusion should be sampled by needle aspiration. When an effusion produces respiratory compromise, it should be drained with a thoracostomy tube.

Postoperative pneumothorax may follow insertion of a subclavian catheter or positive-pressure ventilation, but it sometimes appears after an operation during which the pleura has been injured (eg, nephrectomy or adrenalectomy). Pneumothorax should usually be treated with a thoracostomy tube, depending upon the size and etiology of the pneumothorax.

► Fat Embolism

Fat embolism is relatively common but only rarely causes symptoms. Fat particles can be found in the pulmonary vascular bed in 90% of patients who have had fractures of long bones or joint replacements. Fat embolism can also be caused by exogenous sources of fat, such as blood transfusions, intravenous fat emulsion, or bone marrow transplantation. *Fat embolism syndrome* consists of neurologic dysfunction, respiratory insufficiency, and petechiae of the axillae, chest, and proximal arms. It was originally described

in trauma victims—especially those with long bone fractures—and was thought to be a result of bone marrow embolization. However, the principal clinical manifestations of fat embolism are seen in other conditions. The existence of fat embolism as an entity distinct from posttraumatic pulmonary insufficiency has been questioned.

Fat embolism syndrome characteristically begins 12-72 hours after injury but may be delayed for several days. The diagnosis is clinical. The finding of fat droplets in sputum and urine is common after trauma and is not specific. Decreased hematocrit, thrombocytopenia, and other changes in coagulation parameters usually occur.

Once symptoms develop, supportive treatment should be provided until respiratory insufficiency and central nervous system manifestations subside. Respiratory insufficiency is treated with positive end-expiratory pressure ventilation and diuretics. The prognosis is related to the severity of the pulmonary insufficiency.

GI COMPLICATIONS

► Alterations in Gastrointestinal Motility

The presence, strength, and direction of normal peristalsis are governed by the enteric nervous system. Anesthesia and surgical manipulation result in a decrease of the normal propulsive activity of the gut, or postoperative ileus. Several factors worsen ileus or prolong its course. These include medications—especially opioids—electrolyte abnormalities, inflammatory conditions such as pancreatitis or peritonitis, and pain. The degree of ileus is related to the extent of operative manipulation.

Gastrointestinal peristalsis returns within 24 hours after most operations that do not involve the abdominal cavity. In general, laparoscopic approaches cause less ileus than open procedures. After laparotomy, gastric peristalsis returns in about 48 hours. Colonic activity returns after 48 hours, starting at the cecum and progressing caudally. The motility of the small intestine is affected to a lesser degree, except in patients who have had small bowel resection or who were operated on to relieve bowel obstruction. Normal postoperative ileus leads to slight abdominal distention and absent bowel sounds. Return of peristalsis is often noted by the patient as mild cramps, passage of flatus, and return of appetite. Feedings should be withheld until there is evidence of return of normal gastrointestinal motility. There is no specific therapy for postoperative ileus.

► Gastric Dilation

Gastric dilation, a rare life-threatening complication, consists of massive distention of the stomach by gas and fluid. Predisposing factors include asthma, recent surgery, gastric outlet obstruction, and absence of the spleen. Infants and children in whom oxygen masks are used in the immediate

postoperative period and adults subjected to forceful assisted respiration during resuscitation are also at risk. Occasionally, gastric dilation develops in patients with anorexia nervosa or during serious illnesses without a specific intercurrent event.

As the air-filled stomach grows larger, it hangs down across the duodenum, producing a mechanical gastric outlet obstruction that contributes further to the problem. The increased intragastric pressure produces venous obstruction of the mucosa, causing mucosal engorgement and bleeding and, if allowed to continue, ischemic necrosis and perforation. The distended stomach pushes the diaphragm upward, which causes collapse of the lower lobe of the left lung, rotation of the heart, and obstruction of the inferior vena cava. The acutely dilated stomach is also prone to undergo volvulus.

The patient appears ill, with abdominal distention and hiccups. Hypochloremia, hypokalemia, and alkalosis may result from fluid and electrolyte losses. When the problem is recognized early, treatment consists of gastric decompression with a nasogastric tube. In the late stage, gastric necrosis may require gastrectomy.

▶ Bowel Obstruction

Failure of postoperative return of bowel function may be the result of paralytic ileus or mechanical obstruction. Mechanical obstruction is most often caused by postoperative adhesions or an internal (mesenteric) hernia. Most of these patients experience a short period of apparently normal intestinal function before manifestations of obstruction supervene. About half of cases of early postoperative small bowel obstruction follow colorectal surgery.

Diagnosis may be difficult because the symptoms are difficult to differentiate from those of paralytic ileus. If plain films of the abdomen show air-fluid levels in loops of small bowel, mechanical obstruction is a more likely diagnosis than ileus. Enteroclysis or an ordinary small bowel series with barium sulfate may aid diagnosis.

Strangulation is uncommon because the adhesive bands are broader and less rigid than is typical of late small bowel obstruction. The death rate is high (about 15%), however, probably because of delay in diagnosis and the postoperative state. Treatment consists of nasogastric suction for several days and, if the obstruction does not resolve spontaneously, laparotomy.

Small bowel intussusception is an uncommon cause of early postoperative obstruction in adults but accounts for 10% of cases in the pediatric age group. Ninety percent of postoperative intussusceptions occur during the first 2 postoperative weeks, and more than half in the first week. Unlike idiopathic ileocolic intussusception, most postoperative intussusceptions are ileoileal or jejunojejunal. They most often follow retroperitoneal and pelvic operations. The cause is unknown. The symptom complex is not typical,

and x-ray studies are of limited help. The physician should be aware that intussusception is a possible explanation for vomiting, distention, and abdominal pain after laparotomy in children and that early reoperation will avoid the complications of perforation and peritonitis. Operation is the only treatment, and if the bowel is viable, reduction of the intussusception is all that is needed.

▶ Postoperative Fecal Impaction

Fecal impaction after operative procedures is the result of colonic ileus and impaired perception of rectal fullness. It is principally a disease of the elderly but may occur in younger patients who have predisposing conditions such as megacolon or paraplegia. Postoperative ileus and the use of opioid analgesics and anticholinergic drugs are aggravating factors. Early manifestations are anorexia and obstipation or diarrhea. In advanced cases, marked distention may cause colonic perforation. The diagnosis of postoperative fecal impaction is made by rectal examination. The impaction should be manually removed, enemas given, and digital examination then repeated.

Barium remaining in the colon from an examination done before surgery may harden and produce barium impaction. This usually occurs in the right colon, where most of the water is absorbed, and is a more difficult management problem than fecal impaction. The clinical manifestations are those of bowel obstruction. Treatment includes enemas and purgation with polyethylene glycol-electrolyte solution (eg, CoLyte, GoLYTELY). Diatrizoate sodium (Hypaque), a hyperosmolar solution that stimulates peristalsis and increases intraluminal fluid, may be effective by enema if other solutions fail. Operation is rarely necessary.

▶ Postoperative Pancreatitis

Postoperative pancreatitis accounts for 10% of all cases of acute pancreatitis. It occurs in 1%-3% of patients who have operations in the vicinity of the pancreas and with higher frequency after operations on the biliary tract. For example, pancreatitis occurs in about 1% of patients undergoing cholecystectomy and in 8% of patients undergoing common bile duct exploration. In the latter cases, it does not appear to be related to the performance of intraoperative cholangiograms or choledochoscopy. Postoperative pancreatitis after biliary surgery is worse in patients who have had biliary pancreatitis preoperatively. Pancreatitis occasionally occurs following cardiopulmonary bypass, parathyroid surgery, and renal transplantation. Postoperative pancreatitis is frequently of the necrotizing type. Infected pancreatic necrosis and other complications of pancreatitis develop with a frequency three to four times greater than in biliary and alcoholic pancreatitis. The reason postoperative pancreatitis is so severe is unknown, but the mortality rate is 30%-40%.

The pathogenesis in most cases appears to be mechanical trauma to the pancreas or its blood supply. Nevertheless, manipulation, biopsy, and partial resection of the pancreas are usually well tolerated, so the reasons that some patients develop pancreatitis are unclear. Prevention of this complication includes careful handling of the pancreas and avoidance of forceful dilation of the choledochal sphincter or obstruction of the pancreatic duct. The 2% incidence of pancreatitis following renal transplantation is probably related to special risk factors such as use of corticosteroids or azathioprine, secondary hyperparathyroidism, or viral infection. Acute changes in serum calcium are thought to be responsible for pancreatitis following parathyroid surgery. Serum amylase elevation develops in about half of patients undergoing heart surgery with extracorporeal bypass, but clinical evidence of pancreatitis is present in only 5% of these patients.

The diagnosis of postoperative pancreatitis may be difficult in patients who have recently had an abdominal operation. Serum amylase elevation may or may not be present. One must be alert to renal and respiratory complications and the consequences of necrotizing or hemorrhagic pancreatitis. Because of the high frequency with which complications develop, frequent monitoring of the pancreas and retroperitoneum with CT scans is useful.

► Postoperative Hepatic Dysfunction

Hepatic dysfunction, ranging from mild jaundice to life-threatening hepatic failure, follows 1% of surgical procedures performed under general anesthesia. The incidence is greater following pancreatectomy, biliary bypass operations, and portacaval shunt. Postoperative hyperbilirubinemia may be categorized as prehepatic jaundice, hepatocellular insufficiency, and posthepatic obstruction (Table 5-1).

Table 5-1 Causes of postoperative jaundice.

Prehepatic jaundice (bilirubin overload)
Hemolysis (drugs, transfusions, sickle cell crisis)
Reabsorption of hematomas
Hepatocellular insufficiency
Viral hepatitis
Drug-induced (anesthesia, others)
Ischemia (shock, hypoxia, low-output states)
Sepsis
Liver resection (loss of parenchyma)
Others (total parenteral nutrition, malnutrition)
Posthepatic obstruction (to bile flow)
Retained stones
Injury to ducts
Tumor (unrecognized or untreated)
Cholecystitis
Pancreatitis
Occlusion of biliary stents

Prehepatic Jaundice

Prehepatic jaundice is caused by bilirubin overload, most often from hemolysis or reabsorption of hematomas. Fasting, malnutrition, hepatotoxic drugs, and anesthesia are among the factors that impair the ability of the liver to excrete increased loads of bilirubin in the postoperative period.

Increased hemolysis may result from transfusion of incompatible blood but more often reflects destruction of fragile transfused red blood cells. Other causes include extracorporeal circulation, congenital hemolytic disease (eg, sickle cell disease), and effects of drugs.

Hepatocellular Insufficiency

Hepatocellular insufficiency, the most common cause of postoperative jaundice, occurs as a consequence of hepatic cell necrosis, inflammation, or massive hepatic resection. Drugs, hypotension, hypoxia, and sepsis are among the injurious factors. Although posttransfusion hepatitis is usually observed much later, this complication may occur as early as the third postoperative week.

Benign postoperative intrahepatic cholestasis is a vague term used to denote jaundice following operations that often involve hypotension and multiple transfusions. Serum bilirubin ranges from 2 to 20 mg/dL and serum alkaline phosphatase is usually high, but the patient is afebrile and postoperative convalescence is otherwise smooth. The diagnosis is one of exclusion. Jaundice clears by the third postoperative week.

Hepatocellular damage occasionally occurs after intestinal bypass procedures for morbid obesity. Cholestatic jaundice may develop in patients receiving total parenteral nutrition.

Posthepatic Obstruction

Posthepatic obstruction can be caused by direct surgical injury to the bile ducts, retained common duct stones, tumor obstruction of the bile duct, or pancreatitis. Acute postoperative cholecystitis is associated with jaundice in one-third of cases, though mechanical obstruction of the common duct is usually not apparent.

One must determine if a patient with postoperative jaundice has a correctable cause that requires treatment. This is particularly true for sepsis (when decreased liver function may sometimes be an early sign), lesions that obstruct the bile duct, and postoperative cholecystitis. Liver function tests are not helpful in determining the cause and do not usually reflect the severity of disease. Liver biopsy, ultrasound and CT scans, and transhepatic or endoscopic retrograde cholangiograms are the tests most likely to sort out the diagnostic possibilities. Renal function must be monitored closely, since renal failure may develop in these patients. Treatment is otherwise expectant.

► Postoperative Cholecystitis

Acute postoperative cholecystitis may follow any kind of operation but is more common after gastrointestinal procedures. Acute cholecystitis develops shortly after endoscopic sphincterotomy in 3%-5% of patients. Chemical cholecystitis occurs in patients undergoing hepatic arterial chemotherapy with mitomycin and floxuridine with such frequency that cholecystectomy should always be performed before infusion of these agents is begun. Fulminant cholecystitis with gallbladder infarction may follow percutaneous embolization of the hepatic artery for malignant tumors of the liver or for arteriovenous malformation involving this artery.

Postoperative cholecystitis differs in several respects from the common form of acute cholecystitis: It is frequently acalculous (70%-80%), more common in males (75%), progresses rapidly to gallbladder necrosis, and is not likely to respond to conservative therapy. The cause is clear in cases of chemical or ischemic cholecystitis but not in other forms. Factors thought to play a role include biliary stasis (with formation of sludge), biliary infection, and ischemia.

► Abdominal Compartment Syndrome

Aggressive resuscitation of patients, particularly those involved in trauma or requiring an emergent celiotomy, may result in increased abdominal pressure. Intra-abdominal hypertension, as measured by bladder pressure, is generally self-limiting; however, it can become dangerous when pressures exceed 30 mm Hg. In this scenario venous outflow from the bowel and kidney may become compromised. Furthermore, respiratory complications may ensue as the pressure exerted upon the diaphragm may decrease tidal volume and result in respiratory acidosis. In this situation, the abdominal compartment must be rapidly decompressed, usually by opening the abdomen, in order to reestablish flow from the viscera.

Similar to compartment syndrome of the extremities, the fascia resists stretch exerted by the muscle and other tissue after injury and resuscitation. Unlike the extremities, patients with abdominal compartment syndrome do not exhibit the five Ps (pain, paresthesia, pallor, paralysis, and pulselessness) that may be easily followed in the limb. However, a high index of suspicion, rapid diagnosis, and expeditious treatment result in restoration of flow and prevention of morbidity in both scenarios.

GENITOURINARY COMPLICATIONS

► Postoperative Urinary Retention

Inability to void postoperatively is common, especially after pelvic and perineal operations or operations conducted under spinal anesthesia. Factors responsible for postoperative urinary retention are interference with the neural

mechanisms responsible for normal emptying of the bladder and overdistention of the urinary bladder. When its normal capacity of approximately 500 mL is exceeded, bladder contraction is inhibited. Prophylactic bladder catheterization should be considered whenever an operation is likely to last 3 hours or longer or when large volumes of intravenous fluids are anticipated. The catheter can be removed at the end of the operation if the patient is expected to be able to ambulate within a few hours. When bladder catheterization is not performed, the patient should be encouraged to void immediately before coming to the operating room and as soon as possible after the operation. During abdominoperineal resection, operative trauma to the sacral plexus alters bladder function enough so that an indwelling catheter should be left in place for 4-5 days. Patients with inguinal hernia who strain to void as a manifestation of prostatic hypertrophy should have the prostate treated before the hernia.

The treatment of acute urinary retention is catheterization of the bladder. In the absence of factors that suggest the need for prolonged decompression, such as the presence of 1000 mL of urine or more, the catheter may be removed.

► Urinary Tract Infection

Infection of the lower urinary tract is the most frequently acquired nosocomial infection. Preexisting contamination of the urinary tract, urinary retention, and instrumentation are the principal contributing factors. Bacteriuria is present in about 5% of patients who undergo short-term (< 48 hours) bladder catheterization, though clinical signs of urinary tract infection occur in only 1%. Cystitis is manifested by dysuria and mild fever and pyelonephritis by high fever, flank tenderness, and occasionally ileus. Diagnosis is made by examination of the urine and confirmed by cultures. Prevention involves treating urinary tract contamination before surgery, prevention or prompt treatment of urinary retention, and careful instrumentation when needed. Treatment includes adequate hydration, proper drainage of the bladder, and specific antibiotics.

INFECTIOUS COMPLICATIONS

Infectious complications are perhaps the most common postoperative complication and include those related directly to the surgical incision, termed *surgical site infection* (SSI), and those that involve other systems, such as *Clostridium difficile* colitis and parotitis. Certain infections such as a urinary tract infection and postoperative pneumonia have already been discussed and will not be noted in this section.

A wide range of organisms are involved in these infections, but what is very concerning is the increasing prevalence of antibiotic-resistant bacteria, such as methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant *Enterococcus* (VRE).

► Surgical Site Infection

The Center for Disease Control (CDC) classifies SSIs into three locations:

1. Superficial incisional
2. Deep incisional
3. Organ space

The risk for developing an SSI has been estimated at 4% rate in clean wounds and 35% in grossly contaminated wounds.

Risk factors for SSI include systemic factors (diabetes, immunosuppression, obesity, smoking malnutrition, and previous radiation) and local factors (surgical wound classification and surgical techniques).

Prevention of SSI includes meticulous surgical techniques (skin preparation, maintaining sterility, judicious use of cautery, respecting dissection planes, approximating tissue neatly, etc) and administration of appropriate preoperative antibiotics as determined by the type of operation being performed (see http://www.cdc.gov/hicpac/pdf/guidelines/SSI_1999.pdf). Clean cases such as an inguinal hernia repair, for instance, would necessitate administration of antibiotics that would target skin flora such as cefazolin. Contaminated cases that enter the gastrointestinal tract, on the other hand, would require antibiotics such as cefazolin and metronidazole that would target both skin flora and gastrointestinal bacteria such as anaerobes.

The diagnosis of SSI is primarily clinical. Common symptoms include pain, warmth, and erythema with drainage through the incision. Deep and organ space infections may be further diagnosed with radiographic imaging.

Treatment for an SSI emphasizes primary source control. Gaining such control may require an operative procedure such as an incision and drainage of the infectious source. For superficial infections, the treatment would simply include opening the incision, exploring the space, irrigating, debriding, and leaving the wound open with local wound care. Deep incisional and organ space infections may necessitate open operative drainage and debridement or percutaneous drainage procedures. Antibiotics by themselves do not usually address the underlying focus of infection.

► *Clostridium difficile* Colitis

Postoperative diarrhea due to *C difficile* is a common nosocomial infection in surgical patients. The spectrum of illness ranges from asymptomatic colonization to—rarely—severe toxic colitis. Transmission from hospital personnel probably occurs. The main risk factor is perioperative antibiotic use. The diagnosis is established by identification of a specific cytopathic toxin in the stool or culture of the organism from stool samples or rectal swabs. In severely affected patients, colonoscopy reveals pseudomembranes.

Prevention is accomplished by strict handwashing, enteric precautions, and minimizing antibiotic use. Treatment of established infection is with intravenous metronidazole or, for infections with resistant pathogens, oral vancomycin.

► Drug-Resistant Organisms

An increase in the prevalence of multidrug-resistant organisms has been noted over the past two decades, particularly MRSA and VRE. Although routine screening of patients has found the prevalence as high as 30% in the community, these organisms are much more frequently found in the hospital or other institutions (nursing homes, prisons, gymnasiums, etc). Increased antibiotic usage in the inpatient and outpatient settings has been speculated to be the cause of the drug resistance; however, the spread within institutions has been demonstrated to be due to direct patient contact. Continuous surface decontamination, utilization of barrier techniques when examining patients, and assiduous hand hygiene have been shown to decrease transmission. Furthermore, discontinuation of inappropriate antibiotics has been shown to limit the colonization of patients with most drug-resistant organisms, including *C difficile*.

HEMATOLOGIC COMPLICATIONS

Besides causing bleeding, major surgery such as abdominal and trauma operations alter the fine balance of the body's hematologic system especially with regards to the coagulation pathway.

► Venous Thromboembolism

Rudolf Virchow first postulated the pathophysiology of thrombosis in 1846. The tenets of his triad: hypercoagulable state, stasis, and vessel damage, largely hold today. Patients involved in trauma, cancer operations, or dissections of the pelvis are particularly susceptible to the phenomenon. Postoperative patients should be carefully monitored for lower extremity swelling, hypoxia, or new-onset pleuritic chest pain, as these may be harbingers of the syndrome. Risk factors include those that are nonmodifiable (thrombophilia, prior VTE, congestive heart failure, chronic lung disease, paralytic stroke, malignancy, spinal cord injury, obesity, age > 40, varicosities) and modifiable (type of surgery: hip, lower extremity, major general surgery, mechanical ventilation, major trauma, central venous lines, chemotherapy, hormone replacement therapy, pregnancy, immobility). Outcomes from pulmonary embolism vary in severity from being relatively asymptomatic to resulting in cardiac arrest or sudden death. Long-term complications, such as pulmonary hypertension, may ensue in patients who are not adequately treated.

Prevention of VTE is much more effective than management of this complication. The CHEST guidelines are a

useful adjunct to stratifying risk and assigning appropriate preventive therapy. This usually requires heparin therapy with regular or low-molecular-weight heparin, sequential compression stockings, and early ambulation. Inferior vena cava filters may be considered as a preventive method in patients who have contraindications to anticoagulation or have progression of disease despite adequate anticoagulation.

Diagnosis of deep vein thrombosis may be performed in a cost-effective manner by utilizing duplex ultrasonography. CT, MRI, or traditional venography are more expensive and more invasive methods for establishing disease occurrence. Pulmonary embolism can be diagnosed by echocardiography, ventilation/perfusion scan, and formal angiography; however, helical CT angiography is the most commonly utilized technique. Unfortunately, although physical examination leads to a high degree of suspicion, it alone remains neither specific nor sensitive.

The goals of treatment of VTE remain stabilization of clot, revascularization of affected vessels, and prevention of long-term complications. The majority of these patients respond to anticoagulation with intravenous heparin or higher doses of subcutaneous low-molecular-weight heparin and, subsequent, conversion to oral therapy with warfarin. In patients who have hemodynamic instability due to a pulmonary embolus, consideration to system thrombolysis, suction embolectomy, or a Trendelenburg procedure should be given.

► Heparin-Induced Thrombocytopenia

Thrombocytopenia is a commonly found finding in the postoperative period and its cause may be several. Postoperative thrombocytopenia is generally considered to be a 50% reduction in total platelet volume. The platelet reduction in HIT generally is seen 1 week after initial exposure to heparin. The incidence is greater with unfractionated heparin than low-molecular-weight heparin. Although generally associated with thrombocytopenia, the initial phase is a procoagulative and thrombotic with many patients experiencing VTE, myocardial infarction, or stroke. Thrombocytopenia is a late finding in patients. Once suspicious of HIT, all heparin, including flushes and coated catheters, should be discontinued and an antibody assay should be performed.

If the diagnosis of HIT is confirmed, the discontinuation of heparin and heparin-coated products should be maintained. If anticoagulation is necessary, use of Lepirudin or Argatroban should be considered. The choice of agent is generally made by patient factors: Lepirudin should be avoided in patients with renal failure and Argatroban should be avoided in patients with hepatic failure. Long-term anticoagulation may be transitioned to warfarin; however, warfarin must not be administered during the acute phase of HIT as this may lead to a pronounced procoagulant phase.

SYSTEMIC COMPLICATIONS

► Postoperative Fever

Fever occurs in about 40% of patients after major surgery. In most patients the temperature elevation resolves without specific treatment. However, postoperative fever may herald a serious infection, and it is therefore important to evaluate the patient clinically. Features often associated with an infectious origin of the fever include preoperative trauma, ASA class above 2, fever onset after the second postoperative day, an initial temperature elevation above 38.6°C, a postoperative white blood cell count greater than 10,000/L, and a postoperative serum urea nitrogen of 15 mg/dL or greater. If three or more of the above are present, the likelihood of associated bacterial infection is nearly 100%.

Fever within 48 hours after surgery is usually caused by atelectasis. Reexpansion of the lung causes body temperature to return to normal. Because laboratory and radiologic investigations are usually unrevealing, an extensive evaluation of early postoperative fever is rarely appropriate if the patient's convalescence is otherwise smooth.

When fever appears after the second postoperative day, atelectasis is a less likely explanation. The differential diagnosis of fever at this time includes catheter-related phlebitis, pneumonia, and urinary tract infection. A directed history and physical examination complemented by focused laboratory and radiologic studies usually determine the cause.

Patients without infection are rarely febrile after the fifth postoperative day. Fever this late suggests wound infection or, less often, anastomotic breakdown and intra-abdominal abscesses. A diagnostic workup directed to the detection of intra-abdominal sepsis is indicated in patients who have high temperatures (> 39°C) and wounds without evidence of infection 5 or more days postoperatively. CT scan of the abdomen and pelvis is the test of choice and should be performed early, before overt organ failure occurs.

Fever is rare after the first week in patients who had a normal convalescence. Allergy to drugs, transfusion-related fever, septic pelvic vein thrombosis, and intra-abdominal abscesses should be considered.

MULTIPLE CHOICE QUESTIONS

- All of the following are true of respiratory complications, *except*
 - They are common after chest procedures, but rare after abdominal operations
 - They are the most common single cause of morbidity after major surgical procedures
 - They occur more commonly in the elderly, smokers, and obese patients
 - Predisposing factors can be moderated by preoperative and postoperative activities
 - They include atelectasis, pneumonia, aspiration, and pulmonary emboli
- A 64-year-old woman is 12 days after total abdominal hysterectomy for benign disease. She returns to the emergency room with nausea and vomiting, and has an abdominal examination that is distended, but not very tender, and her wound is clean. An abdominal series shows some dilated loops of small bowel but no free air.
 - She should return to the operating room as soon as is practical for lysis of adhesions.
 - The abdominal focus of her symptoms rules out chest problems such as pneumonia.
 - Her initial management can include intravenous hydration and nasogastric suction.
 - The presence of dilated loops of bowel on radiographs rules out the possibility of a benign ileus.
 - Both A and C are true.
- A 82-year-old woman underwent a laparoscopic hand-assisted sigmoid colectomy with diverting loop ileostomy 5 days ago for a rectal cancer after neoadjuvant radiation therapy. She is tolerating a regular diet and her ileostomy is healthy and functional. The nurses report that she is somewhat somnolent, and has not urinated during the past two shifts. Which is the most likely cause of her anuria?
 - Acute renal failure
 - Inadequate fluid resuscitation in the operating room
 - High ileostomy output with inadequate postoperative replacement
 - Low cardiac output
 - Urinary retention
- A 30-year-old man is 16 hours s/p emergency laparotomy for blunt abdominal trauma from a motor vehicle accident. His spleen was removed, a liver laceration was managed with sutures and topical procoagulants, and a segment of damaged jejunum was resected. His operation took 3 hours, and he received 12 units of crystalloid, 6 units of blood, 4 units of fresh frozen plasma, and 5 units of platelets. His abdominal wall was closed primarily. He remains intubated and ventilated in the SICU. His urine output was 55 mL over the last 6 hours. Further steps in his management should include the following:
 - Early extubation is preferable to limit the risk of pneumonia, even if his mental status is not yet clear.
 - Aggressive early diuresis can promote continued renal function.
 - Further fluid resuscitation is rarely necessary after the bleeding is controlled.
 - Bladder pressure measurement may be useful to determine the likelihood of abdominal compartment syndrome.
 - A and C.
- All of the following are true about surgical site infection, *except*
 - Classified by the Centers for Disease Control into: (1) wound only, (2) organ space, and (3) involving organ parenchyma
 - Risk varies based upon degree of wound contamination by bacteria
 - Risk is modified by patient factors such as diabetes and ongoing immunosuppression
 - May have reduced risk by the use of appropriately chosen and timed antibiotics
 - Treatment emphasizes primary source control

6

Wound Healing

Michael G. Franz, MD

► Acute Wound

An acute wound results from the sudden loss of anatomic structure in tissue following the transfer of kinetic, chemical, or thermal energy. Functionally, an acute wound should pass predictably through the phases of wound healing to result in complete and sustained repair. Acute wounds typically occur in recently uninjured and otherwise normal tissue. Acute wound healing is timely and reliable, completing the entire process within 6-12 weeks. Most surgical wounds are acute wounds.

► Chronic Wound

Wound healing fails in a chronic wound. The process of tissue repair is prolonged and pathologic. The usual mechanism is dysregulation of one of the phases of normal acute wound healing. Most often, healing arrest occurs in an inflammatory phase. This prolonged inflammatory phase may be due to wound infection or another form of chronic irritation. Tissue and wound hypoxia is the other important mechanism for the development of a chronic wound. Failed epithelialization due to repeat trauma or desiccation may also result in a chronic partial thickness wound. Surgeons may sharply convert a chronic wound into an acute wound.

GENERAL CONSIDERATIONS

► Clinical Wound Healing

Surgeons often describe wound healing as primary or secondary. *Primary healing* occurs when tissue is cleanly incised and anatomically reapproximated. It is also referred to as healing by primary intention, and tissue repair usually proceeds without complication. *Secondary healing* occurs in wounds left open through the formation of granulation tissue and eventual coverage of the defect by migration of epithelial cells. Granulation tissue

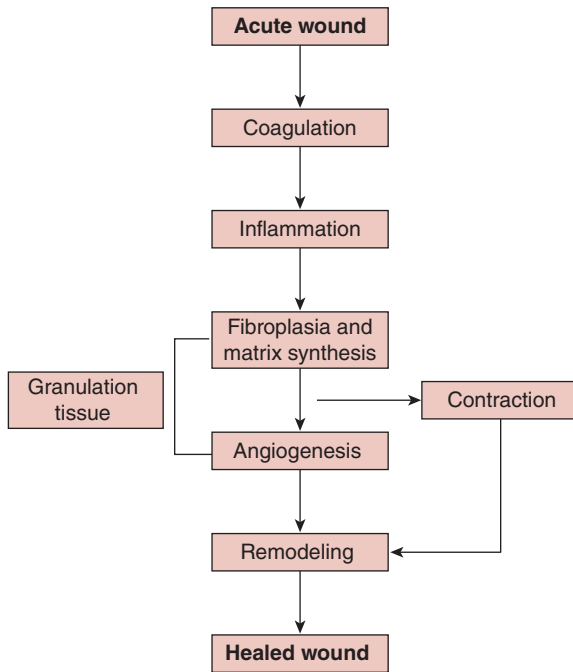

is composed of new capillaries, fibroblasts, and a provisional extracellular matrix that forms at the base of the early wound. This process is also referred to as healing by secondary intention. Most infected wounds and burns heal in this manner. Primary healing is simpler and requires less time and tissue synthesis than secondary healing. A wound healing primarily repairs a smaller volume than an open wound healing secondarily. The principles of primary and secondary healing are combined in *delayed primary closure*, when a wound is left open to heal under a carefully maintained, moist wound healing environment for approximately 5 days and is then closed as if primarily. Wounds treated with delayed primary closure are less likely to become infected than if closed immediately because bacterial balance is achieved and oxygen requirements are optimized through capillary formation in the granulation tissue.

► The Mechanism of Wound Healing

The complex process of wound healing normally proceeds from coagulation and inflammation through fibroplasia, matrix deposition, angiogenesis, epithelialization, collagen maturation, and finally wound contraction (Figure 6-1). Wound healing signals include peptide growth factors, complement, cytokine inflammatory mediators, and metabolic signals such as hypoxia and accumulated lactate. Many of these cellular signaling pathways are redundant and pleiotropic.

A. Hemostasis and Inflammation

Following injury, a wound must stop bleeding in order to heal and for the injured host to survive. It is therefore not surprising that cellular and molecular elements involved in hemostasis also signal tissue repair. Immediately after injury, the coagulation products fibrin, fibrinopeptides,

▲ **Figure 6-1.** Acute wound healing normally proceeds from coagulation and inflammation, through angiogenesis, fibroplasia, matrix deposition (granulation tissue formation), collagen maturation, epithelialization, and finally wound contraction. A chronic wound fails to heal anywhere along this wound healing pathway.

thrombin split products, and complement components attract inflammatory cells into the wound. Platelets activated by thrombin release insulinlike growth factor 1 (IGF-1), transforming growth factor α (TGF- α), transforming growth factor β (TGF- β), and platelet-derived growth factor (PDGF), which attract leukocytes, particularly macrophages, and fibroblasts into the wound. Damaged endothelial cells respond to a signal cascade involving the complement products C5a, tumor necrosis factor α (TNF- α), interleukin-1 (IL-1), and interleukin-8 (IL-8), and express receptors for integrin molecules on the cell membranes of leukocytes. Circulating leukocytes then adhere to the endothelium and migrate into the wounded tissue. Interleukins and other inflammatory components, such as histamine, serotonin, and bradykinin, cause vessels first to constrict for hemostasis and later to dilate, becoming porous so that blood plasma and leukocytes can migrate into the injured area.

The very early wound inflammatory cells increase metabolic demand. Since the local microvasculature is damaged, a local energy sink results, and PaO_2 falls while CO_2 accumulates. Lactate in particular plays a critical role, since its

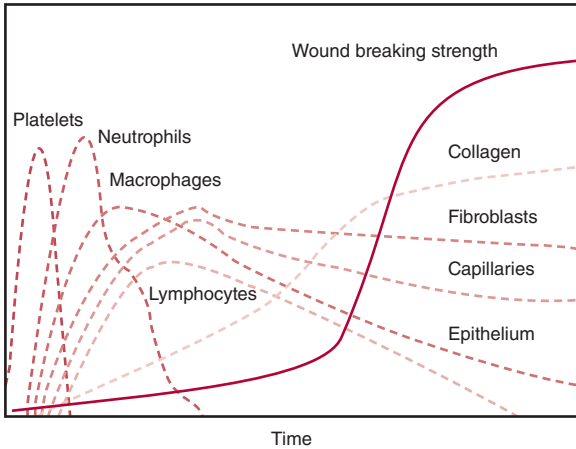

source is mainly aerobic, and its level is tightly regulated by tissue oxygen levels. Oxidative stress is an important signal for tissue repair. These conditions trigger reparative processes and stimulate their propagation.

Macrophages assume a dominant role in the synthesis of wound healing molecules as coagulation-mediated tissue repair signals fall. Importantly, macrophages, stimulated by fibrin, continue to release large quantities of lactate. This process continues even as oxygen levels begin to rise, thereby maintaining the “environment of injury.” Lactate alone stimulates angiogenesis and collagen deposition through the sustained production of growth factors. Unless the wound becomes infected, the granulocyte population that dominated the first days diminishes. Macrophages now cover the injured surface. Fibroblasts begin to organize, mixed with buds of new blood vessels. It has been shown that circulating stem cells, such as bone marrow–derived mesenchymal stem cells, contribute fibroblasts to the healing wound, but the extent of this process is as yet unknown.

B. Fibroplasia and Matrix Synthesis

Fibroplasia—Throughout wound healing, fibroplasia (the replication of fibroblasts) is stimulated by multiple mechanisms, starting with PDGF, IGF-1, and TGF- β released by platelets and later by the continual release of numerous peptide growth factors from macrophages and even fibroblasts within the wound. Growth factors and cytokines shown to stimulate fibroplasia and wound healing include fibroblast growth factor (FGF), IGF-1, vascular endothelial growth factor (VEGF), IL-1, IL-2, IL-8, PDGF, TGF- α , TGF- β , and TNF- α . Dividing fibroblasts localize near the wound edge, an active tissue repair environment with tissue oxygen tensions of approximately 40 mm Hg in normally healing wounds. In cell culture, this PaO_2 is optimum for fibroblast replication. Smooth muscle cells are also likely progenitors because fibroblasts seem to migrate from the adventitia and media of wound vessels. Lipocytes, pericytes, and other cell sources may exist for terminal differentiation into repair fibroblasts.

Matrix synthesis—Fibroblasts secrete the collagen and proteoglycans of the connective tissue matrix that hold wound edges together and embed cells of the healing wound matrix. These extracellular molecules assume polymeric forms and become the physical basis of wound strength (Figure 6-2). Collagen synthesis is not a constitutive property of fibroblasts but must be signaled. The mechanisms that regulate the stimulation and synthesis of collagen are multifactorial and include both growth factors and metabolic inputs such as lactate. The collagen gene promoter has regulatory binding sites to stress corticoids, the TGF- β signaling pathway, and retinoids, which control collagen gene expression. Other growth factors regulate glycosaminoglycans, tissue inhibitors of metalloproteinase (TIMP), and fibronectin synthesis.

▲ **Figure 6-2.** The fundamental cellular and molecular elements activated during normal wound healing.

The accumulation of lactate in the extracellular environment is shown to directly stimulate transcription of collagen genes as well as posttranslational processing of collagen peptides. It is clear that the redox state and energy stores of repair cells occupying the wound regulate collagen synthesis.

The increase in collagen messenger RNA (mRNA) leads to an increased procollagen peptide. This, however, is not sufficient to increase collagen deposition because procollagen peptide cannot be transported from the cell to the extracellular space until, in a posttranslational step, a proportion of its proline amino acids are hydroxylated. In this reaction, catalyzed by prolyl hydroxylase, an oxygen atom derived from dissolved O_2 is inserted (as a hydroxyl group) into selected collagen prolines in the presence of the cofactors ascorbic acid, iron, and α -ketoglutarate. Thus, accumulation of lactate, or any other process that decreases the nicotinamide adenine dinucleotide (NAD^+) pool, leads to production of collagen mRNAs, increased collagen peptide synthesis, and (provided enough ascorbate and oxygen is present) increased posttranslational modification and secretion of collagen monomers into the extracellular space.

Another enzyme, lysyl hydroxylase, hydroxylates many of the procollagen lysines. A lysyl-to-lysyl covalent link then occurs between collagen molecules, maximizing mature collagen fiber strength. This process, too, requires adequate amounts of ascorbate and oxygen. These oxygenase reactions (and therefore collagen deposition) are rate limited by tissue oxygen level, PaO_2 . The rates are half-maximal at about 20 mm Hg and maximal at about 200 mm Hg. Hydroxylation can be “forced” to supernormal rates by tissue hyperoxia. Collagen deposition, wound strength, and angiogenesis rates may be increased and accelerated as tissue PaO_2 is elevated.

C. Angiogenesis

Angiogenesis is required for wound healing. It is clinically evident about 4 days following injury but begins earlier when new capillaries sprout from preexisting venules and grow toward the injury in response to chemoattractants released by platelets and macrophages. In primarily closed wounds, budding vessels soon meet and fuse with counterparts migrating from the other side of the wound, establishing blood flow across the wound. In wounds left open, newly forming capillaries connect with adjacent capillaries migrating in the same direction, and granulation tissue forms. Numerous growth factors and cytokines are observed to stimulate angiogenesis, but animal experiments indicate that the dominant angiogenic stimulants in wounds are derived first from platelets in response to coagulation and then from macrophages in response to hypoxia or high lactate, fibrin, and its products.

D. Epithelialization

Epithelial cells respond to several of the same stimuli as fibroblasts and endothelial cells within the mesenchymal area of a wound. A variety of growth factors also regulate epithelial cell replication. TGF- α and keratinocyte growth factor (KGF), for instance, are potent epithelial cell mitogens. TGF- β tends to inhibit epithelial cells from differentiating and thus may potentiate and perpetuate mitogenesis, though it is itself not a mitogen for these cells. During wound healing, mitoses appear in the epithelium a few cells away from the wound edge. The new cells migrate over the cells at the edge and into the unhealed area and anchor to the first unepithelialized matrix position encountered. The PaO_2 on the underside of the cell at the anchor point is usually low. Low PaO_2 stimulates squamous epithelial cells to produce TGF- β , likely suppressing terminal differentiation and again supporting further mitosis. This process of epidermal-mesenchymal communication repeats itself until the wound is closed.

Squamous epithelialization and differentiation proceed maximally when surface wounds are kept moist. It is clear that even short periods of drying impair the process, and therefore wounds should not be allowed to desiccate. The exudates from acute, uninfected superficial wounds also contain growth factors and lactate, and therefore recapitulate the growth environment found at the base of the wound.

E. Collagen Fiber Remodeling and Wound Contraction

Remodeling of the wound extracellular matrix is also a well-regulated process. First, fibroblasts replace the provisional fibrin matrix with collagen monomers. Extracellular enzymes, some of which are PaO_2 -dependent, quickly polymerize these monomers, initially in a pattern that is more random than in uninjured tissue, predisposing early

▲ **Figure 6-3.** The very early wound matrix is weak and susceptible to mechanical failure, especially in load-bearing tissues like the abdominal wall. After 5 days, mechanical failure occurs at the interface of the wound matrix and the uninjured surrounding tissue.

wound to mechanical failure. Progressively, the very early provisional matrix is replaced with a more mature one by forming larger, better organized, stronger, and more durable collagen fibers. The very early wound provisional matrix usually mechanically fails within the matrix itself (days 0-5). Next, mechanical failure occurs at the matrix-tissue interface or fusion point (Figure 6-3). The mechanism for connecting the wound matrix to the uninjured tissue border is poorly understood.

Reorganization of the new matrix is an important feature of healing, and fibroblasts and leukocytes secrete collagenases that ensure the lytic component. Turnover occurs rapidly at first and then more slowly. Even in simple wounds, wound matrix turnover can be detected chemically for as long as 18 months. Healing is successful when a net excess of matrix is deposited despite concomitant lysis. Lysis, in contrast to anabolic synthesis, is less dependent upon energy and nutrition. If synthesis is impaired, however, lysis weakens wounds.

During rapid turnover, wounds normally gain strength and durability but are vulnerable to contraction or stretching. Fibroblasts exert the force for contraction. Fibroblasts attach to collagen and each other and pull the collagen network together when the cell membranes shorten as the fibroblasts migrate. The wound myofibroblast, a specialized phenotype, expresses intracellular actin filaments that also contribute force to fibroblast-mediated wound contraction. The collagen fibers are then fixed in the packed positions by a variety of cross-linking mechanisms. Both open and closed wounds tend to contract if not subjected to a superior counterforce. The phenomenon is best seen in surface wounds, which may close 90% or more by contraction alone in loose skin. For example, the residual of a large open wound on the back of the neck may be only a small area of epithelialization. On the back, the buttock, or the neck, this is often a beneficial process, whereas in the face

and around joints, the results may be disabling or disfiguring. Pathological wound contraction is usually termed a contracture or a stricture. Skin grafts, especially thick ones, may minimize or prevent disabling wound contractures. Dynamic splints, passive or active stretching, or insertion of flaps containing dermis and subdermis also counteract contraction. Prevention of a stricture often depends on ensuring that opposing tissue edges are well perfused so that healing can proceed quickly to completion and contraction stops. Healing wounds may also stretch during active turnover when tension overcomes contraction. This may account for the laxity of scars in ligaments of injured but unsplinted joints and the tendency for incisional hernia formation in abdominal wounds of obese patients.

F. Healing of Specialized Tissues

Tissue other than skin heals generally by the same fundamental pathways. Although tissue structure may be specialized, the initial repair processes are shared. It does appear that the rate and efficiency of wound healing in different tissue types depends in large part on total collagen content, collagen organization, and blood supply.

Gastrointestinal tract—The rate of repair varies from one part of the intestine to the other in proportion to blood supply. Anastomoses of the colon and esophagus heal least reliably and are most likely to leak, whereas failure of stomach or small intestine anastomoses is rare. Intestinal anastomoses regain strength rapidly when compared to skin wounds. After 1 week, bursting strength may exceed the uninjured surrounding intestine. However, the surrounding intestine also participates in the reaction to injury, initially losing collagen by lysis, and as a result may lose strength. For this reason, leakage can occur a few millimeters from the anastomosis. A tight suture line causing ischemia will exacerbate this surgical problem.

The mesothelial cell lining of the peritoneum also is important for healing in the abdomen and GI tract. The esophagus and retroperitoneal colon lack a serosal mesothelial lining, which may contribute to failed wound healing. There is evidence that mesothelial cells signal the repair of peritoneal linings and are a source of repair cells.

Comorbidities that delay collagen synthesis or stimulate collagen lysis are likely to increase the risk of perforation and leakage. The danger of leakage is greatest from the fourth to seventh days, when tensile strength normally would rise rapidly but may be impeded by impaired collagen deposition or increased lysis. Local infection, which most often occurs near esophageal and colonic anastomoses, promotes lysis and delays synthesis, thus increasing the likelihood of perforation.

Bone—Bone healing is controlled by many of the same mechanisms that control soft tissue healing. It too occurs in

predictable, morphologic stages: inflammation, fibroplasia, and remodeling. The duration of each stage varies depending on the location and extent of the fracture.

Injury (fracture) causes hematoma formation from the damaged blood vessels of the periosteum, endosteum, and surrounding tissues. Within hours, an inflammatory infiltrate of neutrophils and macrophages is recruited into the hematoma as in soft tissue injuries. Monocytes and granulocytes debride and digest necrotic tissue and debris, including bone, on the fracture surface. This process continues for days to weeks depending on the amount of necrotic tissue. As inflammation progresses to fibroplasia, the hematoma is progressively replaced by granulation tissue that can form bone. This bone wound tissue, known as callus, develops from both sides of the fracture and is composed of fibroblasts, endothelial cells, and bone-forming cells (chondroblasts, osteoblasts). As macrophages (osteoclasts) phagocytose the hematoma and injured tissue, fibroblasts (osteocytes) deposit a collagenous matrix, and chondroblasts deposit proteoglycans in a process called enchondral bone formation. This step, prominent in some bones, is then converted to bone as osteoblasts condense hydroxyapatite crystals at specific points on the collagen fibers. Endothelial cells form a vasculature structure characteristic of uninjured bone. Eventually the fibrovascular callus is completely replaced by new bone. Unlike healing of soft tissue, bone healing has features of regeneration, and bone often heals without leaving a scar.

Bone healing also depends on blood supply. Following injury, the ends of fractured bone are avascular. Osteocyte and blood vessel lacunae become vacant for several millimeters from the fracture. New blood vessels must sprout from preexisting ones and migrate into the area of injury. As new blood vessels cross the bone ends, they are preceded by osteoclasts just as macrophages precede them in soft tissue repair. In bone, this unit is called the cutting cone because it bores its way through bone in the process of connecting with other vessels. Excessive movement of the bone ends during this revascularization stage will break the delicate new vessels and delay healing. Osteomyelitis originates most often in ischemic bone fragments. Hyperoxygenation optimizes fracture healing and aids in the cure (and potentially the prevention) of osteomyelitis. Acute or chronic hypoxia slows bone repair.

Bone repair may occur through primary or secondary intention. Primary repair can occur only when the fracture is stable and aligned, and its surfaces closely apposed. This is the goal of rigid plate fixation or rod fixation of fractures. When these conditions are met, capillaries can grow across the fracture and rapidly reestablish a vascular supply. Little or no callus forms. Secondary repair with callus formation is more common. Once the fracture has been bridged, the new bone remodels in response to the mechanical stresses upon it, with restoration to normal or near-normal strength.

During this process, as in soft tissue, preexisting bone and its vascular network are simultaneously removed and replaced. Increased bone turnover may be detected as long as 10 years after injury. Although remodeling is efficient, it cannot correct deformities of angulation or rotation in misaligned fractures. Careful fracture reduction is still important.

Bone repair can be manipulated. Electrical stimulation, growth factors, and distraction osteogenesis are three tools for this purpose. Electrical currents applied directly (through implanted electrodes) or induced by external alternating electromagnetic fields accelerate repair by inducing new bone formation in much the same way as small piezoelectric currents produced by mechanical deformation of intact bone controls remodeling along lines of stress. Electrical stimulation has been used successfully to treat nonunion of bone (where new bone formation between bone ends fails, often requiring long periods of bed rest). Bone morphogenetic protein (BMP)-impregnated implants have accelerated bone healing in animals and have been used with encouraging results to treat large bony defects and nonunions, including during spinal fusion.

The Ilizarov technique, linear distraction osteogenesis, can lengthen bones, stimulate bone growth across a defect, or correct defects of angulation. The Ilizarov device is an external fixator attached to the bones through metal pins or wires. A surgical break is created and then slowly pulled apart (1 mm/d) or slowly reangulated. The vascular supply and subsequent new bone formation migrate along with the moving segment of bone.

PATHOGENESIS

► Effect of Tissue Hypoxia

Impaired perfusion and inadequate oxygenation are the most frequent causes of healing failure. Oxygen is required for successful inflammation, bactericidal activity, angiogenesis, epithelialization, and matrix (collagen) deposition. The critical collagen oxygenases involved have K_m values for oxygen of about 20 mm Hg and maximums of about 200 mm Hg, meaning that reaction rates are regulated by P_{aO_2} and blood perfusion throughout the entire physiologic range. The P_{aO_2} of wound fluid in human incisions is about 30-40 mm Hg, suggesting that these enzymes normally function just beyond half capacity. Wound P_{aO_2} is depressed by hypovolemia, catecholamine infusion, stress, fear, or cold. Under ideal conditions, wound fluid P_{aO_2} can be raised above 100 mm Hg by improved perfusion and breathing of oxygen. Human healing is profoundly influenced by local blood supply, vasoconstriction, and all other factors that govern perfusion and blood oxygenation. Wounds in well-vascularized tissues (eg, head, anus) heal rapidly and are remarkably resistant to infection (Figure 6-4).

▲ **Figure 6-4.** Tissue oxygen concentration ($TcPO_2$) is a critical determinant of wound healing. Human healing is profoundly influenced by local blood supply, vasoconstriction, and all other factors that govern perfusion and blood oxygenation. Despite raising FiO_2 to 50% or 100%, the $TcPO_2$ remains in the ischemic range when flow is reduced to less than 25% of baseline. Supplementing the FiO_2 of oxygen will not benefit healing of ischemic ulcers. Flow must be increased to improve the $TcPO_2$.

► Dysregulated Inflammation During Impaired Wound Healing

Molecular growth signals and lytic enzymes released by inflammatory cells are necessary for repair. Inhibited or excessive inflammatory responses lead to wound complications. Failure to heal is common in patients taking anti-inflammatory corticosteroids, immune suppressants, or cancer chemotherapeutic agents that inhibit inflammatory cells. Open wounds are more affected than primarily repaired wounds. Anti-inflammatory drugs impair the wound less after the third day of healing, as the normal level of inflammation in wound healing is reduced. Inflammation may also be excessive. Increased wound inflammation (eg, in response

to infection and endotoxin or foreign bodies like mesh implants during hernia repair) can stimulate inflammatory cells to produce cytolytic cytokines and excessive proteases with the consequence of pathologic lysis of newly formed tissue. A pathological cycle of wound healing may ensue and result in an impaired quantity and quality of wound scar.

► Impaired Healing Due to Malnutrition

Malnutrition impairs healing, since healing depends on nucleic acid and protein synthesis, cell replication, specific organ function (liver, heart, lungs), and extracellular matrix production. Weight loss and protein depletion have been shown experimentally and clinically to be risk factors for poor healing. Deficient healing is seen mainly in patients with acute malnutrition (ie, in the weeks just before or after an injury or operation). Even a few days of starvation measurably impairs healing, and an equally short period of repletion can reverse the deficit. Wound complications increase in severe malnutrition. A period of preoperative corrective nutrition is generally helpful for patients who have recently lost 10% or more of their body weight.

► Scar Formation Versus Regeneration

In excessive healing or proliferative scarring, it is as if the equilibrium point between collagen deposition and collagen lysis is never reached. It is unclear why some wounds seem to continue in the dysregulated repair process. Upregulation of fibroplastic growth factors like TGF- β is implicated during hypertrophic or keloid scar formation. Because the mechanism of excessive scar formation is unknown, there is no universally accepted treatment regimen. In a recent meta-analysis of pathologic scar treatments, the mean amount of improvement to be expected was only 60%. Hypertrophic scars are generally self-limited, are related to residual inflammation, and may regress after a year or so. Keloids by definition extend beyond the borders of the wound and are most common in pigmented skin. The last areas of a burn to heal are the most often hypertrophic, possibly due to traction, reinjury, and tension. Immune mechanisms may also contribute to pathological scar. Prolonged inflammatory reactions potentiate scar. Therapy includes intralesional injection of anti-inflammatory steroids and dressing with Silastic sheets, which are shown to increase protease-based lytic activity in the scar. Excessive or hypertrophic scarring is rare in burn injuries that heal within 21 days. Pressure garments or compression dressings are effective in decreasing scarring in burn injuries that require more than 21 days to heal. The exact mechanism by which pressure is effective is unknown.

CLINICAL FINDINGS

Impediments to wound healing may be broadly categorized as those local to the wound, and those that are systemic comorbidities and diseases. Often, a clinical intervention is

Table 6–1. Local and systemic impediments to wound healing.

Systemic	Local
Malnutrition	Wound infection
Diabetes mellitus	Wound necrosis
Drugs (steroids, cytotoxins)	Foreign bodies
Obesity	Wound hypoperfusion and hypoxia
Shock	Repeat trauma
Immunodeficiency	Irradiated tissue
Renal failure	Neoplasm

possible to minimize or eliminate these obstacles to tissue repair (Table 6–1).

► Acute Wounds

Acute wounds express normal wound healing pathways and are expected to heal. Over days and weeks, the undisturbed acute wound can be observed to progress reliably through the phases of hemostasis, normal inflammation, normal fibroplasia, and ultimately scar maturation with epithelialization. The most common acute wound complications are pain, infection, mechanical dehiscence, and hypertrophic scar.

► Chronic Wounds & Decubiti

A. Chronic Wounds

Chronically unhealed wounds, especially on the lower extremity, are common in the setting of vascular, immunologic, and neurologic disease. Venous ulcers, largely of the lower leg, reflect poor perfusion and perivascular leakage of plasma into tissue. The extravasation of plasma proteins into the soft tissue stimulates chronic inflammation. This is the result of venous hypertension produced by incompetent venous valves. Most venous ulcers will heal if the venous congestion and edema are relieved by leg elevation, compression stockings, or surgical procedures that eliminate or repair incompetent veins or their valves.

Arterial or ischemic ulcers, which tend to occur on the lateral ankle or foot, are best treated by revascularization. Hyperbaric oxygen, which provides a temporary source of enhanced oxygenation that stimulates angiogenesis, is an effective though expensive alternative when revascularization is not possible. Useful information can be obtained by transcutaneous oximetry. Tissues with a low P_{aO_2}

will not heal spontaneously. However, if oxygen tension can be raised into a relatively normal range by oxygen administration even intermittently, the wound may respond to oxygen therapy.

Sensory loss, especially of the feet, can lead to ulceration. Bony deformities due to chronic fractures, like the Charcot deformity, cause pathologic pressure on wounded tissue. Ulcers in patients with diabetes mellitus may have two causes. Patients with neuropathic ulcers usually have good circulation, and their lesions will heal if protected from trauma by off-loading, special shoes, or splints. Recurrences are common, however. Diabetics with ischemic disease, whether they have neuropathy or not, are at risk for gangrene, and they frequently require amputation when revascularization is not possible.

In pyoderma gangrenosum, granulomatous inflammation, with or without arteritis, causes skin necrosis, possibly by a mechanism involving excess cytokine release. These ulcers are associated with inflammatory bowel disease and certain types of arthritis and chondritis. Corticosteroids or other anti-inflammatory drugs are helpful. However, anti-inflammatory corticosteroids can also contribute to poor healing by inhibiting cytokine release and collagen synthesis.

B. Decubiti

Decubitus ulcers can be major complications of immobilization. The morbidity of decubitus ulcers lengthens hospital stays and increases health care costs. They result from prolonged pressure that reduces tissue blood supply, irritative or contaminated injections, and prolonged contact with moisture, urine, or feces. Most patients who develop decubitus ulcers are also poorly nourished. Pressure ulcers are common in paraplegics, immobile elderly patients following fractures, and intensive care unit patients. The ulcers vary in depth and often extend from skin to a bony pressure point such as the greater trochanter, the sacrum, the heels, or the head. Most decubitus ulcers are preventable. Hospital-acquired ulcers are nearly always the result of immobilization, unprotected positioning on operating tables, and ill-fitting casts or other orthopedic appliances.

COMPLICATIONS

► Wound Infection

A wound infection results when bacterial proliferation and invasion overcomes wound immune defense mechanisms. When an imbalance in this quantitative equilibrium results in infection, a delay in wound healing occurs. Therefore, prevention and treatment of wound infection involves maintenance or reestablishment of the balanced equilibrium.

Wounds containing more than 10^5 bacteria/gram of tissue or any tissue level of β -hemolytic streptococci are at high risk for wound infection if closed by direct wound edge approximation, skin graft, pedicled, or free flap. Clean-contaminated and contaminated wounds result in high rates of postoperative infection (6%-15%), while clean cases have lower infection rates (1%-3%). When wounds are considered at risk for having a significant bacterial bioburden (clean-contaminated or contaminated cases), prophylactic operative antibiotics reduce wound infection rates. Wounds following clean cases with negligible bacterial bioburden do not clearly benefit from prophylactic antibiotics except when implanted prosthetic materials are used.

► Mechanical Wound Failure

Mechanical factors play an important and often underappreciated role in acute wound healing. Primary closure of an incision stabilizes distractive forces to allow wound healing and an optimized anatomic result (Figure 6–5). Cellular studies confirm that mechanical load forces are an important signal for acute wound repair. When anatomic stability of a wound is achieved, a particular suture material or suturing technique is of secondary importance. The increased use of foreign material implants, like meshes for hernia repair, are

suggested to manipulate the mechanical environment of the acute wound, even to the point of promoting “tension-free” wound healing. Negative pressure wound therapy is increasingly applied to stabilize acute wounds and to support acute wound healing. Mechanical microdeformation of repair cells in the wound bed is thought to stimulate acute wound healing.

Mechanical signaling pathways are important for the regulation of tissue repair, especially in load-bearing structures like the abdominal wall and Achilles tendon. From this perspective, the midline fascia behaves more like a ligament or tendon than skin, for example. It is observed that scars placed under mechanical loads ultimately will assume the morphology and function of tendons and, conversely, that incisions placed under “low” loads organize scars with reduced tensile strengths. The empiric observation that a suture length (SL)–wound length (WL) ratio of 4:1 results in the most reliable midline abdominal wall closure may reflect the technique resulting in establishing the optimal acute wound healing–load set point for the abdominal wall. When a laparotomy wound mechanically fails, a fundamental repair signal may be lost, contributing to the biology of hernia formation. Clinically, laparotomy dehiscence of only 12 mm on postoperative day 30 predicts a 94% incisional hernia rate after 3 years.

▲ **Figure 6–5. A.** In a healing laparotomy wound (HW), fibroplasia, matrix synthesis, and angiogenesis stabilize the rectus muscles at the wound edges until repair is complete. **B.** When laparotomy wounds fail to heal (FW), there is an absence of fibroplasia and herniated preperitoneal fat occupies the wound space.

TREATMENT

► Acute Wounds

A. Sutures

The ideal suture material is flexible, strong, easily tied, and securely knotted. It stimulates little tissue reaction and does not serve as a nidus for infection.

Silk is an animal protein but is relatively inert in human tissue. It is commonly used because of its track record and favorable handling characteristics. It loses strength over long periods and is unsuitable for suturing arteries to plastic grafts or for insertion of prosthetic cardiac valves. Silk sutures are multifilament, providing mechanical immune barriers for bacteria. Occasionally, silk sutures form a focus for small abscesses that migrate and “spit” through the skin, forming small sinuses that will not heal until the suture is removed.

Synthetic nonabsorbable sutures are generally inert polymers that retain strength. However, their handling characteristics are not as good as those of silk, and they must usually be knotted at least four times, resulting in increased amounts of retained foreign material. Multifilament plastic sutures may also become infected and migrate to the surface like silk sutures. Monofilament plastics will not harbor bacteria. Nylon monofilament is extremely nonreactive, but it is difficult to tie. Monofilament polypropylene is intermediate in these properties. Vascular anastomoses to prosthetic vascular grafts rely indefinitely on the strength of sutures; therefore, use of absorbable sutures may lead to aneurysm formation.

Synthetic absorbable sutures are strong, have predictable rates of loss of tensile strength, incite a minimal inflammatory reaction, and have special usefulness in gastrointestinal, urologic, and gynecologic operations that are contaminated. Polyglycolic acid and polyglactin retain tensile strength longer in gastrointestinal anastomoses. Polydioxanone sulfate and polyglycolate are monofilament and lose about half their strength in 50 days, thus solving the problem of premature breakage in fascial closures. Poliglecaprone monofilament synthetic sutures have faster reabsorption, retaining 50% tensile strength at 7 days and 0% at 21 days. This suture is suitable for low-load soft tissue approximation but is not intended for fascial closure.

Stainless steel wire is inert and maintains strength for a long time. It is difficult to tie and may have to be removed late postoperatively because of pain. It does not harbor bacteria, and it can be left in granulating wounds, when necessary, and will be covered by granulation tissue without causing abscesses. However, sinuses due to motion are fairly common.

Catgut (now made from the submucosa of bovine intestine) will eventually resorb, but the resorption time is

highly variable. It stimulates a considerable inflammatory reaction and tends to potentiate infections. Catgut also loses strength rapidly and unpredictably in the intestine and in infected wounds as a consequence of acid and enzyme hydrolysis.

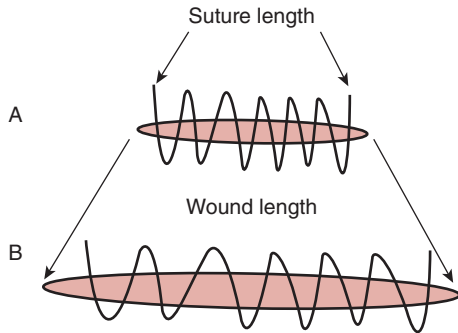

Staples, whether for internal use or skin closure, are mainly steel-tantalum alloys that incite a minimal tissue reaction. The technique of staple placement is different from that of sutures, but the same basic rules pertain. There are no real differences in the healing that follows sutured or stapled closures. Stapling devices tend to minimize errors in technique, but at the same time, they do not offer a feel for tissue and have limited ability to accommodate to exceptional circumstances. Staples are preferable to sutures for skin closure, since they do not provide a conduit for contaminating organisms. There is no reliable evidence that absorbable sutures lead to more incisional hernias or gastrointestinal anastomotic leaks.

Surgical glues or tissue adhesives are now established as safe and effective for the repair of small skin incisions. The most common forms are cyanoacrylate-based glues. Tissue adhesives are often less painful than sutures or staples, and the seal can serve as the wound dressing as well.

► Surgical Technique

Primarily closed wounds are of a smaller volume and heal mainly by the synthesis of a new matrix. Wound contraction and epithelialization, as in an open wound healing by secondary intent, contribute a small part to primary wound healing. An open wound, healing by secondary intent, must synthesize granulation tissue to fill in the wound bed, contract at the wound periphery, and cover the surface area with epithelial cells. Wounds heal faster following delayed primary closure than by secondary intent, as well. The mechanical load forces transmitted through a primarily reconstructed wound will stimulate repair. Successful delayed primary closure requires that the acute wound be in bacterial balance. Primary repair should approximate, but not strangulate, the incision. The type of suture material used does not matter, as long as the primary repair is anatomic and perfused.

The most important means of achieving optimal healing after operation is good surgical technique. Many cases of surgical wound failure are due to technical errors. Tissue should be protected from drying and contamination. The surgeon should use fine instruments; should perform clean, sharp dissection; and should make minimal, skillful use of electrocautery, ligatures, and sutures. All these precautions contribute to the most important goal of surgical technique, gentle handling of tissue. Anatomic tissue approximation should be achieved when possible but optimum tissue perfusion preserved.

▲ **Figure 6-6.** The most reliable laparotomy closure uses a continuous technique at a suture length–wound length ratio of 4:1 (A). This allows for the normal 10% strain that occurs along the length of the incision, while maintaining mechanical integrity (B).

A. Wound Closure

As with many surgical techniques, the exact method of wound closure may be less important than how well it is performed. The tearing strength of sutures in fascia is no greater than 4 kg. There is little reason to use sutures of greater strength than this. Excessively tight closure strangulates tissue, likely leading to hernia formation or infection.

The most reliable laparotomy closure uses a continuous technique at SL-WL ratio of 4:1, which allows for the normal 10% strain that occurs along the length of the incision, while maintaining mechanical integrity. A 4:1 SL-WL ratio is achieved with suture placed 1-cm deep on normal fascia (the bite) followed by 1 cm of progress. The depth of the suture-line bite must extend beyond the wound lytic zone. Normal collagen lysis occurs for approximately 5 mm perpendicular to the incision, weakening the adjacent fascia. The most common technical causes of dehiscence are an SL-WL ratio less than 4:1, infection, and excessively tight sutures. Tight suture lines impair wound perfusion and oxygen delivery that is required for wound healing. If wound healing is impaired, wider, interrupted internal retention sutures may be added, although improved outcomes are not proven (Figure 6-6).

Delayed primary closure is a technique by which the subcutaneous portion of the wound is left open for 4-5 days prior to primary repair. During the delay period, angiogenesis and fibroplasia start, and bacteria are cleared from the wound. The success of this method depends on the ability of the surgeon to detect the signs of wound infection. Merely leaving the wound open for 4 days does not guarantee that it will not become infected. Some wounds (eg, fibrin-covered or inflamed wounds) should not be closed but should be left open for secondary closure. Quantitative

bacterial counts less than 10^5 non- β -hemolytic streptococcus organisms per gram of wound tissue predict successful healing after delayed primary closure. Any level of β -hemolytic streptococcal wound infection predicts delayed wound healing.

► Implantable Materials

Soft tissue prostheses reduce the incidence of wound failure and recurrence following hernia repair. The recurrence rate following inguinal hernia repairs using autologous tissues ranges from 5% to 25% in most series. The recurrence rate following primary incisional hernia repair using autologous tissues is even worse, ranging from 20% to 60%. The introduction of synthetic soft tissue prostheses to inguinal and incisional hernia repair has significantly reduced recurrence rates across general surgery. The prevailing view is that the mechanism for the reduced hernia recurrence rates is the reduction of tension along suture lines when using mesh and the replacement abnormal tissue.

No implantable prosthesis is ideal in regard to tissue compatibility, permanent fixation, and resistance to infection. Two principles are paramount: biocompatibility and a material that is incorporated into tissue. Both specific and nonspecific immune mechanisms are involved in the inflammatory reaction to foreign materials. Highly incompatible materials, such as wood splinters, elicit an acute inflammatory process that includes massive local release of proteolytic enzymes (inflammation). Consequently, the foreign body is never incorporated and instead is isolated loosely in a fibrous pocket. In less severe incompatibility, rejection is not so vigorous and proteolysis is not so prominent. Mononuclear cells and lymphocytes, the major components of wound inflammatory tissue, direct a response that creates a fibrous capsule that may be acceptable in a joint replacement but may distort a breast reconstruction (encapsulation). Newer biological prostheses are composed of acellularized tissue to abrogate the immune response. The expectation is that these materials recellularize with host cells and blood vessels during incorporation and assume a more physiological function (regeneration).

Most implants must become anchored to adjacent normal tissues through fibrous tissue ingrowth. This process requires biocompatibility and interstices large enough to permit repair fibroblast migration, just as in a wound, and to allow pedicles of vascularized tissue to enter and join similar units. In bone, this tissue incorporation imparts stability. In vascular grafts, the invading tissue supports neointima formation, which retards mural thrombosis and distal embolization. Soft tissue will grow into pores larger than about 50 μm in diameter. Of the vascular prostheses, woven Dacron is best for tissue incorporation. In bone, sintered, porous metallic surfaces are best. Large-screen

polypropylene mesh can be used to support the abdominal wall or chest and is usually well incorporated into the granulation tissue that penetrates the mesh. Mesh porosity is increasingly recognized as an important design element for reliable implantation and wound healing. Microporous polytetrafluoroethylene (PTFE) sheets are often not well incorporated and are not suitable for use in infected tissues.

The implantation space remains vulnerable to infection for years and is a particular problem in implants that cross the body surface. Mesh cuffs around vascular access devices that incite incorporation have successfully forestalled infection for months, but infections that arise from bacteria entering the body along “permanently” implanted foreign bodies traversing the skin surface, such as ventricular assist devices, remain an unsolved problem.

► Negative Pressure Wound Therapy

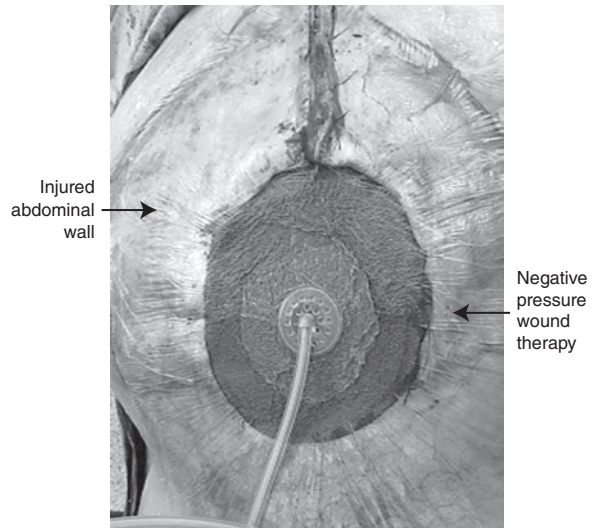

Negative pressure wound therapy (NPWT) mechanically stabilizes the distractive forces of an open acute wound and supports healing. Distractive tissue forces keep a wound open with force vectors that oppose wound contraction, thereby delaying healing. NPWT also reduces periwound edema and improves wound perfusion. NPWT may directly stimulate repair fibroblast activity through mechanical microdeformation of the cell surface.

NPWT can also stabilize a therapeutically open abdomen (laparotomy), minimizing wound size and supporting closure of the abdominal wall. Distractive force from the rectus muscle components and lateral oblique muscles acts to keep the laparotomy open, leading to incisional hernia formation and potentially loss of abdominal, peritoneal volume (domain) (Figure 6–7).

A. Chronic Wounds

The first principle in managing chronic wounds is to diagnose and treat tissue hypoxia, such as underlying circulatory disease. The second principle is never to allow open wounds to dry—that is, use moist dressings, which may also relieve pain. A third principle is to control any infection with topical or systemic antibiotics. A fourth principle is to recognize that chronically scarred or necrotic tissue is usually poorly perfused. Debridement of unhealthy tissue, often followed by skin grafting, may be required for healing. A fifth principle is to reduce autonomic vasoconstriction by means of warmth, moisture, and pain relief.

A number of growth factors have been shown to accelerate healing of acute wounds in animals. They include FGFs, TGF- β , IGF-1, PDGF, and epidermal growth factor (EGF). However, in the setting of chronic human wounds, with the perfusion problems noted above and the hostile wound environment with elevated protease levels, proof of efficacy has been difficult to develop, and no clear-cut advantage to

▲ **Figure 6–7.** Negative pressure dressings oppose distractive soft tissue vectors and mechanically stabilize a wound.

any formulation has yet been convincingly demonstrated. The one exception is the randomized, prospective, double-blind, placebo-controlled multicenter trial by the Diabetic Ulcer Study Group, which demonstrated that daily topical application of recombinant human PDGF-BB homodimer moderately accelerated healing and resulted in more wounds that healed completely.

B. Ducubiti

The first principle is to incise and drain any infected spaces or debride necrotic tissue. Dead tissue is debrided until the exposed surfaces are viable. Sources of pressure must again be unloaded. Many will then heal spontaneously. However, deep ulcers may require surgical closure, sometimes with removal of underlying bone. The defect may require closure by judicious movement of thick, well-vascularized tissue into the affected area. Musculocutaneous flaps are the treatment of choice when chronic infection and significant tissue loss are combined. However, recurrence is common because the flaps are usually insensate.

► Postoperative Care

Optimum postoperative care of the wound requires cleanliness, maintenance of a moist wound environment, protection from trauma, and support of the patient. Even closed wounds can be infected by surface contamination, particularly within the first 2-3 days. Bacteria gain entrance most easily through suture tracts. If a wound is likely to be

traumatized or contaminated, it should be protected during this time. Such protection may require special dressings such as occlusive dressings or sprays and repeated cleansing.

Some mechanical stress enhances healing. Even fracture callus formation is greater if slight motion is allowed. Patients should move and stress their wounds a little. Early ambulation and return to normal activity are, in general, good for repair.

The appearance of delayed wound infections, weeks to years after operation, reinforces that all wounds are contaminated and may harbor bacteria. Most frequently, poor tissue perfusion and oxygenation of the wound during the postoperative period weakens host resistance. Regulation of perfusion is largely due to sympathetic nervous activity. The major stimuli of vasoconstriction are cold, pain, hypovolemia, cigarette smoking, and hypoxemia. Recent studies show that efforts to limit these impediments to wound healing reduce the wound infection rate by more than half. Maintenance of intraoperative normothermia and blood volume is particularly important. Appropriate assurance that peripheral perfusion is adequate is best obtained from peripheral tissues rather than urine output, central venous pressure, or wedge pressure, none of which correlate with peripheral wound tissue oxygenation. What does correlate with tissue oxygenation is the capillary refill time on the forehead or patella, which should be less than 2 and 5 seconds respectively. Collagen deposition is increased also by the addition of oxygen breathing (nasal prongs or light mask) but only in well-perfused patients.

The ideal care of the wound begins in the preoperative period and ends only months later. The patient must be prepared so that optimal conditions exist when the wound is made. Surgical technique must be clean, gentle, and skillful. Nutrition should be optimized preoperatively when possible. Cessation of cigarette smoking will improve wound outcomes. Postoperatively, wound care includes maintenance of nutrition, blood volume, oxygenation, and careful restriction of immunosuppressant drugs when possible. Although wound healing is in many ways a local phenomenon, ideal care of the wound is essentially ideal care of the patient.

MULTIPLE CHOICE QUESTIONS

- Which phase of acute wound healing is prolonged during progression to a chronic wound?
 - Coagulation
 - Inflammation
 - Fibroplasia
 - Angiogenesis
 - Remodeling
- Which cell is most important for signaling wound healing?
 - Platelet
 - PMN
 - Macrophage
 - Fibroblast
 - Endothelial cell
- Which is the most predictive direct measure of impaired or delayed wound healing?
 - Vitamin C deficiency
 - Low serum albumin
 - Irradiated tissue
 - Smoking
 - TcO₂ less than 30 mm Hg

4. Which of the following is not a clinical impediment to wound healing?
 - A. Repeated trauma
 - B. Wound infection
 - C. A moist wound environment
 - D. Foreign bodies
 - E. Obesity

5. The fundamental mechanism for incisional hernia formation is
 - A. Long-term fascial scar failure
 - B. Suture failure
 - C. Suture pulling through the fascia
 - D. Early fascial dehiscence and wound failure
 - E. Poor technique

Power Sources in Surgery

K. Barrett Deatrck, MD
Gerard M. Doherty, MD

INTRODUCTION

Modern surgery has been redefined by powered instruments, technological tools that in many ways have revolutionized the delicacy, precision, and accuracy of the various operations performed. Yet many people who use these implements every day have very little understanding of the technology behind these tools. Although a complete treatise on electromagnetic generation of heat and the physics of current generation are beyond the scope of this chapter (and are available elsewhere), understanding some fundamental rules governing the behavior of electrical currents and some relatively straightforward principles helps guide the use of these technologies.

ELECTROSURGERY

► Principles of Electricity

An electrical **circuit** is any pathway that allows the uninterrupted flow of electrons. Electrical **current** is the flow of electricity (the number of electrons) in a given circuit over a constant period of time and is measured in **amperes** (A). Current can be supplied either as direct current (DC) with constant positive and negative terminals or as alternating current (AC) with constantly reversing poles. The electromotive force, or **voltage**, is a measurement of the force that propels the current of electrons and is related to the difference in potential energy between two terminals. The **resistance** is the tendency of any component of a circuit to resist the flow of electrons and applies to DC circuits. The equivalent of this tendency in an AC circuit is known as impedance. Any electromagnetic wave, from household electricity to radio broadcasts to visible light, can be described by three components: speed, frequency, and wavelength. Because all electromagnetic waves travel at the speed of light, which is a constant, these waves depend on the relationship between

their frequency and wavelength. Since these three characteristics are defined by the equation:

$$c = f\lambda$$

(where c is the speed of light, 2.998×10^8 m/s)

frequency (f) and wavelength (λ) are inversely related; that is, as frequency increases, wavelength decreases, and vice versa. The ability to pass high-frequency current through the human body without causing excess damage makes electro-surgery possible.

► Electrocautery

Electrosurgery is often incorrectly termed electrocautery, which is a separate technique. Electrocautery is a closed-circuit DC device in which current is passed through an exposed wire offering resistance to the current (Figure 7–1). The resistance causes some of the electrical energy to be dissipated as heat, increasing the temperature of the wire, which then heats tissue. In true electrocautery, *no current passes through the patient*. Electrocautery is primarily applied for microsurgery, such as ophthalmologic procedures, where a very small amount of heat will produce the desired effect or where more heat or current may be dangerous.

► Principles of Electrosurgery

True electrosurgery, colloquially referred to as the “Bovie” (following its inventor, William T. Bovie, engineer and collaborator of Harvey Cushing), is perhaps the most ubiquitous power source in surgery. While the principle of using heat to cauterize bleeding wounds dates back to the third millennium BC, the directed use of electrical current to produce these effects is a far more recent development. While other scientists and engineers made significant contributions to the development of this new technology, it was Bovie who refined the electrical generator and made it practical

▲ **Figure 7-1.** In electrocautery, current passes through a wire loop and heats it. This heat cauterizes tissue. No current passes through the patient.

and applicable to everyday surgery. At the most fundamental level, electrosurgery uses high-frequency (radiofrequency) electromagnetic waves to produce a localized heating of tissues, leading to localized tissue destruction. The effect produced (cutting vs coagulation) depends on how this energy is supplied.

A useful exercise to understand the way electrosurgery works is to follow the flow of current from the power outlet as it travels through the patient and returns to the wall outlet. By convention, charge is depicted as moving from positive (cathode) to negative (anode) despite that the particles that are actually moving are electrons, which have a negative charge. These descriptions are based on that convention, following the flow of positive charge.

A. Monopolar Circuits

The electrosurgical circuit consists of four primary parts: the electrosurgical generator, the active electrode, the patient, and the return electrode. Current flows from the electrosurgical generator after it is modulated to a high-frequency, short wavelength current and where multiple waveforms can be produced. (The importance of the waveform is discussed in later sections.) The current flows from the machine, through the handpiece, out the tip of the device, to the patient. If the patient were not connected in some way either to a negative terminal or to ground, no current would flow, as there would be no way to complete the circuit, hence nowhere for the charge to go. However, the patient is always connected to the electrosurgical generator by a return electrode, which allows

the charge delivered by the electrosurgical probe to pass through the patient, exerting its effect, and back to the generator, completing the circuit. In reality, the term *monopolar circuit* is incorrect, as there are in fact two poles (the active and return electrodes); it is distinguished from bipolar electrosurgery in which both electrodes are under the surgeon's direct control (Figure 7-2A).

B. Bipolar Circuits

The essential components of the bipolar electrosurgical circuit are the same as those in the monopolar circuit; however, in this system, the active and return electrodes are in the same surgical instrument. In this technique, high-frequency current is passed through the active electrode and through the patient to heat and disrupt tissue. In this arrangement, however, the return electrode is in the handpiece, as the opposite pole of the active electrode. This method enables the surgeon to heat only a discrete amount of tissue (Figure 7-2B).

▶ The Electromagnetic Spectrum & Tissue Effects

The current that powers the electrosurgical generator is supplied at a frequency of 60 Hz. This type of electromagnetic energy can indeed cause very strong (potentially lethal) neuromuscular stimulation, making it unsuitable for use in its pure form. Muscle and nerve stimulation, however, ceases at around 100 kHz. Current with a frequency above this threshold can be delivered safely, without the risk of electrocution. The outputs of electrosurgical generators deliver current with a frequency greater than 200 kHz. Current at this frequency is known as **radiofrequency (RF)**; it is in the same portion of the spectrum as some radio transmitters. This level of RF, released from a radio antenna, can produce serious RF burns if the proper precautions are not taken.

Applying electrosurgical current to a patient produces localized tissue destruction via intense heat production, yet barring a mishap, no other lesions are produced during application of this technique. The reason the effect is exerted only at the site where the surgeon is operating, and not at the site of the return electrode, is that the surface area by which the charge is delivered is much smaller than that to which it returns. Thus, there is a far greater density of charge at the site of the handpiece ("active" electrode) contact than there is at the site of return. If there is another connection between the patient and ground that offers less resistance to the flow of current, and if it also comprises a relatively small surface area, then the patient could be in danger of suffering an electrosurgical burn. Similarly, it is possible that if the return electrode were to be damaged, or if contact was not maintained, a burn could occur in this area. The possibility of a burn at the site of the return electrode is eliminated in most

▲ **Figure 7-2.** **A.** In monopolar electrocautery, current from an electrocautery generator passes from an active electrode (the “Bovie” tip) through the patient to a return electrode of greater area. **B.** In bipolar electrocautery, the active and return electrodes are in the handpiece, and current only flows through the surgical site.

modern machines by the presence of a monitoring system that assesses the completeness of contact (by maintaining a smaller, secondary circuit) and automatically disables power if full contact of the pad is lost (as could be caused by tripping over a wire and tearing the return pad).

► Types of Electrocautery

All types of electrocautery exert their effects via the localized production of heat and the subsequent changes in the heated tissue. Therefore, the different effects produced by electrocautery instruments are created by altering the manner in which this heat is produced and delivered.

Adjustment is made possible by altering the wave pattern of the current.

A. Cutting

Cutting depends on the production of a continuous sine wave of current (Figure 7-3A). Compared with coagulation current (discussed later), cutting current has a relatively low voltage and a relatively high crest factor, which is the ratio of the peak voltage to the mean (root mean square) voltage of the current. Additionally, it has a relatively high “duty cycle”—that is, once the current is applied, the current is actively flowing during the entire application. In this

▲ **Figure 7-3.** Electrosurgical waveforms. **A.** Cutting current. **B.** Coagulation current.

technique, the tip of the electrode is held just slightly off the surface of the tissue. The flow of the high-frequency current through the resistance of the patient's tissue at a very small site produces intense heat, vaporizing water and exploding the cells in the immediate vicinity of the current. Thus, cutting occurs with minimal coagulum production and consequently minimal hemostasis. A combination of coagulation and cutting can be produced by setting the electrosurgical generator to blend, which damps down a portion of the waveform, allowing greater formation of a coagulum and consequently more control of local bleeding.

B. Coagulation: Desiccation and Fulguration

In contrast with cutting currents, **coagulation** currents do not produce a constant waveform. Rather, they rely on spikes of electric wave activity (Figure 7-3B). Although these currents produce less heat overall than the direct sine wave, enough heat is produced to disrupt the normal cellular architecture. Because the cells are not instantly vaporized, however, the cellular debris remains associated with the edge of the wound, and the heat produced is enough to denature the cellular protein. This accounts for the formation of a coagulum, a protein-rich mixture that allows sealing of smaller blood vessels and control of local bleeding. Compared to cutting, coagulation currents have a higher crest factor and a shorter duty cycle (94% off, 6% on). In part, the increased voltage is necessary to overcome the impedance of air during the process of arcing current to the tissues. Coagulation can be accomplished in one of two ways. With **desiccation**, the conductive tip is placed in direct contact with the tissue. Direct contact of the electrode with tissue

reduces the concentration of the current; less heat is generated, and no cutting action occurs. A relatively low power setting is used, resulting in a limited area of tissue ablation with coagulation. Desiccation is achieved most efficiently with the cutting current. The cells dry out and form a coagulum rather than vaporize and explode.

In **fulguration**, the tip of the active electrode is not actually brought into contact with the tissues but rather is held just off the surface, and following activation, the current arcs through the air to the target. Again, this process disrupts normal cellular protein to form a coagulum; the tissue is charred, and a black eschar forms at the site of operation. It is possible to cut with the coagulation current and, conversely, to coagulate with the cutting current by holding the electrode in direct contact with tissue. It may be necessary to adjust power settings and electrode size to achieve the desired surgical effect. The benefit of using the cutting current is that far less voltage is needed, an important consideration during minimally invasive procedures.

C. Variables

Just as the power setting and the waveform affect the results of the current application, any change in the circuit that influences the impedance of the system will influence the tissue effect. These include the size of the electrode, the position of the electrode, the type of tissue, and the formation of eschar.

Size of the electrode—The smaller the electrode, the higher the current concentration. Consequently, the same tissue effect can be achieved with a smaller electrode, even though

▲ **Figure 7-4.** A. Knife electrode. B. Ball electrode. C. Needle electrode. D. Loop electrode. E. Wire electrode.

the power setting is reduced. At any given setting, the longer the generator is activated, the more heat is produced. The greater the heat, the farther it will travel to adjacent tissue (thermal spread). (See various electrodes, Figure 7-4.)

Placement of the electrode—Placement can determine whether vaporization or coagulation occurs. Which one occurs is a function of current density and the heat produced while sparking to tissue versus holding the electrode in direct contact.

Type of tissue—Tissues vary widely in resistance.

Eschar—Eschar is relatively high in resistance to current. Electrodes should be kept clean and free of eschar, maintaining lower resistance within the surgical circuit.

D. Disadvantages and Potential Hazards

Alternate site burns—Early electrocautery generators used a **ground referenced** circuit design. In this type of construction, grounded current from the wall outlet was directly modulated, and it was assumed that it would return to the generator via the return electrode. With this type of system, however, any path of low resistance to ground, including metal instruments, EKG leads, and other wire and conductive surfaces, can complete the circuit. The ground referenced circuit design presented a relatively high hazard for alternate site burns when current was not distributed over a great enough area to dissipate the current.

Modern electrocautery units use isolated generator technology. The isolated generator separates the therapeutic

current from ground by referencing it within the generator circuitry. In an isolated electrocautery system, the circuit is completed by the generator, and electrocautery current from isolated generators will not recognize grounded objects as pathways to complete the circuit. Isolated electrocautery energy recognizes the patient return electrode as the preferred pathway back to the generator. Since the ground is not the reference for completion of the circuit, the potential for alternate site burns is greatly reduced. However, if the return electrode were to become partially disconnected, a burn could occur at the site of the return electrode if the area was too small to distribute the current widely enough to prevent heating of the tissue or if the impedance was too high. It is important to place the return electrode over a well-vascularized tissue mass, not over areas of vascular insufficiency or over bony prominences where contact might be compromised. Therefore, some electrocautery generators use a monitoring system that assesses the quality of the contact between the return electrode and the patient by monitoring impedance, which is related to surface area. Any loss of contact between the electrode and the generator results in interruption of the circuit and deactivation of the system.

Surgical fires—In any setting with high heat sources and an ample supply of oxygen, vigilance against combustion is essential. Drapes, gowns, gas (particularly in bowel surgery and cases involving the upper airway), and hair, for example, are flammable and must be kept away from heat sources. Careful application of electrocautery and use of a protective holster to store the electrode while not in use are important to minimize the risk of fire.

Minimally invasive surgery—Several safety concerns are unique to minimally invasive surgery, given the limited and relatively tight environment in which operations occur. One potential danger is that of direct coupling between the electrode and other conductive instruments, leading to inadvertent tissue damage. Another is the risk, with the use of high-voltage currents (especially those used for coagulation), of breakdown in the insulation, resulting in arcing from an exposed conductor to adjacent tissue, again, causing unwanted tissue damage. The risk can be reduced by using cutting current instead of coagulation current to lower the voltage used.

Yet another unique hazard is the potential for creating a capacitor with the cannula. A capacitor is any conductor separated from another conductor by a dielectric. The conductive electrode separated from either a metal cannula or the abdominal wall (both good conductors) can induce capacitance in either of these structures. For maximum safety, an all-metal cannula (by which current can escape to the rest of the body) rather than a combination of metal and plastic should be used, and vigilance must be maintained at all times.

E. Principal Applications for Electrosurgery

Electrosurgery is ubiquitous in its presence within the modern operating room. In its earliest use by Dr. Cushing, it allowed surgery on previously inoperable vascular tumors in neurosurgery. Today, electrosurgery is an essential component of all types of surgery. Applications include dissection in general and vascular surgery, allowing tissue to be resected with minimal blood loss. Additionally, use in urology facilitates transurethral prostatectomy (TURP) and other procedures. In gynecologic practice, electrosurgical instruments are essential in cervical resections and biopsies.

► Argon Beam Coagulation

A. Principles

Argon beam coagulation is closely related to basic electrosurgery. Argon beam coagulation uses a coaxial flow of argon gas to conduct monopolar RF current to the target tissue. Argon is an inert gas that is easily ionized by the application of an electrical current. When ionized, argon gas becomes far more conductive (has less impedance) than normal air and provides a more efficient pathway for transmitting current from the electrode to tissues (Figure 7-5). The current arcs along the pathway of the ionized gas, which is heavier than both oxygen and nitrogen, and thereby displaces air. Whereas current can sometimes follow unpredictable pathways while arcing through the air, the argon gas allows more accurate placement of current flow. Once the current arrives at the tissue, it produces

▲ **Figure 7-5.** Ionized argon gas facilitates the flow of current from the handpiece to the tissue.

its coagulating effect in the same manner as conventional electrosurgery. Argon beam coagulation devices can operate only in two modes: pinpoint coagulation and spray coagulation. The method does not cut even the most delicate tissue.

B. Advantages

There are multiple advantages to this type of electrosurgical current delivery. First, it allows use of the coagulation mode without contact of the electrode. This prevents buildup of eschar, which diminishes electrode efficiency, on the electrode tip. Second, there is generally less smoke and less odor from coagulating with this type of current. Third, tissue loss and tissue damage are reduced when the current is more accurately targeted. Fourth, because the argon gas is delivered at room temperature, there is less danger of the instrument igniting gowns or drapes. Finally, the beam of coagulation generally improves coagulation and reduces blood loss and the risk of rebleeding.

C. Disadvantages

Argon beam coagulation cannot be used to produce a cutting effect in the same manner as other types of electrosurgical equipment. Also, the nozzle for gas delivery can become clogged, reducing its efficiency, and just as with other electrosurgical instruments, if it is used for a prolonged period of time, it may overheat and cause inadvertent damage when set aside.

D. Applications

Argon beam coagulation is especially useful for procedures in which the surgeon must rapidly and efficiently coagulate a wide area of tissue. It is especially suited to dissecting very vascular tissues and organs, such as the liver. Its efficient delivery of a consistent current load and its inability to become occluded with eschar are advantageous for operation with a significant risk of hemorrhage.

MECHANICAL (ULTRASONIC) TISSUE DISRUPTION

Apart from passing current through the patient to produce localized heating and tissue destruction (either cutting or coagulation), there are other means of transforming electrical potential energy into energy for surgery. Two of the most prominent technologies depend on the production of ultrasonic vibrations, although each produces its effect in a unique manner.

► Ultrasonic Scalpels & Clamps

A. Principles

Several types of ultrasonic “scalpels” and clamps allow cutting and coagulation of tissue in a technique completely

different from that employed in electrosurgery. In this type of an instrument, electrical energy from a power source is transformed into ultrasonic vibrations by a transducer, a unit that expands and contracts in response to electrical current at a frequency of up to 55.5 kHz/s. The vibration is amplified in the shaft of the instrument to magnify the vibrating distance of the blade, which moves longitudinally. The blade tip vibrates through an amplitude of around 200 μm . As the blade tip vibrates, it produces cellular friction and denatures proteins. The denatured proteins form a coagulum, which allows sealing of coapted blood vessels. With longer instrument applications, significant secondary heat is produced, and larger blood vessels may be sealed by coagulation of tissue at a small distance from the instrument. By producing cellular disruption in this fashion, the temperatures achieved are between 50°C and 100°C. In contrast, in conventional electrosurgery, tissues are subjected to temperatures between 150°C and 400°C. Thus, with an ultrasonic device, tissues can be dissected without burning or oxidizing tissues and without producing an eschar; there is also less potential to disrupt the coagulum when removing the instrument. When cutting using the clamp portion of the instrument, energy is transferred to the tissue through the active blade under applied force, minimizing lateral spread. Additionally, the motion of the blade induces cavitation along the cell surfaces, whereby low pressure causes cell fluid to vaporize and rupture (Figure 7-6).

B. Advantages

The advantages of an ultrasonic scalpel system are clearest when operating in tight spaces with the attendant risks of damage to adjacent structures. Ultrasonic instruments are especially suited for laparoscopic and other types of minimally invasive procedures. While the potential still exists for damaging adjacent tissue by inadvertently touching it with an active tip, there is no risk of current inadvertently arcing to adjacent structures, since the current is converted into mechanical energy in the handpiece. Further, there is no neuromuscular stimulation produced, since no current passes through the patient. Because the tissue effects are exerted through mechanical disruption of the cells, and coagulation occurs at much lower temperatures than used in conventional electrosurgery, lateral thermal tissue damage is minimized. And because tissue is not heated to the point of

▲ **Figure 7-6.** Ultrasonic scalpel.

combustion or carbonization of proteins, there is no eschar formation on the blade, and less smoke is produced.

C. Disadvantages

A primary disadvantage of ultrasonic scalpels and clamps is that the components are more expensive than those used for conventional electrosurgery, and with more mechanical parts, there are more potential points of equipment failure. Further, whereas electrosurgery can be applied throughout an operation, ultrasonic scalpels are typically used for more controlled dissection around the site of interest.

D. Applications

The primary applications of ultrasonic instruments are found when traditional electrosurgery is unsuitable or undesirable. As mentioned, they are particularly useful during minimally invasive procedures because they mitigate the risk of running an active electrode through a cannula and into a body cavity. Additionally, the reduced smoke production by instruments of this type is advantageous in this setting. When electrophysiology is involved (such as in patients with implantable cardiac defibrillators or pacemakers), ultrasonic instruments eliminate a source of concern by avoiding the hazard of passing current through the patient's body.

► Cavitational Ultrasonic Surgical Aspiration

A. Principles

Cavitational ultrasonic surgical aspirators work on many of the same principles as ultrasonic scalpels. In the hand-piece, current passes through a coil and induces a magnetic field. The magnetic field excites a transducer of a nickel alloy (either a piezoelectric or magnetostrictive device), expanding and contracting to produce an oscillating motion (vibration) in the longitudinal axis with a frequency of 23 or 36 kHz. These ultrasonic mechanical vibrations are magnified over the length of the handpiece. The amount of oscillation varies: with low frequency, there is greater amplitude; with high frequency, there is lower amplitude. The oscillating tip, when brought into contact with tissue, causes fragmentation of tissue by producing cavitation at the cell surface, with low pressure outside the cell leading to cellular disruption. This high-frequency vibration produces heat, which is reduced via a closed, recirculating cooling-water system. This system maintains the temperature of the tip at approximately 40°C. As tissue is fragmented, the debris must be carried away, which is another function of the cavitational ultrasonic surgical aspirator, as its name implies. For irrigation, IV fluid (water or saline) is fed through tubing to the handpiece, where it irrigates the surgical site and suspends the fragmented tissue debris. Removal of this debris is possible because the instrument contains a vacuum pump that provides suction. Suction pulls irrigation fluid, fragmented

▲ **Figure 7-7.** Cavitation ultrasonic surgical aspirator.

tissue, and other material through the distal tip of the handpiece. The material is contained in a separate canister.

Some ultrasonic surgical aspirator instruments enable the surgeon to influence the selectivity of the disruption induced by the instrument itself. Some surgeons attempt to gain extra control by lowering the amplitude of the tip oscillations. Lowering amplitude to gain greater selectivity when fragmenting tissue near critical structures, however, only results in reduced speed of tissue removal. By using a mode in which on/off power intervals are supplied, the reserve power (which governs the tip response when encountering tissue) is reduced. The total amount of power in the oscillating hollow tip is determined by the amount of reserve power available. Reserve power maintains tip oscillation when a resistive load is placed on the tip, as occurs when it contacts tissue. As the resistance increases, more power is supplied to the tip (Figure 7-7).

B. Applications

Ultrasonic surgical aspirator systems are primarily applicable in situations where fragmentation, emulsification, and aspiration of a significant amount of tissue are desirable. Since minimal additional hemostasis is provided, this instrument is not as versatile in its application to general surgery

as electrocautery or the more high-power ultrasonic scalpel. In general surgery, its primary application is in liver resection, where it can disrupt parenchyma while leaving major vasculature and the biliary ducts intact.

MULTIPLE CHOICE QUESTIONS

- All of the following are true about electrocautery, except
 - In monopolar electrocautery, the current flows through the patient from the active electrode to the return electrode
 - In bipolar electrocautery, the current flows from the handpiece to the return electrode
 - The cutting mode of monopolar electrocautery utilizes a continuous sine wave of current
 - The coagulation mode of monopolar electrocautery relies on spikes of electric wave activity
 - The resistance of the tissue influences the effect of the electrocautery
- Fire in the operating room
 - Is preventable by keeping the oxygen levels used for ventilation low
 - Depends upon the presence of an oxygen source, an ignition source, and fuel
 - Cannot be fed by alcohol from skin prep solutions because this is not flammable
 - Cannot be ignited by electrocautery instruments
 - Has been eliminated by the abandonment of flammable anesthetic agents

Inflammation, Infection, & Antimicrobial Therapy in Surgery

Haytham M.A. Kaafarani, MD, MPH

8

INTRODUCTION

TERMINOLOGY

Surgery and infection are unfortunately intimately intertwined. For the purpose of this chapter, we will differentiate between infections resulting from surgery (*surgical site infections*) and those resulting from other disease processes but *requiring surgical management*. Surgical incisions involve a breach of the skin and immune barriers, and can thus be complicated by infection. The term “wound infection” has been replaced by the more accurate term “surgical site infection” (SSI), to emphasize that the infection can occur anywhere within any of the areas accessed surgically (not exclusively at the skin level) and to differentiate it from “traumatic wound infection.”

As opposed to SSI, the term “surgical infection” is used to indicate infections that are unlikely to respond to medical and antimicrobial treatments, and require surgical intervention or management. Common examples include abscesses, empyema, intra-abdominal infections, and necrotizing skin and soft tissue infections. Surgical decision making involves, at its core, the knowledge and experience to determine the timing of surgery and a right balance between surgery and other adjunct therapy such as antibiotic therapy, resuscitative efforts, and nutritional optimization, in order to provide the patient with the best chances to cure the infection with the best overall outcomes.

► Pathogenesis

The development of a surgical infection involves a close interplay between three elements:

1. A susceptible host
2. An infectious agent
3. A suitable medium or environment (Figure 8–1).

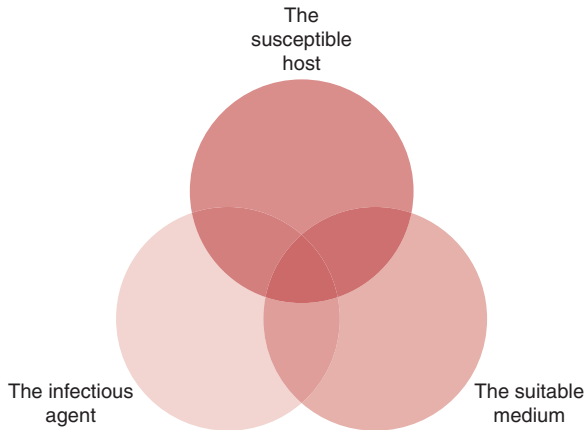

The degree of contribution of each of these three factors to the eventual occurrence of the infection depends on the individual patient and the specific nature and site of the infection. Whether a given inoculum of bacteria results in an established infection or not depends on the virulence of the bacteria, the strength of the immune and inflammatory host response (eg, chemotaxis, phagocytosis, B- and T-lymphocyte activation), and the amount of blood perfusion and oxygen tension in the medium where the inoculum resides.

A. The Susceptible Host

Many surgical infections occur in patients with no evidence of decreased immune defenses. However, with the major advances in medicine and health care services over the last century, more immunocompromised patients (eg, transplant, HIV, and diabetic patients) are presenting with infections requiring surgical management or with SSIs following surgical interventions. Table 8–1 delineates a list of patient-related conditions associated with decreased immunity and potential predisposition to surgical infections. The mechanisms by which the listed conditions affect a host’s immunity are diverse in nature. For example, diabetic patients have suboptimal neutrophil adherence, migration and anti-bacterial functions, making them less able to fight an occult infection. Such effect of diabetes on immunity is much more pronounced in patients whose glucose levels are poorly controlled than in those with appropriate and consistent management of their diabetes.

B. The Infectious Agent

Identification of the organism causing the infection is crucial. This is often achieved through the use of Gram stains and cultures of the tissue or purulent material at the site of infection. *Staphylococcus aureus* is the most common pathogen in SSIs, and its ability to develop resistance to antimicrobial therapy continues to be one of the biggest challenges currently faced

▲ **Figure 8-1.** The interaction between susceptible host, infectious agent, and suitable medium to result in infection.

by the medical community. *Staphylococcus epidermidis* is one of the other 33 known species of the genus *Staphylococcus*, and is usually a skin and mucous membrane nonpathogenic colonizer. Nonetheless, in immunosuppressed individuals and those with indwelling surgical catheters or implants, *S epidermidis* can cause serious infections requiring treatment. In necrotizing skin and soft tissue infections, the etiology

Table 8-1. Patient-related conditions associated with decreased immunity and a higher risk for surgical infections.

Advanced age
Diabetes mellitus
Malnutrition
Smoking
Obesity
Immunosuppressive therapy (eg, posttransplant)
Systemic corticosteroid use
Peripheral vascular disease
Malignancy and anti-neoplastic treatment
Concomitant remote site infection
Human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS)
Liver failure
Renal failure

is often polymicrobial with gram-positive, gram-negative, and anaerobic bacteria involved. Monobacterial necrotizing infections can result from either clostridial species (especially *Clostridium perfringens*) or *Streptococcus pyogenes*. Streptococci are well known for their ability to invade even minor breaks in the skin and to cause superficial skin and skin structure infections by spreading through connective tissue planes and lymphatic channels. When surgical procedures involve the small or large intestines, gram-negative and anaerobic bacteria are implicated in a significant proportion of the SSIs in addition to the regular gram-positive colonizers. Among these, *Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter*, and *Bacteroides* species are the most commonly isolated pathogens. In immunocompromised or critically ill patients, fungi (eg, *Candida*, *Aspergillus*, *Histoplasma*) may result in localized or systemic life-threatening infections. Parasites such as amebas and echinococcus may also cause abscesses in internal organs, especially the liver.

C. The Suitable Medium

A suitable medium for bacteria consists of a closed space with poor vascular perfusion, low oxygen tension, and low pH. Ischemic and necrotic tissues are perfect examples of such a medium where microorganisms can thrive. The appendix, with its narrow orifice presents a classical example. When an appendicolith blocks the orifice of the appendix, the intraluminal pressure increases and eventually blocks lymphatic and venous outflow. As the vascular perfusion of the appendix diminishes, the tissue oxygen tension decreases, the milieu becomes acidotic, and the appendix becomes ischemic and necrotic. Unless removed, the inflamed appendix and its blocked lumen contain colonic bacteria that will result in an appendiceal infection followed by perforation and a periappendiceal abscess and/or peritonitis.

A foreign body such as a joint prosthesis can become seeded in the event of a systemic infection. As with necrotic tissue, the lack of vascularity decreases the formation of free oxygen radicals within prosthesis and prevents the immune system from readily fighting microorganisms in that area.

SURGICAL SITE INFECTION

► Definition

The Centers for Disease Control and Prevention (CDC) define SSI as an infection that occurs at or near the surgical incision within 30 postoperative days of the surgical procedure, or within 1 year if an implant is left in place (eg, mesh, heart valve [www.cdc.gov]). The CDC further classifies SSI as

1. Superficial incisional
2. Deep incisional
3. Organ/space SSI

Table 8–2. Criteria and definitions of surgical site infection.

<p>Superficial incisional SSI</p> <p>Infection occurs <i>within 30 d</i> after the operative procedure and Involves only skin and subcutaneous tissue of the incision and Patient has at least one of the following:</p> <ul style="list-style-type: none"> • Purulent drainage from the superficial incision. • Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision. • At least one of the following signs or symptoms of infection: pain or tenderness, localized swelling, redness, or heat, and superficial incision are deliberately opened by surgeon, and are culture-positive or not cultured. A culture-negative finding does not meet this criterion. • Diagnosis of superficial incisional SSI by the surgeon or attending physician.
<p>Deep incisional SSI</p> <p>Infection occurs <i>within 30 d</i> after the operative procedure if no implant is left in place or <i>within 1 y</i> if <i>implant</i> is in place and the infection appears to be related to the operative procedure and Involves deep soft tissues (eg, fascial and muscle layers) of the incision and Patient has at least one of the following:</p> <ul style="list-style-type: none"> • Purulent drainage from the deep incision but not from the organ/space component of the surgical site. • A deep incision spontaneously dehisces or is deliberately opened by a surgeon and is culture-positive or not cultured and the patient has at least one of the following signs or symptoms: fever (> 38°C), or localized pain or tenderness. A culture-negative finding does not meet this criterion. • An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination. • Diagnosis of a deep incisional SSI by a surgeon or attending physician.
<p>Organ/space SSI</p> <p>Infection occurs <i>within 30 d</i> after the operative procedure if no implant is left in place or <i>within 1 y</i> if <i>implant</i> is in place and the infection appears to be related to the operative procedure and Infection involves any part of the body, excluding the skin incision, fascia, or muscle layers, that is <i>opened or manipulated</i> during the operative procedure and Patient has at least one of the following:</p> <ul style="list-style-type: none"> • Purulent drainage from a drain that is placed through a stab wound into the organ/space. • Organisms isolated from an aseptically obtained culture of fluid or tissue in the organ/space. • An abscess or other evidence of infection involving the organ/space that is found on direct examination, during reoperation, or by histopathologic or radiologic examination. • Diagnosis of an organ/space SSI by a surgeon or attending physician.

CDC definition of an implant:

A nonhuman-derived object, material, or tissue that is placed in a patient during an operative procedure. Examples include porcine or synthetic heart valves, mechanical heart, metal rods, mesh, sternal wires, screws, cements, internal staples, hemoclips, and other devices. Nonabsorbable sutures are excluded because infection preventionists may not easily identify and/or differentiate the soluble nature of suture material used.

Table 8–2 illustrates the criteria that define each of these three classes of SSIs. It is noteworthy that a skin infection at or around the site of a traumatic wound is classified as a skin and skin structure infection.

► Epidemiology

At least 234 million surgical procedures are performed globally each year, including more than 16 million in the United States alone; SSIs develop in 2%-5% of these patients.

In this surgical patient population, SSI accounts for up to 38% of nosocomial infections, and as such is considered the most common nosocomial infection in surgical patients. If asymptomatic bacteriuria is excluded, SSI is arguably the most common nosocomial infection overall. The rate of SSI depends on the nature of the surgical procedure performed and the extent of concomitant intraoperative contamination. In an attempt to quantify the inoculum of bacteria typical of certain surgical procedures, a wound classification was developed in 1964 by the National Academy of Sciences (Table 8–3). This classification divides wounds into clean (eg, inguinal hernia repair), clean-contaminated (eg, right hemicolectomy), contaminated (eg, laparotomy for penetrating injury to small intestines), and dirty (eg, laparotomy for peritonitis and intra-abdominal abscesses) wounds. Several studies have emerged since the conception of the classification confirming that, with reasonable risk adjustment, the classes of contamination correlate well with the incidence of postoperative SSI. A more recent 2012 American College of Surgeons–National Surgical Quality Improvement (ACS-NSQIP) study of more than 600,000 patients, suggested that the rates of SSI increases as the degree of contamination increases: 2.58% for clean wounds, 6.67% for clean-contaminated wounds, 8.61% for contaminated wounds, and 11.80% for dirty wounds.

Table 8–3. Wound classification.

Clean	These are uninfected operative wounds in which no inflammation is encountered and the respiratory, alimentary, genital, or uninfected urinary tracts are not entered.
Clean/ contaminated	These are operative wounds in which the respiratory, alimentary, genital, or urinary tract is entered under controlled conditions and without unusual contamination.
Contaminated	These include open, fresh, accidental wounds, operations with major breaks in sterile technique or gross spillage from the gastrointestinal tract, and incisions in which acute, nonpurulent inflammation is encountered.
Dirty	These include old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera.

User Guide for the 2008 Participant Use Data File American College of Surgeons National Surgical Quality Improvement Program.

► **Attributable Cost & Impact**

In addition to the morbidity incurred by patients, the health care and economic burden of SSIs is significant. Multiple studies have consistently documented that SSIs lead to a considerable increase in length of hospital stay (LOS), hospital charges, and societal health services cost. In a 2012 study, SSI occurring after colorectal surgery increased the LOS by 2.8–23.9 days, depending on the nature of the procedure (colon vs rectum resection), the operative approach (open vs laparoscopic), and the depth of the SSI. In another study of cardiac surgery, it was estimated that the total excess cost attributable to SSI is more than \$12,000 per patient. This excess cost resulted from the additional procedures (eg, incision and drainage, wound washout, skin grafts), antibiotics and increased hospital LOS. Another study in general and vascular surgery patients estimated the excess cost and LOS at \$10,497 and 4.3 days, respectively. In addition, even when SSI patients are successfully discharged, their rate of hospital readmission is at least doubled. Another study using patient-centered surveys and large administrative databases suggested almost a three-fold increase in the total cost for patients diagnosed with SSI following discharge from the hospital compared to those who do not develop SSI. The increased costs were accounted for by a significant increase in the use of visiting nurses for wound care, diagnostic imaging, as well as an increase in readmissions to emergency departments and to the hospital.

► **Pathophysiology**

The etiology of SSI is multifactorial; patient’s comorbidities, the nature of the surgical procedure and technique, and the perioperative environment including infrastructure and processes of care all interact in SSI. It is thought that most SSIs are directly caused by the patient’s endogenous flora at the time of surgery. This is further supported by the fact that, in clean wounds, SSIs are most commonly caused by *S aureus* or coagulase negative *Staphylococcus*, both abundantly present on patient’s skin. On the other hand, SSIs following bowel surgery are usually caused by endogenous intestinal flora. When a surgical device or implant is left in place, bacteria can secrete special glycocalyx-based biofilms that shield the offending bacteria from the body’s immune defenses. One of the immediate sequelae of such a phenomenon is the fact that the inoculums needed to cause a SSI in the presence of a foreign body such as a surgical implant or device is typically smaller than the inoculum needed to cause the same infection in the absence of a foreign body.

Despite the belief that most SSIs originate from endogenous microbes, there is convincing literature suggesting that nonendogenous sources are implicated in the occurrence of SSIs as well. Breach of the strict sterile surgical field, undetected surgical gloves’ perforations, increased personnel traffic through the operating room, suboptimal air flow and

ventilation in the operating room, and poor surgical technique with excessive tissue injury or tension are some of the many factors implicated in SSI that will be discussed further in the next few sections.

► Risk Factors

Many risk factors have been implicated as predictors of SSI. Some are directly related to the patient's health status, immune system, and comorbidities, while others are inherent to the nature of the procedure being performed and therefore are not easily modifiable. A few risk factors reflect suboptimal health care systems' design and less than reliable processes of care delivery, and their importance relies in the possibility of subjecting them to improvement and optimization strategies.

A. Patient-Related Risk Factors

Several studies have shown that advanced age, diabetes mellitus, obesity, smoking, malnutrition, and immunosuppression (eg, chronic steroid use, HIV/AIDS, postransplant) are all risk factors for the development of SSI (Table 8–1). Most of these factors are not amenable to immediate preoperative modification or prevention, although long-term control of glucose levels (reflected in better HBA1C levels), smoking cessation, and attempts to improve nutrition may help in the overall performance of the patient perioperatively and may also decrease complications, including SSI.

B. Procedure-Related Risk Factors

The nature of the procedure, especially the wound classification (Table 8–3) and the expected inoculum of bacteria into the surgical site are key factors that influence the risk of developing a SSI. For example, the rate of SSIs complicating eye surgery, where the inoculum of bacterial contamination is minimal, is almost non-existent. In comparison, the rate of SSI complicating colorectal surgery remains closer to 20% despite strategies and efforts aimed at prevention. In the early 1990s, the National Healthcare Safety Network (NHSN) risk index, previously called the National Nosocomial Infections Surveillance System (NNIS), was developed in an attempt to better define a priori, a patient's risk of developing SSI. This index considered the following three factors:

1. An American Society of Anesthesiologists (ASA) score ≥ 3
2. A surgical wound classification as either contaminated or dirty
3. A prolonged duration of procedure over a certain number of hours T, where T depends on the nature of the procedure being performed

The analysis of the CDC data by Culver and colleagues revealed that the rates of SSIs are 1.5%, 2.9%, 6.8%, and 13%

in the presence of none, 1, 2, or 3 of the above risk index factors, respectively. More recently, The NHSN has introduced improved SSI risk adjustment models for specific operations based on easily tractable patient risk factors.

C. Process- and System-Related Risk Factors

Several process- and system-related risk factors have been identified over the years as potential factors contributing for a higher rate of SSI.

Suboptimal choice and timing of perioperative antibiotics—In a systematic review of more than 30,000 Medicare patients, Bratzler and colleagues found that less than 56% of patients undergoing surgery received their perioperative antibiotics within the recommended 60-minute window before incision. In the same study, up to 10% of patients did not receive the appropriate antibiotic regimen that would cover the type of pathogens specific to the procedures the patients were undergoing. The two main components of prophylactic perioperative antibiotics, namely, choice and timing, will be discussed in further detail in the SSI prevention section below.

Unrecognized breach of asepsis—Operating room staff, including nursing, anesthesia and surgical personnel, are strongly encouraged to immediately report to the surgeon when suspecting a potential breach of the sterile field (eg, inadequate skin preparation, soiled clothes or equipment, glove perforation). In a study of gynecological laparotomies, glove perforations were found to occur in 27 out of 29 laparotomies. The relationship between the rates of SSIs and glove perforation is less than evident when the data is analyzed. In a study of more than 4000 procedures, the rates of SSIs increased with glove perforation only in the absence of appropriate antibiotic prophylaxis.

Preoperative hair removal—Preoperative hair removal has been correlated in several studies with a higher rate of SSI, even when the procedure involves the scalp or the patient has abundant hair at the surgical site. A 2006 Cochrane database systematic review and meta-analysis concluded that preoperative shaving increases the rate of SSI by at least twofold; it is noteworthy that there was no difference in the rates of SSI when hair clipping was compared to no hair removal. Therefore, if hair removal is deemed necessary, preoperative hair clipping is preferred to shaving.

Surgical technique—The use of “rough” surgical techniques with unnecessary or excessive tissue disruption and trauma, whether resulting from electrocautery, traction or blunt dissection, is believed to lead to higher rates of SSI. Even though most surgeons and common sense suggest the above correlation, strong evidence supporting a cause-effect relationship has not been demonstrated.

Operating room traffic—It is well established that the burden of airborne bacteria in a closed space is directly related to the number of people in the space, as well as to the number of people entering and exiting a closed space such as the OR. The link between increased traffic through the OR doors and SSIs has been studied mostly in the orthopedic literature, but has not been clearly established. Nonetheless, the CDC has issued guidelines that include a decrease in OR traffic.

Perioperative hypothermia—Even though hypothermia may protect tissue from ischemia and necrosis by decreasing cellular oxygen consumption, perioperative hypothermia may cause vasoconstriction at the skin level, and therefore decrease oxygen delivery. Two randomized trials attempted to study the effect of hypothermia on the incidence of SSI. The first one found an increased SSI risk with hypothermia in colorectal surgery, while the second failed to find any correlation in cardiac surgery. At present, maintenance of perioperative normothermia is recommended.

► Prevention Strategies

Prevention of SSI relies primarily on optimizing the patient's comorbidities and creating a systematic method to ensure that all modifiable risk factors are addressed. All processes of care proven or arguably thought to prevent SSIs should be executed in all patients at all times. Table 8-4 lists potential measures to minimize the risk of SSI. Although level-one evidence is lacking for many of those measures, inclusion of some or all in a bundle might prove to be a beneficial strategy. The surgical improvement project (SIP) established in 2004 and folded within the surgical care improvement program in 2006 (SCIP) created performance measures out of several of these preventative measures based on best evidence in literature (Table 8-5). A detailed discussion of SCIP is beyond the scope of this text and the reader is referred to the CDC and CMS websites for more details. Perioperative antibiotics and the choice of the skin preparation solution are discussed below.

A. Perioperative Antibiotics

The timing of prophylactic antibiotic administration (SCIP 1) and the choice of the appropriate perioperative antibiotic (SCIP 2) are key components in the strategy to prevent SSI. Prophylaxis implies discontinuation of the antibiotic within 24 hours in noncardiac surgery and within 48 hours in cardiac surgery (SCIP 3); this will also prevent side effects of the antibiotic and the emergence of drug resistance. Proper antibiotic dosing based on the patient's weight and manufacturer's recommendation for the antibiotic is an important consideration in prophylaxis. In addition, redosing of the antibiotic during surgery based on the antibiotic

Table 8-4. Potential^a measures to prevent surgical site infections.

Optimizing the patient's nutritional status
Appropriate perioperative antibiotic prophylaxis (choice, dosing, and timing)
Adequate glucose level control in diabetic patients
Maintenance of perioperative normoglycemia in all patients
Maintenance of strict asepsis
Preoperative skin preparation with alcohol-based solutions
Gentle skin handling and minimization of cautery-related tissue damage
Improving ventilation and laminar air flow in the OR
Maintenance of perioperative normothermia
Avoiding hair removal; clipping instead of shaving, if necessary
Perioperative oxygen supplementation
Preoperative antibacterial soap showers
Antibacterial coated sutures
Antibacterial irrigation solutions
Operative wound barriers
Antibacterial dressings

^aMany of these measures have shown controversial and nondefinitive results in the prevention of SSI.

Table 8-5. Surgical Care Improvement Project (SCIP) measures aimed at prevention of surgical site infections.

SCIP Infection Measure 1	Prophylactic antibiotic received within 1 h prior to surgical incision
SCIP Infection Measure 2	Appropriate prophylactic antibiotic selection for the surgical patient
SCIP Infection Measure 3	Prophylactic antibiotic discontinued within 24 h after surgery end time (within 48 h after cardiac surgery end time)
SCIP Infection Measure 4	Blood glucose level at 6 AM < 200 mg/dL on postoperative days 1 and 2 in cardiac surgery
SCIP Infection Measure 6	No or appropriate hair removal (clippers not shaving)
SCIP Infection Measure 7	Immediate postoperative normothermia (temperature > 96.8°F within 15 min postoperatively) in colorectal surgery

Table 8–6. Suggested initial dose and time to redosing for antimicrobial drugs commonly utilized for surgical prophylaxis.

Antimicrobial	Renal Half-Life (h)		Recommended Infusion Duration	Standard Dose	Weight-Based Dose Recommendation ^a	Recommended Redosing Interval, ^b (h)
	Patients With Normal Renal Function	Patients With End-Stage Renal Disease				
Aztreonam	1.5-2	6	3-5 min, ^c 20-60 min ^d	1-2 g iv	2 g maximum (adults)	3-5
Ciprofloxacin	3.5-5	5-9	60 min	400 mg iv	400 mg	4-10
Cefazolin	1.2-2.5	40-70	3-5 min, ^c 15-60 min ^d	1-2 g iv	20-30 mg/kg (if < 80 kg, use 1 g; if > 80 kg, use 2 g)	2-5
Cefuroxime	1-2	15-22	3-5 min, ^c 15-60 min ^d	1.5 g iv	50 mg/kg	3-4
Cefamandole	0.5-2.1	12.3-18	3-5 min, ^c 15-60 min ^d	1 g iv		3-4
Cefoxitin	0.5-1.1	6.5-23	3-5 min, ^c 15-60 min ^d	1-2 g iv	20-40 mg/kg	2-3
Cefotetan	2.8-4.6	13-25	3-5 min, ^c 20-60 min ^d	1-2 g iv	20-40 mg/kg	3-6
Clindamycin	2-5.1	3.5-5 ^f	10-60 min (do not exceed 30 mg/min)	600-900 mg iv	If < 10 kg, use at least 37.5 mg; if > 10 kg, use 3-6 mg/kg	3-6
Erythromycin base	0.8-3	5-6	NA	1 g po 19, 18, and 9 h before surgery	9-13 mg/kg	NA
Gentamicin	2-3	50-70	30-60 min	1.5 mg/kg iv ^g	... ^g	3-6
Neomycin	2-3 (3% absorbed orally)	12-24 or longer	NA	1g po 19, 18, and 9 h before surgery	20 mg/kg	NA
Metronidazole	6-14	7-21; no change	30-60 min	0.5-1 g iv	15 mg/kg initial dose (adult); 7.5 mg/kg on subsequent doses	6-8
Vancomycin	4-6	44.1-406.4 (CCI < 10 mL/min)	1 g over 60 min (use longer infusion time if dose > 1 g)	1 g iv	10-15 mg/kg (adult)	6-12

CCI, creatinine clearance.

^aData are primarily from published pediatric recommendations.

^bFor procedures of long duration, antimicrobials should be readministered at intervals of one to two times the half-life of the drug. The intervals in this table were calculated for patients with normal renal function.

^cDose injected directly into vein or via running intravenous fluids.

^dIntermittent intravenous infusion.

^eIn patients with a serum creatinine level of 5-9 mg/dL.

^fThe half-life of clindamycin is the same or slightly increased in patients with end-stage renal disease, compared with patients with normal renal function.

^gIf the patient's body weight is > 30% higher than their ideal body weight (IBW), the dosing weight (DW) can be determined as follows: DW = IBW + (0.4 × [total body weight – IBW]).

Reproduced, with permission, from Bratzler DW, Houck PM: Antimicrobial prophylaxis for surgery: an advisory statement from the National Surgical Infection Prevention Project, *Clin Infect Dis*. 2004 Jun 15;38(12):1706–1715.

half-life, amount of fluid administration and blood loss is more important than the continuation of the antibiotic after the wound is closed. Table 8–6 is a practical guide to dosing and time for redosing for commonly used prophylactic antibiotics.

B. Antiseptic Skin Preparation

Based on a prospective randomized trial and an observational study, the National Quality Forum has recommended the use of alcohol-containing solutions for the preparation of patient's skin prior to surgery.

C. Additional Preventative Measures

Maintenance of perioperative normoglycemia (SCIP 4), normothermia (SCIP 7), and hair clipping or avoiding hair removal (SCIP 6) are definitely advocated and monitored as performance measures for certain operations. The use of preoperative antibacterial soap showers, perioperative oxygen administration, the use of antibacterial coated sutures, wound barriers, antimicrobial irrigants, and antibacterial dressings are additional measures that remain controversial in the prevention of SSI (Table 8–4). Mechanical bowel preparation and oral antibiotics in patients undergoing colorectal surgery are the subjects of renewed controversy and discussion but remain an important strategy in the prevention of SSI in this field.

► Treatment

The treatment of an established SSI consists of opening the incision, draining the purulent material, and debridement of any necrotic tissue. Adjunctive antimicrobial treatment is given when the patient has systemic symptoms, associated cellulitis or a deep SSI with risk for fascial and subcutaneous spread. Cultures are important to track emergence of resistant organisms, to de-escalate from broad-spectrum empiric antibiotics, and for epidemiological surveillance. In the case of an organ/space SSI, percutaneous drainage using radiological guidance, along with adequate antibiotic coverage, is the preferred approach.

INFECTIONS NEEDING SURGICAL MANAGEMENT

When infections fail to respond or are deemed unlikely to respond to medical and antimicrobial treatments alone, surgical intervention might be needed. The list of surgical infections necessitating surgical management is long, but the most common ones include abscesses, empyema, necrotizing skin and soft tissue infections (NSSTIs), intra-abdominal infections, and *Clostridium difficile* (*C difficile*) colitis. Many of these surgical infections can become life threatening by causing sepsis, septic shock, and multiple organ dysfunction syndrome (MODS) if not controlled and treated promptly. Spreading can occur through tissue planes (necrotizing infections), abscess/fistulae formation, or through the lymphatic system and the bloodstream. Spread of an infection through the bloodstream (bacteremia) can lead to distant seeding of bacteria and subsequent abscess formation (eg, brain, liver, adrenal glands, heart valves).

INFLAMMATION, SEPSIS, THE SYSTEMIC INFLAMMATORY RESPONSE SYNDROME, BACTEREMIA, & MULTIPLE ORGAN DYSFUNCTION SYNDROME

Microbial infection results in tissue damage that leads to an inflammatory response at the local tissue level in an effort by

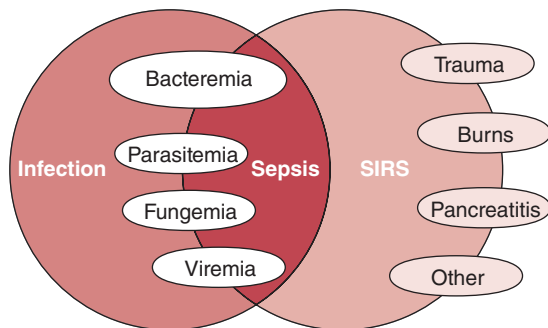

the patient's immune system to overcome the infection. At the site of injury, endothelial cells and leukocytes coordinate the local release of mediators of the inflammatory response, including cytokines (tumor necrosis factor- α), interleukins, interferons, leukotrienes, prostaglandins, nitric oxide, reactive oxygen species, and products of the classic inflammatory pathway (complement, histamine, and bradykinin) (Table 8–7). Once these mediators reach the infected site, they are extremely effective at recruiting and priming cells of both the innate and adaptive immune systems to identify and attack invading pathogens. In addition, these inflammatory mediators initiate the damaged tissue healing processes. However, if the degree of the infectious or traumatic insult overwhelms the ability of the body to control it, the inflammatory mediators might trigger a systemic inflammatory reaction of serious damaging consequences. Such a quasi-maladaptive systemic response can disrupt normal cellular metabolism and jeopardize tissue perfusion at the cellular level. From a terminology perspective, when the systemic response occurs in the absence of a documented infection (eg, burns, trauma, pancreatitis), it is called *systemic inflammatory response syndrome* (SIRS). The term sepsis is used when the systemic response results from a documented infection rather than systemic inflammation alone. Severe sepsis is reported when sepsis is associated with at least one sign of tissue or organ hypoperfusion. Septic shock occurs when severe sepsis is associated with hypotension or hemodynamic instability. When septic shock leads to progressive dysfunction of multiple organs such as the brain (delirium), lungs (hypoxia and respiratory failure), heart (hypotension, pulmonary edema), and kidneys (oliguria and renal failure), it is referred to as *multiple organ dysfunction syndrome* (MODS). Bacteremia is the presence of viable bacteria in blood, often documented through blood cultures. Transient bacteremia (eg, following dental work) is common, benign, and self-limited. It usually has no clinical implications except in patients with damaged heart valves; cardiac, vascular, or orthopedic implants; or impaired immunity. Bacteremia happening in a patient with an uncontrolled source of infection can be devastating and may result in severe sepsis, septic shock, and MODS. The interrelationships among infection, bacteremia, sepsis, and SIRS are depicted in Figure 8–2, and the detailed clinical definitions of sepsis, severe sepsis, septic shock, SIRS, and MODS are presented in Table 8–8.

► Diagnosis

Localizing the source of the suspected infection or sepsis is crucial, and a good and thorough physical examination is indispensable. Laboratory evaluation often shows leukocytosis, but leukopenia is not infrequent in cases of severe infection or sepsis. Acidosis is occasionally present and might be helpful in making the diagnosis. Radiologic examinations, including plain films for suspected pneumonia, computed

Table 8-7. Cytokines and growth factors.

Peptide	Site of Synthesis	Regulation	Target Cells	Effects
G-CSF	Fibroblasts, monocytes	Induced by IL-1, LPS, IFN- α	Committed neutrophil progenitors (CFU-G, Gran)	Supports the proliferation of neutrophil-forming colonies. Stimulates respiratory burst.
GM-CSF (IL-3 has almost identical effects)	Endothelial cells, fibroblasts, macrophages, T lymphocytes, bone marrow	Induced by IL-1, TNF	Granulocyte-erythrocyte-monocyte-megakaryocyte progenitor cells (CFU-GEMM, CFU-MEG, CFU-Eo, CFU-GM)	Supports the proliferation of macrophage-, eosinophil-, neutrophil-, and monocyte-containing colonies.
IFN- α , IFN- β , IFN- γ	Epithelial cells, fibroblasts, lymphocytes, macrophages, neutrophils	Induced by viruses (foreign nucleic acids), microbes, microbial foreign antigens, cancer cells	Lymphocytes, macrophages, infected cells, cancer cells	Inhibits viral multiplication. Activates defective phagocytes, direct inhibition of cancer cell multiplication, activation of killer leukocytes, inhibition of collagen synthesis.
IL-1	Endothelial cells, keratinocytes, lymphocytes, macrophages	Induced by TNF- α , IL-1, IL-2, C5a; suppressed by IL-4, TGF- β	Monocytes, macrophages, T cells, B cells, NK cells, LAK cells	Stimulates T cells, B cells, NK cells, LAK cells. Induces tumoricidal activity and production to other cytokines, endogenous pyrogen (via PGE ₂ release). Induces steroidogenesis, acute phase proteins, hypotension; chemotactic neutrophils. Stimulates respiratory burst.
IL-1ra	Monocytes	Induced by GM-CSF, LPS, IgG	Blocks type 1 IL-1 receptors on T cells, fibroblasts, chondrocytes, endothelial cells	Blocks type 1 IL-1 receptors on T cells, chondrocytes, endothelial cells. Ameliorates animal models of arthritis, septic shock, and inflammatory bowel disease.
IL-2	Lymphocytes	Induced by IL-1, IL-6	T cells, NK cells, B cells, activated monocytes	Stimulates growth of T cells, NK cells, and B cells
IL-4	T cells, NK cells, mast cells	Induced by cell activation, IL-1	All hematopoietic cells and many others express receptors	Stimulates B-cell and T-cell growth. Induces HLA class II molecules.
IL-6	Endothelial cells, fibroblasts, lymphocytes, some tumors	Induced by IL-1, TNF- α	T cells, B cells, plasma cells, keratinocytes, hepatocytes, stem cells	B-cell differentiation. Induction of acute phase proteins, growth of keratinocytes. Stimulates growth of T cells and hematopoietic stem cells.
IL-8	Endothelial cells, fibroblasts, lymphocytes, monocytes	Induced by TNF, IL-1, LPS, cell adherence (monocytes)	Basophils, neutrophils, T cells	Induces expression of endothelial cell LECAM-1 receptors, β_2 integrins, and neutrophil transmigration. Stimulates respiratory burst.
M-CSF	Endothelial cells, fibroblasts, monocytes	Induced by IL-1, LPS, IFN- α	Committed monocyte progenitors (CFU-M, mono)	Supports the proliferation of monocyte-forming colonies. Activates macrophages.
MCP-1, MCAF	Monocytes; some tumors secrete a similar peptide	Induced by IL-1, LPS, PHA	Unstimulated monocytes	Chemoattractant specific for monocytes
TNF- α (LT has almost identical effects)	Macrophages, NK cells, T cells, transformed cell lines, B cells (LT)	Suppressed by PGE ₂ , TGF- β , IL-4; induced by LPS	Endothelial cells, monocytes, neutrophils	Stimulates T-cell growth. Direct cytotoxin to some tumor cells. Profound proinflammatory effect via induction of IL-1 and PGE ₂ . Systemic administration produces many symptoms of sepsis. Stimulates respiratory burst and phagocytosis.

▲ **Figure 8-2.** The interplay between infection, sepsis, and systemic inflammatory response syndrome (SIRS).

Table 8-8. Definitions of sepsis, severe sepsis, septic shock, and systemic inflammatory response syndrome (SIRS).

SIRS
Two or more of the following: Temperature > 38.3°C or < 36°C Heart rate > 90 beats/min Respiratory rate > 20 breaths/min or $Paco_2$ < 32 mmHg WBC > 12,000 cells/mm ³ , < 4000 cells/mm ³ , or > 10% immature (band) forms
Sepsis
SIRS and a culture-proven or clinically evident infection
Severe sepsis
Sepsis and at least one of the following: Areas of mottled skin Capillary refilling requires three seconds or longer Urine output < 0.5 mL/kg for at least 1 h, or renal replacement therapy Lactate > 2 mmol/L Abrupt change in mental status Abnormal electroencephalographic (EEG) findings Platelet count < 100,000 platelets/mL Disseminated intravascular coagulation Acute respiratory distress syndrome (ARDS) Cardiac dysfunction (ie, left ventricular systolic dysfunction)
Septic shock
Severe sepsis and at least one of the following: MAP < 60 mm Hg despite adequate fluid resuscitation Hemodynamic pressor agents requirement to maintain MAP > 60 mm Hg despite adequate fluid resuscitation

MAP, mean arterial pressure.

Adequate fluid resuscitation is defined by one of the three following parameters:

- Infusion of at least 40-60 mL/kg of saline solution
- Pulmonary capillary wedge pressure of 12-20 mm Hg
- A central venous pressure of 8-12 mm Hg

tomography or ultrasound for suspected intra-abdominal or intrathoracic abscesses, and bone scans or magnetic resonance imaging (MRI) for suspected osteomyelitis, are often essential for making the diagnosis and establishing the source of infection.

Identifying the causative organism by culturing the infected site, followed by testing the implicated pathogen's sensitivity to diverse antimicrobial agents are the two next key steps. If infection is suspected but the source remains unclear, cultures of blood, sputum, and urine should be performed. Culturing other body fluids (eg, cerebrospinal fluid, pleural and joint effusions, ascites) can be performed if warranted based on the patient's history, physical examination, and the degree of clinical suspicion.

► Treatment

Infectious source control and antibiotics constitute the mainstay of surgical infection treatment. When patients are septic with or without shock, "goal-directed" management of the sepsis with prompt patient resuscitation and immediate initiation of the appropriate empiric antibiotics are of ultimate importance, and have been shown by high-level evidence to improve patient survival. The *Surviving Sepsis Guidelines* emphasize the systematic and evidence-based approach to treating sepsis and septic shock patients. These guidelines are available at www.survivingsepsis.org.

▼ SURGICAL SKIN & SKIN STRUCTURE INFECTIONS

Surgical cutaneous infections span the spectrum of the superficial skin abscesses such as furuncles and carbuncles to the devastating and often fatal necrotizing deeper soft tissue infections.

FURUNCLE

► Pathophysiology

A furuncle (boil) is a superficial skin abscess usually caused by *S aureus* infection at the level of the hair follicle. Bacteria asymptotically inhabit most hair follicles, but it is thought that obstruction of the pilosebaceous apparatus is the triggering event for the formation of furuncles.

► Risk Factors

Some of the identified risk factors include puberty, male gender, obesity, diabetes, poor hygiene, as well as living in weathers characterized by a high level of humidity.

► Causative Organisms

Even though staphylococci are the most common causative organisms, streptococci, gram-negative organisms, and anaerobic diphtheroids can also cause furuncles.

► Clinical Presentation

Furuncles present as itchy indurated small abscesses, surrounded by skin erythema. A small white area of skin necrosis is often notable at the top of the abscess.

► Treatment

Most furuncles resolve spontaneously, although larger lesions require incision and drainage. The use of antibiotics following incision and drainage is not routinely needed and is controversial. We recommend antibiotics only in the presence of concomitant extensive surrounding cellulitis. When antibiotics are prescribed, they should be stopped with resolution of the local and systemic symptoms. Antibacterial soap showers might be helpful in both treatment and prevention of recurrence.

CARBUNCLE

► Pathophysiology

Carbuncles are rare and result when several furuncles coalesce, extend to the subcutaneous tissue, and/or form a “network” of multilocular interconnected abscesses and tracts.

► Risk Factors

Carbuncles on the back of the neck are seen almost exclusively in diabetic or relatively immunocompromised patients. In addition to obesity and diabetes, chronic steroid intake and malnutrition are potential risk factors for carbuncles.

► Causative Organism

Similar to furuncles, *S aureus* remains the most common organism involved in carbuncles.

► Clinical Presentation

Carbuncles often have the appearance of multiple large furuncles with several openings draining pus. As carbuncles enlarge, the blood supply to the skin is destroyed and the tissue over the top of the abscess becomes white in color and necrotic in appearance. Patients might show some systemic signs such as fever and malaise.

► Treatment

Carbuncles often require incision and drainage; occasionally, a more extensive excision is required. When appropriate, the excision is continued until the many associated deep sinus tracts are removed. Antibiotics are usually needed in view of the associated extensive skin cellulitis and induration.

HIDRADINITIS SUPPURATIVA

► Pathophysiology

Hidradenitis suppurativa is a serious skin condition characterized by blockage and infection of the apocrine sweat glands. Hidradenitis most commonly involves the axilla or the groin. Since apocrine glands develop postpuberty, prepubertal disease is very rare. Even though hidradenitis often becomes chronic with serious patient morbidity and disability, systemic complications, and constitutional signs and symptoms are uncommon.

► Risk Factors

Obesity, puberty, female gender, and smoking are some of the identified risk factors associated with hidradenitis.

► Causative Agents

Hidradenitis is a polymicrobial infection involving gram-positive, gram-negative, and anaerobic organisms. Superinfection with fungal organisms is not uncommon, especially in the patient with chronic or recurrent hidradenitis.

► Clinical Presentation

Hidradenitis can affect any area where apocrine glands exist, most commonly the axilla and groin, but also the perineum, inframammary folds, gluteal folds, areola, and scrotum. On examination, erythematous tender skin nodules characterize early stages. This can quickly progress to deeper indurated abscesses with interconnected sinuses, purulent drainage, and associated regional lymphadenopathy.

► Treatment

Drainage of the individual abscesses and their associated sinuses is needed. If healing is delayed, fungal superinfections should be suspected and, if confirmed, should be treated as well. With chronic and recurrent infections, the involved skin and apocrine glands can be excised, and the underlying soft tissue left to heal by secondary intention. Skin flaps and grafts might be needed in later stages, as the resultant scarring can be severe. Topical clindamycin, systemic tetracycline, and isotretinoin are potential adjunctive therapies. Weight loss and hygiene-focused interventions should be encouraged to decrease the risk of recurrence.

NECROTIZING SKIN & SKIN STRUCTURE INFECTIONS

► Introduction

Accurate data on the incidence of necrotizing skin and skin structure infections (NSSSIs) is lacking, and most existing data are based on single institutions' experiences, suggesting

a large variability in clinical presentation, severity as well as outcome. NSSSIs are skin and soft tissue infections characterized by widespread and severe tissue necrosis resulting from aggressive and life-threatening bacteria that are often able to secrete toxins. NSSSIs are also known as gas gangrene, necrotizing fasciitis (when involving fascial layers), Fournier gangrene (when involving the perineum and genitalia), and Ludwig angina (when involving the floor of the mouth).

► Pathophysiology

NSSSIs can be caused by single agents such as clostridia or streptococci species, but most are polymicrobial in etiology. An inciting site (eg, puncture wound, insect bite) can occasionally be discovered by history or physical examination. In the perineum, manipulation of the urogenital tract and diabetes are known to be associated with NSSTI. The infection is classically one of sudden onset and rapid progression through ischemic tissue planes, occasionally with air formation at deeper layers. Small vessel thrombosis occurs along the infection progression pathway, and thus, the underlying deeper tissue damage is almost always much more pronounced than what the overlying skin appearance suggests.

► Causative Agents

By definition, type I NSSSIs are polymicrobial (eg, streptococci, clostridia), while type II NSSSIs are monomicrobial. *C perfringens* secretes exotoxins (eg, lecithinases, collagenases, proteases, hemolysins) that lead to small vessel thrombosis and allow for rapid progression and aggressive invasion of fascial and muscle planes. These toxins contribute to the serious deep tissue destruction and the overlying skin grayish discoloration. The alpha toxin (a lecithinase) is believed to be an essential contributor to clostridial virulence. In addition to their local effect, these toxins may lead to severe sepsis, pronounced SIRS, and not uncommonly MODS. Streptococci can also secrete several exotoxins with similar virulence leading to fascial and deeper plane disruptions. *S pyogenes* (group A strep), although rare, is classically described to secrete a superantigen toxin that can result in toxic shock syndrome with resultant organ failure. NSSSIs are often caused by mixed nonclostridial, nonstreptococcal bacteria, including staphylococci, gram negatives, and anaerobes.

► Risk Factors

Immunocompromised (eg, HIV, diabetes), intravenous drug abuse, and cancer patients are at a particularly higher risk of developing NSSSIs, as well as malnourished and obese patients.

► Clinical Presentation

Prompt suspicion and early diagnosis of NSSSIs are essential. In early stages, patients often have fever and pain out of proportion to physical examination findings. Erythema, induration, hemorrhagic skin bulla, blisters, and vesicles are occasionally present. Grayish discoloration of the underlying skin and pain beyond the affected skin area are especially suggestive of deeper underlying tissue involvement. “Dishwasher-like” gray discharge might be seen and should raise suspicion of NSSSIs. Patients can quickly develop systemic signs of toxicity with hypotension, tachycardia, electrolyte imbalances, lethargy, and even organ failure. Laboratory workup typically shows leukocytosis (with or without bandemia) or leucopenia, hyponatremia, and acidosis. Several models have been developed over the years in an attempt to predict the probability of a skin infection being a NSSTI versus a more benign superficial skin infection. The Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score assigns different point scores to each of six laboratory values (Table 8–9). A LRINEC score of six or more was found in a study of 89 NSSSIs to have a positive predictive value of 92% and a negative predictive of 96% for NSSTI. Radiologically, plain films showing deep soft tissue air are pathognomonic. Computed tomography (CT) scan is the standard of care when difficulty arises in differentiating between “benign” skin or soft tissue infection and NSSSIs. CT images often show inflammation and edema at the deeper fascial or muscular layers, and occasionally will show gas between these tissue layers. Although crepitus as felt on physical examination and/or deep tissue air as diagnosed by plain radiography or CT imaging have been classically described with several (but not all) clostridial species, they

Table 8–9. The Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) Score.

Variable	Points
C-reactive protein (mg/L) > 150	4
WBC count (× 103 cells/ml)	
< 15	0
15–25	1
> 25	0
Hemoglobin (g/dL)	
> 13.5	0
11–13.5	1
< 11	2
Sodium (mmol/L) < 135	2
Creatinine (μmol/L) > 141	2
Glucose (mmol/L) > 10	1

may occur with nonclostridial infections as well. When the clinical picture and the radiological imaging fail to differentiate between benign soft tissue infection and NSSSIs, diagnostic surgical exploration of the area in question is needed. Operative findings suggestive of NSSSIs include pale and/or necrotic deep tissue, “dishwasher” nonpurulent gray discharge, nonbleeding soft tissue, and thrombosed microvessels. Easy separation with unopposed finger “sliding” between the tissue planes (the “finger test”) is highly suggestive of NSSSIs. Pathologic examination will reveal severe inflammation and tissue necrosis.

► Treatment

A NSSSI is a surgical emergency and requires immediate

1. Wide surgical debridement
2. Broad-spectrum antibiotics
3. Hemodynamic and fluid resuscitation

Wide Surgical Debridement

All tissue that appears pale, ischemic, or necrotic, “lifts off” easily, or does not bleed appropriately needs to be removed. This should include the overlying skin, even when it appears viable, as studies have documented severe vasculitis and microvessel thrombosis that eventually lead to loss of skin, if not adequately debrided. Extensive debridement is usually needed, with one or more repeat trips to the operating room, until viable tissue is ensured. When an extremity is involved, amputation might be required, although attempts at debridement and limb salvage, with a planned “second look” are reasonable and might be preferred. Perirectal NSSSI and Fournier gangrene occasionally necessitate creation of an ostomy and/or urinary diversion. Depending on the extent and location of debridement, many patients, if they survive and recover, are disfigured and will need reconstructive surgery ranging from simple split thickness skin grafts to major flap reconstructions.

A. Antibiotics

As soon as a NSSSI is suspected, broad-spectrum antibiotics should be initiated. Gram-positive, gram-negative, and anaerobic organisms need to be covered. A combination of a penicillin-based agent or cephalosporin with an aminoglycoside or fluoroquinolone and an anti-anaerobic agent (eg, metronidazole or clindamycin) is a reasonable starting empiric regimen. Clindamycin has been shown by in vitro studies to have anti-inflammatory and toxin-neutralizing effects, in addition to its antibacterial effects. If methicillin-resistant *S aureus* is suspected, penicillins can be replaced by vancomycin or linezolid. Aminoglycosides can be replaced by third- or fourth-generation cephalosporins (eg, cefepime, cefotaxime) or by carbapenems (eg, imipenem, meropenem, ertapenem), if indicated (eg, in patients with acute

renal failure). The Infectious Diseases Society of America (IDSA) published guidelines for the antibiotic choices in NSSSIs are reported in Table 8–10.

B. Hyperbaric Oxygen

The usefulness of hyperbaric oxygen in the treatment of NSSTI is controversial. Several small retrospective studies have suggested decreased mortality with hyperbaric therapy, but the absence of supportive level one evidence, combined with the logistical difficulties in critically ill patients remain the main obstacles to recommend its routine utilization.

► Prognosis

NSSSI has a poor prognosis with reported mortality as high as 20%–50%, and an even higher morbidity rate. Diabetic patients and/or those presenting with septic shock and/or multisystem organ failure are at a particularly higher risk of mortality. Shorter time from onset of infection to operative debridement has been shown consistently to correlate with better survival.

ORGAN/SPACE INFECTIONS

Organ/space infections are often deep infections resulting from uncontrolled infection or perforation of an internal organ. Internal postoperative abscesses are termed organ/space SSIs, and have been discussed previously. In addition to antibiotic treatment, many of these organ/space infections will need drainage.

► Intra-Abdominal Abscesses and Infections

In the era of high-resolution CT imaging, diseases like acute diverticulitis and acute perforated appendicitis are more likely to be successfully managed nonoperatively in the acute clinical setting. When patients have no signs of diffuse peritonitis, periappendiceal, pericolic abscesses, and other contained intraperitoneal abscesses may be drained percutaneously under radiological guidance when accessible. With the combination of percutaneous drainage and adequate antibiotic coverage, patients’ intra-abdominal infections can be treated adequately, allowing for the inflammation to resolve with potentially one-stage and less complicated surgical intervention at a later time to address the diseased organ. When percutaneous drainage is not possible, usually because of the abscess location and its inaccessibility to radiological interventions, surgical drainage with removal of the infected organ (eg, appendectomy, colectomy) is warranted. If the abscess is less than 3–4 cm in diameter, an attempt at treatment with antibiotics alone without percutaneous or surgical drainage is a reasonable option in the stable patient without peritoneal signs. The management of complicated intra-abdominal infections, whether community acquired or health care associated,

Table 8–10. The Infectious Diseases Society of America guidelines for antibiotic treatment of NSSTIs.

First-Line Antimicrobial Agent, by Infection Type	Adult Dosage	Antimicrobial Agent(s) for Patients With Severe Penicillin Hypersensitivity
Mixed infection		
Ampicillin-sulbactam or piperacillin-tazobactam plus clindamycin plus ciprofloxacin	1.5–3.0 g every 6–8 h iv 3.37 g every 6–8 h iv 600–900 mg/kg every 8 h iv 400 mg every 12 h iv	Clindamycin or metronidazole ^a with an aminoglycoside or fluoroquinolone
Imipenem/cilastatin	1 g every 6–8 h iv	...
Meropenem	1 g every 8 h iv	...
Ertapenem	1 g every day iv	...
Cefotaxime plus metronidazole or clindamycin	2 g every 6 h iv 500 mg every 6 h iv 600–900 mg/kg every 8 h iv	...
Streptococcus infection		
Penicillin plus clindamycin	2–4 MU every 4–6 h iv (adults) 600–900 mg/kg every 8 h iv	Vancomycin, linezolid, quinupristin/dalfopristin, or daptomycin
S aureus infection		
Nafcillin	1–2 g every 4 h iv	Vancomycin, linezolid, quinupristin/dalfopristin, daptomycin
Oxacillin	1–2 g every 4 h iv	...
Cefazolin	1 g every 8 h iv	...
Vancomycin (for resistant strains)	30 mg/kg/day in 2 divided doses iv	...
Clindamycin	600–900 mg/kg every 8 h iv	Bacteriostatic; potential of cross-resistance and emergence of resistance in erythromycin-resistant strains; inducible resistance in methicillin-resistant <i>S aureus</i>
Clostridium infection		
Clindamycin	600–900 mg/kg every 8 h iv	...
Penicillin	2–4 MU every 4–6 h iv	...

iv, intravenously.

^aIf *Staphylococcus* infection is present or suspected, add an appropriate agent.

whether originating from the hepatobiliary system or the gastrointestinal system, is beyond the scope and goal of this chapter. The IDSA has recently published useful guidelines for diagnosis and treatment of intra-abdominal infections that emphasize

1. Source control (surgical or percutaneous drainage)
2. Early and appropriate antibiotics coverage
3. Fluid resuscitation
4. Microbiological evaluation, when feasible

These guidelines can be accessed at www.idsociety.org.

► Empyema

Empyema is a collection of pus in the pleural cavity, most commonly related to bacterial pneumonia and resulting parapneumonic effusions. Occasionally, empyemas occur postprocedurally, such as following thoracentesis, chest tube placement, or lung resection. When empyema occurs, drainage is needed. In addition to antibiotics, tube thoracostomy is the recommended initial management. Unfortunately, chest tubes lumens often get clogged with thick pus, leading to placement of additional tubes, and not infrequently, failure to completely drain the pleural cavity and re-expand

the lung. When that occurs, surgical drainage with decortication using a video-assisted thoracoscopic approach or an open thoracotomy is indicated. In cases of recurrent or persistent empyema despite surgical management, creation of an Eloesser flap or window with an open track between the pleural cavity and the outside skin might be needed to allow adequate and definitive drainage of the empyema.

CLOSTRIDIUM DIFFICILE COLITIS

Clostridium difficile as an organism can be recovered in the feces of 5% of healthy individuals. The use of antibiotics can alter the colonic flora allowing for *C difficile* overgrowth and colonization of the colon. The result is *C difficile* colitis with severity ranging from simple watery diarrhea to life-threatening sepsis. *C difficile* is currently considered one of the most common and most serious health care–associated infections.

Risk Factors

Antibiotic intake is the single most important risk factor for *C difficile* colitis and has been described even following a single antibiotic dose administration as with SSI prophylaxis. Although all antibiotics can be implicated, fluoroquinolones, clindamycin, penicillins, and cephalosporins are the most frequently encountered culprits, partly because of their widespread utilization. A Canadian study conducted during a relatively recent *C difficile* outbreak in Quebec strongly suggested that fluoroquinolones are currently the antibiotics most commonly associated with *C difficile* infections rather than clindamycin as classically and historically described. Table 8–11 lists the different antibiotics classified into those with high, moderate, and small risk of *C difficile* infection.

Transmission of *C difficile* by health care providers caring for patients with *C difficile* colitis has resulted in outbreaks of *C difficile* among patients within hospitals and the emergence of multidrug-resistant organisms. These epidemics are addressed and prevented by proper hand hygiene among health care providers and the isolation of patients with *C difficile* colitis.

Clinical Presentation

The presentation of *C difficile* colitis can range from the asymptomatic carrier state that requires no treatment, and the mild diarrhea state that can easily be treated with oral antibiotics as an outpatient, to the severely toxic, septic, and MODS patient presentation. Across all the severity range, watery diarrhea, and abdominal distention remain the sine-qua-non of *C difficile* colitis. Lower abdominal pain may also be present, and is usually of a crampy nonspecific nature. Constitutional symptoms such as fever and malaise are also frequently reported. The presence of peritoneal signs such as rebound tenderness or guarding may be indicative of colonic perforation (rare) or severe and/or fulminant *C difficile* colitis. Leukocytosis is often present and not infrequently elevated above 20K cells/mcL. In fact, it is not unreasonable to test the hospitalized patient with unclear etiology of leukocytosis for occult *C difficile* infection, even in the absence of diarrhea. In a small study of inpatients with white blood cell counts above 15K cells/mcL, and without a clear etiology of the leukocytosis, Wanahita et al found that 58% of the patients tested positive for *C difficile*. Fecal leukocytes are also often present, but nonspecific. On colonoscopy, when performed, patients with *C difficile* colitis frequently show mucosal ulcerations with the pathognomonic pseudomembranes, often described as raised yellow plaques composed of fibrinous exudates. Abdominal x-rays may show “thumb printing” suggestive of colonic inflammation, but are often nonspecific. CT examination of the abdomen shows thickening of the colonic wall. In fulminant *C difficile* colitis, the abdominal x-rays and CT may show toxic megacolon with a diffusely dilated colon.

Diagnosis

In addition to the clinical patient presentation described above, diagnostic tests for *C difficile* currently consist of either *C difficile* organism detection (eg, anaerobic stool culture, antigen testing) or toxin A or B detection tools (eg, cytotoxin assays, enzyme immunoassays, or polymerase chain reaction [PCR] testing). The best approach to diagnose

Table 8–11. Antibiotics associated with *Clostridium difficile* colitis.

Association With <i>C Difficile</i>	Very Strong	Strong	Moderate	Weak/Rare
Antibiotic class	Fluoroquinolones Lincosamides	Cephalosporins Penicillins Carbapenems	Sulfonamides Macrolides	Aminoglycosides Nitroimidazoles Glycopeptides
Common examples	Ciprofloxacin Levofloxacin Clindamycin	Ceftriaxone Cefoxitin Imipenem Amoxicillin	Trimethoprim- sulfamethoxazole Erythromycin Azithromycin	Gentamicin Amikacin Vancomycin (IV) Metronidazole

C difficile remains controversial and institution-dependent. The stool culture is a sensitive test, but has a long turnover time (2-3 days) that is suboptimal in the critically ill patient who needs a fast and accurate diagnosis. Antigen detection is a reasonable screening test, but needs further confirmation when positive. The most sensitive test (considered standard by many) is the cytotoxin assay. Its sensitivity is above 95%, and its specificity approaches 100%, but it is an expensive test with 24-48 hours turnover time.

► Treatment

Treatment of asymptomatic patients is not indicated. On the other hand, the clinical, laboratory, and radiological presentation of the patient might carry a sufficient suspicion for *C difficile* infection that empiric antibiotics are justified pending *C difficile* organism or toxin detection tests. For patients with mild disease, level 1 evidence suggests the safety and equivalency of single-agent oral antibiotic treatment with PO metronidazole (500 mg every 8 hours) or PO vancomycin (125 mg every 6 hours). PO vancomycin is not systemically absorbed and is thus wholly available in the colonic lumen where the *C difficile* infection exists. A 2-week course of either antibiotics is recommended. Patients might still test positive for *C difficile* for many weeks despite treatment, and therefore retesting these patients for *C difficile* when the antibiotic course is done and the patient's signs and symptoms resolved, is not recommended. Adjunct therapies for *C difficile* such as probiotics, toxin-binding resins, and immunoglobulins have been used, but the evidence for their utility is still controversial.

► Treatment of Severe *C difficile* Colitis

The definition of severe *C difficile* infection varies, but the IDSA 2010 guidelines define it as leukocytosis above 15K cells/mL or a creatinine 1.5 times higher than the patient's predisease baseline. For severe *C difficile* colitis, these same guidelines recommend PO vancomycin rather than metronidazole as a first-line agent. Combination therapy with PO vancomycin, intravenous metronidazole +/- vancomycin enemas might be indicated in case of failure of single-agent therapy. Vancomycin enemas are particularly useful in patients with ileus (questionable adequate intracolonic concentration from PO vancomycin alone), those with PO intolerance, and possibly those with severe distal colonic inflammation (rectosigmoid colon). Fidaxomicin (200 mg every 12 hours) is a relatively new bactericidal antibiotic with promising results as an alternative therapy. In a randomized clinical trial comparing fidaxomicin and vancomycin, the cure rates were equivalent. Patients with refractory severe *C difficile* colitis, those who progress to toxic megacolon, or those with hemodynamic instability or showing signs of early MODS should be considered for prompt surgical intervention. The timing and decision to operate

are controversial, but there is certainly value in earlier intervention in critically ill patients, as the mortality of fulminant *C difficile* infection remains as high as 30%-50%. Independent predictors of mortality include age more than 70 years, leukocytosis more than 35K cells/mL, leucopenia less than 4K cells/mL, hemodynamic instability and respiratory failure. When surgery is indicated, the procedure of choice is a subtotal colectomy with end ileostomy. A single-center study has recently demonstrated improved outcomes in severe *C difficile* colitis using an alternative approach where a loop ileostomy is created and subsequent intraoperative colonic washout was performed with polyethylene glycol solution. In this small study of fewer than 50 patients, the new approach was associated with decreased mortality and more than 90% colon preservation, when compared to the traditional subtotal colectomy approach.

ANTIMICROBIAL MANAGEMENT

► General Principles

Antibiotic optimal management includes the following guiding principles:

1. Establishing a clinical diagnosis of infection and/or sepsis
2. Establishing an "evidence-based-guess" of the likely nature of the involved pathogen(s)
3. Attempting to obtain microbiological data (Gram stain and culture), when possible
4. Prompt initiation of broad-spectrum empiric antibiotics likely to cover the culprit pathogen(s)
5. Selectively narrowing the antibiotic regimen to cover the pathogen recovered in microbiological testing

The decisions to initiate, continue, or tailor the antibiotic choices for each patient should be carefully balanced against the increasingly serious challenge facing health care, namely, the epidemic emergence of multidrug-resistant organisms such as methicillin-resistant *S aureus* (MRSA), vancomycin-resistant *Enterococcus* (VRE), and multidrug-resistant gram-negative organisms.

EMPIRIC & PATHOGEN-DIRECTED ANTIBIOTIC SELECTION

Selecting the appropriate empiric antibiotics entails an understanding of the nature of the infectious process affecting the patient, the most likely organisms causing the infection, as well as awareness of the antibiotic resistance map at the local health care institution level. For example, simple skin infections are most likely caused by skin flora such as **staphylococci** and **streptococci**, and therefore an appropriate empiric treatment should at least cover gram-positive organisms. Acute diverticulitis with a pericolonic abscess

is more likely to be caused by colonic flora, such as gram-negative and anaerobic bacteria, and therefore empiric treatment should focus on covering these pathogens. Once a specific organism has been recovered from the tested microbiological specimen, it is often possible to narrow the antibiotic regimen, even before the specific data on antibacterial susceptibilities is available using the microbiological properties of antibiotics and the currently available clinical experience. The use of local antibiograms is crucial and highly encouraged, as the patterns of bacterial susceptibilities and resistance vary not only from a region to the other but also from one institution to the other. Susceptibility testing methods include disk diffusion and dilution (broth microdilution, plates, and E-tests) procedures. Disk diffusion tests indicate whether a microbial culture is susceptible or resistant to serum-achievable, in vivo drug concentrations with conventional dosage regimens. In contrast, dilution procedures allow report of the minimal inhibitory concentration (MIC) and minimal bactericidal concentration (MBC). The MIC is the lowest concentration of a specific antimicrobial agent that inhibits the test organism, while the MBC is the lowest concentration of a specific antimicrobial agent that kills the test organism. Tailoring therapy based on reported of susceptibility via disk diffusion or MIC is recommended.

► Antibiotic Duration of Therapy

If all the sent cultures were found to be negative, and the suspicion for continuing infection is low, empiric antibiotics should be discontinued, as unnecessary antibiotic therapy clearly increases the risk of multidrug-resistant bacteria, *C difficile* colitis, and other side effects. The duration of antibiotic treatment depends on the nature of the infection and the severity of the clinical presentation. Treatment of acute uncomplicated infections should be continued at least until the patient is afebrile, the white blood cell count is normal, and the patient looks clinically well. Evidence-based guidelines for type of antibiotics and duration in the treatment of various infections have been developed and should be followed when possible. Most antibiotic regimens are now limited, although more difficult infections such as liver abscesses, brain abscesses, endocarditis, septic arthritis, or osteomyelitis require prolonged antibiotic therapy.

► Failure of Clinical Response

Upon failure of clinical response to initial surgical intervention and antibiotic therapy, the clinician is encouraged to think of all the possible following explanations of failure of therapy:

1. The existence of another organism
2. The presence of an uncontrolled source of infection needing additional interventions
3. The presence of a concomitant super-infection (eg, with fungal organisms)
4. The development of a new drug resistance by the same isolated organism
5. Failure of the chosen antibiotic medication (despite favorable susceptibility data) to penetrate the site of infection

The latter may be due to the properties of the antibiotic itself, the chosen route of administration, or the specific physiology and morbidity of the patients themselves.

► Antibiotics' Side Effects

Adverse antibiotic reactions may occasionally mimic infection by causing fever, skin rashes, and mental status changes. Clinicians should consider this possibility in patients with persistent fevers despite appropriate antibiotic coverage and seeming resolution of the infectious process. In addition, antibiotics can result in microbial superinfections (eg, fungi, *C difficile*), emergence of new bacterial drug resistance, or organ toxicity.

► Antibiotics in Renal or Hepatic Failure

Several antibiotics may induce or exacerbate existing organ dysfunction, most commonly renal or hepatic, and thus require intermittent assessment of kidney and liver function. Aminoglycosides and renal failure is a classic example.

In addition, decreased creatinine clearance at baseline or due to critical illness has an important influence on antimicrobial drug dosage, since most of these drugs are excreted, at least partially, by the kidneys. Therefore, many of these medications, such as vancomycin, penicillins, and aminoglycosides require adjustments in dosage or frequency of administration in the presence of renal insufficiency to prevent toxicity. Table 8–12 provides practical guidance into adjusting diverse antibiotic dosage and frequency for patients with hepatic or renal insufficiency, although additional assistance from the pharmacy department in these cases is universally advisable.

CONCLUSION

In conclusion, surgery can result in infection (such as SSI), but may also be the adjunct treatment to obtain source control in many infectious processes (ie, surgical infections). In the former, prevention by implementing processes of care (eg, timely provision of perioperative antibiotics, maintenance of strict sterile techniques) and patient risk factors optimization prior to surgery should be the goal of every surgeon, as SSI remains one of the biggest health care-associated perioperative challenges. For the latter (surgical infections), source control is the cornerstone in the prevention of systemic progression of the infection into sepsis, septic shock,

Table 8–12. Use of antibiotics in patients with renal failure and hepatic failure.

	Principal Mode of Excretion or Detoxification	Approximate Half-Life in Serum		Proposed Dosage Regimen in Renal Failure		Removal of Drugs by Dialysis	Dose After Dialysis	Dosage in Hepatic Failure
		Normal	Renal Failure ^a	Initial Dose ^b	Maintenance Dose			
Acyclovir	Renal	2.5-3.5 h	20 h	2.5 mg/kg	2.5 mg/kg q24h	Yes	2.5 mg/kg	NC
Ampicillin	Tubular secretion	0.5-1 h	8-12 h	1 g	1 g q8-12h	Yes	1 g	NC

Cefepime	Renal	120 min	600 min	1-2 g IV	1-2 g IV q12h	Yes	1 g q48h	NC

and/or MODS. Alongside surgical treatment of infections, antibiotic stewardship with appropriate timing, duration, and choice of antibiotics are needed now more than ever to prevent the emergence of resistant organisms as well as *C difficile* infection.

MULTIPLE CHOICE QUESTIONS

- Development of a SSI requires
 - A susceptible host
 - An infectious agent
 - As suitable medium or environment
 - Both A and C
 - All of A, B, and C
- The Centers for Disease Control classification of SSIs includes
 - Infection at or near the surgical incision within 30 days of the procedure
 - Infection at or near the surgical site within 2 months if an implant is left in place
 - Subcategories of infection including deep incisional and organ/space
 - Excludes superficial infections that involve only the skin.
 - Both A and C are true
- The efficacy of efforts to prevent SSI
 - Is not affected by the timing of antibiotic dosing as long delivery occurs by the time of skin closure
 - Is independent of the choice of antibiotic
 - Can be improved by the use of alcohol-containing skin preparation solutions
 - Is very similar at hospitals around the world
 - Is currently well-known, and best practices are no longer controversial

4. The treatment of SSI includes
 - A. Opening the incision for superficial SSI
 - B. Antibiotics in every case
 - C. Debridement of necrotic tissue if present
 - D. Avoidance of wound cultures as this is expensive and unnecessary
 - E. Both A and C
5. All of the following are true about necrotizing skin and skin structure infections (NSSSIs), except
 - A. NSSSIs are generally self-limited and non-threatening
 - B. Can be caused by single or polymicrobial infections
 - C. Small vessel thrombosis occurs along the infection progression pathway
 - D. Immunocompromised (eg, HIV, diabetes), intravenous drug abuse, and cancer patients are at a particularly higher risk of developing NSSSIs
 - E. Grayish discoloration of the underlying skin and pain beyond the affected skin area are especially suggestive of deeper underlying tissue involvement

9

Fluid, Electrolyte, & Acid-Base Disorders

Tracey Dechert, MD

Fluid status, electrolyte homeostasis, and acid-base balance are clinical parameters of critical significance in surgical patients. Understanding normal physiology and pathophysiology related to these parameters is crucial.

FLUIDS & ELECTROLYTES

Surgical patients are at high risk for derangements of body water distribution, electrolyte homeostasis, and acid-base physiology. These disturbances may be secondary to trauma, preexisting medical conditions which alter normal physiology, or the nature of the surgery.

BODY WATER DISTRIBUTION & COMPOSITION

Total body mass is 45%-60% water. The percentage in any individual is influenced by age and lean body mass, therefore the percentage is higher in men compared to women, in children compared to adults, and in people of normal body habitus compared to the obese (Table 9-1). Two-thirds of total body water (TBW), 30%-40% of body mass, is intracellular; one-third, 15%-20% of total body mass, is extracellular. The extracellular fluid is divided into two compartments, with 80% (12%-16% of total body mass) in the interstitial compartment, and 20% (3%-4%) in the intravascular compartment. One-fifth of intravascular fluid is proximal to the arterioles, the remaining four-fifths is distal to the arterioles.

The intracellular, interstitial, and intravascular compartments each hold fluid characterized by markedly different electrolyte profiles (Figure 9-1). The main intracellular cation is the potassium ion (K^+), while the main extracellular cation is the sodium ion (Na^+). Not only the electrolyte profile, but also the protein composition of the fluids differs: intracellular cations are electrically balanced mainly by the polyatomic ion phosphate (PO_4^{3-}) and negatively charged

proteins, while extracellular cations are balanced mainly by the chloride ion (Cl^-). The intravascular fluid has a relatively higher concentration of protein and lower concentration of organic acids than the interstitial fluid. This higher concentration of protein, chiefly albumin, is the main cause of the high colloid osmotic pressure of serum, which in turn is the chief regulator of the fluid distribution between the two extracellular compartments. The relationship between colloid osmotic pressure and hydrostatic pressure governs the movement of water across the capillary membrane, and is modeled by the Starling equation.

The body's volume status and electrolyte composition are determined largely by the kidneys. The kidneys maintain a constant volume and osmolality by modulating how much free water and Na^+ is reabsorbed from the renal filtrate. Antidiuretic hormone (ADH), also known as arginine vasopressin, is the chief regulator of osmolality. The peptide hormone is released from the posterior pituitary in response to increased serum osmolality. ADH induces translocation of aquaporin channels to the collecting duct epithelium, increasing permeability to water and causing reabsorption of free water from the renal filtrate. Thus water is retained, and the urine concentrated. In the absence of ADH, the collecting duct is impermeable to water, leading to water loss and production of dilute urine. At high physiologic levels ADH has a direct vasoconstrictive effect on arterioles.

The main determinant of Na^+ reabsorption is the Na^+ load in the renal filtrate. Most filtered Na^+ (60%-70%) is reabsorbed in the proximal tubule. A further 20%-30% of filtered Na^+ is reabsorbed in the thick ascending limb of the loop of Henle; reabsorption here is determined by the Na^+ load delivered to the loop and a variety of hormones. The remaining distal tubule reabsorbs 5%-10% of filtered Na^+ ; again, the exact percentage is determined by the Na^+ load and a variety of hormonal factors, particularly aldosterone. The collecting duct reabsorbs a small percentage of filtered

Table 9-1. Approximate percentage water of total body mass.

Patient	%
Children	60
Nonelderly males	60
Nonelderly females	50
Elderly males	50
Elderly females	45

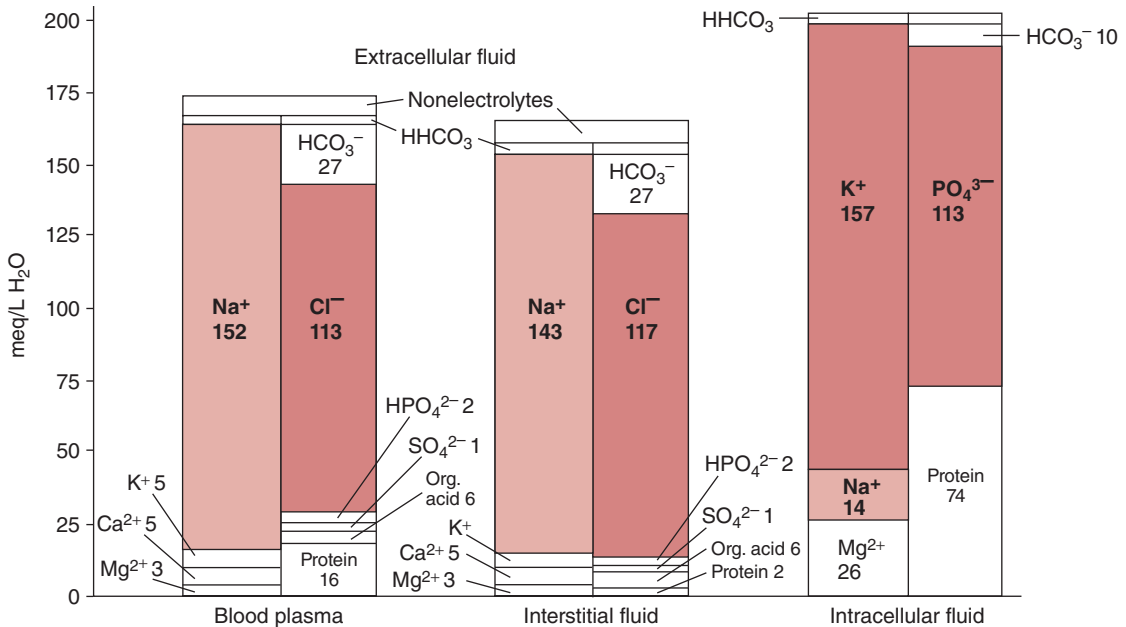

Na⁺ under the influence of aldosterone and natriuretic hormone. Under normal circumstances the kidneys will adjust excreted water and Na⁺ to match a wide spectrum of dietary intake.

Although the movement of ions and proteins between the different fluid compartments is normally restricted, water itself is freely diffusible between them. Consequently the osmolality of the different fluid compartments is identical, normally approximately 290 mOsm/kg. Control of osmolality occurs through regulation of water intake through diet and excretion through urine and insensible losses.

VOLUME DISORDERS

Hypo- and hypervolemia commonly occur in surgical patients, both following elective surgery and in the setting of trauma and acute care surgery. Volume disturbances run the gamut from being clinically insignificant to being immediately life threatening. The underlying cause of any volume disorder must be sought and addressed while the volume disorder itself is managed.

- Hypovolemia
 - Etiology: Hypovolemia is common in surgical patients. It is typically caused by loss of isotonic fluids in the setting of hemorrhage, gastrointestinal losses (eg, gastric suctioning, emesis, and diarrhea), sequestration of fluids in the gut lumen (eg, bowel obstruction, ileus, and enteric fistulas), burns, and excessive diuretic therapy. In resource poor settings sweat is often an additional important fluid loss, for example, in a non-air-conditioned operating room. In all of these cases, loss of isotonic fluid results in loss of Na⁺ and water without significantly affecting the osmolality of the extracellular fluid compartment, thus there is very little shift of water into or out of the intracellular compartment. Hypovolemia stimulates aldosterone secretion from the zona glomerulosa of

▲ Figure 9-1. Electrolyte composition of human body fluids. Note that the values are in mEq/L of water, not of body fluid. (From Leaf A, Newburgh LH: *Significance of the Body Fluids in Clinical Medicine*, 2nd ed. Thomas, 1955.)

the adrenal cortex, leading to increased reabsorption of Na^+ and water from the renal filtrate and excretion of low volumes (oliguria) of hypertonic urine with a low Na^+ concentration.

Fractional excretion of Na^+ (FENa) is a useful tool for differentiating causes of oliguria:

$$\text{FENa} = 100 \times \frac{(\text{Na}_u * \text{Cr}_p)}{(\text{Cr}_u * \text{Na}_p)}$$

where U: urine, P: plasma, Na: sodium, Cr: creatinine.

FENa $\leq 1\%$ usually indicates prerenal azotemia. However, FENa $\leq 1\%$ may be found in patients with oliguria secondary to hepatorenal syndrome, as the liver does not effectively metabolize aldosterone. In patients already receiving diuretic therapy, fractional excretion of urea nitrogen (FEUN) is more helpful than FENa. FEUN is calculated analogously; FEUN $\leq 35\%$ indicates prerenal azotemia.

- Presentation: Hypovolemia is suggested by a patient's history, physical examination, and laboratory data. Diagnosis by physical examination alone in the immediate postoperative setting is difficult, especially when volume loss is mild to moderate, and especially in very old and very young patients. One review found that longitudinal furrows on a patient's tongue and dry oral and nasal mucous membranes are 85% sensitive for hypovolemia; increased capillary refill time, unclear speech, upper or lower extremity weakness, a dry axilla, and postural hypotension were all relatively specific indicators of hypovolemia. The same review found that a postural (supine to standing) increase in heart rate of at least 30 beats per minute or severe postural dizziness which prevented the patient from standing had 6%-48% sensitivity for mild to moderate hypovolemia but 91%-100% sensitivity for severe hypovolemia. Laboratory evidence of hypovolemia includes elevated blood urea nitrogen (BUN): creatinine (Cr) ratio, as hypovolemia decreases renal perfusion, causing prerenal azotemia characterized by a disproportionate rise in BUN compared to Cr. However, an elevated BUN:Cr ratio may also be associated with renal failure and with gastrointestinal bleeding, independent of volume status. No single highly sensitive test to diagnose hypovolemia exists, thus the diagnosis must be made by examining all available data with a high index of suspicion.
- Treatment: Hypovolemia is corrected with intravenous administration of an isotonic fluid. Coexistent electrolyte abnormalities should be addressed simultaneously. Care must be taken in patients in renal or heart failure not to exacerbate these conditions. If hypovolemia is allowed to worsen unimpeded it will eventually lead to circulatory collapse and shock, which is covered elsewhere.
- Hypervolemia
 - Etiology: Hypervolemia is also common in surgical patients. It often occurs after treatment of shock with colloid and crystalloid fluids, with or without attendant renal failure. It also occurs in the postoperative period as ADH is secreted in response to nonphysiologic stimuli, disrupting its role in regulation of osmolality. High physiologic levels of ADH have a vasoconstrictive effect, leading to a decreased filtered Na^+ load and thus greater Na^+ and water retention. This secretion of ADH typically ceases 2-3 days after the surgical insult, after which ADH levels return to an appropriate level and patients experience a so-called "autodiuresis." Heart failure, liver disease, renal disease, and malnutrition all exacerbate hypervolemia in the surgical patient. Preexisting heart failure decreases the range across which a patient will adequately compensate for increased intravascular volume. Liver disease decreases metabolism of circulating ADH and aldosterone, increasing the homeostatic set point for intravascular volume and thus decreasing the physiologic reserve remaining to respond to surgical insults. Renal disease disrupts all aspects of volume regulation. Syndrome of inappropriate ADH hypersecretion (SIADH) causes hypervolemia secondary to a sustained ADH release independent of the normal physiologic triggers. SIADH typically occurs in the setting of traumatic brain injury, brain tumors and abscesses, pneumonia and lung abscesses, as a paraneoplastic syndrome associated with small cell lung cancer and other neoplasias, and with a variety of drugs including morphine and the chemotherapeutic agents cyclophosphamide and vincristine.
 - Presentation: Like hypovolemia, hypervolemia is often suggested by the patient's history and physical examination. Signs include hypertension, decreased arterial oxygen saturation and basilar crackles, jugular venous distention, dependent soft tissue edema, gallop rhythms on cardiac auscultation, and rapid weight gain. Examination of recorded fluid administration may assist in the diagnosis. Eventually a hypervolemic patient may show signs of pulmonary edema, easily diagnosed on chest x-ray, or even congestive heart failure (CHF).
 - Treatment: If the hypervolemic patient develops CHF or pulmonary edema, treatment with diuretics, or in extreme cases hemodialysis, may be required. Mechanical ventilation may be lifesaving if pulmonary edema and/or CHF have progressed to the point of respiratory failure.

ELECTROLYTE DISORDERS

Electrolyte derangements may occur independently of each other, but are often closely linked. Like volume disorders, disturbances of electrolyte homeostasis run the gamut from mild and inconsequential to severe and immediately life threatening.

The underlying cause of any electrolyte disorder must be sought while the electrolyte disorder itself is managed. Special care must always be taken when repleting electrolytes in patients with renal insufficiency. These patients require slower repletion and more frequent monitoring of electrolyte levels.

- Sodium: Hypo- and hypernatremia reflect excessive gain or loss of TBW, respectively. Significant derangements of Na^+ homeostasis result in significant changes to plasma tonicity and eventually whole body osmolality, with potentially devastating consequences for the central nervous system (CNS).
 - Hyponatremia
 - Etiology: Hyponatremia is a sign of relative water gain; total body Na^+ may be decreased, normal or even increased. Hyponatremia is common in surgical patients postoperatively, as ADH is secreted in response to pain, nausea and vomiting, opiate administration, and positive-pressure ventilation. Typically, this hyponatremia is mild and inconsequential; however, it may be exacerbated by rapid parenteral administration of hypotonic fluids. Hyponatremia may result from severe hyperglycemia, or any other condition in which an osmotically active solute draws water from the intracellular space to the extracellular space. In the setting of hyperglycemia, a corrected Na^+ is calculated as:

$$\text{Na}^+_{\text{corrected}} = \text{Na}^+_{\text{measured}} + 0.016 (\text{plasma glucose in mg/dL} - 100)$$

The correction factor 0.016 accounts for the unit conversion from mg/dL to mmol/L. Some investigators believe a correction factor of 0.024 is more appropriate.

Other causes of hyponatremia include cerebral salt-wasting syndrome, liver disease, congestive heart failure, and SIADH.

- Presentation: The signs of hyponatremia are caused by CNS dysfunction, as brain cells swell in a fixed-volume space (the Monro-Kellie hypothesis). Mental status changes, obtundation, coma, and seizures typically are not seen until serum Na^+ is less than 120 mmol/L. Such hyponatremia is a medical emergency requiring immediate intervention.
- Treatment: CNS signs and symptoms attributable to hyponatremia require administration of normal saline and free water restriction. In general,

hypertonic saline should not be used to correct hyponatremia. Unless serum Na^+ falls very rapidly, it should be corrected slowly, as too-rapid correction has the devastating complication of osmotic demyelination. No consensus exists on the appropriate rate of correction. One review recommended correction by no more than 8 mmol/L/d, starting with correction of 1-2 mmol/L/h in patients with severe manifestations. Sodium levels should not be corrected beyond what is needed to alleviate CNS disturbances. Correction of Na^+ does not replace pharmacologic intervention in a seizing patient.

One formula used to calculate the expected change in Na^+ from intravenous administration of 1 L of any fluid is:

$$\text{Change in serum Na}^+ = \frac{(\text{fluid Na}^+ + \text{fluid K}^+ \text{ in mmol/L}) - \text{serum Na}^+}{\text{TBW in L} + 1}$$

Total body water is estimated as a fraction of body mass (Table 9-1). Hyponatremia causing CNS disturbances should prompt admission to an intensive care unit given the close monitoring needed in such patients, the need for rapid intervention, and the potentially devastating consequences of delays in management.

- Hypernatremia
 - Etiology: Loss of free water alone occurs when patients do not have access to water (eg, preverbal, bed-bound or otherwise incapacitated patients), in diabetes insipidus, in the setting of high fevers, and in patients in whom enteral feeds do not contain adequate water. Hypernatremia typically occurs simultaneously with volume derangements, and total body Na^+ may be increased, normal or even decreased. Induced hypernatremia is a useful treatment modality in patients with traumatic brain injury to reduce cerebral edema, decrease intracranial pressure, and increase cerebral perfusion pressure.
 - Presentation: As with hyponatremia, the signs and symptoms of hypernatremia are caused by CNS dysfunction: lethargy, fatigue, hyperactive deep tendon reflexes, seizure, and coma may occur. Signs and symptoms are rare with Na^+ less than 158 mmol/L.
 - Treatment: Development of CNS symptoms requires parenteral administration of free water, typically as 5% dextrose in water. If the patient's hypernatremia developed over a period of hours it may safely be corrected at a rate of 1 mmol/L/h. In patients whose hypernatremia developed more slowly, a rate of 0.5 mmol/L/h is safe. As derangements in Na^+ are caused by derangements in TBW, the concept of a "water deficit" is a useful one in

treating hypernatremia. The free water deficit is calculated as:

$$\text{water deficit} = (\text{TBW} \times (1 - [140/\text{Na}^+ \text{ in mmol/L}]))$$

This formula is accurate when calculating the water deficit in patients with pure water loss, but is inaccurate in patients with hypernatremia caused by loss of hypotonic fluid. Using the formula in the section on hyponatremia, one may calculate the estimated correction 1 L of any fluid will have on Na^+ . As with hyponatremia, hypernatremia with clinical manifestations warrants admission to an intensive care unit so that correction may be achieved safely and effectively.

- Potassium: Potassium is the major intracellular cation. Plasma potassium ion (K^+) concentration is determined primarily by two factors. The first is acid-base homeostasis. Hydrogen ion (H^+) and K^+ are exchanged between the intracellular and extracellular spaces, thus disturbances of acid-base balance (see below) tend to cause disturbances in serum K^+ . The second is the size of the total body K^+ pool. Intracellular stores of K^+ are large, but may be exhausted, especially in the setting of prolonged ketoacidosis.
 - Hypokalemia
 - Etiology: In the surgical setting, total body K^+ is typically decreased by gastrointestinal losses, excessive diuretic administration, and prolonged malnutrition, particularly in alcoholic patients. Prolonged alkalosis (see below) that also results in hypokalemia (eg, due to gastric losses of hydrochloric acid and K^+) results in a so-called “paradoxical aciduria” as the nephron conserves K^+ at the expense of H^+ , which maintains the alkalosis instead of correcting it an attempt to prevent life-threatening hypokalemia (see below for details).
 - Presentation: The hallmark signs of hypokalemia are decreased muscle contractility eventually leading to diaphragmatic paralysis, EKG changes including a flattened or inverted T wave and a prominent U wave, and cardiac arrhythmias, which may present an immediate threat to life.
 - Treatment: When hypokalemia develops acutely it should be corrected with parenteral supplementation. Parenteral administration of K^+ must be done carefully so as not to cause iatrogenic hyperkalemia. Hypomagnesemia may cause hypokalemia refractory to parenteral administration. In such cases hypomagnesemia should be corrected along with hypokalemia (see below). In cases of chronic hypokalemia in which neuromuscular and cardiac manifestations are absent, oral supplementation (either through dietary changes or oral potassium chloride administration) should suffice.
 - Hyperkalemia
 - Etiology: In the surgical setting, hyperkalemia is often caused by crush injuries, burns and other catabolism-inducing events, renal insufficiency, adrenal insufficiency, and excessive K^+ administration. Acidosis may cause hyperkalemia as the intracellular space buffers acidemia by exchanging H^+ from the extracellular space for K^+ from within cells (see below).
 - Presentation: Hyperkalemia has few outward signs and symptoms until potentially lethal cardiac arrhythmias manifest. Initial EKG changes include flattened P waves and peaked T waves. Widening of the QRS complex is a later finding and demands immediate intervention, as it portends the imminent onset of ventricular fibrillation.
 - Treatment: A serum K^+ of 6.5 mmol/L or greater is a medical emergency and must prompt immediate intervention. The patient must be placed on continuous EKG monitoring. Initial treatment should consist of intravenous administration of 50% dextrose in water, 10 units of regular insulin, and calcium gluconate, as well as inhaled β -adrenergic agonists like albuterol. Insulin, glucose, and β -agonists drive K^+ from the extracellular space into the intracellular space, while calcium gluconate increases the excitability threshold of the myocardium, protecting against arrhythmias. If these measures are unsuccessful, hemodialysis may be required. Slowly developing hyperkalemia not severe enough to warrant intravenous interventions may be treated with oral sodium polystyrene sulfonate, which causes a slow enteral K^+ wasting.
- Magnesium: The magnesium ion (Mg^{2+}) is an essential cofactor in many of the most important biochemical reactions in the body. Adenosine triphosphate (ATP) must be bound to Mg^{2+} to be biologically active. Mg^{2+} is required for every step of DNA transcription and translation, nerve conduction, ion transport and Ca^{2+} channel activity. Approximately 50%-60% of total body magnesium is found in the bones. The large majority of the rest is intracellular, and approximately 1% is extracellular. A constant proportion of dietary Mg^{2+} is absorbed by the gut. If gut absorption exceeds Mg^{2+} needs, the excess is excreted by the kidneys. If dietary intake is insufficient the kidney retains Mg^{2+} , with urinary levels dropping to nearly zero.
 - Hypomagnesemia
 - Etiology: Hypomagnesemia occurs in the setting of malnutrition (especially malnutrition associated with alcoholism), gastrointestinal losses (especially prolonged diarrheal losses), diuretic or aminoglycoside use, hyper- or hypocalcemia, and hypophosphatemia.

- Presentation: In the surgical setting, hypomagnesemia most commonly presents as hypokalemia refractory to parenteral K^+ administration. Hypomagnesemia may cause sedation, muscle paralysis, tetany, seizures, and coma.
- Treatment: Parenteral administration of Mg^{2+} is generally preferred to oral supplementation, as orally-administered magnesium is a cathartic agent.
- Hypermagnesemia
 - Etiology: Hypermagnesemia is rare in the surgical setting, but may develop in acute renal failure.
 - Presentation: At high concentrations, Mg^{2+} acts as a Ca^{2+} antagonist. Thus although hypermagnesemia may cause lethargy, weakness and diminished deep tendon reflexes, it most often presents as cardiac arrhythmias. Peaked T waves and widening of the QRS complex occur, which may progress to complete heart block, arrhythmias, and eventually asystole.
 - Treatment: If hypermagnesemia is mild and caused by supplementation, withdrawal of supplementation, and close monitoring should be sufficient treatment. If hypermagnesemia is significant and causing EKG changes, calcium gluconate should be administered intravenously so as to overwhelm the Ca^{2+} -antagonizing effect of Mg^{2+} in neuromuscular function. Diuretic therapy may be required. In severe cases and in cases caused by renal failure, hemodialysis may be required.
- Calcium: Calcium (Ca^{2+}) is involved in a wide variety of physiologic processes, from maintenance of bone strength to neuromuscular function. Half of serum Ca^{2+} is protein-bound, chiefly to albumin. The unbound fraction is physiologically active, while the bound fraction is not; this unbound (or “ionized”) fraction is normally held constant across a wide range of plasma Ca^{2+} . Ca^{2+} homeostasis is influenced by vitamin D, parathyroid hormone, calcitonin, acid-base balance, and PO_4^{3-} homeostasis.

Standard laboratory tests measure total serum Ca^{2+} , including the fraction bound to albumin. Thus, a low Ca^{2+} value on a serum chemistry may reflect hypoalbuminemia rather than true hypocalcemia. Many formulas exist to correct Ca^{2+} in the setting of hypoalbuminemia. The most commonly used is:

$$Ca^{2+}_{\text{corrected}} = 0.8(4 - \text{serum albumin in g/dL}) + Ca^{2+}_{\text{measured}}$$

This and other such formulas are inaccurate in the setting of hemodialysis. In dialyzed patients, the uncorrected Ca^{2+} should be used to determine if the patient is hypo- or hypercalcemic. If doubt exists, an ionized Ca^{2+} measurement should be obtained.
- Hypocalcemia
 - Etiology: Hypocalcemia in the surgical setting is often caused by hypothyroidism and hypoparathyroidism (either organic or iatrogenic after thyroid or parathyroid surgery), pancreatitis, renal insufficiency, crush injuries, severe soft tissue infections, and necrotizing infections like necrotizing fasciitis.
 - Presentation: Hypocalcemia manifests as neuromuscular dysfunction, causing hyperactive deep tendon reflexes, Chvostek sign, muscle cramps, abdominal pain, and in severe cases tetany and cardiac arrhythmias.
 - Treatment: In persistent hypocalcemia, whole blood pH must be determined, and any alkalosis corrected. Calcium supplementation, enterally if possible and parenterally if necessary, may be required. Chronic hypoparathyroidism and hypothyroidism require chronic vitamin D and Ca^{2+} supplementation, and may require aluminum hydroxide to decrease PO_4^{3-} absorption from the gut.
- Hypercalcemia
 - Etiology: Hypercalcemia in the surgical setting is often caused by primary or tertiary hyperparathyroidism, hyperthyroidism, bony cancer metastases, paraneoplastic syndromes in which parathyroid hormone-related peptide is elaborated, and as a complication of thiazide diuretic use.
 - Presentation: Signs and symptoms of acute hypercalcemia include anorexia, nausea and vomiting, polydipsia, polyuria, depression, confusion, memory loss, stupor, coma, psychosis, and cardiac arrhythmias. Dyspepsia, constipation, acute pancreatitis, nephrolithiasis, osteoporosis, osteomalacia, and osteitis fibrosa cystica are indicative of chronic hypercalcemia. Untreated longstanding hypercalcemia, especially in conjunction with untreated hyperphosphatemia and especially in patients with chronic renal failure, may lead to calciphylaxis and high morbidity and mortality.
 - Treatment: In a patient with healthy kidneys, administration of large volumes of normal saline over 1-3 days will often correct even a profound hypercalcemia. Treatment may be followed by targeting a urine output of 2-3 mL/kg/h and monitoring serum Ca^{2+} levels closely. Loop diuretics (eg, furosemide) inhibit Ca^{2+} reabsorption in the nephron, and will aid in calciuresis, but should not be used until the patient is clinically euvolemic. Calcitonin increases osteoblastic activity and inhibits osteoclastic activity, locking Ca^{2+} into the skeleton. In severe hypercalcemia or hypercalcemia secondary to renal failure, hemodialysis may be required. In patients whose hypercalcemia is caused by malignancy, bisphosphonates may provide a

means of controlling Ca^{2+} levels in the medium and long term. In hypercalcemia caused by hyperparathyroidism, parathyroidectomy is potentially curative, but is reserved for the elective setting unless the patient is in hypercalcemic crisis which is refractory to optimal medical management.

- Phosphate: Like Ca^{2+} and Mg^{2+} , the majority of PO_4^{3-} is found in the skeleton. The large majority of the remainder is found intracellularly, where it functions as a constituent of ATP. Like Mg^{2+} , it is essential to energy metabolism.
 - Hypophosphatemia
 - Etiology: As with hypomagnesemia, chronic hypophosphatemia is typically found in malnourished patients, especially alcoholic patients. It may also occur in patients who consume large amounts of antacids, and following liver resection. An important and often overlooked cause of hypophosphatemia is refeeding syndrome. This syndrome occurs after a patient who has been without significant caloric intake for at least 5 days begins to eat again. Severe hypophosphatemia may occur as phosphofructokinase binds PO_4^{3-} to glucose to begin glycolysis, and as PO_4^{3-} is consumed in production of large amounts of ATP. The syndrome usually manifests within 4 days of starting refeeding.
 - Presentation: Hypophosphatemia results in muscular and neurologic dysfunction. Muscle weakness, diplopia, depressed cardiac output, respiratory depression due to diaphragmatic weakness, confusion, delirium, coma, and death may all develop. An uncommon presentation is with rhabdomyolysis. Hypophosphatemia may leave a patient ventilator-dependent as they are unable to replenish ATP stores for proper functioning of the muscles of respiration.
 - Treatment: Severe hypophosphatemia is a medical emergency, requiring parenteral administration of Na_3PO_4 or K_3PO_4 , depending on the patient's electrolyte profile. If hypophosphatemia is not severe it may be treated with oral supplementation, either with sodium phosphate/potassium phosphate or with high-phosphate foods like milk.
 - Hyperphosphatemia
 - Etiology: Hyperphosphatemia is unusual in the surgical setting, typically developing in the setting of severe renal disease or after severe trauma.
 - Presentation: Hyperphosphatemia is usually asymptomatic, but it may cause hypocalcemia as calcium phosphate precipitates and is deposited in tissues.
 - Treatment: Hyperphosphatemia is treated by diuresis, administration of phosphate-binders like aluminum hydroxide, or hemodialysis in the setting of renal failure.

ACID-BASE

The body's handling of hydrogen ion (H^+) is a particularly complex example of electrolyte management, as it involves not only dietary intake and renal clearance but also extracellular and intracellular buffer systems and respiratory as well as renal excretion.

NORMAL PHYSIOLOGY

An acid is a chemical that donates a H^+ in solution, for example, HCl or H_2CO_3 . A base is a chemical that accepts H^+ in solution, for example, Cl^- or HCO_3^- . The concentration of H^+ in a solution determines the acidity of the solution. Acidity of a solution is measured by pH, which is the negative logarithm of H^+ concentration expressed in mol/L. The strength of an acid is determined by its degree of dissociation into H^+ and the corresponding base, as expressed in the Henderson-Hasselbalch (H-H) equation:

$$\text{pH} = \text{pK} + \log \frac{[\text{A}^-]}{[\text{HA}]}$$

where K = dissociation constant, $[\text{A}^-]$ = concentration of acid, $[\text{HA}]$ = concentration of base. Stronger acids have a higher K than weaker acids.

The main buffer system in human blood is a carbonic acid/bicarbonate ($\text{H}_2\text{CO}_3/\text{HCO}_3^-$) system. Using the H-H equation, the pH of this buffer system is calculated as:

$$\text{pH} = \text{pK} + \log \frac{[\text{HCO}_3^-]}{[\text{H}_2\text{CO}_3]}$$

H_2CO_3 in the blood exists mostly as CO_2 (the so-called "volatile acid"); conversion of one to the other is catalyzed by the enzyme carbonic anhydrase. The dissociation constant of CO_2 is 0.03. Making these substitutions into the equation, we have:

$$\text{pH} = \text{pK} + \log \frac{[\text{HCO}_3^-]}{[\text{pCO}_2 \times 0.03]}$$

where Pco_2 is the partial pressure of CO_2 . The pK for this buffer system is 6.1. In arterial blood, HCO_3^- normally ranges from 21 to 37 mmol/L, while Pco_2 ranges from 36 to 44 mm Hg. Thus, arterial pH normally ranges from 7.36 to 7.44. Venous blood is easier to sample than arterial blood (Table 9-2). Venous blood gas sampling varies significantly between institutions, and between central, mixed,

Table 9-2. Estimated arterial to venous blood gas conversions.

$\text{pH}_a = \text{pH}_v \times 1.005$
$\text{PaCO}_2 = \text{PvCO}_2 \times 0.8$
$\text{HCO}_3^-_a = \text{HCO}_3^-_v \times 0.90$

a, arterial; p, partial pressure; v, venous.

and different peripheral sites of sampling, and thus must be interpreted with caution.

Acid-base homeostasis is maintained by pulmonary excretion of CO₂ and renal excretion of nonvolatile acids, which is discussed in further sections.

ACID-BASE DISORDERS

The fundamental acid-base disorders are:

- Acidemia: pH below the normal range
- Alkalemia: pH above the normal range
- Acidosis: a process that lowers the pH of the extracellular fluid
- Alkalosis: a process that raises the pH of the extracellular fluid

There are four primary or simple (as opposed to mixed) acid-base disorders:

- Metabolic acidosis: a disorder in which decreased HCO₃⁻ causes decreased pH
- Metabolic alkalosis: a disorder in which increased HCO₃⁻ causes increased pH
- Respiratory acidosis: a disorder in which increased Pco₂ causes decreased pH
- Respiratory alkalosis: a disorder in which decreased Pco₂ increased pH are found

Acid-base disorders are classified as simple or mixed. In a simple acid-base disorder, only one primary acid-base disorder is present, and the compensatory response is appropriate. In a mixed acid-base disorder, more than one primary acid-base disorder is present. Mixed acid-base disorders are suspected from a patient's history, from a lesser or greater than expected compensatory response, and from analysis of the serum electrolytes and anion gap (AG) (see below).

The use of a systematic approach to identifying and diagnosing acid-base disorders is essential. One must first determine alkalemia or acidemia based on pH. One must then determine whether a metabolic derangement with respiratory compensation or a respiratory derangement with metabolic compensation exists, based on the HCO₃⁻ and Pco₂ values (Table 9-3).

Whether the disturbance is primarily respiratory or metabolic, some degree of compensatory change occurs in an attempt to maintain normal pH. Changes in Pco₂ (respiratory disorders) are compensated for by changes in HCO₃⁻ (metabolic/renal compensation), and vice versa.

Acute respiratory disorders may develop in matter of moments. Such circumstances may not allow sufficient time for renal compensation, resulting in severe pH changes without significant compensatory changes. By contrast, chronic respiratory disturbances allow the full range of renal

Table 9-3. Changes in HCO₃⁻ and pCO₂ in primary acid-base disorders.

Disorder	pH	HCO ₃ ⁻	Pco ₂
Metabolic acidosis	↓	↓	↓ (compensatory)
Metabolic alkalosis	↑	↑	↑ (compensatory)
Respiratory acidosis	↓	↑ (compensatory)	↑
Respiratory alkalosis	↑	↓ (compensatory)	↓

compensatory mechanisms to function. In these circumstances, pH may remain normal or nearly normal despite wide variations in Pco₂. By contrast, respiratory compensation for metabolic disorders occurs quickly. Thus there is little difference in respiratory compensation for acute and chronic metabolic disorders.

► Metabolic Acidosis

Metabolic acidosis is caused by increased production of H⁺ or by excessive loss of HCO₃⁻. In the surgical setting, metabolic acidosis is commonly encountered in trauma, critically ill, and postoperative patients, and especially in patients in shock.

A. The Anion Gap

The serum AG is vital to determining the cause of any metabolic acidosis. AG may help differentiate between metabolic acidosis caused by accumulation of acid and that caused by loss of HCO₃⁻.

AG represents the difference between the primary measured serum cation, Na⁺, and the primary measured serum anions, Cl⁻ and HCO₃⁻:

$$AG = Na^+ - (Cl^- + HCO_3^-)$$

The AG is normally less than 12; however, the highest normal value varies by institution.

Increased acid production causes an increased AG, as unmeasured anions electrically neutralize Na⁺. Thus metabolic acidosis caused by increased H⁺ production is associated with a high AG. The most common causes of an AG metabolic acidosis include methanol ingestion, uremia/renal failure, diabetic ketoacidosis, polypropylene glycol ingestion, isoniazid ingestion, lactic acidosis, ethylene glycol ingestion, and salicylate poisoning. In the surgical setting lactic acidosis is by far the most common cause, seen in hypoperfused states like shock and sepsis.

A non-AG metabolic acidosis is caused by excessive HCO₃ loss. The nephron maintains electrical neutrality by reabsorbing Cl⁻ as HCO₃⁻ is lost, hence the normal AG. Non-AG metabolic acidosis in the surgical setting typically

results from diarrhea or high small bowel output, for example, from an ileostomy. Non-AG acidosis also occurs in renal tubular acidosis, as the nephron fails to reabsorb HCO_3^- . Iatrogenic hyperchloremia, especially from administration of large amounts of normal saline to trauma and postoperative patients, may induce a non-AG metabolic acidosis.

The AG may be influenced by phenomena unrelated to acid-base balance, which must be kept in mind. Hypoalbuminemia may lower AG, as Cl^- and HCO_3^- increase to electrically balance Na^+ which was previously balanced by albumin. Similarly, hyper- or hypostates of positively charged ions like calcium, magnesium, and potassium may affect the AG.

Treatment of metabolic acidosis involves identifying the underlying cause of the acidosis and correcting it. Often, this is sufficient. If this is not sufficient, correction may require administration of exogenous alkali in the form of NaHCO_3^- to correct the derangement in pH. The degree of restoration is estimated by subtracting the plasma HCO_3^- from the normal value (24 mmol/L at our institution) and multiplying the resulting number by half TBW. This is a useful empiric formula, as in practice it is unwise (and unnecessary) to administer enough NaHCO_3^- to completely correct pH. Doing so will likely cause fluid overload from the large Na^+ load delivered, and will likely overcorrect the acidosis. In patients with a chronic metabolic acidosis, often seen in chronic renal failure, alkali may be administered chronically as oral NaHCO_3^- . Efforts to minimize the magnitude of HCO_3^- loss in these patients must be undertaken as well.

B. Compensation

The body's response to metabolic acidosis is respiratory hyperventilation, "blowing off" H_2CO_3 as CO_2 and correcting the acidosis. This response is rapid, beginning within 30 minutes of the onset of acidosis and reaching full compensation within 24 hours. The adequacy of the respiratory response to metabolic acidosis is evaluated using Winter's formula:

$$\text{Pco}_2 = (1.5 \times \text{HCO}_3^- \text{ in mmol/L}) + (8 \pm 2)$$

If compensation is inadequate or excessive—that is, if Pco_2 is not within the range predicted by Winter's formula—one must evaluate for a mixed acid-base disorder (see below).

► Metabolic Alkalosis

Metabolic alkalosis is often encountered in surgical patients. The pathogenesis is complex, but often involves:

1. Loss of H^+ , usually via gastric losses of HCl
2. Hypovolemia
3. Total body K^+ depletion

All three are commonly encountered with vomiting or gastric suctioning, diuretic use, and renal failure.

HCl is secreted by chief cells in the gastric mucosa; simultaneously, HCO_3^- is absorbed in the blood. NaHCO_3 is then secreted by the pancreas into the lumen of the duodenum, neutralizing the gastric acid, after which the neutralized acid and base are reabsorbed by the small intestine. Thus, under normal circumstances there is no net alteration of acid-base balance in the function of the gastrointestinal tract. However, when H^+ is lost from the gastric lumen, for example, through emesis, gastric suctioning or gastric drainage—the result is loss of H^+ from the gastric lumen and a corresponding gain of HCO_3^- in the blood, leading to metabolic alkalosis.

Normally, the kidneys excrete excess HCO_3^- ; however, if volume depletion accompanies HCO_3^- excess, the kidneys attempt to maintain normovolemia by increasing tubular reabsorption of Na^+ , which is reabsorbed in an electrically neutral fashion by increasing reabsorption of Cl^- and HCO_3^- . This impairs HCO_3^- excretion, perpetuating the metabolic alkalosis.

Severe K^+ depletion further exacerbates metabolic alkalosis. To preserve K^+ , Na^+ is exchanged for H^+ in the kidney, through the $\text{Na}^+\text{-K}^+$ and $\text{Na}^+\text{-H}^+$ ATPases in the distal renal tubule. This explains why severe metabolic alkalosis with hypokalemia results in paradoxical aciduria. In such cases, urine Na^+ , K^+ , and Cl^- concentrations are low, and the urine is acidic. In simple volume depletion, urine Cl^- alone is low and the urine is alkaline. Severe metabolic alkalosis may lead to tetany and seizures, as seen in hypokalemia and hypocalcemia.

Treatment of metabolic alkalosis includes fluid administration, usually normal saline. With adequate fluid repletion, tubular reabsorption of Na^+ is diminished, and the kidneys will excrete excess HCO_3^- . K^+ must be repleted, both to allow for correction of the alkalosis and to prevent life-threatening hypokalemia. Repletion of volume with normal saline and of potassium with KCl also provides the nephron with needed Cl^- , allowing for reabsorption of K^+ and Na^+ with Cl^- instead of HCO_3^- . Acetazolamide, a carbonic anhydrase inhibitor diuretic, may also be used to treat metabolic alkalosis as long as the patient is euvolemic. Administration of exogenous acid in the form of HCl may be employed in the case of profound alkalosis.

A. Compensation

Adequate respiratory compensation for metabolic alkalosis should raise Pco_2 by 0.7 mm Hg for every 1 mmol/L elevation in HCO_3^- . Generally, respiratory compensation will not raise Pco_2 beyond 55 mm Hg. Thus a Pco_2 greater than 60 mm Hg in the setting of metabolic alkalosis suggests a mixed metabolic alkalosis and respiratory acidosis.

► Respiratory Acidosis

Acute respiratory acidosis occurs when ventilation suddenly becomes inadequate. CO_2 accumulates in the blood, and as carbonic anhydrase converts it to H_2CO_3 , acidosis develops.

Acute respiratory acidosis is most common in conditions where gas exchange is physically impaired, resulting in decreased ventilation. These conditions typically involve decreased oxygenation as well. They include respiratory arrest, acute airway obstruction, pulmonary edema, pneumonia, saddle pulmonary embolus, aspiration of introral contents, and acute respiratory distress syndrome. Hypoventilation may occur in patients postoperatively who are oversedated (eg, from narcotics, benzodiazepines, or as they recover from general anesthesia). Pain, especially from large abdominal incisions or from rib fractures, leads to respiratory splinting and hypoventilation. Excess ethanol ingestion decreases respiratory drive, thereby impairing ventilation. Head trauma, either by direct damage to central nervous system respiratory centers or by global brain damage and brainstem herniation, may impair ventilation.

Patients with obesity hypoventilation syndrome and obstructive sleep apnea may develop a periodically recurring acute respiratory acidosis, leading eventually to some renal compensation. True chronic respiratory acidosis arises from chronic respiratory failure in which impaired ventilation leads to persistently elevated PCO_2 , for example, as seen in chronic obstructive pulmonary disease. Chronic respiratory acidosis is usually well tolerated with adequate renal compensation, thus pH may be normal or near normal.

Treatment of respiratory acidosis involves restoration of adequate ventilation by treating the underlying cause. Aggressive chest physical therapy and pulmonary toilet should be instituted on all postsurgical patients. Patients with pulmonary edema should receive appropriate diuretic therapy, and patients with pneumonia should receive appropriate antibiotics. Naloxone or flumazenil should be used as needed in the setting of narcotic or benzodiazepine overdose, respectively. If necessary, endotracheal intubation and mechanical ventilation should be employed in order to correct pCO_2 .

Acute respiratory acidosis should be corrected rapidly. However, too rapid correction of chronic respiratory acidosis risks causing posthypercapnic metabolic alkalosis syndrome, characterized by muscle spasms and by potentially lethal cardiac arrhythmias.

A. Compensation

Over 80% of increased acid produced in respiratory acidosis is buffered by the body's tissues and intracellular hemoglobin. The remaining minority is buffered by HCO_3^- in the blood, which the kidney reclaims and reabsorbs. Thus, metabolic (renal) compensation for respiratory disorders is a much slower process than respiratory compensation for metabolic disorders. Furthermore, in acute respiratory acidosis renal mechanisms may not have had time to function at all, and HCO_3^- may be within normal limits.

Adequate renal compensation for respiratory acidosis involves an increase in HCO_3^- of 1 mmol/L for every 10 mm Hg increase in PCO_2 .

► Respiratory Alkalosis

Hyperventilation decreases PCO_2 (hypocapnia), leading to a respiratory alkalosis. In the surgical setting, anxiety, agitation, and pain are common causes of respiratory alkalosis. Hyperventilation and respiratory alkalosis may be an early sign of sepsis and of moderate pulmonary embolism. Chronic respiratory alkalosis occurs in chronic pulmonary and liver disease.

Acute respiratory alkalosis is treated by addressing the underlying cause. Patients may require pain control, sedation/anxiolytics, and even paralyzation and mechanical ventilation if necessary. Well-compensated chronic respiratory alkalosis does not require treatment. In these cases, rapid correction of pCO_2 leads to so-called posthypocapnic hyperchloremic metabolic acidosis, which is often severe.

A. Compensation

The renal response to respiratory alkalosis is decreased reabsorption of filtered HCO_3^- and increased urinary HCO_3^- excretion. HCO_3^- decreases as Cl^- increases, since Na^+ is reabsorbed with Cl^- instead of with HCO_3^- . This same pattern is seen in hyperchloremic metabolic acidosis; the two are distinguished only by pH measurements.

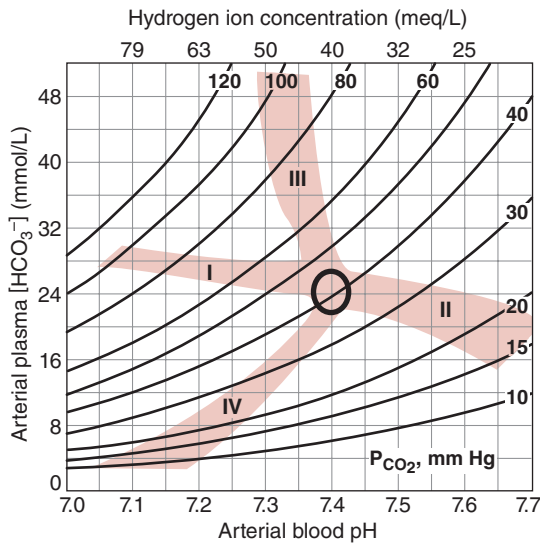

Adequate renal compensation for respiratory alkalosis involves a decrease in HCO_3^- of 2 mmol/L for every 10 mm Hg decrease in PCO_2 .

► Mixed Acid-Base Disorders

Many common pathophysiologic processes cause mixed acid-base disorders. In these situations, pH may be normal or near normal, but compensatory changes are either inadequate or exaggerated. One way of determining the presence of a simple versus mixed disorder is to plot the patient's acid-base disorder on a nomogram (Figure 9–2). If the set of data falls outside one of the confidence bands, then by definition the patient has a mixed disorder. If the acid-base data falls within one of the confidence bands, the patient more likely has a simple acid-base disorder.

As with simple acid-base disorders, a systematic approach to mixed acid-base disorders is essential. First, determine the primary acid-base disorder. Next, determine whether or not adequate compensation has occurred, using the equations and rules given above (Table 9–4). If compensation is “inadequate,” meaning too little or too much, the patient has a mixed acid-base disorder.

An additional step is needed in the case of metabolic acidosis. After AG has been calculated, the “delta-delta” or

▲ **Figure 9-2.** Acid-base nomogram for use in evaluation of clinical acid-base disorders. Hydrogen ion concentration (top) or blood pH (bottom) is plotted against plasma HCO_3^- concentration; curved lines are isopleths of CO_2 tension (Paco_2 , mm Hg). Knowing any two of these variables permits estimation of the third. The circle in the center represents the range of normal values; the shaded bands represent the 95% confidence limits of four common acid-base disturbances: I, acute respiratory acidosis; II, acute respiratory alkalosis; III, chronic respiratory acidosis; IV, sustained metabolic acidosis. Points lying outside these shaded areas are mixed disturbances and indicate two primary acid-base disorders.

“delta ratio” or “gap-gap” (three names for the same parameter) should be calculated:

$$\Delta\Delta = \Delta\text{AG}/\Delta\text{HCO}_3^-$$

where $\Delta\Delta$ = delta-delta, ΔAG = $\text{AG} - \text{maximum normal AG}$, ΔHCO_3^- = $\text{normal HCO}_3^- - \text{HCO}_3^-$.

Table 9-4. Expected compensation in primary acid-base disorders.

Metabolic acidosis	Winter's formula: $\text{pCO}_2 = 1.5 \times \text{HCO}_3^- + (8 \pm 2)$
Metabolic alkalosis	$\uparrow \text{Pco}_2$ 0.7 mm Hg for every 1 mmol/L increase in HCO_3^-
Respiratory acidosis	$\uparrow \text{HCO}_3^-$ 1 mmol/L for every 10 mm Hg increase in Pco_2
Respiratory alkalosis	$\downarrow \text{HCO}_3^-$ 2 mmol/L for every 10 mm Hg decrease in Pco_2

At our institution, maximum normal AG is 12 mmol/L and normal HCO_3^- concentration is 24 mmol/L, thus $\Delta\Delta = (\text{AG} - 12)/(24 - \text{HCO}_3^-)$.

$\Delta\Delta < 1$ indicates the coexistence of an AG and a non-AG metabolic acidosis, that is, a metabolic acidosis caused by increased production of acid and by renal loss of HCO_3^- . This may occur in the setting of diabetic ketoacidosis.

$\Delta\Delta > 1$ indicates the coexistence of an AG metabolic acidosis and a metabolic alkalosis. This can occur in the intensive care unit in patients who have an underlying AG metabolic acidosis and are also undergoing diuresis or gastric suctioning, leading to the concurrent metabolic alkalosis.

The most common mixed acid-base disorder in surgical patients is a metabolic acidosis superimposed on a respiratory alkalosis. This occurs in patients with septic shock and hepatorenal syndrome, and also in the case of salicylate poisoning. Since the two acid-base disorders disrupt H^+ homeostasis in opposite directions, the patient's pH may be normal or near normal. Mixed respiratory acidosis and metabolic alkalosis is less common, occurring in the setting of cardiorespiratory arrest, which is a medical emergency.

MULTIPLE CHOICE QUESTIONS

1. A 28-year-old man with history of depression is found down and brought to the emergency department. He responds to voice, moves his extremities spontaneously, and opens his eyes to pain only. Initial vital signs: T 98.0°F, P 72, BP 118/65 mm Hg, RR 28 breaths/min, O₂ saturation 99% on a non-rebreather mask. Primary survey is within normal limits, secondary survey reveals only superficial abrasions. Initial laboratory data include

ABG: pH 7.36, Pco₂ 38 mm Hg, Pao₂ 173 mm Hg, HCO₃⁻ 20 mmol/L

$$\begin{array}{r} \begin{array}{c} 14.1 \\ \diagdown \quad \diagup \\ 13.2 \times 285 \\ \diagup \quad \diagdown \\ 41.1 \end{array} \quad \begin{array}{c} 145 \mid 102 \mid 18 \\ 4.2 \mid 21 \mid 0.82 \end{array} < 97 \end{array}$$

CPK 125

Serum salicylate 824 mg/L (normal 30-300 mg/L)

Based on this patient's history, examination findings and laboratory data, what is this patient's acid-base derangement?

- A. No disorder
 B. Respiratory acidosis with appropriate renal compensation
 C. Anion gap metabolic acidosis with appropriate respiratory compensation
 D. Nonanion gap metabolic acidosis with appropriate respiratory compensation
 E. Mixed metabolic acidosis and metabolic alkalosis
2. A 54-year-old alcoholic man is discovered to have a new gastric cancer. He reports 15 lb weight loss over the past month. Laboratory data includes an albumin of 2.4 g/dL, indicating significant longstanding malnutrition. Postoperatively, which of the following electrolyte derangements would be of initial concern, especially when he starts to eat or receive some other form of nutrition?
- A. Hypophosphatemia
 B. Hyperphosphatemia
 C. Hypermagnesemia
 D. Hyponatremia
 E. Hyperkalemia
3. A 70-year-old man undergoes a laparoscopic cholecystectomy for acute cholecystitis. On postoperative day 1 he complains of light-headedness while attempting to transfer from his bed to a chair. His vital signs include T 99.1°F, P 82, BP 109/63 mm Hg, RR 14 breaths/min, O₂ saturation 99% on room air. The nurse informs you

that he has had poor enteral intake since the operation, and his urine output has diminished to 10 mL/h. She also informs you that his intravenous access was lost soon after his surgery and was never reestablished. His BUN and Cr preoperatively were 16 mg/dL and 0.8 mg/dL, respectively. Laboratory data include

Urine Na 153 mmol/L Urine Cr 284 mg/dL

You suspect the cause of his orthostasis and oliguria is hypovolemia. Which of the following findings would most strongly confirm your hypothesis?

$$\begin{array}{r} 139 \mid 99 \mid 32 \\ 3.6 \mid 24 \mid 1.47 \end{array} < 88$$

- A. BUN:Cr ratio < 20
 B. Fractional excretion of sodium (FENa) > 1%
 C. FENa < 1%
 D. Renal ultrasonography demonstrating normal kidney parenchyma and vasculature
 E. Fractional excretion of urea nitrogen (FEUN) > 35%

4. A 19-year-old woman arrives in the trauma bay after a helmeted motorcycle crash. She is hemodynamically unstable, and immediately taken to the operating room. Exploratory laparotomy reveals 3 L of hemoperitoneum, a grade 5 splenic laceration, and a grade 3 liver laceration. A splenectomy is performed and the liver laceration is packed. Inspection of the rest of the abdomen reveals no additional injuries. Two hours into the case anesthesia alerts you that her temperature is 93°F and her pH is 7.2; thus you decide to suspend the operation, leave her abdomen open, and admit her to the surgical intensive care unit (SICU) for resuscitation before returning to the operating room. Despite aggressive resuscitation with packed red blood cells (PRBCs) and other blood products, she remains hemodynamically unstable. Pelvic angiography reveals a bleeding right inferior gluteal artery, which is embolized. She is returned to the SICU for further resuscitation. You take over her care at this point, and notice that she has received 21 units of PRBCs, 19 units of fresh frozen plasma, and 20 units of platelets, but has not had her serum electrolytes checked in 5 hours. Which of the following electrolyte disorders is she most at risk for?
- A. Hypocalcemia
 B. Hypomagnesemia
 C. Hyperkalemia
 D. All of the above
 E. None of the above
5. A 61-year-old woman undergoes a sigmoid colectomy for perforated sigmoid diverticulitis. Postoperatively she is transferred to the surgical intensive care unit, still

intubated and mechanically ventilated. On postoperative day 3 she develops an ileus, and her orogastric tube is put to low wall suction. On postoperative day 8 she develops hypotension and tachycardia to 140 beats/min, and requires a norepinephrine infusion to maintain adequate mean arterial blood pressure. Laboratory data includes

13.4	8.1	147	139	101	34	88
25.2	3.4	22	1.2			

ABG 7.32/40/154/20

What is the most likely explanation for her acid-base disorder?

- A. AG metabolic acidosis with adequate respiratory compensation
- B. Mixed metabolic alkalosis and AG metabolic acidosis
- C. Metabolic alkalosis with respiratory compensation
- D. Mixed metabolic alkalosis and respiratory acidosis
- E. Mixed AG metabolic acidosis and respiratory alkalosis

Surgical Metabolism & Nutrition

Thomas M. Shary, MD
Emily A. Chapman, RD, LD, CNSC
Virginia M. Herrmann, MD

10

The effects of malnutrition on the surgical patient are well characterized in the literature but are often overlooked in the clinical arena. Between 30% and 50% of hospitalized patients are malnourished. Protein-calorie malnutrition produces a reduction in lean muscle mass, alterations in respiratory mechanics, impaired immune function, and intestinal atrophy. These changes result in diminished wound healing, predisposition to infection, and increased postoperative morbidity. Although most healthy individuals can tolerate up to 7 days of starvation (with adequate glucose and fluid replacement), those subjected to major trauma, the physiologic stress of surgery, sepsis, or cancer-related cachexia require earlier nutritional intervention. Methods to identify those at greatest need for supplemental nutrition and to adequately address their needs are discussed in this chapter.

NUTRITIONAL ASSESSMENT

Nutrition screening is the process of identifying patients who are either malnourished or at risk for developing malnutrition. Major trauma and surgical stress alter the intake and absorption of nutrients, as well as their utilization and storage by the body. In select patients (eg, those with severe malnutrition as determined below), preoperative nutritional support has been shown to significantly reduce perioperative morbidity and mortality. Although most patients do not require this level of support, nutrition screening is imperative to identify the patient at high risk for malnutrition or its sequelae. A comprehensive nutritional assessment incorporates the initial history, physical examination, and laboratory testing to provide a snapshot of the patient's recent nutritional health.

► History & Physical Examination

The history and physical examination are the foundation of nutritional assessment. A complete medical history is essential to identify factors that predispose the patient to alterations in

nutritional status (Table 10–1). Chronic illnesses such as alcoholism are commonly associated with protein-calorie malnutrition as well as vitamin and mineral deficiencies. Previous operative procedures such as gastrectomy or ileal resection may predispose to generalized malabsorption or isolated deficiency of iron, vitamin B₁₂, or folate. In most cases, the possibility of malnutrition is suggested by the underlying disease or by a history of recent weight loss. Patients with renal failure who require hemodialysis lose amino acids, vitamins, trace elements, and carnitine in the dialysate. Cirrhotics often suffer from whole-body sodium overload despite being hyponatremic, and they are typically protein-deficient. Patients with inflammatory bowel disease, particularly those with ileal involvement, may develop protein deficiency due to a combination of poor intake, chronic diarrhea, and treatment with corticosteroids. Furthermore, alterations in the enterohepatic circulation of bile salts lead to fat, vitamin, calcium, magnesium, and trace element deficiencies. Approximately 30% of patients with cancer have protein, calorie, and vitamin deficiencies due either to the underlying disease or to antimetabolite chemotherapy (eg, methotrexate). Patients infected with HIV are frequently malnourished and have protein, trace metal (selenium and zinc), mineral, and vitamin deficiencies.

A complete history of current medications is essential to alert caregivers to potential underlying deficiencies and drug-nutrient interactions. Although rarely the sole cause of malnutrition, certain over-the-counter herbal preparations can alter nutrient absorption. Agents containing ephedra and caffeine may be abused to induce excessive weight loss. Ginkgo and other preparations enhance cytochrome p450 metabolism of various drugs. Information about socioeconomic factors and a detailed dietary history may uncover other risk factors.

A careful physical examination begins with an overall assessment of the patient's appearance. Patients with severe malnutrition may appear frankly emaciated, but more subtle signs of malnutrition include temporal muscle wasting, skin pallor, edema, and generalized loss of body fat. Protein status

Table 10–1. Nutritional assessment.**History (Factors Predisposing to Malnutrition)**

Absorption disorders (eg, celiac sprue)
 AIDS
 Alcoholism
 Chronic renal insufficiency
 Cirrhosis
 Diabetes mellitus
 Enteric obstruction
 Inflammatory bowel disease
 Malignancy
 Past surgical history, especially involving gastrointestinal tract
 Prolonged starvation
 Psychiatric disorders (eg, anorexia nervosa)
 Recent major surgery, trauma, or burn
 Severe cardiopulmonary disease

Physical Examination

Skin: Quality, texture, rash, follicles, hyperkeratosis, nail deformities
 Hair: Quality, texture, recent loss
 Eyes: Keratoconjunctivitis, night blindness
 Mouth: Cheilosis, glossitis, mucosal atrophy (eg, temporal wasting), dentition
 Heart: Chamber enlargement, murmurs
 Abdomen: Hepatomegaly, abdominal mass, ostomy, fistulas
 Rectum: Stool color, perineal fistula, Guaiac test
 Neurologic: Peripheral neuropathy, dorsolateral column deficit, mental status
 Extremities: Muscle size and strength, pedal edema

Laboratory Tests

CBC: Hemoglobin, hematocrit, mean corpuscular volume (MCV), white blood cell count and differential, total lymphocyte count, platelet count
 Electrolytes: Sodium, potassium, chloride, calcium, phosphate, magnesium
 Liver function tests: AST (SGOT), ALT (SGPT), alkaline phosphatase, bilirubin, albumin, prealbumin, retinol-binding protein, prothrombin/INR
 Miscellaneous: BUN, creatinine, triglycerides, cholesterol, free fatty acids, ketones, uric acid, calcium, copper, zinc, magnesium, transferrin

is evaluated from the bulk and strength of the extremity muscles and visible evidence of temporal and thenar muscle wasting. Cardiac flow murmurs may result from anemia. Vitamin deficiencies may be indicated by changes in skin texture, the presence of follicular plugging or a skin rash, corneal vascularization, cracks at the corners of the mouth (cheilosis), hyperemia of the oral mucosa (glossitis), cardiac enlargement, altered sensation in the hands and feet, absence of vibration and position sense (dorsal and lateral column deficits), or abnormal quality and texture of the hair. Trace metal deficiencies produce cutaneous and neurologic abnormalities similar to those associated with vitamin deficiency and may cause changes in the mental status of the patient.

▶ Anthropometric Measurements

Anthropometry is the science of assessing body size, weight, and proportions. Anthropometric measurements gauge body weight and composition with the intent of providing specific information about lean body mass and fat stores. Body composition studies may be used to determine total body water, fat, nitrogen, and potassium. Anthropometric measurements that can be easily performed in the clinic or at the bedside include determination of height and weight, with calculation of body mass index (BMI). Additional measurements such as arm span, body part summation, or knee-height measurement can also be used in nutrition assessment. More advanced techniques allow the clinician to assess the patient's visceral and somatic protein mass and fat reserve. Accurate weight is important, as is current weight expressed as a percentage of ideal body weight. Ideal body weight values are taken from the 1983 Metropolitan Height-Weight Tables.

The BMI is used to measure protein-calorie malnutrition as well as overnutrition (eg, obesity). A BMI between 18.5 and 24.9 is considered normal in most Western civilizations. Overweight is defined as a BMI from 25 to 29.9, and a BMI greater than 30 defines obesity. BMI is calculated as follows:

$$\text{BMI} = \frac{\text{Weight (kg)}}{\text{Height (m)}^2} = 703 \times \frac{\text{Weight (lb)}}{\text{Height (in)}^2}$$

Dual-energy x-ray absorptiometry (DEXA) is increasingly available in hospitals and can be used to assess various body compartments (mineral, fat, lean muscle mass). Most protein resides in skeletal muscle. Somatic (skeletal) protein reserve is estimated by measuring the mid-humeral circumference. This measurement is corrected to account for subcutaneous tissue, yielding the mid-humeral muscle circumference (MHMC). The result is compared with normal values for the patient's age and gender to determine the extent of protein depletion. Fat reserve is commonly estimated from the thickness of the triceps skin fold (TSF). Reliability of anthropometric measurements is dependent on the skill of the person performing the measurement and is subject to error if performed by different caregivers on the same patient.

▶ Laboratory Data

The visceral protein reserve is estimated from various serum protein levels, total lymphocyte count, and antigen skin testing (Table 10–2). The serum albumin level provides a rough estimate of the patient's nutritional status but is a better prognostic indicator than tool for nutritional assessment. Serum albumin less than 3.5 mg/dL correlates with increased perioperative morbidity and mortality and increased length of hospital stay. Because albumin has a relatively long half-life (20 days), other serum proteins with shorter half-lives have greater utility for assessing response to nutritional repletion. Transferrin has a shorter half-life of 8–10 days and is a

Table 10–2. Staging of malnutrition.

Clinical & Laboratory Parameters	Extent of Malnutrition		
	Mild	Moderate ¹	Severe ¹
Albumin (g/dL)	2.8-3.5	2.1-2.7	< 2.1
Transferrin (mg/dL)	200-250	100-200	< 100
Prealbumin (mg/dL)	10-17	5-10	< 5
Retinol-binding protein (mg/dL)	4.1-6.1 (normal)	< 4.1	
Total lymphocyte count (cells/ μ L)	1200-2000	800-1200	< 800
Creatinine-height index (%)	60-80	40-60	< 40
Ideal body weight (%)	80-90	70-80	< 70
Weight loss/time	< 5%/month < 7.5%/3 months < 10%/6 months	< 2%/week > 7.5%/3 months > 10%/6 months	> 2%/week
Skin antigen testing (No. reactive/No. placed)	4/4 (normal)	1-2/4 (weak)	0/4 (anergic)
Anthropometric Measurements	Male	Female	
Triceps skin fold (mm)	\leq 12.5	\leq 16.5	
Mid-humeral circumference (cm)	> 29	> 28.5	

¹Nutritional supplementation is indicated.

more sensitive indicator of adequate nutrition repletion than albumin. Prealbumin has a half-life of 2-3 days, and retinol-binding protein has a half-life of 12 hours. Unfortunately, their serum levels are also influenced by other factors, limiting their utility in assessing nutritional status or repletion.

Immune function may be assessed by hypersensitivity skin testing as well as total lymphocytic count, a reflection of T- and B-cell status. Subcutaneous injection of common antigens provides a semiobjective assessment of the antibody-mediated immune response, commonly impaired in malnourished patients. A low total lymphocyte count (TLC) correlates directly with the degree of malnutrition, though the count may be altered by infection, chemotherapy, and other factors, thus limiting its usefulness.

► Nutritional Indices

Indices provide a means of risk-stratification and objective comparison among patients (Table 10–3). Additionally, many nutritional indices have been prospectively validated and can provide prognostic information to further guide nutrition support services. Along with the BMI, these indices can assist surgeons in determining the correct timing for intervention and the progress being made toward the goal of adequate nourishment.

A. Creatinine-Height Index

Creatinine-height index (CHI) may be used to determine the degree of protein malnutrition, although it is less valid in patients who are severely catabolic or have chronic renal disease. A 24-hour urinary creatinine excretion is measured and compared with normal standards. CHI is calculated by the following equation:

$$\text{CHI} = \frac{\text{Actual 24 - hour urine creatine excretion}}{\text{Predicted creatine excretion}}$$

The urinary excretion of 3-methylhistidine is a more precise measurement of lean body mass and associated protein stores. The amino acid histidine is irreversibly methylated in muscle. During protein turnover, 3-methylhistidine is not reutilized for synthesis, so the urinary excretion of this compound correlates well with muscle protein breakdown. Unfortunately, measurement of 3-methylhistidine is too expensive for use as a routine clinical test.

B. Prognostic Nutrition Index

The prognostic nutrition index (PNI) has been validated in patients undergoing either major cancer or gastrointestinal

Table 10–3. Nutritional indices.

Body Mass Index (BMI)	
$BMI = \text{weight (kg)} / [\text{height (m)}]^2 = 703 \times \text{weight (lbs)} / [\text{height (in)}]^2$	
Normal	18.5–24.9
Overweight	25–29.9
Obese	30–40
Morbid obesity	> 40
Prognostic Nutritional Index (PNI)	
$PNI = 158 - [16.6 \times \text{Alb}^1] - [0.78 \times \text{TSF}^2] - [0.2 \times \text{TFN}^3] - [5.8 \times \text{DH}^4]$	
Note: for DH, > 5 mm induration = 2; 1–5 mm induration = 1; anergy = 0	
Risk for complications:	
Low	< 40%
Intermediate	40–49%
High	> 50%
Nutrition Risk Index (NRI)	
$NRI = [15.19 \times \text{Alb}] + 41.7 \times [\text{actual weight (kg)} / \text{ideal weight (kg)}]$	
Well-nourished	> 100
Mild malnutrition	97.5–100
Moderate malnutrition	83.5–97.5
Severe malnutrition	< 83.5
Malnutrition Universal Screening Tool (MUST)	
BMI score: weight loss score (unplanned weight loss): BMI > 20 (> 30 obese) = 0; weight loss < 5% = 0 BMI 18.5–20 = 1; weight loss 5–10% = 1 BMI < 18.5 = 2; weight loss > 10% = 2	
Acute disease effect: add 2 if there has been or is likely to be no nutritional intake for > 5 days.	
Risk of malnutrition: 0 = low risk; 1 = medium risk; ≥ 2 = high risk	
Geriatric Nutrition Risk Index (GNRI)	
$GNRI = [1.489 \times \text{albumin (g/L)}] + [41.7 \times (\text{weight}/\text{WLo})]$	
The GNRI results from replacement of ideal weight in the NRI formula by usual weight as calculated from the Lorentz formula (WLo). Four grades of nutrition-related risk: major risk (GNRI < 82), moderate risk (GNRI 82–91), low risk (GNRI 92 to ≤ 98), no risk (GNRI > 98).	
Instant Nutritional Assessment Parameters (INA)	
Parameter: abnormal if Serum albumin < 3.5 g Total lymphocyte count < 1500/mm ³	

¹Alb, albumin (g/dL).²TSF, triceps skin fold (mm).³TFN, transferrin (mg/dL).⁴DH, delayed cutaneous hypersensitivity.

surgery and found to accurately identify a subset of patients at increased risk for complications. Furthermore, preoperative nutritional repletion has been shown to reduce postoperative morbidity in this patient group. The PNI has been widely adapted to identify patients at risk in nonsurgical populations, who may benefit from nutritional support.

C. Nutrition Risk Index

The nutrition risk index (NRI) was used by the VA TPN Cooperative Study Group for determining preoperative malnutrition, and it has since been prospectively cross-validated against other nutritional indices with good results. The index successfully stratifies perioperative morbidity and mortality using serum albumin and weight loss as predictors of malnutrition. Of note, the NRI is not a tool for tracking the adequacy of nutritional support, since supplemental nutrition often fails to improve serum albumin levels.

D. Subjective Global Assessment

Subjective global assessment (SGA) is a clinical method that has been validated as reproducible and that encompasses the patient's history and physical examination. It is based on five features of the medical history (weight loss in the past 6 months, dietary intake, gastrointestinal symptoms, functional status or energy level, and metabolic demands) along with four features of the physical examination (loss of subcutaneous fat, muscle wasting, edema, and ascites). Limitations of the SGA include its focus on chronic instead of acute nutritional changes and its enhanced specificity at the expense of sensitivity.

E. Mini-Nutritional Assessment

The mini-nutritional assessment (MNA) is a rapid and reliable tool for evaluating the nutritional status of the elderly. It is composed of 18 items and takes approximately 15 minutes to complete. The assessment includes an evaluation of a patient's health, mobility, diet, anthropometrics, and a subject self-assessment. An MNA score of 24 or higher indicates no nutritional risk, while a score of 17–23 indicates a potential risk of malnutrition and a score of less than 17 indicates definitive malnutrition.

F. Malnutrition Universal Screening Tool

The malnutrition universal screening tool (MUST) detects protein-energy malnutrition and identifies individuals at risk of developing malnutrition using three independent criteria: current weight status, unintentional weight loss, and acute disease effect. The patient's current body weight is determined by calculating the BMI (kg/m²). Weight loss (over the past 3–6 months) is determined by looking at the individual's medical record. An acute disease factor is then included if the patient is currently affected by a pathophysiologic

condition and there has been no nutritional intake for more than 5 days. A total score is calculated placing the patients in a low, medium, or high category for risk of malnutrition. A major advantage of this screening tool is its applicability to adults of all ages across all health care settings. Additionally, this method provides the user with management guidelines once an overall risk score has been determined. Studies have shown that MUST is quick and easy to use and has good concurrent validity with most other nutrition assessment tools tested.

G. Geriatric Nutritional Risk Index

The geriatric nutritional risk index (GNRI) is adapted from the NRI and is specifically designed to predict the risk of morbidity and mortality in hospitalized elderly patients. The GNRI is calculated using a formula incorporating both serum albumin and weight loss. After determining the GNRI score, patients are categorized into four grades of nutrition-related risk: major, moderate, low, and no risk. Finally, the GNRI scores are correlated with a severity score that takes into account nutritional status-related complications. The GNRI is not an index of malnutrition but rather a “nutrition-related” risk index.

H. Instant Nutritional Assessment

The quickest and simplest measure of nutritional status is the instant nutritional assessment (INA). Serum albumin level and the TLC form the basis of this evaluation. Significant correlations between depressed levels of these parameters and morbidity and mortality have been noted. Not surprisingly, abnormalities of these same parameters are even more significant in critically ill patients. Although not designed to replace more extensive assessment measures, this technique allows for quick identification and early intervention in those individuals in greatest danger of developing complications of malnutrition.

► Determining Energy Requirements

Adult basal energy expenditure (BEE) is calculated using a modification of the Harris-Benedict equation (Table 10-4). This calculation includes four variables: height (cm), weight (kg), gender, and age (y). Total energy expenditure (TEE) represents the caloric demands of the body under certain physiologic stresses. TEE is determined by multiplying BEE by a disease-specific stress factor. TEE should be used to guide nutritional supplementation.

Indirect calorimetry is the most accurate method for direct measurement of daily caloric requirements. Using a metabolic cart, oxygen consumption ($\dot{V}O_2$) and carbon dioxide production ($\dot{V}CO_2$) are directly measured from the patient's pulmonary gas flow. Based on these measurements and the amount of nitrogen excreted in the urine, the resting

Table 10-4. Total energy expenditure equation for adults.

Basal energy expenditure (BEE) in kcal/day	
Male:	$66.4 + [13.7 \times \text{weight (kg)}] + [5.0 \times \text{height (cm)}] - [6.8 \times \text{age (yrs)}]$
Female:	$655 + [9.6 \times \text{weight (kg)}] + [1.7 \times \text{height (cm)}] - [4.7 \times \text{age (yrs)}]$
Stress factors	
Starvation	0.80-1.00
Elective surgery	1.00-1.10
Peritonitis	1.05-1.25
Adult respiratory distress syndrome (ARDS) or sepsis	1.30-1.35
Bone marrow transplant	1.20-1.30
Cardiopulmonary disease (uncomplicated)	0.80-1.00
Cardiopulmonary disease with dialysis or sepsis	1.20-1.30
Cardiopulmonary disease with major surgery	1.30-1.55
Acute renal failure	1.30
Liver failure	1.30-1.55
Liver transplantation	1.20-1.50
Pancreatitis or major burns	1.30-1.80
Total energy expenditure (TEE) in kcal/day	
TEE = BEE \times stress factor	

energy expenditure (REE) can be derived using the Weir formula as follows:

$$\text{REF (Kcal/min)} = 3.9 (\dot{V}O_2) + 1.1 (\dot{V}CO_2) - 2.2 (\text{urine nitrogen})$$

where $\dot{V}O_2$ and $\dot{V}CO_2$ are expressed in milliliters per minute and urine nitrogen is in grams per minute. The utility of this technique is limited by the expense and cumbersome nature of the metabolic cart.

The respiratory quotient (RQ) is the ratio of carbon dioxide production to oxygen consumption in the metabolism of fuels by the body. When the RQ is 1, pure carbohydrate is being oxidized. Patients metabolizing lipids only will have an RQ of 0.67. Lipogenesis occurs in patients with excess caloric intake (overfeeding). When excessive calories are ingested or administered, the RQ is greater than 1 and can theoretically approach 9. The excess production of CO_2 may impair ventilator weaning in patients, particularly those with intrinsic lung disease (eg, chronic obstructive pulmonary disease).

NUTRIENT REQUIREMENTS & SUBSTRATES

The body requires an energy source to remain in steady state. About 50% of the basal metabolic rate (BMR) reflects the work of ion pumping, 30% represents protein turnover, and the remainder is expended on recycling of amino acids, glucose, lactate, and pyruvate. Total energy expenditure is the sum of energy consumed by basal metabolic processes, physical activity, the specific dynamic action of protein, and extra requirements resulting from injury, sepsis, or burns.

Energy consumed in physical activity constitutes 10%-50% of the total in normal subjects but decreases to 10%-20% for hospitalized patients. Energy expenditure and requirements vary, depending on the illness or trauma. The increase in energy expenditure above basal needs is about 10% for elective operations, 10%-30% for trauma, 50%-80% for sepsis, and 100%-200% for burns (depending on the extent of the wound). Metabolic energy can be derived from carbohydrates, proteins, or fats.

► Carbohydrate Metabolism

Carbohydrates are the body's primary fuel source, accounting for 35% of total caloric intake. Each gram of enteric carbohydrate provides 4.0 kilocalories (kcal) of energy. Parenterally administered carbohydrates (eg, intravenous dextrose) yield 3.4 kcal/g.

Carbohydrate digestion is initiated by salivary amylase, and absorption occurs within the first 150 cm of the small intestine. Salivary and pancreatic amylases cleave starches into oligosaccharides. Surface oligosaccharidases then hydrolyze and transport these molecules across the gastrointestinal tract mucosa. Deficiencies in carbohydrate digestion and absorption are rare in surgical patients. Pancreatic amylase is abundant, and maldigestion of starch is unusual, even in patients with limited pancreatic exocrine function. Patients with diseases such as celiac sprue, Whipple disease, and hypogammaglobulinemia often have generalized intestinal mucosal flattening leading to oligosaccharidase deficiency and diminished carbohydrate uptake.

More than 75% of ingested carbohydrate is broken down and absorbed as glucose. Hyperglycemia stimulates insulin secretion from pancreatic β cells, which stimulates protein synthesis. Intake of 400 kcal of carbohydrate per day minimizes protein breakdown, particularly after adaptation to starvation. Cellular uptake of glucose, stimulated by insulin, inhibits lipolysis and promotes glycogen formation. Conversely, pancreatic glucagon is released in response to starvation or stress; it promotes proteolysis, glycogenolysis, lipolysis, and increased serum glucose. Glucose is vital for wound repair, but excessive carbohydrate intake or repletion with excessive amounts of glucose can cause hepatic steatosis and neutrophil dysfunction.

► Protein Metabolism

Proteins are composed of amino acids, and protein metabolism produces 4.0 kcal/g. Digestion of proteins yields single amino acids and dipeptides, which are actively absorbed by the gastrointestinal tract. Gastric pepsin initiates digestion. Pancreatic proteases, activated by enterokinase in the duodenum, are the principal effectors of protein degradation. Once digested, half of protein absorption occurs in the duodenum, and complete protein absorption is achieved by the mid-jejunum.

Table 10-5. Nitrogen balance.

$$\begin{aligned} \text{Nitrogen}_{(\text{balance})} &= \text{Nitrogen}_{(\text{intake})} - \text{Nitrogen}_{(\text{output})} \\ \text{Nitrogen}_{(\text{intake})} &= \text{g protein}_{(\text{intake})} / 6.25 \\ \text{Nitrogen}_{(\text{output})} &= (\text{UUN} \times \text{Vol}) + 3 \end{aligned}$$

UUN, urine urea nitrogen; Vol, volume of urine produced over the time of measurement.

Protein absorption occurs efficiently throughout the small intestine; therefore, protein malabsorption is relatively infrequent even after extensive intestinal resection. Protein balance reflects the sum of protein synthesis and degradation. Because protein turnover is dynamic, the published requirements for protein, amino acids, and nitrogen are only approximations.

Total body protein in a 70-kg person is approximately 10 kg, predominantly in skeletal muscle. Daily protein turnover is 300 g, or roughly 3% of total body protein. The daily protein requirement in healthy adults is 0.8 g/kg body weight. In the United States, the typical daily intake averages twice this amount. Protein synthesis or breakdown can be determined by measuring the nitrogen balance (Table 10-5). Protein intake of 6.25 g is equivalent to 1 g of nitrogen. Nitrogen intake is the sum of nitrogen delivered from enteric and parenteral feeding. Nitrogen output is the sum of nitrogen excreted in the urine and feces, plus losses from drainage (eg, exudative wounds, fistula). Urea nitrogen losses are determined from a 24-hour urine collection. Fecal nitrogen loss can be approximated by 1 g/d, and an additional 2-3 g/d of nonurea nitrogen loss occurs in the urine (eg, ammonia). The accuracy of nitrogen balance calculations can be improved through measurement over several weeks. When losses of nitrogen are large (eg, diarrhea, protein-losing enteropathy, fistula, or burn exudate), measurements of nitrogen balance lose accuracy because of the difficulty in collecting secretions for nitrogen measurement. Despite these shortcomings, 24-hour urine collection is the best practical means of measuring net protein synthesis and breakdown.

The 20 amino acids are divided into essential amino acids (EAAs) and nonessential amino acids (NEAAs) depending on whether they can be synthesized *de novo* in the body. They are further divided into aromatic (AAAs), branched chain (BCAAs), and sulfur-containing amino acids. Only the L-isotype of an amino acid is utilized in human protein. Certain amino acids have unique metabolic functions, particularly during starvation or stress. Alanine and glutamine preserve carbon during starvation, and leucine stimulates protein synthesis and inhibits catabolism. Specific amino acids are addressed below.

A. Glutamine

As the respiratory fuel for enterocytes, glutamine plays an important role in the metabolically stressed patient.

Following injury and other catabolic events, intracellular glutamine stores may decrease by over 50% and plasma levels by 25%. The decline of glutamine associated with injury or stress exceeds that of any other amino acid and persists during recovery after the concentrations of other amino acid have normalized. Supplementation with glutamine maintains intestinal cell integrity, villous height, and mucosal DNA activity and helps minimize reduction in numbers of T and B cells during stress.

Catabolic states are characterized by accelerated skeletal muscle proteolysis and translocation of amino acids from the periphery to the visceral organs. Glutamine accounts for a major portion of the amino acids released by muscle in these states. Intravenous supplementation with glutamine may improve neutrophil and macrophage function as well as decrease bacterial translocation across the intestinal mucosal barrier in burn and other critically ill patients. However, the utility of enteral supplementation remains controversial.

B. Arginine

Arginine is a substrate for the urea cycle and nitric oxide production and a secretagogue for growth hormone, prolactin, and insulin. Arginine has been identified as the sole precursor of nitric oxide (endothelial-derived relaxing factor). The effects of arginine on T cells may be very important in maintaining the gut barrier. Formulas supplemented with arginine have been shown to improve nitrogen balance and wound healing, promote T-cell proliferation, enhance neutrophil phagocytosis, and reduce production of inflammatory mediators and infectious complications.

▶ Lipid Metabolism

Lipids comprise 25%-45% of caloric intake in the typical diet. Each gram of lipid provides 9.0 kcal of energy. The introduction of fat to the duodenum results in secretion of cholecystokinin and secretin, leading to gallbladder contraction and pancreatic enzyme release. Reabsorption of bile salts in the terminal ileum (eg, the enterohepatic circulation) is necessary to maintain the bile salt pool. The liver is able to compensate for moderate intestinal bile salt losses by increased synthesis from cholesterol. Ileal resection may lead to depletion of the bile salt pool and subsequent fat malabsorption. Lipolysis is stimulated by steroids, catecholamines, and glucagon but is inhibited by insulin.

The body can synthesize fats from other dietary substrates, but two of the long-chain fatty acids (linoleic and linolenic) are essential. Insufficient intake of these essential fats leads to fatty acid deficiency and can be prevented by supplying a minimum of 3% of the total caloric intake as essential fatty acids.

The polyunsaturated fatty acids (PUFAs) are grouped into two families: ω -6 and ω -3 fatty acids. Linoleic acid

is an example of the ω -6 PUFAs; ω -linolenic acid of the ω -3 PUFAs. Both linoleic and linolenic acid can be processed into arachidonic acid, a precursor in the synthesis of eicosanoids.

Eicosanoids are potent biochemical mediators of cell-to-cell communication and are involved in inflammation, infection, tissue injury, and immune system modulation. They also modulate numerous events involving cell-mediated and humoral immunity and can be synthesized in varying amounts by immune cells, particularly macrophages and monocytes.

Medium-chain fatty acids are not components of most oral diets but are widely used in enteral tube feedings. They are easily digested, absorbed, and oxidized and are not precursors to the inflammatory or immunosuppressive eicosanoids. Short-chain fatty acids, such as butyrate and to a lesser extent propionate, are utilized by colonocytes and provide up to 70% of their energy requirements. Since butyrate is not synthesized endogenously, the colonic mucosa relies on intraluminal bacterial fermentation to obtain this fuel.

▶ Nucleotides, Vitamins, & Trace Elements

In addition to the principal sources of metabolic energy (calories), many other substances are necessary to ensure adequate nutrition. Nucleotides are recognized as an important nutritional substrate in critically ill patients. Vitamins are essential for normal metabolism, wound healing, and immune function, and cannot be synthesized *de novo*. The normal requirements for vitamins are shown in Table 10-6. Vitamin requirements may increase acutely in illness. Trace elements are integral cofactors for many enzymatic reactions and are generally not stored by the body in excess of requirements.

A. Nucleotides

Nucleic acids are precursors of DNA and RNA and are not normally considered essential for human growth and development. The need for dietary nucleotides increases in severe stress and critical illness. Nucleotides are formed from purines and pyrimidines, and their abundance is especially important for rapidly dividing cells such as enterocytes and immune cells. Immunosuppression has been reported in renal transplant patients being maintained on nucleotide-free diets. Dietary nucleotides are necessary for helper-inducer T-lymphocyte activity. Diets supplemented with RNA or the pyrimidine uracil have been shown to restore delayed hypersensitivity and augment both the lymphoproliferative response and IL-2 receptor expression. Nucleotides may facilitate recovery from infection. These substrates are often incorporated into enteral formulas as potential immunomodulators.

Table 10–6. Daily electrolyte, trace element, vitamin, and mineral requirements for adults.

B. Fat-Soluble Vitamins

Vitamins A, D, E, and K are fat soluble and are absorbed in the proximal small bowel in association with bile salt micelles and fatty acids. After absorption, they are delivered to the tissues in chylomicrons and stored in the liver (vitamins A and K) or subcutaneous tissue and skin (vitamins D and E). Although rare, there are reports of toxicity from excessive intake of fat-soluble vitamins (eg, hypervitaminosis A from consuming polar bear liver). Fat-soluble vitamins participate in immune function and wound healing. For example, intake of vitamin A 25,000 IU daily counteracts steroid-induced inhibition of wound healing, largely through increases in TBG-β.

C. Water-Soluble Vitamins

Vitamins B₁, B₂, B₆, and B₁₂, vitamin C, niacin, folate, biotin, and pantothenic acid are absorbed in the duodenum and proximal small bowel, transported in portal vein blood, and utilized in the liver and peripherally. Water-soluble vitamins serve as cofactors to facilitate reactions involved in the generation and transfer of energy and in amino acid and nucleic acid metabolism. Water-soluble vitamins have limited storage in the body. Because of their limited storage, water-soluble vitamin deficiencies are relatively common.

D. Trace Elements

The daily requirements for the trace elements (Table 10–6) vary geographically depending on differences in soil composition. There are currently nine identified essential trace minerals (Fe, Zn, Cu, Se, Mn, I, Mb, Cr, Co). Trace elements have important functions in metabolism, immunology, and wound healing. Subclinical trace element deficiencies occur commonly in hospitalized patients and various disease states.

Iron serves as the core of the heme prosthetic group in hemoglobin and in the mitochondrial cytochrome respiratory process. Impaired cerebral, muscular, and immunologic function can occur in patients with iron deficiency before anemia becomes clinically evident. Particular attention should be paid to assessing iron stores in pregnant and lactating women.

Zinc deficiency is characterized by a perioral pustular rash, darkening of skin creases, neuritis, cutaneous anergy, hair loss, and alterations in taste and smell. Copper deficiency is manifested by microcytic anemia (unresponsive to iron), defective keratinization, or pancytopenia. Chromium deficiency presents as glucose intolerance during prolonged parenteral nutrition administration without evidence of sepsis. Selenium deficiency, which can occur in patients receiving parenteral nutrition for a prolonged period, is manifested by proximal neuromuscular weakness or cardiac failure with electrocardiographic changes. Manganese deficiency is associated with weight loss, altered hair pigmentation, nausea,

and low plasma levels of phospholipids and triglycerides. Molybdenum deficiency results in elevated plasma methionine levels and depressed uric acid concentrations, producing a syndrome consisting of nausea, vomiting, tachycardia, and central nervous system disturbances.

Iodine is a key component of thyroid hormone. Deficiency is rare in the United States because of the use of iodinated salt. Chronically malnourished patients can become iodine-deficient. Since thyroxine participates in the neuroendocrine response to trauma and sepsis, iodine should be included in parenteral nutrition solutions.

NUTRITIONAL PATHOPHYSIOLOGY

Physiologic processes, immunocompetence, wound healing, and recovery from critical illness all depend upon adequate

nutrient intake. A working knowledge of nutritional pathophysiology is essential in planning nutritional regimens.

► Starvation

During an overnight fast, liver glycogen is rapidly depleted after a fall in insulin and parallel rise in plasma glucagon levels (Figure 10–1). Carbohydrate stores are depleted after a 24-hour fast. In the first few days of starvation, caloric needs are met by fat and protein degradation. There is an increase in hepatic gluconeogenesis from amino acids derived from the breakdown of muscle protein. Hepatic glucose production must satisfy the energy demands of the hematopoietic and the central nervous systems, particularly the brain, which is dependent on glucose oxidation during acute starvation. The release of amino acids from muscle is regulated

▲ **Figure 10–1.** The plasma substrate concentrations and hormone levels following an overnight fast. The brain is dependent on glucose, which is supplied predominantly by hepatic glycogenolysis until glycogen supplies are exhausted.

by insulin, which signals hepatic amino acid uptake, polyribosome formation, and protein synthesis. The periodic rise and fall of insulin associated with ingestion of nutrients stimulates muscle protein synthesis and breakdown. During starvation, chronically depressed insulin levels result in a net loss of amino acids from muscle. Protein synthesis drops while protein catabolism remains unchanged. Hepatic gluconeogenesis requires energy, which is supplied by the oxidation of unesterified free fatty acid (FFA). The fall in insulin along with a rise in plasma glucagon levels leads to an increase in the concentration of cyclic adenosine monophosphate (cAMP) in adipose tissue, stimulating hormone-sensitive lipase to hydrolyze triglycerides and release FFA. Gluconeogenesis and FFA mobilization require the presence of ambient cortisol and thyroid hormone (a permissive effect).

During starvation, the body attempts to conserve energy substrate by recycling metabolic intermediates. The hematopoietic system utilizes glucose anaerobically, leading to lactate production. Lactate is recycled back to glucose in the liver via the gluconic (not gluconeogenic) Cori cycle (Figure 10–2). The glycerol released during peripheral triglyceride hydrolysis is converted into glucose via

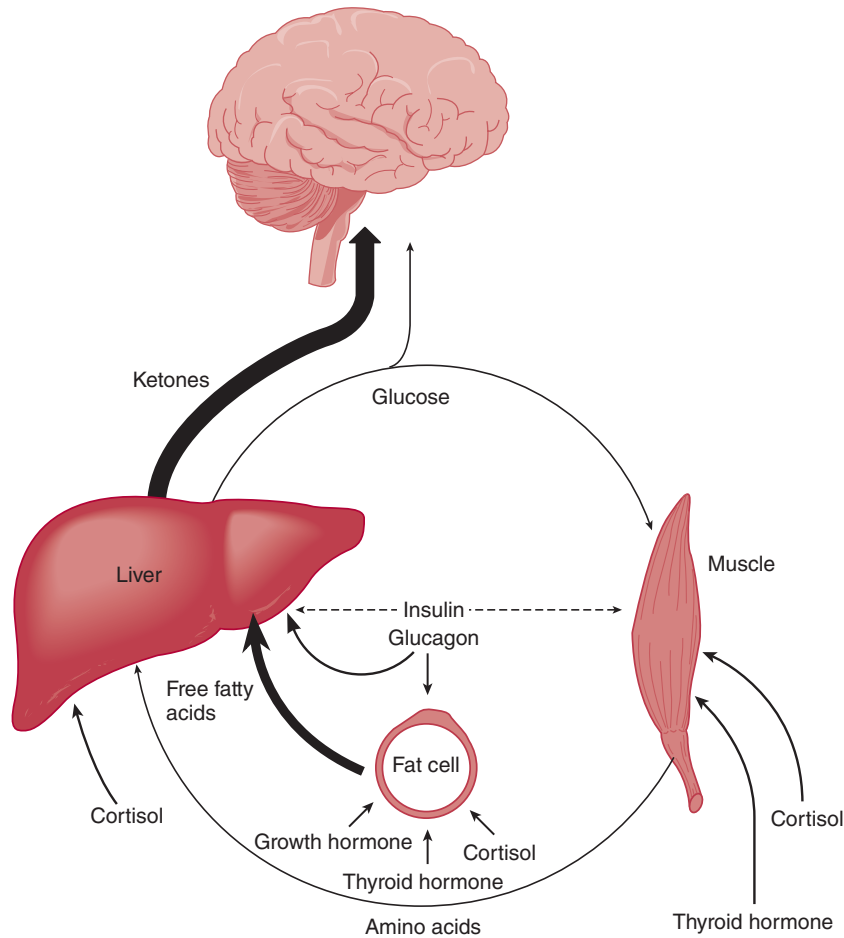

gluconeogenesis. Alanine and glutamine are the preferred substrates for hepatic gluconeogenesis from amino acids and contribute 75% of the amino acid–derived carbon for glucose production.

BCAAs are unique because they are secreted rather than taken up by the liver during starvation; they are oxidized by skeletal and cardiac muscle to supply a portion of the energy requirements of these tissues; and they stimulate protein synthesis and inhibit catabolism. The amino groups derived from oxidation of BCAAs or transamination of other amino acids are donated to pyruvate or α -ketoglutarate to form alanine and glutamine. Glutamine is taken up by the small bowel, transaminated to form additional alanine, and released into the portal circulation. Along with glucose, these amino acids participate in the glucose-alanine/glutamine-BCAA cycle, which shuttles amino groups and carbon from muscle to liver for conversion into glucose.

Gluconeogenesis from amino acids results in a urinary nitrogen excretion of 8–12 g/d, predominantly as urea, which is equivalent to a loss of 340 g/d of lean tissue. At this rate, 35% of the lean body mass would be lost in 1 month, a uniformly fatal amount. However, starvation can be survived for 2–3 months as long as water is available. The body

▲ **Figure 10–2.** The cycles that preserve metabolic intermediates during fasting. Lactate is recycled to glucose via the Cori cycle, while pyruvate is transaminated to alanine in skeletal muscle and converted to glucose by hepatic gluconeogenesis.

▲ **Figure 10-3.** The metabolic adaptation to chronic starvation whereby the brain shifts its substrate preference to ketones produced by the liver. Hepatic gluconeogenesis falls and protein breakdown is diminished, thus conserving lean tissue.

adapts to prolonged starvation by decreasing energy expenditures and shifting the substrate preference of the brain to ketones (Figure 10-3). After roughly 10 days of starvation, the brain adapts to use lipid as its primary fuel in the form of ketones. The BMR decreases by slowing the heart rate and reducing stroke work, while voluntary activity declines owing to weakness and fatigue. The RQ, which in early starvation is 0.85 (reflecting mixed carbohydrate and fat oxidation), falls to 0.70, indicating near-exclusive fatty acid utilization. Blood ketone levels rise sharply, accompanied by increased cerebral ketone oxidation. Brain glucose utilization drops from 140 g to 60-80 g/d, decreasing the demand for gluconeogenesis. Ketones also inhibit hepatic gluconeogenesis, and urinary nitrogen excretion falls to 2-3 g/d. The main component of urine nitrogen is now ammonia

(rather than urea), derived from renal transamination and gluconeogenesis from glutamine, and it buffers the acid urine that results from ketonuria. Acute or chronic starvation is characterized by hormone and fuel alterations orchestrated by changing blood substrate levels and can be conceptualized as a “substrate-driven” process. In summary, the adaptive changes in uncomplicated starvation are a decrease in energy expenditure (as much as a 30% reduction), a change in type of fuel consumed to maximize caloric potential, and preservation of protein.

► Elective Operation or Trauma

The metabolic effects of both surgical procedures and trauma (Figure 10-4) differ from those of starvation due

▲ **Figure 10-4.** The metabolic response to trauma is a result of neuroendocrine stimulation, which accelerates protein breakdown, stimulates gluconeogenesis, and produces glucose intolerance.

to neurohormonal activation, accelerating the loss of lean tissue and inhibiting metabolic adaptation of starvation. Following injury, neural impulses stimulate the hypothalamus. Norepinephrine is released from sympathetic nerve endings, epinephrine from the adrenal medulla, aldosterone from the adrenal cortex, antidiuretic hormone (ADH) from the posterior pituitary, insulin and glucagon from the pancreas, and corticotropin, thyrotropin, and growth hormone from the anterior pituitary. This results in elevation of serum cortisol, thyroid hormone, and somatomedins. The effects of the heightened neuroendocrine secretion include peripheral lipolysis from activation of lipase by glucagon, epinephrine, cortisol, and thyroid hormone; accelerated catabolism, with a rise

in proteolysis stimulated by cortisol; decreased peripheral glucose uptake due to insulin antagonism by growth hormone and epinephrine.

These effects result in a rise in plasma FFA, glycerol, glucose, lactate, and amino acids. The liver subsequently increases glucose production, as a result of glucagon-stimulated glycogenolysis and enhanced gluconeogenesis induced by cortisol and glucagon.

Accelerated glucose production, along with inhibited peripheral uptake, produces the glucose intolerance commonly observed in traumatized patients. The kidney retains water and sodium due to increases in ADH and aldosterone. Urinary nitrogen excretion increases up to 15-20 g/d following severe trauma, equivalent to a daily lean tissue loss of

750 g. Without exogenous nutrients, the median survival under these circumstances is only 15 days.

In contrast to the substrate dependency of uncomplicated starvation, elective surgical procedures and trauma are “neuroendocrine-driven” processes. In contrast, however, metabolic responses observed following elective procedures are vastly different from those following major trauma. During general anesthesia, the neuroendocrine response is blunted in the operating room through the use of analgesics and immobilization. Sedated patients lack cortical stimulation to the hypothalamus. Careful intraoperative handling of tissues reduces proinflammatory cytokine release. The net result is that the REE rises only 10% in postoperative

patients, compared with up to 30% following severe injury or trauma.

► Sepsis

The metabolic changes during sepsis differ from those observed after acute injury (Figure 10–5). The REE may increase by 50%-80%, and urinary nitrogen excretion can reach up to 30 g/d, predominantly due to profound muscle catabolism and impaired synthesis. Catabolism at this rate results in a median survival of 10 days without nutritional input. The plasma glucose, amino acid, and FFA levels increase more than with trauma. Hepatic protein synthesis is

▲ **Figure 10–5.** During sepsis, cytokines (IL-1, IL-2, TNF) released by lymphocytes and macrophages contribute to catabolism of muscle and adipose tissue and amplify the neurohormonal response to antecedent trauma.

stimulated, with both enhanced secretion of export protein and accumulation of structural protein. The RQ falls to near 0.7, indicative of lipid oxidation. Lipolysis and gluconeogenesis continue despite supplementation with carbohydrate or fat, leading to the hyperglycemia and insulin resistance commonly observed in septic patients.

Sepsis results in elaboration of inflammatory cytokines, most notably TNF- α , IL-1, and IL-6. Alteration in hepatic protein synthesis toward production of acute-phase proteins is triggered by IL-6. Septic patients also develop an abnormal plasma amino acid pattern (increased levels of AAAs and decreased levels of BCAAs). In contrast to simple starvation, protein conservation does not occur in sepsis. Terminal sepsis results in further increases in plasma amino acids and a fall in glucose concentration, as hepatic amino acid clearance declines and gluconeogenesis ceases.

ENTERAL NUTRITIONAL THERAPY

► Enteral Versus Parenteral Nutrition

Enteral nutritional support is safer and less expensive than parenteral nutrition and has the added benefit of preserving gut functionality. Prospective, randomized trials have demonstrated the superiority of enteral nutrition in reducing postoperative complications and length of hospital stay. “Feeding the gut” also results in fewer septic complications. Parenteral nutrition has a role in the management of surgical patients, but utilizing the gastrointestinal tract should remain the preferred treatment option. Enteral supplementation is not risk-free; physicians must know how to prevent and treat the complications associated with enteral feedings to ensure safe and successful administration.

► Benefits of Enteral Feeding

A. Physiologic and Metabolic Benefits

The gastrointestinal tract can be used for administration of complex nutrients, such as intact protein, peptides, and fiber, that cannot be given intravenously. Gut processing of intact nutrients provides a stimulus for hepatic synthetic function of proteins, whereas administration of nutrients directly into the systemic circulation bypasses the portal circulation. In addition to its systemic benefits, enteral feeding has beneficial local effects on gastrointestinal mucosa. These include trophic stimulation and maintenance of absorptive structures by nourishing the enterocytes directly, thus supporting epithelial cell repair and replication. Luminal nutrients such as glutamine and short-chain fatty acids are used as fuel by the cells of the small bowel and colon, respectively.

B. Immunologic Benefits

The presence of food in the gut, particularly complex proteins and fats, triggers feeding-dependent neuroendocrine

activity. This activity stimulates the transport of immunoglobulins into the gut, particularly secretory immunoglobulin A, which is important for preventing bacterial adherence to gut mucosa and bacterial translocation. Enteral feeds also prevent villus atrophy, minimizing subsequent loss of epithelial border function and help to maintain normal gut pH and flora, diminishing opportunistic bacterial overgrowth in the small bowel. In recent animal studies enteral nutrition has been shown to reverse the aberrant cytokine profile associated with parenteral nutrition that is believed to lead to enterocyte apoptosis.

C. Safety Benefits

Enteral feeding is generally considered safer than parenteral feeding. Systematic review of randomized trials involving critically ill adults has demonstrated fewer infectious complications with enteral nutrition compared with parenteral nutrition; however there was no significant difference in mortality. Hyperglycemia, and its resulting inhibition of neutrophil-mediated immunity, also occurs more frequently with parenteral feeding. Enteral nutrition has its own potential complications (discussed shortly).

D. Cost Benefits

The direct costs of enteral feeding are generally less than those with parenteral nutrition. Direct costs include formula, feeding pumps, and tube placement. The cost advantage for enteral feeding is even greater when indirect costs such as central line placement, infection or thrombosis, and home health care are considered.

► Indications for Enteral Feeding

Enteral nutrition is the preferred method of nutrition support for malnourished patients or those at risk for developing malnutrition and who have an intact gastrointestinal tract. Patients who are either unable or unwilling to eat to meet their daily needs are candidates for enteral support. Factors influencing the timing of initiation of enteral nutrition include evidence of preexisting malnutrition, expected degree of catabolic activity, duration of the current illness, and anticipated return to intake by mouth. Patients with partially functioning gastrointestinal tracts (eg, short bowel syndrome, proximal enterocutaneous fistula) often can tolerate some enteral feeding but may require a combined regimen of both parenteral and enteral nutrition to meet total caloric needs.

► Possible Contraindications to Enteral Feeding

Aside from complete bowel obstruction, contraindications to enteral feeding are relative or temporary rather than absolute. Patients with short bowel, gastrointestinal

obstruction, gastrointestinal bleeding, protracted vomiting and diarrhea, fistulas, ileus, or active gastrointestinal ischemia may require a period of bowel rest. In times of physiologic stress, the body shunts blood away from the splanchnic circulation. Feeding a patient who is hemodynamically unstable or requires vasopressors may produce bowel ischemia in the setting of preexisting tenuous perfusion. The choice of an appropriate feeding site, administration technique, formula, and equipment may circumvent many of these contraindications.

► Implementing Enteral Supplementation

A. Delivery Methods

Prepyloric access via nasogastric tube is beneficial because it is less expensive, easier to secure and maintain, and less labor-intensive than small bowel access. Contraindications to delivery in the stomach are delayed gastric emptying, gastric outlet obstruction, and a history of repeated aspiration of tube feedings due to reflux. Some physicians consider the inability to protect the airway (eg, in comatose patients) a relative contraindication to gastric feeding. Diabetics and patients with severe head injuries may have profound gastroparesis. Postpyloric access via a duodenal or jejunal nasoenteric tube is preferred when gastric feedings are not tolerated, when patients are at risk for reflux or aspiration, or when early enteral nutrition is desired. A new feeding tube, guided in place by an external magnet, may provide ease of bedside placement of postpyloric tubes. Although a number of bedside methods (eg, auscultation, feeding tube aspirate pH measurements, observation for patient coughing) have been described to check tube placement, these methods can be unreliable. Therefore, tube position below the diaphragm should always be confirmed radiographically before initiating enteral feeding.

Permanent gastrostomy or jejunostomy tubes may be inserted when long-term enteral feeding is indicated. Placement of a feeding tube at the time of the initial operation requires forethought, with consideration given to the patient's expected postoperative course, anticipated ileus, and possible future need for supplementation (eg, during chemoradiation therapy).

B. Formulas

Currently available dietary formulations for enteral feedings may be divided into polymeric commercial formulas, chemically defined formulas, and modular formulas (Table 10-7). Selection of the correct formulation is predicated on patient need, cost, availability, and institutional custom.

Nutritionally complete commercial formulas or standard enteral diets vary in protein, carbohydrate, and fat composition. Most formulas use sucrose or glucose as the carbohydrate source and are suitable for lactose-deficient patients.

Commercial formulas are convenient, sterile, and affordable. They are recommended for patients experiencing minimal metabolic stress who have normal gut function.

Chemically defined formulas are commonly called *elemental diets*. The nutrients are provided in a predigested and readily absorbed form. They contain protein in the form of free amino acids or polypeptides. Amino acid (elemental) and polypeptide diets are efficiently absorbed in the presence of compromised gut function. However, they are more expensive than commercial formulas and are hyperosmolar, which may cause cramping, diarrhea, and fluid losses.

Modular formulations include special formulas used for specific clinical situations such as pulmonary, renal, or hepatic failure or immune dysfunction. The available preparations vary in (1) caloric and protein content; (2) protein, carbohydrate, and fat compositions; (3) non-protein carbohydrate calorie-to-gram nitrogen ratio; (4) osmolality; (5) content of minor trace metals (selenium, chromium, and molybdenum); and (6) content of various amino acids (glutamine, glutamate, BCAAs).

C. Initiating Feedings

In the past, elaborate protocols for initiating tube feedings were used. It is currently recommended that feedings be started with full-strength formula at a slow rate and steadily advanced. This approach reduces the risk of microbial contamination and achieves full nutrient intake earlier. Formulas are often introduced at full strength at 10-40 mL/h initially and advanced to the goal rate in increments of 10-20 mL/h every 4-8 hours as tolerated. Conservative initiation and advancement rates are recommended for patients who are critically ill, those who have not been fed for some time, and those who are receiving high-osmolality or calorie-dense formula. In such patients, starting feeding at 10 mL/h yields the trophic benefit of enteral feeds without unduly stressing the gut. In patients with active lifestyles, gastric feeds can be provided as boluses of up to 400 mL each, delivered at intervals of 4-6 hours.

D. Monitoring Feedings

Assessing gastrointestinal tolerance to enteral feeding includes monitoring for abdominal discomfort, nausea and vomiting, abdominal distention, and abnormal bowel sounds or stool patterns. Gastric residual volumes are used to evaluate gastric emptying of enteral feedings. High residuals raise concerns about intolerance to gastric feedings and the potential risk for regurgitation and aspiration. While differences in the recommended threshold for gastric residual volume vary, a residual greater than 200-250 mL or associated signs or symptoms of intolerance should prompt holding of tube feeds. If the abdominal examination is unremarkable, feedings should be postponed for at least an hour and the residual volume rechecked. If high residuals persist without

All enteral products included are lactose and gluten free.

associated clinical signs and symptoms, a promotility agent (eg, erythromycin, metoclopramide) may be added to the feeding regimen.

► Complications of Enteral Feeding

Technical complications occur in about 5% of enterally fed patients and include clogging of the tube; esophageal, tracheal, bronchial, or duodenal perforation; and tracheobronchial intubation with tube feeding aspiration.

Patients with decreased consciousness or impaired gag reflexes or those who have undergone endotracheal intubation are at increased risk for technical complications. The tip of the feeding tube must be positioned and verified radiographically. Other methods to evaluate tube placement are not consistently reliable. Generally, the wire stylet used for positioning should not be reinserted once removed. The incidence of tube clogging can be reduced by periodic water flushes and avoiding administration of syrup-based medications through the tube.

Functional complications occur in up to 25% of tube-fed patients and include nausea, vomiting, abdominal distention, constipation, and diarrhea. Feeding the small bowel instead of the stomach can diminish abdominal symptoms. In the critically injured patient, diarrhea is typically multifactorial; it results from polypharmacy (eg, multiple antibiotics), mechanical gut dysfunction (eg, partial small bowel obstruction), intestinal bacterial overgrowth (eg, *Clostridium difficile*), and protein content or osmolarity of the diet. Treatment consists of stopping any unnecessary medications, correcting gut dysfunction, changing enteral formulation (eg, intact protein vs amino acid or polypeptide formula), or reducing the osmolarity of the formula. In some circumstances, adding highly fermentable or viscous soluble fibers, such as guar gum, psyllium, pectin, or banana flakes have been shown to decrease diarrhea more than using fiber containing enteral formulas. Administering antidiarrheal agents can be beneficial after establishing that infection is not the source of diarrhea.

In the surgical population, *C difficile* is a common cause of diarrhea due to the routine use of perioperative antibiotics. The diagnosis of pseudomembranous colitis is confirmed by *C difficile* polymerase chain reaction or toxin assay, or sigmoidoscopy. The primary treatment is stopping unnecessary antibiotics. Additionally, either oral or intravenous metronidazole or vancomycin (oral or retention enema) can be started. Antimotility agents should be avoided.

Abnormalities in serum electrolytes, calcium, magnesium, and phosphorus can be minimized through vigilant monitoring. Hyperosmolarity (hyponatremia) may lead to mental lethargy or obtundation. The treatment of hyponatremia includes the administration of free water by giving either D₅W intravenously or additional water flushes. Volume overload and subsequent congestive heart failure may occur as a result of excess sodium administration and is typically observed in patients with impaired ventricular function or valvular heart disease. Hyperglycemia may occur in any patient but is particularly common in individuals with preexisting diabetes or sepsis. The serum glucose level should be determined frequently and regular insulin administered accordingly.

PARENTERAL NUTRITION THERAPY

The development of parenteral nutritional support in the late 1960s revolutionized care of the surgical patient, particularly those with permanent inability to obtain adequate enteral nourishment. Despite its utility in select patients and circumstances, overuse of parenteral nutrition not only is costly but also poses unnecessary risk to patients. In general, parenteral nutrition should be employed only when the gastrointestinal tract cannot be utilized. Parenteral formulas usually deliver 75-150 nonprotein carbohydrate kcal/g of

nitrogen infused, a ratio that maximizes carbohydrate and protein assimilation and minimizes metabolic complications (aminoaciduria, hyperglycemia, and hepatic glycogenesis). Nonenteral nutrition can be given as peripheral parenteral nutrition (PPN) or total parenteral nutrition (TPN) via a central line. In addition to route of administration, the two differ in (1) dextrose and amino acid content of the parenteral solution, (2) primary caloric source (glucose vs fat), (3) frequency of fat administration, (4) infusion schedule, and (5) potential complications.

▶ Peripheral Parenteral Nutrition

Because peripheral parenteral nutrition (PPN) avoids the complications associated with central venous access, it is safer to administer than TPN. PPN is indicated for patients with compromised gut function who require supplemental nutrition for less than 14 days. It can be infused via an 18-gauge peripheral IV catheter or via a peripherally inserted central catheter (PICC line). Standard PPN therapy orders should include the administration schedule for the PPN solution and fat supplement, as well as explicit catheter care orders and monitoring guidelines.

A. PPN Formulation

The osmolarity of the PPN solution is limited to 900 mOsm to avoid phlebitis. Consequently, unacceptably large volumes of solution, greater than 2.5 L/d, are needed to fulfill the typical patient's total nutritional requirements (Figure 10-6).

▶ Total Parenteral Nutrition

Total parenteral nutrition (TPN) via a central line is indicated for patients who cannot obtain adequate nourishment via the gastrointestinal tract or, very rarely, in patients with severe preoperative undernutrition who cannot tolerate adequate enteral nutrition. A minimum duration of treatment of 7-10 days of adequate TPN is needed for preoperative nutritional repletion. Likewise, the use of postoperative TPN for only 2-3 days (eg, while awaiting return of bowel function) is discouraged, as the risks outweigh the benefits incurred over this short a period of time.

A. TPN Formulation

TPN is typically formulated for patients on the basis of their individual nutritional assessment. Most frequently, TPN is prepared in the pharmacy and provided as a 3-in-1 admixture of protein, carbohydrates, and fat. Alternatively, the lipid emulsion can be administered as a separate intravenous piggyback infusion. Other additives, vitamins, and trace minerals are added to TPN formulations as required (Table 10-8).

1. TPN components:

Routine additives	Recommended dosage ranges per liter TPN	BAG #	BAG #	BAG #

K ⁺ acetate	0-40 meq	meq	meq	meq
Regular insulin	0-40 units	units	units	units
H ₂ antagonist**				
25% albumin***	25 g	g	g	g
<i>Nurse's signature</i>				

* Total potassium content per liter of TPN should not exceed 40 meq.

** Divide the daily dosage equally into each liter of TPN.

*** Only if the serum albumin < 2.5g/dl and enteral diet therapy is anticipated.

Rate: 40 mL/h via pump.

Final dextrose concentration 25 % Final AA concentration 4.25 %

- Pharmacy to add vitamin K 10 mg to 1 L of TPN solution every Mon. and Thurs.
- Fat emulsion 20% 500 mL every Mon., Wed., and Fri. IVPB per pump over 6-8 hours via at least an 18-gauge peripheral IV or via the subclavian catheter.
- STAT upright and expirational portable chest x-ray to check the position of the subclavian catheter and to rule out a pneumothorax. Notify the physician when the chest x-ray is completed.
- Heparin lock the TPN catheter with 2 mL of heparin (100 units/mL) until notified by the physician to start the first liter of TPN solution.
- Strict I/O every shift. Total the I/O every 24 hours.
- Record the daily weight in kilograms on the vital signs sheet.
- Check the urine for sugar and acetone every shift and record on the vital signs sheet. If the urine sugar is 4+, request a STAT serum glucose measurement to be drawn by the physician. If the serum glucose is > 160 mg/dL, contact the physician for treatment orders.
- Notify the physician if the oral temperature is >38C (>100.4F).
- Routine TPN laboratory tests are to be drawn weekly on the days and times specified below:
Sun. AM: CBC, SMAC-20
Tues. AM: Electrolytes, BUN, creatinine, and glucose
Thurs. AM: CBC, SMAC-20, copper, zinc, magnesium, transferrin, and triglycerides
- Begin a 24-hour urine collection for urinary urea nitrogen (UUN) at 6:00 AM every Mon. and Thurs. for nitrogen balance determination.
- TPN catheter dressing and tubing changes per the hospital TPN protocol.
- Contact the physician for all problems related to TPN.
- All changes in TPN therapy must be approved by the physician.

▲ **Figure 10-6.** TPN therapy orders.

B. Administration

The high osmolarity of TPN solutions necessitates administration via a central vein. The use of multilumen central venous catheters (CVCs) for TPN does not increase the risk of catheter infection; however, a port should be designated

Table 10-8. TPN solution formulation.

Components in 1 L of Standard TPN:	
<i>Routine additives</i>	
D ₅ W ¹	500 mL
8.5% amino acid ¹	500 mL
Sodium chloride ²	0-140 meq
Sodium phosphate ³	0-20 mmol
Potassium chloride ⁴	0-40 meq
Magnesium sulfate ⁵	0-12 meq
Calcium gluconate ^{5,6}	4.5-9.0 meq
Trace element-5 ⁷	1 mL
M.V.I.-13 ⁷	10 mL
<i>Optional additives</i>	
Sodium acetate ²	0-140 meq
Potassium acetate ⁴	0-40 meq
H ₂ antagonist ⁸	Variable
Regular insulin ⁹	0-40 units
Vitamin K ¹⁰	10 mg
Heparin ¹¹	Variable
Fat emulsion schedule:	
Infuse 20-25% fat emulsion intravenously via pump at least 3 times per week	

¹The solution is formulated to deliver 125 nonprotein kcal/g of nitrogen infused.

²Add sodium chloride if the serum CO₂ > 25 meq/L. Add sodium acetate if the serum CO₂ ≤ 25 meq/L.

³The total phosphate dosage should not exceed 20 mmol/L or 60 mmol daily.

⁴Add potassium chloride if the serum CO₂ > 25 meq/L. Add potassium acetate if the serum CO₂ ≤ 25 meq/L. The potassium dosage should not exceed 40 meq/L.

⁵Added to each liter.

⁶Add calcium gluconate 9 meq to each liter if the serum calcium < 8.5 meq/L.

Add 4.5 meq if the serum calcium ≥ 8.5 meq/L.

⁷Administered in only 1 L per day.

⁸Dosage depends upon the H₂ antagonist selected. Divide the daily dosage equally in all liters of TPN administered.

⁹Total dosage should not exceed 40 units/L.

¹⁰Administered only once per week.

¹¹Heparin administration in TPN is not required, but it may be added in place of subcutaneous dosing.

for exclusive use for TPN infusion to minimize handling of the line. CVC placement in the subclavian vein is ideal and well tolerated by the patient. Furthermore, the rate of catheter infection is lower for catheters placed in the subclavian compared to catheters placed in either the femoral or internal jugular vein. Femoral vein catheterization has the highest infectious rate and therefore should be avoided if possible.

The CVC should be dressed with a sterile, dry gauze, and transparent (nonocclusive) dressing; a chlorhexidine gluconate impregnated sponge may be used as well.

If refeeding syndrome is suspected, the introduction of TPN should be gradual, with approximately 10 kcal/kg/d for the first 3 days. This amount is increased 15-20 kcal/kg/d for days 4-10. For all patients, additional maintenance IV fluids should be tapered or discontinued accordingly to maintain an even fluid balance.

Standard TPN therapy orders (Figure 10-6) should include the administration schedule for the TPN solution and fat supplement as well as explicit catheter care orders and monitoring guidelines (Figure 10-7). For active patients on long-term TPN, cycling the intravenous nutrition therapy over 8-16 hours at night allows freedom from the infusion pump during the remainder of the day.

C. Special TPN Solutions

The TPN solution may be concentrated for patients who require fluid restriction (eg, those with pulmonary and cardiac failure). One liter of concentrated TPN solution usually contains a combination of D₆₀W or D₇₀W, 500 mL, and 10% or 15% amino acids, 500 mL, plus additives.

Patients in renal failure who cannot be dialyzed and who require fluid restriction should receive low-nitrogen TPN solution. Patients in renal failure who can undergo dialysis may receive the standard or high-nitrogen TPN formulations, with special attention directed toward minimizing potassium and phosphate intake.

COMPLICATIONS OF PARENTERAL NUTRITION

► PPN Therapy

Technical complications of PPN are few. The most common problem is maintaining adequate venous access due to frequent incidence of phlebitis. The PPN infusion catheter must be moved frequently to other sites; therefore, prolonged PPN is rarely possible. Infectious complications such as catheter site skin infections and septic phlebitis develop in 5% of patients.

► TPN Therapy

Complications resulting from parenteral nutrition can be broken down into those of a technical, infectious, and metabolic nature (Table 10-9). Many of the complications originate from the CVC, with more than 15% of patients developing some line-related complication. Other morbidity is attributable to line infection (typically bacterial) or metabolic abnormalities.

A. Technical Complications

The risks of patient injury while placing a CVC are directly related to surgeon experience with the procedure.

Arterial puncture (more common in internal jugular or femoral attempts) can occur in up to 10% of patients, while pneumothorax (predominantly during subclavian insertion) can develop in 2%-5%. The risk for injury increases dramatically after three failed insertion attempts at the same site.

Air embolism occurs when negative intrathoracic pressure draws air into a catheter or needle into a central vein. This is particularly serious in the presence of pulmonary-systemic shunts (eg, patients with a patent foramen ovale). It is characterized by sudden, severe respiratory distress, hypotension, and a cogwheel cardiac murmur. To reduce this risk, the patient should be placed in the Trendelenburg position (head down) during line insertion. When suspicion of air embolism is high, treatment involves placing the patient in the Durant position (Trendelenburg and left lateral decubitus) to direct the embolus to the apex of the right ventricle. Catheter-based aspiration can then be attempted.

The use of peripherally introduced central catheters (PICCs) allows peripherally initiated solutions to be delivered to the central venous system. They are well tolerated and easy to care for because of their location in an upper extremity. PICCs may be preferable to CVCs because of lower cost and fewer mechanical complications at placement.

B. Infectious Complications

Infection of the catheter exit site is frequently characterized by mild fever (37.5°-38°C), purulent discharge around the catheter, and erythema/tenderness of the surrounding skin. Late changes include induration of the skin and systemic sepsis. Local wound care and sterile dressing changes every 3 days can reduce site infection rates.

Primary line (catheter) infection can occur in up to 15% of patients with CVCs. Line infection should be strongly considered in any patient with a CVC who develops fever, new-onset glucose intolerance, leukocytosis, or positive blood cultures. There may be a slight increase in infectious risk with multilumen catheters. The use of antibiotic-impregnated catheters has been shown to significantly reduce nosocomial bloodstream infections. As noted previously, insertion in the subclavian vein reduces the risk of infection. The most common offending organisms are skin flora (*Staphylococcus aureus*, *Staphylococcus epidermidis*), although gram-negative rods can also colonize an indwelling catheter. Table 10-10 depicts one treatment algorithm for treating suspected CVC infections. With documented positive blood cultures or more than 15 colony-forming units on catheter cultures, the catheter should be removed and a line holiday attempted with peripheral access. Insertion of a new CVC can then be performed at a separate site once bacteremia has resolved. Antibiotics should be started empirically in patients with sepsis.

NUTRITION GUIDELINES FOR THE ADULT PATIENT

ADULT PARENTERAL NUTRITION (PN) GUIDELINES

Table 1: INDICATIONS FOR PARENTERAL NUTRITION:

- Patient has failed enteral nutrition (EN) trial with appropriate tube placement (post-pyloric).
- Enteral nutrition is contraindicated. Examples include patients with a paralytic ileus, mesenteric ischemia, small bowel obstruction, or GI fistula, except when enteral access can be placed distal to the fistula or the volume of fistula output (< 230 mL/day) justifies a trial of EN.
- Wound healing would be impaired if PN is not started within 5-10 days postoperatively unable to eat or tolerate EN.

Table 2: BODY WEIGHT CALCULATIONS

Actual body weight (ABW) = pt weight (kg) IF GREATER THAN 125% OF IDEAL. WEIGHT SEE**

Ideal body weight (IBW) male = 50 kg + (2.3 × # inches > 5 ft) OR 48 kg + (2.7 × # inches > 5 ft)
female = 45 kg + (2.3 × # inches > 5 ft)

**Dosing weight (DW) = IBW + 0.25 (ABW – IBW)

Table 3:

A. DAILY CALORIC NEEDS

Maintenance-mild stress:	20-25 kcal/kg/day (15-20 NPC*/kg/day)
Mild-moderate stress (routine surgery, minor infection):	26-30 kcal/kg/day (21-25 NPC*/kg/day)
Moderate-severe stress (major surgery, sepsis).	31-35 kcal/kg/day (26-30 NPC*/kg/day)

*NPC = nonprotein calories

CONVERSIONS FOR KCAL TO GRAMS

3.4 kcal = 1 gm dextrose

10 kcal = 1 gm lipid

B. *HARRIS-BENEDICT (HB) ESTIMATE OF BASAL CALORIES STRESS FACTOR

Male: 66 + 13.8 (weight in kg) + 5 (height in cm**) – 6.8 (age in year)	Maintenance-mild stress :	1-1.2
Female: 655 + 9.6 (weight in kg) + 1.8 (height in cm**) – 4.7 (age in years)	Moderate stress :	1.3 -1.4
	Severe stress:	1.5

*HB × stress factor = total caloric need/day ** height in cm = inches × 2.54

Table 4: DAILY PROTEIN NEEDS

Maintenance-Mild	0.8-1.2 gm/kg/day

C. Metabolic Complications

The refeeding syndrome was first described in prisoners freed from concentration camps after World War II. Similar pathophysiology may develop when initiating TPN in patients with severe malnutrition and weight loss (> 30% of their usual weight). In starvation, energy is derived principally from fat metabolism. TPN results in a shift from fat to glucose as the predominant fuel, and rapid anabolism increases the production of phosphorylated intermediates of glycolysis. These intermediates trap phosphate, producing profound hypophosphatemia. Hypokalemia and hypomagnesemia also occur. The lack of phosphate and potassium lead to a relative adenosine triphosphate (ATP) deficiency, resulting in the insidious onset of respiratory failure and reduced cardiac stroke volume. Because of these risks, the rate of TPN administration in a severely malnourished patient should be slowly increased over several days. Twice-daily monitoring of electrolytes is also indicated, with repletion as appropriate.

Hepatic dysfunction is a common manifestation of long-term parenteral nutrition support. The exact etiology is unclear; however, in part it is related to the initial bypassing of the portal circulation when providing intravenous nutrition. Severe hepatic steatosis may progress to cirrhosis. Acalculous cholecystitis can also occur in these patients, likely from biliary stasis and lack of gallbladder contraction. Patients on TPN need weekly liver function tests and lipid panels.

► Home Nutrition Support

Patients requiring home nutrition support (HNS) present clinical challenges different from those in an acute care setting. Route of enteral or parenteral administration must be based on length of therapy, frequency of use, and caregiver/patient ability. Regular physical examinations and frequent laboratory monitoring (Figure 10-8) should continue as

long as patients remain on HNS therapy. Home care services must be established prior to discharge and are vital to the success of these patients.

For patients requiring home parenteral nutrition, weekly laboratory monitoring continues until electrolytes stabilize. Once stable, laboratory values can often be checked on a monthly basis, and changes can be made to the TPN formula as needed. Electrolyte and hepatic enzymes must be followed to monitor for metabolic derangements and end-organ damage. Parenteral nutrition-associated liver disease is the most devastating complication of long-term parenteral nutrition therapy. Early clinical intervention with a combination of nutritional, medical, hormonal, and surgical therapies is potentially effective in preventing liver disease progression. However, as progression is frequently subtle, it is often not recognized until liver injury is irreversible. Although parenteral nutrition-associated liver failure is hypothesized to be multifactorial in origin, the etiology is poorly understood. When end-stage liver disease (ESLD) develops in these patients, multiorgan transplantation (liver and small bowel) is generally required.

DIETS

► Optimal Diet

The optimal diet should have the following distribution of energy sources: carbohydrate 55%-60%, fat 30%, and protein 10%-15%. Refined sugar should constitute less than 15% of dietary energy and saturated fats no more than 10%, the latter balanced by 10% monounsaturated and 10% polyunsaturated fats. Cholesterol intake should be limited to about 300 mg/d (one egg yolk contains 250 mg of cholesterol). The amount of salt in the average American diet, 10-18 g daily, far exceeds the recommended 3 g/d. For Western societies to meet the criteria for an optimal diet, consumption of fat must decrease (from 40%) and consumption of complex

carbohydrate should increase. Meat is presently overemphasized as a protein source, at the expense of grain, legumes, and nuts. Diets that include substantial fish intake have been associated with a decrease in mortality from cardiovascular disease and are attributed to high concentrations of ω -3 fatty acids, principally eicosapentaenoic and docosahexaenoic acids.

Many adults, particularly those who do not drink milk, consume inadequate amounts of calcium. In women this may result in calcium deficiency and skeletal calcium depletion, predisposing women to osteoporosis and axial bony fractures. “Fiber” is the generic term for a chemically complex group of indigestible carbohydrate polymers, including cellulose, hemicellulose, lignins, pectins, gums, and mucilages. The amount of fiber in Western diets averages 25 g/d, but some people ingest as little as 10 g daily. Those who consume low-fiber diets are more likely to develop chronic constipation, appendicitis, diverticular disease, and possibly diabetes mellitus and colonic neoplasms. Bran cereals and bread, fruit, potatoes, rice, and leafy vegetables are rich sources of fiber.

► Regular Diets

Many concepts regarding diets are archaic and based on currently unaccepted views of illness. For example, the utility of a low-residue diet in diverticular disease is questionable. The “progressive diet,” designed for postoperative feeding and consisting of a clear liquid (high in sodium), then a full liquid (high in sucrose), then a regular diet, is based on outmoded concepts. When peristalsis returns after operation, as evidenced by bowel sounds and ability to tolerate water, most patients are able to ingest a regular diet. Regular diets have an unrestricted spectrum of foods and are most attractive to the patient. An average regular hospital diet for 1 day contains 95–110 g of protein, with a total caloric content of 1800–2100 kcal. This composition reflects the nutritional needs of healthy persons of average height and weight and will not meet the increased demands imposed by malnutrition or disease.

► Lactose Intolerance & Lactose-Free Diets

A lactose-free diet is indicated for patients who have symptoms such as diarrhea, bloating, or flatulence after the ingestion of milk or milk products. Lactose intolerance is genetically determined and occurs in 5%–10% of European Caucasians, 60% of Ashkenazi Jews, and 70% of African Americans. Subclinical lactose intolerance may become unmasked following surgery on gastrointestinal tract (eg, gastrectomy). Similarly, avoidance of lactose-containing products is often beneficial advice for patients with Crohn disease, ulcerative colitis, and AIDS. The efficiency of lactose digestion and absorption can be measured by giving 100 g of oral lactose, then measuring the blood glucose concentration at 30-minute intervals over 2 hours.

Table 10–10. Complications of TPN.

Complication	Treatment
Catheter sepsis	Algorithms:
<p>Incidence:</p> <ul style="list-style-type: none"> Single-lumen catheter: 3.5% Triple-lumen catheter: 10% <p>Diagnosis:</p> <ul style="list-style-type: none"> • Unexplained hyperglycemia (> 160 mg/dL) • “Plateau” temperature elevation (> 38°C) for several hours or days. (Note: An isolated spike or “picket fence” temperature pattern is usually not indicative of an infected catheter.) • Leukocytosis (> 10,000/μL) • Exclusion of other potential sources of infection, <li style="text-align: center;">or • A positive blood culture (> 15 colony count) aspirated via the TPN catheter or obtained peripherally, <li style="text-align: center;">or • Catheter site induration, erythema, or purulent drainage. 	<p><i>Negative blood cultures and no cardiovascular signs of sepsis:</i></p> <ol style="list-style-type: none"> (1) Aspirate a blood specimen via the TPN catheter and peripherally for bacterial and fungal culture and then sterily exchange the preexisting TPN catheter for a new catheter over a guidewire; submit the previous catheter tip for bacterial and fungal culture and colony count; and continue the TPN infusion. <li style="text-align: center;"><i>then</i> (2) Monitor the patient’s temperature closely. If the patient defervesces, no further therapy is necessary. If the fever continues or recurs, remove the catheter and insert a new one on the contralateral side and continue the TPN infusion. <p><i>Positive blood culture or cardiovascular signs of sepsis:</i></p> <ol style="list-style-type: none"> (1) Aspirate a blood specimen via the TPN catheter and peripherally for bacterial and fungal culture. Then remove the catheter immediately, and submit the catheter tip for bacterial and fungal culture and colony count. <li style="text-align: center;"><i>then</i> (2) Insert a new TPN infusion catheter on the contralateral side and continue the TPN infusion. <li style="text-align: center;"><i>then</i> (3) Initiate appropriate antibiotic therapy.
Hyperglycemia (> 160 mg/dL)	Algorithms:
	<ol style="list-style-type: none"> (1) Maintain the current TPN infusion rate. If the patient is critically ill, initiate intravenous regular insulin infusion. Otherwise initiate a sliding scale with regular insulin and add regular insulin in 10-unit increments to the TPN solution until the serum glucose is maintained at ≤ 140 mg/dL. (Note: The maximum allowable insulin dosage per liter of TPN is 40 units.) <li style="text-align: center;"><i>then</i> (2) If blood glucose levels remain elevated, consider decreasing the dextrose concentration (eg, decrease the grams of carbohydrate) to 60.80% of the estimated needs until blood glucose levels are within goal range. In addition, either maintain regular insulin infusion or continue to adjust the amount of insulin in the TPN bag based on the amount taken via sliding scale. One-half to two-thirds of the previous day’s regular insulin requirements can be added to the TPN bag. <li style="text-align: center;"><i>then</i> (3) Once goal blood glucose achieved, restart the original TPN solution as in (1) above with adequate insulin to maintain goal blood glucose range.
Hypoglycemia (< 65 mg/dL)	May occur with the sudden discontinuance of TPN infusion. If the TPN infusion administered to either an NPO patient or a patient consuming inadequate oral calories is suddenly discontinued, immediately begin an infusion of D ₁₀ NS at the previous TPN infusion rate via either the TPN catheter or a peripheral IV to prevent rebound hypoglycemia.
Hypernatremia (> 145 meq/L)	Determine the cause. Hypernatremia secondary to dehydration is treated by administering additional “free water” and providing only the daily maintenance sodium requirements (90-150 meq/L) via the TPN infusion. Hypernatremia secondary to increased sodium intake is treated by reducing or deleting sodium from the TPN solution until the serum sodium ≤ 145 meq/L.
Hyponatremia (< 135 meq/L)	Determine the cause. Hyponatremia secondary to dilution is treated by fluid restriction and by providing only the daily maintenance sodium requirements (90-150 meq/L). Hyponatremia secondary to inadequate sodium intake is treated by increasing the sodium content of the TPN solution until the serum sodium is ≥ 135 meq/L. (Note: The maximum sodium content per liter of TPN should not exceed 154 meq.)

(continued)

Table 10–10. Complications of TPN. (Continued)

Complication	Treatment
Hyperkalemia (> 5 meq/L)	Immediately discontinue the current TPN infusion containing potassium and begin an infusion of D ₁₀ NS at the previous TPN infusion rate. Then reorder a new TPN solution without potassium and continue to delete potassium from the TPN solution until the serum potassium ≤ 5 meq/L.
Hypokalemia (< 3.5 meq/L)	A TPN solution should not be utilized for the primary treatment of hypokalemia. The potassium content per liter of TPN solution should not exceed 40 meq. If additional potassium is necessary, it should be administered via another route, eg, IV interrupts.
Hyperphosphatemia (> 4.5 mg/dL)	Immediately discontinue the present phosphate-containing TPN infusion and begin an infusion of D ₁₀ NS at the previous infusion rate. Then reorder a new TPN solution without phosphate and continue to delete phosphate from the TPN solution until the serum phosphate is ≤ 4.5 mg/dL.
Hypophosphatemia (< 2.5 mg/dL)	Increase the phosphate content of the TPN solution to a maximum of 20 mmol/L. (Note: <i>The total daily phosphate dosage should not exceed 60 mmol.</i>) If severe hypophosphatemia exists, carbohydrate infusion or delivery should be restricted.
Hypermagnesemia (> 3 mg/dL)	Immediately discontinue the present magnesium-containing TPN infusion and begin an infusion of D ₁₀ NS at the previous infusion rate.
Hypomagnesemia (< 1.6 mg/dL)	Increase the magnesium content of the TPN solution to a maximum of 12 meq/L. (Note: <i>The total daily dosage of magnesium should not exceed 36 meq.</i>)
Hypercalcemia (> 10.5 mg/dL)	Immediately discontinue the present calcium-containing TPN infusion and begin an infusion of D ₁₀ NS at the previous TPN infusion rate. Then reorder a new TPN solution without calcium and continue to delete calcium from the TPN dilution until the serum calcium is ≤ 10.5 mg/dL.
Hypocalcemia (< 8.5 mg/dL)	Increase the calcium content of the TPN solution to a maximum of 9 meq/L. (Note: <i>The total daily calcium dosage should not exceed 27 meq.</i>)
High serum zinc (> 150 µg/L)	Discontinue the trace metal supplement (Multitrace 5 mL) in the TPN solution until the serum zinc is ≤ 150 µg/L.
Low serum zinc (< 55 µg/dL)	Add elemental zinc 2-5 mg daily to 1 L of TPN solution only until the serum zinc is ≥ 55 µg/dL. (Note: <i>The elemental zinc is added in addition to the daily supplement.</i>)
High serum copper (> 140 µg/dL)	Discontinue the trace metal supplement in the TPN solution until the serum copper is ≤ 140 µg/dL.
Low serum copper (< 70 µg/dL)	Add elemental copper 2-5 mg daily to 1 L of TPN solution only until the serum copper is ≥ 70 µg/dL. (Note: <i>The elemental copper is added in addition to the daily Multitrace 5 mL.</i>)
Hyperchloremic metabolic acidosis (CO ₂ < 22 mmol/L and Cl ⁻ > 110 meq/L)	Reduce the chloride intake by administering the Na ⁺ and K ⁺ in the acetate form as either sodium or potassium acetate (or both) until the acidosis resolves (serum CO ₂ ≥ 22 mmol/L) and the serum chloride level returns to normal (< 110 meq/L).

Patients with lactose intolerance exhibit a rise in blood glucose of 20 mg/dL or less. A lactose-free diet may be deficient in calcium, vitamin D, and riboflavin.

► Postgastric Bypass Diet

The popularity of gastric bypass surgery for weight loss continues to increase. The diet changes that must occur to ensure safe and appropriate weight loss are quite specific after surgery. Immediately after surgery, only small amounts of liquids (eg, 30 mL q3h) should be consumed.

After tolerance of liquids is established, pureed foods should be consumed for the 4 weeks after surgery. Food should be consumed as very small meals and snacks throughout the day. Choosing a variety of foods, avoiding concentrated sweets, and consuming adequate protein are essential to the success of these patients. Protein supplements are often required to ensure adequate protein consumption postoperatively. Particularly with gastric bypass procedures, patients are prone to deficiencies of the fat-soluble vitamins (A, D, E, and K), calcium, iron, vitamin B₁₂, and folate necessitating the indefinite supplementation of daily multivitamins.

DISEASE-SPECIFIC NUTRITION SUPPORT

► Burns

Thermal injury has a tremendous impact on metabolism because of prolonged, intense neuroendocrine stimulation. Extensive burns can double or triple the REE and urinary nitrogen losses, producing a nitrogen loss of 20-25 g/m² TBSA/d. If left unattended, lethal cachexia becomes imminent in less than 30 days. The increase in metabolic demands following thermal injury is proportional to the extent of ungrafted body surface. The principal mediators of burn hypermetabolism are catecholamines, corticosteroids, and inflammatory cytokines, which return to baseline only after skin coverage is complete. Decreasing the intensity of neuroendocrine stimulation by providing adequate analgesia and a thermoneutral environment lowers the accelerated metabolic rate and helps to decrease catabolic protein loss until the burned surface can be grafted. Burned patients are prone to infection, and the cytokines activated by sepsis further augment catabolism.

Because infection often complicates the clinical course of patients with burn injury, and infectious complications are more likely with parenteral nutrition, the enteral route of feeding is preferred whenever tolerated. Enteral feeding may be started within the first 6-12 hours post burn to attenuate the hypermetabolic response and improve postburn survival. Gastric ileus can be avoided through the use of a nasojejun tube.

Patients with burns have increased caloric requirements. In addition to estimated maintenance needs (females, 22 kcal/kg/d; males, 25 kcal/kg/d), these patients require an additional 40 kcal per percentage point of burned total body surface area (TBSA). A 70-kg man with 40% TBSA burns would require 48 kcal/kg/d. Protein requirements are also markedly increased from the normal 0.8 g/kg/d to

approximately 1.5-2.5 g/kg/d in severely burned patients. Of course, these are initial estimates, and periodic reassessment of nutritional status (eg, prealbumin levels, nitrogen balance) is required in these patients. During the hypermetabolic phase of burn injury (0-14 days), the ability to metabolize fat is restricted, so a diet that derives calories primarily from carbohydrate is preferable. Following the hypermetabolic phase, the metabolism of fat becomes normal. The burn patient should also be given supplemental arginine, nucleotides, and ω-3 polyunsaturated fat to stimulate and maintain immunocompetence.

► Diabetes

Glucose intolerance often complicates nutritional supplementation, particularly with parenteral administration. Complications associated with TPN administration occur more frequently during prolonged hyperglycemia. Unopposed glycosuria may lead to osmotic diuresis, loss of electrolytes in the urine, and possibly nonketotic coma. Significant controversy exists, but the preponderance of available evidence suggests that intensive insulin therapy, as compared with standard therapy, does not provide an overall survival benefit, but instead may increase mortality, and is associated with a higher incidence of hypoglycemia. Factors that may aggravate hyperglycemia include the use of corticosteroids, certain vasopressors (eg, epinephrine), preexisting diabetes mellitus, and occult infection.

Maintaining normoglycemia in injured or postoperative patients may be challenging. Serial serum glucose levels should be monitored regularly. If hyperglycemia does not occur, these measurements can be obtained less frequently once the nutritional goal is reached. Patients may require subcutaneous insulin administered on a sliding scale or continuous intravenous insulin infusions to control their hyperglycemia. For patients who do not require an insulin

infusion, the previous day's insulin total from a sliding scale may be determined and half to two-thirds of that amount added to the next TPN order to provide a more uniform administration.

▶ Cancer

Cancer is the second leading cause of death in the United States, and over two-thirds of patients with cancer will develop nutritional depletion and weight loss at some time during the course of the illness. Malnutrition and its sequelae are the direct cause of death in 20% of these patients. Weight loss is an ominous presenting sign in many malignancies. Furthermore, antineoplastic treatments, such as chemotherapy, radiation therapy, or operative extirpation, can worsen preexisting malnutrition. Cancer cachexia manifests as progressive involuntary weight loss, fatigue, anemia, wasting, and tissue depletion. It may occur at any stage of the disease. Nutrition support has become an essential adjunct in caring for the cancer patient.

Many studies have evaluated the effectiveness of nutrition support in patients with cancer, with varying results. Increasing efforts have been directed toward the use of enteral rather than parenteral nutrition because it is simpler, presumably safer, and less costly. Nutritional supplementation in cancer patients *may* reduce infectious complications or perioperative morbidity, but convincing evidence of improvement in overall survival is lacking.

Patients with cancer may have altered energy expenditure and abnormalities of protein and carbohydrate metabolism. REE increases by 20%-30% in certain malignant tumors. The increases in REE can occur even in patients with extreme cachexia in whom a similar degree of uncomplicated starvation would produce profound decreases in REE. Changes in carbohydrate metabolism consist of impaired glucose tolerance, elevated glucose turnover rates, and enhanced Cori cycle activity. Owing to the high rate of anaerobic glucose metabolism in neoplastic tissue, patients with extensive tumors are susceptible to lactic acidosis when given large glucose loads during TPN. These patients also exhibit increased lipolysis, elevated FFA and glycerol turnover, and hyperlipidemia.

Patients with cancer avidly retain nitrogen despite losses in most lean tissue. Animal carcass analysis has shown that the retained nitrogen resides in the tumor, which behaves as a nitrogen trap. Synthesis, catabolism, and turnover of body protein are all increased, but the change in catabolism is greatest.

The utility of enteral supplementation with immune-enhancing agents is unclear. These substances include arginine, glutamine, essential fatty acids, RNA, and BCAAs. Several studies have attempted to examine outcomes in patients with cancer who are fed with enteral formulas supplemented with immune-enhancing agents, compared

to routine enteral feeding alone. The findings were summarized by Zhang and coworkers. Meta-analysis of 19 studies with a total of 2231 cancer patients demonstrated a significant decrease in overall postoperative infection complication risk, noninfection complication risk, and hospital stay when perioperative immunonutrition was compared to standard diet. Exactly which elements confer these benefits remains unknown.

▶ Renal Failure

Whether nutritional support improves the outcome from acute renal failure is difficult to determine because of the metabolic complexities of the disease. Patients with acute renal failure may have normal or increased metabolic rates. Renal failure precipitated by x-ray contrast agents, antibiotics, aortic or cardiac surgery, or periods of hypotension is associated with a normal or slightly elevated REE and a moderately negative nitrogen balance (4-8 g/d). When renal failure follows severe trauma, rhabdomyolysis, or sepsis, the REE may be markedly increased and the nitrogen balance sharply negative (15-25 g/d). When dialysis is frequent, losses into the dialysate of amino acids, vitamins, glucose, trace metals, and lipotropic factors can be substantial.

Patients in renal failure (serum creatinine over 2 mg/dL) with a normal metabolic rate who cannot undergo dialysis should receive a concentrated (minimal volume) enteral or parenteral diet containing protein, fat, dextrose, and limited amounts of sodium, potassium, magnesium, and phosphate.

▶ Hepatic Failure

Most patients with hepatic failure present with acute decompensation superimposed on chronic hepatic insufficiency. Typically, a history of poor dietary intake contributes to the chronic depletion of protein, vitamins, and trace elements. Water-soluble vitamins, including folate, ascorbic acid, niacin, thiamin, and riboflavin, are especially likely to be deficient. Fat-soluble vitamin deficiency may be a result of malabsorption due to bile acid insufficiency (vitamins A, D, K, and E), deficient storage (vitamin A), inefficient utilization (vitamin K), or failure of conversion to active metabolites (vitamin D). Hepatic iron stores may be depleted either from poor intake or as a result of gastrointestinal blood loss. Total body zinc is decreased owing to the above factors plus increased urinary excretion.

The use of BCAA-enriched amino acid formulations for TPN in patients with liver disease is controversial because the results of controlled trials are inconclusive. The efficacy of BCAA-enriched amino acid formulations for TPN in patients with hepatic encephalopathy has been studied in numerous controlled trials that had contradicting results. Meta-analysis of these studies demonstrated an improvement in mental state by the BCAA-enriched solutions, however there was no definite benefit in survival.

Therefore, patients with hepatic failure should receive a concentrated enteral or parenteral diet with reduced carbohydrate content, a combination of EFAs and other lipids, a standard mixture of amino acids, and limited amounts of sodium and potassium.

► **Cardiopulmonary Disease**

Malnutrition is associated with myocardial dysfunction, particularly in the late stages, and fatal cardiac failure can develop in extreme cachexia. Cardiac muscle uses FAAs and BCAAs as preferred metabolic fuels instead of glucose. During starvation, the heart rate slows, cardiac size decreases, and the stroke volume and cardiac output decrease. As starvation progresses, cardiac failure ensues, along with chamber enlargement and anasarca.

The profound nutritional depletion that may accompany chronic heart failure, particularly in valvular disease, results from anorexia of chronic disease, passive congestion of the liver, malabsorption due to venous engorgement of the small bowel mucosa, and enhanced peripheral proteolysis due to chronic neuroendocrine secretion. Attempts at aggressive nutritional repletion in patients with cardiac cachexia have produced inconclusive results. Concentrated dextrose and amino acid preparations should be used to avoid fluid overload. Nitrogen balance should be measured to ensure adequate nitrogen intake. Lipid emulsions must be administered cautiously because they can produce myocardial ischemia and negative inotropy. Feeding these patients with either enteral or parenteral nutrition should be undertaken cautiously to avoid refeeding syndrome and hypophosphatemia.

Patients with severe chronic obstructive pulmonary disease may have difficulty weaning from the ventilator if they are overfed. This relates to the RQ, a measure of oxygen consumption and carbon dioxide production by the body in metabolism. An RQ of 1 reflects pure carbohydrate utilization, while an RQ greater than 1 occurs during lipogenesis (energy storage). Although normal lungs can tolerate increased CO₂ production (RQ > 1) without adversely affecting respiration, patients with chronic obstructive pulmonary disease may experience CO₂ retention and inability to wean. The treatment is to increase the percentage of calories delivered as lipid and to avoid overfeeding at all costs.

► **Disease of the Gastrointestinal Tract**

Benign gastrointestinal disease (eg, inflammatory bowel disease, fistula, pancreatitis) often leads to nutritional problems due to intestinal obstruction, malabsorption, or anorexia. Chronic involvement of the ileum in inflammatory bowel disease produces malabsorption of fat- and water-soluble vitamins, calcium and magnesium, anions (phosphate), and the trace elements iron, zinc, chromium, and selenium. Protein-losing enteropathy, accentuated by

transmural destruction of lymphatics, can add to protein depletion. Treatment with sulfasalazine can produce folate deficiency, and glucocorticoid administration may accelerate breakdown of lean tissue and enhance glucose intolerance owing to stimulation of gluconeogenesis. Patients with inflammatory bowel disease who require elective surgery should be evaluated for malnutrition preoperatively.

Patients with gastrointestinal fistulas can develop electrolyte, protein, fat, vitamin, and trace metal deficiencies; dehydration; and acid-base imbalance. Aggressive fluid replacement is often needed. Patients with fistulas often require nutritional support. The choice of feeding route or formula will depend on the level and length of dysfunctional bowel. Patients with proximal enterocutaneous fistulas (from the stomach to the mid-ileum) should receive TPN with no oral intake. Patients with low fistulas should receive TPN initially, but after infection is brought under control, they can often be switched to an enteral formula or even a low-residue diet.

► **Pancreatitis**

The concept of pancreatic rest has evolved over the recent years. Ranson criteria can serve as a rough estimate of the need for nutritional support. Patients with acute pancreatitis who present with three or fewer Ranson criteria should be treated with fluid replacement, pain control, and brief bowel rest. Most of these patients can rapidly resume an oral diet and do not benefit from TPN. Those with more than three Ranson criteria should receive nutritional support. Recent data documents the successful use of enteral diets, particularly elemental products via jejunal access, avoiding TPN if feasible.

► **Short Bowel Syndrome**

Inadequate intestinal absorptive surface leads to malabsorption, excessive water loss, electrolyte derangements, and malnutrition. The absorptive capacity of the small intestine is highly redundant, and resection of up to half its functional length is reasonably well tolerated. Short bowel syndrome typically occurs when less than 200 cm of anatomic small bowel remain, although the presence of the ileocecal valve may reduce this length to 150 cm. However, short bowel syndrome also may occur from functional abnormalities of the small bowel resulting from severe inflammation or motility disorder. The optimal nutritional therapy for a patient with short bowel syndrome must be tailored individually and depends upon the underlying disease process and the remaining anatomy. Following resection, the remaining bowel undergoes long-term adaptation, with observed increases in villous height, luminal diameter, and mucosal thickness. The estimated minimum length of small bowel required for adult patients to become independent of TPN is 120 cm.

Adaptation to short gut occurs over time, and initial management should be directed at avoiding electrolyte imbalance and dehydration while providing daily caloric requirements through TPN. Some patients may eventually supplement TPN with oral intake. In these patients, dietary management includes consuming frequent small meals, avoiding hyperosmolar foods, restricting fat intake, and limiting consumption of foods high in oxalate (precipitates nephrolithiasis).

► AIDS

Patients with AIDS frequently develop protein-calorie malnutrition and weight loss. Many factors contribute to deficiencies of electrolytes (sodium and potassium), trace metals (copper, zinc, and selenium), and vitamins (A, C, E, pyridoxine, and folate). Enteropathy may impair fluid and nutrient absorption and produce a voluminous, life-threatening diarrhea. Dehydration and further immune dysfunction occur as a consequence of refractory diarrhea.

Malnourished AIDS patients require a daily intake of 35-40 kcal and 2.0-2.5 g protein. Those with normal gut function should be given a high-protein, high-calorie, low-fat, lactose-free oral diet. Patients with compromised gut function require an enteral (amino acid or polypeptide) or parenteral nutrition.

► Solid Organ Transplant Recipients

Patients who have undergone organ transplantation present unique issues in relation to nutritional management due to both the preexisting disease state and the medications taken to prevent graft rejection. During the acute posttransplant phase, adequate nutrition is required to help prevent infection, promote wound healing, support metabolic demands, replenish lost stores, and mediate the immune response. Organ transplantation complications, including rejection, infection, wound healing, renal insufficiency, hyperglycemia, and surgical complications, require specific nutritional requirements and therapies.

Obesity is associated with both decreased patient survival and decreased graft survival, in part due to a greater incidence of surgical, metabolic, and cardiovascular complications. Patients with BMI greater than 30 kg/m² show a higher incidence of steroid-induced posttransplant diabetes mellitus. The first 6 weeks following transplantation is characterized by increased nutritional demands due to a combination of surgical metabolic stress and high doses of immunosuppressive medications. Daily protein intake recommendation in the immediate posttransplant phase, as well as during acute rejection episodes, is 1.5 g/kg actual body weight.

Long-term immunosuppression is associated with protein hypercatabolism, obesity, dyslipidemia, glucose intolerance, hypertension, hyperkalemia, and alteration of vitamin D metabolism. Approximately 60% of renal recipients develop

dyslipidemia posttransplant. Alterations in lipid metabolism may be associated with corticosteroids, cyclosporine, thiazide diuretics, or beta-blockers, as well as with renal insufficiency, nephrotic syndrome, insulin resistance, or obesity. There is evidence that abnormal lipoprotein levels lead to glomerulosclerosis, renal disease progression, and even potential graft failure.

Dietary salt restriction is recommended in transplant patients, as salt intake may play a role in cyclosporine-induced hypertension caused by sodium retention. Sodium intake is recommended not to exceed 3 g/d. Cyclosporine is associated with hypomagnesemia and hyperkalemia, especially during the immediate posttransplant phase when the dosage is high. Additionally, antihypertensive treatment with beta-blocker agents or with angiotensin-converting enzyme (ACE) inhibitors may exacerbate hyperkalemia. Calcium, phosphorus, and vitamin D metabolism are influenced by prolonged therapy with steroids leading to osteopenia and osteonecrosis. The daily recommendation for dietary calcium is 800-1500 mg, and the recommended intake of phosphorus is 1200-1500 mg/d. Some patients may also require supplementation of active vitamin D. Patients on a low-protein diet often need multivitamin supplements. During the first year, the major nutritional goal is to treat preexisting malnutrition and prevent excessive weight gain.

► Major Trauma

In severely injured patients, metabolic changes must be acknowledged early and monitored during the posttraumatic phase. Severe trauma induces alteration of metabolic pathways and activation of the immune system. Depending on the severity of the initial injury, catabolic changes in posttraumatic metabolism can last from several days to weeks. The posttraumatic metabolic changes include hypermetabolism with increased energy expenditure, enhanced protein catabolism, insulin resistance associated with hyperglycemia, failure to tolerate glucose load, and high plasma insulin levels ("traumatic diabetes"). As a general rule, the metabolic demands of the patient can increase by 1.3-1.5 times the normal requirements.

After the state of traumatic-hemorrhagic shock has been compensated for, metabolic changes are characterized by an increased metabolic turnover, activation of the immune system, and induction of the hepatic acute-phase response. This results in increased consumption of energy and oxygen. In addition to the acute hypermetabolic state, the systemic inflammatory cascade is initiated, with the release of proinflammatory cytokines and activation of the complement system. Bacterial translocation from the gut may further aggravate these metabolic sequelae and inflammatory response.

Many severely injured patients require inotropic support, and vasoactive drugs promote catabolism by reducing serum

levels of anabolic hormones. In contrast, endogenous catecholamines, cortisol, and glucagon levels are elevated after trauma, leading to increased energy substrate mobilization. Proteinolysis of skeletal muscle and glycolysis are increased to provide the substrates for hepatic gluconeogenesis and biosynthesis of acute-phase proteins. The equilibrium is shifted toward supporting the immune response and wound healing at the cost of enhanced proteinolysis of skeletal muscle. In addition, stimulation of the neuroendocrine axis through stress, pain, inflammation, and shock increases the caloric turnover significantly above baseline. This leads to increased serum levels of catabolic hormones, such as cortisol, glucagon, and catecholamines, and decreased levels of insulin.

Appropriate immunonutrition should be started in the ICU, preferably by enteral route, in order to counteract the effects of the hypermetabolic state after major trauma. Without absolute contraindications, guidelines clearly favor the concept of early enteral nutrition within 24-48 hours after admission in the ICU. It is important not to overfeed critically injured patients with calories, since this may contribute to adverse outcomes. Early overfeeding of severely injured patients leads to an increase in oxygen consumption, carbon dioxide production, lipogenesis, and hyperglycemia and contributes to secondary immune suppression.

Obese patients are particularly susceptible to the adverse effects of overfeeding. Current feeding recommendations for morbidly obese ICU patients are a high protein, hypocaloric diet. Caloric provision should approximate 60%-70% of caloric requirements determined by indirect calorimetry or other predictive equation. A simplistic weight-based approach approximates 22-25 kcal and 2-2.5 g of protein per kg ideal body weight per day.

MULTIPLE CHOICE QUESTIONS

- Which of the following is not a proposed mechanism by which enteral feeding decreases bacterial intestinal wall translocation when compared to IV nutrition?
 - Preserved local cytokine expression pattern
 - Increased villous height and over all mucosal mass
 - Bactericidal activity of enteral nutrition components
 - Stimulation of intraluminal IgA transportation
- Which of the following stressors results in the greatest increase in energy expenditure above basal metabolic needs?
 - Sepsis
 - Trauma
 - Elective operations
 - Burns
- Regarding centrally administered parenteral nutrition in the critically ill patient, which of the following is not true?
 - An initial formulation for nonamino acid calories is generally advised to consist of 70% dextrose and 30% fat emulsion.
 - TPN should be avoided if anticipated use is less than 6-7 days.
 - The recommended amino acid dose ranges from 0.8 to 1 g/kg.
 - The line-related complication rate from CVCs is greater than 15%.
- Which of the following is true?
 - Lactose intolerance is most prevalent in European Caucasians when compared to other populations.
 - Gastric residuals of 100 cc should prompt holding of tube feeds.
 - Gastric bypass patients are prone to deficiencies of the fat-soluble vitamins, calcium, iron, vitamin B₁₂, and folate.
 - Enteral nutrition carries a technical complication rate of 10%.
- Regarding nutritional indices, which of the following is false?
 - PNI has been validated in patients undergoing either major cancer or gastrointestinal surgery and found to accurately identify a subset of patients at increased risk for complications.
 - The NRI is an excellent tool for tracking the adequacy of nutritional support.
 - The MNA is a rapid and reliable tool for evaluating the nutritional status of the elderly.
 - SGA is a reproducible clinical method that has been validated and encompasses the patient's history and physical examination.

Anesthesia

Theodore J. Sanford Jr, MD

Anesthesiology is a “team sport.” Providing the best and safest care for patients depends on all members of the team—surgeons, nurses, and anesthesia providers—communicating in a timely, efficient, and patient-focused manner. Anesthesiologists today not only provide patient care in the operating room but also have patient responsibilities in other areas, including preoperative anesthesia clinics (PACs), postanesthesia care units (PACUs), obstetrics, ambulatory surgery centers, endoscopy suites, postoperative pain management, critical care units, and chronic pain management.

Anesthesia is a term derived from the Greek meaning “without sensation” and is commonly used to indicate the condition that allows patients to undergo a variety of surgical or nonsurgical procedures without the pain or distress they would otherwise experience. More importantly, this blocking of pain and/or awareness is reversible. *Anesthesiology* is the medical practice of providing anesthesia to patients and is most commonly provided by a medical doctor, an anesthesiologist, either alone or in conjunction with a certified registered nurse anesthetist (CRNA), anesthesia assistant, or resident physician-in-training. Anesthesia is most often described as being a general anesthetic, that is, a drug-induced loss of consciousness during which patients are not arousable even by noxious stimulus and often require a controlled airway. Anesthesia can also be provided without inducing unconsciousness by utilizing regional blockade, local anesthesia with monitored anesthesia care (MAC), or conscious sedation.

HISTORY OF ANESTHESIA

One of modern medicine’s most important discoveries was that the application of diethyl ether (ether) could provide the classic requirements of anesthesia: analgesia, amnesia, and muscle relaxation in a reversible and safe manner. Crawford Long was the first to use ether in 1842, and William Morton’s successful 1846 public demonstration of ether as

an anesthetic in the “Ether Dome” of Massachusetts General Hospital ushered in the modern day of anesthesia and surgery. Chloroform was used by Sir James Y. Simpson to provide analgesia to Queen Victoria in 1853 during the birth of Prince Leopold. This royal approval of inhalation agents led to the wide acceptance of their use as surgical anesthesia. Ether (flammability, solubility) and chloroform (liver toxicity) each had significant drawbacks, and over time, inhalation agents were developed with similar anesthetic effects but much safer physiologic and metabolic properties.

Cocaine’s ability to produce topical anesthesia for ophthalmic surgery was discovered in the late 1800s. The hypodermic needle was introduced in 1890 and facilitated the injection of cocaine to produce reversible nerve blockade and later the injection of cocaine via a lumbar puncture to produce a spinal anesthetic and the first spinal headache. The chemical properties of cocaine were soon determined and manipulated to synthesize numerous other local anesthetic agents used to achieve what became known as regional anesthesia, which lacks the unconsciousness and amnesia of the general anesthetics but does produce analgesia and lack of motor movement in the “blocked” region.

Underwood EA: Before and after Morton. A historical survey of anaesthesia. *Br Med J.* 1946;2:525.

OVERALL RISK OF ANESTHESIA

Anesthesia is performed over 70 million times per year in the United States and is remarkably safe. The number of anesthesia-related deaths has decreased dramatically in the last 30 years because of intense scrutiny by the American Society of Anesthesiologists. The realization that most problems are related to airway compromise has led to advanced respiratory monitoring utilizing pulse oximetry and capnography for every patient undergoing anesthesia. The Institute of Medicine’s *To Err Is Human* complimented

the anesthesiology community for its marked decrease in morbidity and mortality from anesthesia. Overall, the risk of anesthesia-related death in the healthy patient is estimated to be as low as 1:100,000-200,000 anesthetics.

The combination of amnesia, with or without unconsciousness, analgesia, and muscle relaxation is purposely induced by an anesthetic caregiver and is achieved either by administering inhalation agents in appropriate doses to affect the central nervous system (CNS) or by using specific intravenous pharmacologic agents to produce the same effects as inhaled vapors. These agents include amnestics, for example, benzodiazepines (midazolam or diazepam); analgesics, for example, the opioids morphine and fentanyl derivatives; the neuromuscular blocking drugs succinylcholine, pancuronium, or vecuronium; and sedative hypnotics, for example, sodium pentothal and propofol. All of the agents have adverse physiologic consequences: respiratory depression, cardiovascular depression, and loss of consciousness. Furthermore, some of these agents may induce allergic reactions. Some have also been known to trigger malignant hyperpyrexia.

The most common problems associated with adverse outcomes today still relate to airway compromise, medication errors, and central venous cannulation. Other concerns are postoperative neurologic complications (eg, nerve injury), ischemic optic neuropathy, coronary ischemia, anesthesia in remote locations (eg, interventional radiology sites), and probably most importantly, inadequate preoperative evaluation and preparation.

The anesthesia provider must be able to (1) achieve a state of anesthesia quickly and safely by choosing the appropriate techniques and agents, taking into consideration the patient's medical condition; (2) maintain and monitor a state of anesthesia throughout the surgical procedure while compensating for the effects of varying degrees of surgical stimulation and blood and fluid losses; (3) reverse the muscle relaxation and amnesia as necessary; and (4) return the patient to physiologic homeostasis while maintaining sufficient analgesia to minimize postprocedure pain.

Kohn LT, Corrigan JM, Donaldson MS (editors): *To Err Is Human: Building a Safer Health System*. Washington, DC: National Academy Press, 2000.

PREOPERATIVE EVALUATION

A preoperative evaluation is a responsibility of the anesthesiologist and is a basic element of anesthesia care (Table 11-1). This evaluation consists of information gathered from multiple sources, including the patient's medical record, history and physical examinations, and findings from medical tests and consults or other evaluations performed prior to the patient being seen by the anesthesiologist. Improved patient outcome and satisfaction is the result of an adequate,

Table 11-1. Preoperative evaluation.

Goals	Optimize patient condition Understand and control comorbidities and drug therapy Ensure patient's questions are answered
Timing	High surgical invasiveness: at least 1 day prior Medium invasiveness: day before or day of surgery Low invasiveness: day of surgery
Content	Review medical records Directed history and physical examination: airway, heart, and lungs Indicated laboratory or additional consultations

structured, formal presurgical, or preprocedure evaluation and preparation performed on all patients.

► Timing

The timing of the preoperative evaluation depends primarily on the degree of planned surgical invasiveness. For high surgical invasiveness, the initial assessment should be done at a minimum the day before the planned procedure by the anesthesia staff. Patients undergoing medium surgical invasive procedures can be evaluated the day before or even on the day of surgery, and for low surgical invasiveness, the initial assessment may be done the day of surgery. Time must be allotted to follow up on conditions discovered during the preoperative visit and to answer patient questions. Perioperative complications and deaths are most often a combination of patient comorbidities, surgical complexity, and anesthesia effects. The Physical Status Classification of the American Society of Anesthesiologists is the best known of many perioperative classification schemes (Table 11-2). This classification system does not assign risk but is a common language used to describe patients' preoperative physical status. The system is an alert to the anesthesia practitioner and all members of the patient care team.

Table 11-2. American Society of Anesthesiologists physical status classification.

ASA 1 (PS1): A normal healthy patient
ASA 2 (PS2): A patient with mild systemic disease
ASA 3 (PS3): A patient with severe systemic disease
ASA 4 (PS4): A patient with severe systemic disease that is a constant threat to life
ASA 5 (PS5): A moribund patient who is not expected to survive without the operation
ASA 6 (PS6): A declared brain-dead patient whose organs are being removed for donor purposes
E: Emergency

Patients should ideally be seen in a PAC staffed by anesthesia personnel who evaluate patients from the anesthetic perspective and who look for physical conditions (airway) and controlled, uncontrolled, or unrecognized medical conditions that can lead to perioperative morbidity and mortality. There must be adequate communication between anesthesiologist and surgeon such that any conditions that may result in patient compromise are optimally addressed. Optimally, a patient's medical status has been adequately addressed by the patient's primary care physician prior to being referred to the PAC. However, in some instances, only a cursory "cleared for anesthesia and surgery" may result in a necessary delay. Any patients other than healthy ASA 1 or 2 patients should be seen in a PAC. Prior to referring patients to the PAC, the surgeon should have already ordered the necessary preoperative labs and in many instances will have already detected uncontrolled medical conditions that require consultations from other specialties in order to recommend and in some instances improve a patient's status.

The optimal preoperative evaluation has the following two elements: (1) content—readily accessible medical records, patient interview, a directed preanesthesia examination, indicated preoperative laboratory tests, and additional consultations when indicated; the minimum acceptable examination includes an assessment of the airway, heart, and lungs well in advance of the planned date of surgery; and (2) preoperative tests—only as indicated by comorbidities and never as a screen, these tests should be specifically aimed at helping the anesthesiologist formulate an anesthetic plan.

Practice advisory for preanesthesia evaluation: a report by the American Society of Anesthesiologists Task Force on Preanesthesia Evaluation. *Anesthesiology*. 2012;116:1-17.

► History & Physical Examination

The anesthesiologist should specifically ask the patient about previous operations, anesthetic type, and any complications, for example, allergic reactions, abnormal bleeding, delayed emergence, prolonged paralysis, difficult airway management, awareness, or jaundice. Each of these describes a possible specific anesthetic morbidity that must be further investigated either by history or specific testing. Medical conditions detected as decreased exercise tolerance, shortness of breath, orthopnea, kidney or liver disease, and metabolic abnormalities, for example, diabetes or thyroid disease, should be ascertained. A comprehensive history seeks to identify serious cardiac conditions, for example, unstable coronary syndromes, angina, myocardial infarctions either recent or past, decompensated congestive heart failure, significant arrhythmias, or severe valvular disease. Any recent changes in cardiac symptoms or other associated diseases, for example, diabetes, renal disease, or cerebrovascular disease symptoms, should be identified.

Any family history of adverse responses to anesthetics (malignant hyperthermia) and social history of smoking, drug use, and alcohol consumption is important. Finally, a comprehensive review of concurrent medications including antihypertensives, insulin, bronchodilators, or any other medications that can interact with anesthetic agents should be documented. Certain medications may result in increased or decreased anesthetic requirements, prolongation of muscle relaxants, abnormal responses to sympathomimetics, delayed or enhanced metabolism of anesthetics, and/or augmentation of the depressant effects of anesthetics. The patient's use of herbal medicines can have an adverse reaction with some anesthetics (Table 11-3) and all should be discontinued 2-3 weeks before surgery.

Wong A, Townley SA: Herbal medicines and anaesthesia. *Br J Anaesth*. 2011;11:15-17.

► Airway Examination & Classification

After the vital signs are obtained, the physical examination begins with the upper airway. Ability to control the airway is mandatory. The focus of the examination is to assess those factors that would make airway control (eg, endotracheal intubation) difficult or impossible. Seven keys to the upper airway examination should be documented:

1. Range of motion of the cervical spine: Patients should be asked to extend and flex their neck to the full range of possible motion so the anesthesiologist may look for any limitations.
2. Thyroid cartilage to mentum distance: ideal is greater than 6 cm.
3. Mouth opening: ideal is greater than 3 cm.
4. Dentition: dentures, loose teeth, poor conservation.
5. Jaw protrusion: ability to protrude the lower incisors past the upper incisors.
6. Presence of a beard.
7. Examination and classification of the upper airway based on the size of patient's tongue and the pharyngeal structures visible on mouth opening with the patient sitting looking forward. This visual description of the airway structures is known as the Mallampati score (Figure 11-1).

Grade I The soft palate, anterior and posterior tonsillar pillars, and uvula are visible—suggests easy airway intubation.

Grade II Tonsillar pillars and part of the uvula obscured by the tongue.

Grade III Only soft palate and hard palate visible.

Grade IV Only the hard palate is visible—suggests challenging airway.

Table 11–3. Perioperative effects of common herbal medicine.¹

Name (Other Names)	Alleged Benefits	Perioperative Effects	Recommendations
Echinacea	Stimulates immune system	Allergic reactions; hepatotoxicity; interference with immune suppressive therapy (eg, organ transplants)	Discontinue as far in advance of surgery as possible
Ephedra (ma huang)	Promotes weight loss; increases energy	Ephedrine-like sympathetic stimulation with increased heart rate and blood pressure, arrhythmias, myocardial infarction, stroke	Discontinue at least 24 h prior to surgery; avoid monoamine oxidase inhibitors
Garlic (ajo)	Reduces blood pressure and cholesterol levels	Inhibition of platelet aggregation (irreversible)	Discontinue at least 7 days prior to surgery
Ginkgo (duck foot, maidenhair, silver apricot)	Improves cognitive performance (eg, dementia), increases peripheral perfusion (eg, impotence, macular degeneration)	Inhibition of platelet-activating factor	Discontinue at least 36 h prior to surgery
Ginseng	Protects against "stress" and maintains "homeostasis"	Hypoglycemia; inhibition of platelet aggregation and coagulation cascade	Discontinue at least 7 days prior to surgery
Kava (kawa, awa, intoxicating pepper)	Decreases anxiety	GABA-mediated hypnotic effects may decrease MAC (see Chapter 7); possible risk of acute withdrawal	Discontinue at least 24 h prior to surgery
St. John's wort (amber, goat-weed, <i>Hypericum perforatum</i> , klatmathe-weed)	Reverses mild to moderate depression	Inhibits serotonin, norepinephrine, and dopamine reuptake by neurons; increases drug metabolism by induction of cytochrome P-450	Discontinue at least 5 days prior to surgery
Valerian	Decreases anxiety	GABA-mediated hypnotic effects may decrease MAC; benzodiazepinelike withdrawal syndrome	Taper dose weeks before surgery if possible; treat withdrawal symptoms with benzodiazepines

¹For more details, see Ang-Lee MK, Moss J, Yuan C: Herbal medicine and perioperative care. *JAMA*. 2001;286:208.

GABA, γ -aminobutyric acid; MAC, minimum alveolar concentration.

Reproduced, with permission, from Mallampati SR: Clinical sign to predict difficult tracheal intubation (hypothesis), *Can Anaesth Soc J*. 1983 May;30(3 Pt 1):316–317.

The physical examination then focuses on heart and lungs, potential intravenous catheter sites, and potential sites for regional anesthesia. Range of motion of limbs must also be noted as this may affect positioning in the operating room. Finally, any neurologic abnormalities must be noted.

When a metabolic or physical finding or symptom is discovered during this visit, the anesthesiologist may believe that a specialty consultation is necessary to suggest ways to optimize the patient for surgery and anesthesia. If this is the case, the anesthesiologist should communicate with the surgeon in order to prevent unnecessary or unexpected delays in the surgical schedule. It is imperative that any consults ordered be completed and the results be available by the day of surgery.

The anesthesiologist can then advise the patient on appropriate options for general anesthesia versus regional techniques based on the patient's history, physical examination, and type of surgery. Although some surgical procedures must

always be performed under general anesthesia, the anesthesiologist may discuss other options with the patient. If the referring surgeon has a particular preference for a type of anesthetic, such preferences should be communicated to the anesthesiologist directly rather than through the patient. It is also best if the referring surgeon does not promise any specific agent or technique without first consulting with the anesthesia care givers.

Mallampati SR et al: A clinical sign to predict difficult tracheal intubation: a prospective study. *Can Anaesth Soc J*. 1985;32:429.

► Preoperative Fasting

The anesthesiologist must discuss with the patient the requirements for preprocedure fasting and the management of medications up to the time of surgery or procedure.

▲ **Figure 11-1.** Mallampati airway classification of oral opening. (Reproduced with permission from Morgan GE, Mikhail MS, Murray MJ: *Clinical Anesthesiology*, 4th ed. McGraw-Hill.)

Current guidelines for preoperative fasting are as follows: (1) No solid food should be eaten after the evening meal. At the minimum, most anesthesiologists delay an anesthetic so that the last solid food was 6-8 hours prior to nonemergent surgery or procedures involving anesthesia. (2) NPO after midnight except for sips of water to take oral medications. Water may be ingested up to 2 hours before checking in for surgery. Some institutions allow other clear liquids, for example, coffee, a few hours prior to surgery or procedure. However, because surgery schedules can change abruptly and procedure time may be moved forward, NPO after midnight is the best policy. (3) Pediatric fasting guidelines vary among institutions, so practitioners should consult with their particular pediatric anesthesia group.

American Society of Anesthesiologists: Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures. *Anesthesiology*. 2011;114:495-511.

▶ **Drugs to Continue Preoperatively**

In the perioperative period patients should continue taking beta-blocking agents, statin medications, antihypertensives except the angiotensin II receptor blockers (ARBs) and angiotensin-converting enzyme inhibitors (ACE) antihypertensive medications. Patients taking ARBs or ACE inhibitors can

experience marked hypotension with the induction of general anesthesia and respond poorly to common vasopressors. Patients taking anticoagulants such as Coumadin, clopidogrel, and the newer anticoagulants such as dabigatran (Pradaxa) should stop these medications prior to most surgeries. The timing and bridging of cessation of these anticoagulants is the responsibility of the surgical service. Continuation of low-dose aspirin for patients with coronary stents or atrial fibrillation is recommended. Oral antihyperglycemic agents need should not be taken the day of surgery. Insulin-dependent patients should receive instructions from the anesthesiologist during the preanesthesia visit as to the management of their insulin. Other medications should be discussed with the patient and surgery team at the time of the preoperative anesthesia visit.

▶ **Comorbidities**

Comorbidities should be well controlled in the preoperative period to avoid postprocedure morbidity, and even mortality.

▶ **Cardiovascular Disease (Hypertension, Coronary Artery Disease, Congestive Heart Failure)**

A. Hypertension

Hypertension is the most common preexisting medical disease identified preoperatively and is a major risk factor for renal, cerebrovascular, peripheral vascular, cardiac ischemia

or infarction, and congestive heart failure. The triad of lipid disorders, diabetes, and obesity is classically found in patients with hypertension and should alert the clinician that further evaluation for these conditions is needed. Hypertension has an association with coronary artery disease, and the preoperative evaluation is a unique opportunity to identify and treat the nonessential causes of hypertension. The literature strongly supports the notion that all hypertensive patients should be treated medically to be as close to normotension as possible before any planned surgical procedure. Diastolic pressures of 110 mm Hg or higher result in a higher incidence of intraoperative hypotension and myocardial ischemia. However, the literature does not support delaying surgery if the delay would be detrimental to the patient. The introduction of perioperative selective beta-blocking drugs provides a marked benefit in reducing the incidence of significant myocardial ischemia during the perioperative period. Although somewhat controversial, starting patients on beta-blockers immediately preoperatively may have some risk, but any patient already taking beta-blockers should continue taking the drug preoperatively.

Sear JW, Giles JW, Howard G, Foex P: Perioperative beta-blockade, 2008: what does POISE tell us, and was our earlier caution justified? *Br J Anaesth.* 2008;101:135-138.

Wax DB et al: Association of preanesthesia hypertension with adverse outcomes. *J Cardiothorac Vasc Anesth.* 2010;24(6): 927-930.

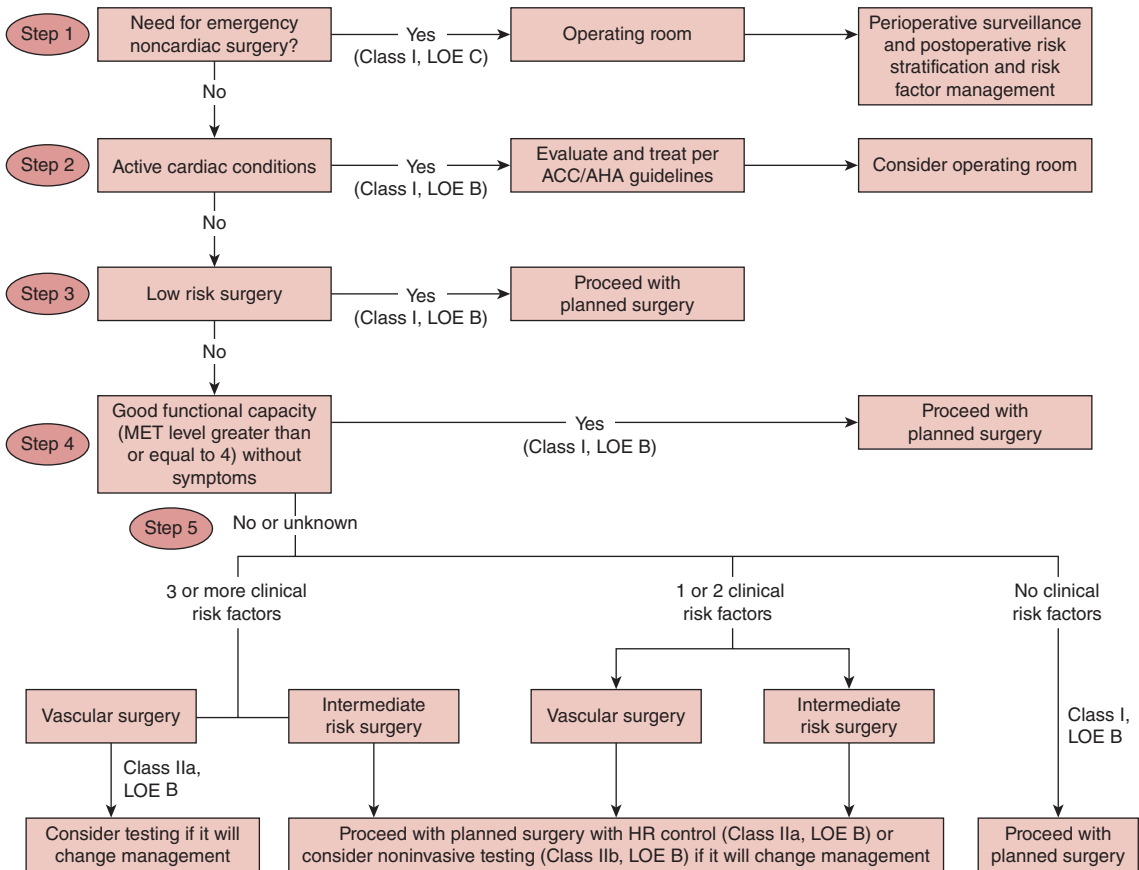

B. Coronary Artery Disease

Ischemic heart disease is a leading cause of death in the United States and is the leading cause of morbidity and mortality in the perioperative period. About 25% of patients who

present for surgery each year have coronary artery disease, and thus much of the preoperative evaluation focuses on detecting the presence and degree of ischemic heart disease and determining whether it is likely to impact anesthesia and surgery. A major goal of preoperative assessment of cardiac status is to determine what, if any, interventions—coronary artery bypass graft (CABG), percutaneous coronary intervention (PCI)—would benefit patients undergoing noncardiac surgery. In general, preoperative cardiac tests are recommended only if the information obtained will lead to changes in patient management. However, certain active clinical conditions (Table 11–4) demand evaluation and treatment before noncardiac surgery. Determining which patient characteristics indicate high perioperative risk is very difficult, but the Revised Cardiac Risk Index (RCRI) factors of (1) ischemic heart disease, (2) heart failure, (3) high-risk surgery, (4) diabetes mellitus, (5) renal insufficiency, and (6) cerebral vascular diseases are a validated set of independent predictors of cardiac risk for patients. The anesthesiologist in a pre-op clinic will screen for these factors and recommend further studies based on the presence or absence of RCRI. Patients with no RCRI have a very low (0.4%) cardiac risk while patients with three or more risk factors have a 5.4% risk of an adverse cardiac event and warrant further testing. Because of the high incidence of silent ischemia, some institutions will require patients older than 50 to have an electrocardiogram (EKG). A simple exercise tolerance description of the functional capacity of the patient (eg, ability to climb two flights of stairs without stopping) is also a practical screening. This initial history by the surgeon or anesthesiologist may be the first cardiac assessment the patient has ever had. The assessment of functional capacity may be the first indication of the need for further evaluation of potential cardiac pathology.

Table 11–4. Active cardiac conditions for which the patient should undergo evaluation and treatment before noncardiac surgery.

Condition	Examples
Unstable coronary syndromes	Unstable or severe angina Recent myocardial infarction (> 7 but < 30 days ago)
Decompensated heart failure (New York Heart Association class IV); worsening or new onset Significant arrhythmias	High-grade atrioventricular block Mobitz II atrioventricular block Third-degree atrioventricular block Symptomatic ventricular arrhythmias Supraventricular arrhythmias (including atrial fibrillation with uncontrolled ventricular rate [> 100] at rest) Symptomatic bradycardia Newly recognized ventricular tachycardia
Severe valvular disease	Severe aortic stenosis (mean pressure gradient > 40 mm Hg or aortic valve area < 1.0 cm ² or symptomatic) Symptomatic mitral stenosis (progressive dyspnea on exertion, exertional syncope, or heart failure)

▲ **Figure 11-2.** Cardiac evaluation and care algorithm for noncardiac surgery based on active clinical conditions, known cardiovascular disease or cardiac risk factors for patients 50 years of age or greater. Summary of ACC/AHA 2007 perioperative guideline algorithm on cardiovascular evaluation and care for noncardiac surgery. HR = heart rate, LOE = loss of evidence, MET = metabolic equivalent.

The American Heart Association (AHA) developed a useful algorithm for all providers (Figure 11-2). This algorithm, updated in 2007, no longer focuses on stress testing but recommends testing only if the results could have an impact on surgery or anesthesia and lead to changes in patient management. The AHA guidelines state that most patients who have asymptomatic heart disease can safely undergo elective noncardiac surgery without performing invasive or even noninvasive cardiac testing.

Fleisher LA et al: 2009 ACCF/AHA Focused Update on Perioperative Beta Blockade Incorporated Into the ACC/AHA 2007 Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery A Report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation*. 2009;120: e169-e276.

Ford MK et al: Systematic review: prediction of perioperative cardiac complications and mortality by the revised cardiac risk index. *Ann Intern Med*. 2010;152:26.

C. Patients With Prior Percutaneous Coronary Intervention (Angioplasty and Stents)

There is much controversy about the best treatment for patients who have had a PCI procedure, angioplasty without stents, or angioplasty with either a bare metal or drug-eluting stent. Because of the risk for thrombosis at the site of intervention, patients are usually placed on a dual antiplatelet therapy of aspirin and clopidogrel for 2-4 weeks following angioplasty, 4-6 weeks for the bare metal stents, and up to 1 year for the drug-eluting stents. Stopping these antiplatelet drugs for a surgical intervention that falls in the therapy

period presents a risk for perioperative cardiac events if the stent thromboses. The AHA guidelines recommend that if the procedure is elective, then the operation should be postponed until the case can be done with aspirin as the only antiplatelet drug. If the operation is urgent, then consideration must be given to the timing of the surgery and the risk of surgical bleeding. If the risk of bleeding is low, then a PCI with a stent should be considered and the patient placed on dual antiplatelet therapy. If the bleeding risk is high, the AHA recommends the following based on the timing of surgery: angioplasty for surgery within 14-29 days, bare metal stent for planned surgery within 30-365 days, and drug-eluting stent for surgery that can be delayed 1 year. Truly urgent and/or emergent surgery necessitates angioplasty for a procedure with a high risk of surgical bleeding and stenting for a case with a low risk for bleeding.

The AHA guidelines recommend several other measures: (1) Perioperative beta-blockade is indicated for patients previously on beta-blockers, patients undergoing major vascular surgery, and patients undergoing intermediate-risk surgery with one or more RCRI. Beta-blockade may be started several days to weeks before planned surgery in order to produce a consistent targeted heart rate between 65 and 70 beats/min. The addition of statin class agents, alpha-2 agonists, and calcium channel blockers may also be effective. (2) Left ventricular function should be assessed preoperatively for patients with unexplained dyspnea or who have active or a history of compensated heart failure with changing symptoms. (3) Coronary revascularization is suggested for patients with left main disease, symptomatic three-vessel disease and poor ejection fraction (EF), two-vessel disease with left anterior descending coronary artery stenosis, poor EF and a positive stress test, or an acute ST segment elevation myocardial infarction. AHA does not recommend prophylactic CABG surgery in patients with stable coronary artery disease. (4) Blood glucose should be tightly controlled. (5) Patients with pacemakers or implanted defibrillator devices should have them checked 3-6 months before major surgery. (6) Patients with drug-eluting cardiac stents should continue aspirin therapy and discontinue other antiplatelet agents for as short a time as possible. (7) Beta-blockers and statin drugs should be continued in the perioperative period. (8) Cardiology consultants should be asked for specific recommendations that would reduce immediate perioperative cardiac risk.

Practice alert for perioperative management of patients with coronary artery stents. *Anesthesiology*. 2009;110:1-2.

D. Pulmonary Disease

The presence of significant pulmonary disease is suspected or confirmed by the history and physical examination. Poor functional capacity may be the first indication that further workup may be necessary. The presence of either obstructive

or restrictive lung disease always puts the patient at risk for perioperative complications, for example, pneumonia and prolonged difficulty weaning from the ventilator. In some instances, arterial blood gas analysis or pulmonary function tests are necessary to determine responsiveness to bronchodilators. Asthmatic patients should be asked about the severity of their disease, hospitalizations, responsiveness to inhalers, and steroid usage. There is no value for routine preoperative chest x-rays. Surgical history and physical examination may be the first indication of significant pulmonary disease, and workup may be initiated before sending the patient to the PAC. Optimally, patients who smoke should stop smoking at least 8 weeks before scheduled surgery. Warner demonstrated that the highest rate of pulmonary complications in 200 patients undergoing CABG was in those who had stopped smoking 1-8 weeks preoperatively. Recent cessation of cigarette smoking may pose a greater risk of pulmonary complication because of the commonly observed increase in cough and sputum production. Patients should abstain from smoking for as long as possible both before and after surgery.

Warner DO: Helping surgical patients quit smoking: why, when, and how. *Anesth Analg*. 2005;101:481.

E. Obesity

The national epidemic of obesity poses particular problems for surgery and anesthesia. The body mass index (BMI), the ratio of weight (kg)/height (m)², gives an idea of the degree of obesity. Normal BMI is about 21.6 kg/m², overweight is 25-30 kg/m², obese is 30-35 kg/m², and extreme obesity is more than 35 kg/m². Extreme obesity patients have a variety of perioperative issues and should be evaluated in a PAC. Particular attention should include the upper airway and evaluation of cardiovascular, respiratory, metabolic, and gastrointestinal systems. Abnormal BMI patients have cardiovascular issues with venous access, hypertension, cardiomegaly, decreased left ventricular function, and cor pulmonale, and they have twice the incidence of ischemic heart disease than patients at normal weight. Extreme obesity is associated with significant pulmonary problems, including restrictive lung volumes, obstructive sleep apnea, hypoxemia, increased Paco₂, increased hematocrit, and right heart failure. The extremely obese patient's airway is often difficult to maintain with mask ventilation secondary to decreased neck mobility and adiposity and requires careful preoperative evaluation. Almost all the major endocrine problems with extreme obesity involve the effects of diabetes mellitus and require preoperative assessment of glycemic control. Obesity also leads to abnormal fatty deposits in the liver that cause increased metabolism of inhalation anesthetics. Morbidly obese patients may have a higher risk of gastric aspiration and development of aspiration pneumonia. Finally, postoperative pain management must be considered.

F. Diabetes Mellitus

The most common metabolic abnormality is diabetes mellitus, and its presence should cause a high index of suspicion for cardiac problems. Patients on insulin therapy are at higher risk for cardiac morbidity and mortality, including myocardial infarction and heart failure. Glucose control may be very difficult to maintain in the perioperative period, and preoperative assessment of control should always be ascertained through history or laboratory testing. Tight glucose control may reduce infections postoperatively but it is controversial whether intensive insulin therapy decrease mortality, perioperative hypoglycemia, or cardiac events. Anesthesia providers are responsible for glucose control during the procedure, and the surgical service is typically responsible for this care in the postoperative period.

Hua J et al: Intensive intraoperative insulin therapy versus conventional insulin therapy during cardiac surgery: a meta-analysis. *J Cardiothoracic Vasc Anesth.* 2012;26(5):829-834. Epub Feb 14, 2012.

G. Patients on Low-Molecular-Weight Heparin

Patients taking low-molecular-weight heparin (LMWH) for deep venous thrombosis prophylaxis present an unusual problem for both surgeon and anesthesiologist. The current guidelines dictate that unless absolutely indicated, neuraxial anesthesia (spinal, epidural) should not be performed unless LMWH has been stopped for at least 12 hours and preferably 24 hours. That means that a substitute anticoagulant should be initiated if neuraxial anesthesia is to be done, or this approach is avoided.

H. Renal Impairment

Acute renal failure (ARF) occurs in approximately 1%-5% of all hospitalized patients and is responsible for increased length of stay and mortality. The preoperative visit can help to identify patient risk factors for ARF in those with previously normal renal function undergoing noncardiac surgery. The perioperative onset of ARF in patients with previously normal renal function is associated with increased postoperative mortality, especially significant within 1 year postsurgery. BMI higher than 32 kg/m², age, emergency surgery, liver disease, high-risk surgery (intrathoracic, intraperitoneal, suprainguinal vascular, large blood loss), peripheral vascular occlusive disease, and chronic obstructive pulmonary disease necessitating chronic bronchodilator therapy place patients at increased risk for perioperative renal impairment.

Kheterpal S et al: Predictors of postoperative acute renal failure after noncardiac surgery in patients with previously normal renal function. *Anesthesiology.* 2007;107:892.

► Preoperative Medications

The use of preoperative medications is hampered by the fact that most patients are not in the medical facility until the day of surgery. Most premedications now consist of an anxiolytic agent (eg, midazolam) and an opiate (eg, fentanyl) given in the immediate preanesthesia period. These premedications are often given because patients have a preconceived notion that they need something to relax. Alternatively, a thorough explanation of what the patient can expect in terms of surgery and anesthesia has a significant calming effect comparable to that of medications given to relieve anxiety. Administration of premedication to prevent pulmonary aspiration syndrome is often considered with the use of agents that increase gastric pH (H₂ blockers, proton pump inhibitors, antacids) or agents that lower gastric volume.

► Informed Consent

Many institutions and practices obtain a signed informed consent from patients for anesthesia, while other institutions include the anesthesia consent in the surgical consent. Regardless of the particular facility requirements, the anesthesiologist should write a note in the patient chart indicating that the patient has been informed of the issues surrounding anesthesia and understands the risks and complications as described. The informed consent for anesthesia should include a discussion of what to expect from the administration of anesthesia and possible adverse effects and risks. A number of issues should be discussed routinely, including timing of surgery, premedication, risks of dental injury, cardiac risks, sequence of events prior to anesthesia induction, awakening from anesthesia, presence of catheters, duration of time in the PACU, anticipated return to a hospital bed or discharge, postoperative pain management, and the likelihood of nausea and vomiting. Patients may have questions concerning perioperative awareness. Rather than cause undue worry, clinical judgment should dictate how detailed a description of each of these issues should be for each patient.

► Choice of Anesthesia

Considerations in choosing an anesthetic technique include the planned surgical procedure, positioning requirements, patient preferences, surgeon preferences, the urgency of the operation, postoperative pain management, and potential for admission to a critical care unit. Some procedures (eg, thoracotomy) cannot be performed under a regional anesthetic or neuraxial blockade and necessitate a general anesthetic. Other procedures (eg, extremity surgery) can be performed under regional, neuraxial, or general anesthesia. Sometimes a combination of an epidural and a general anesthetic may be chosen with continuation of the epidural for postoperative pain management. Emergency surgery

for patients with a full stomach may necessitate a rapid-sequence general anesthetic to protect from pulmonary aspiration. Regional anesthesia may provide anesthesia for hip surgery but may not provide much in the way of patient comfort because of the position requirements of a fracture table. Patient age and preference must also be included in the decision of choice of anesthetic technique. However, some regional anesthesia may be contraindicated for patients with the peripheral neuropathy of diabetes. Notation of the proposed type of anesthesia must be entered into record of the preanesthesia evaluation.

► Holding Room & Operating Room

The nurse, surgeon, and anesthesiologist have many tasks to perform, starting in the holding area before the surgery can begin. The nurse checks the patient in and records vital signs, checks for a signed consent, and starts an intravenous line if needed. The surgeon should confirm and mark the site of surgery. The anesthesiologist should confirm the preoperative evaluation and type of anesthetic selected.

► Wrong Site Surgery

In July 2004, the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) instituted a patient safety mandate known as the Universal Protocol for preventing wrong site, wrong procedure, wrong person surgery. All members of the care team must be familiar with and always participate in and perform the following three steps of this Universal Protocol.

Step 1: Initial verification of the intended patient, procedure, and site of the procedure. This step begins at the time the procedure is scheduled and again at the time of admission into the medical facility, anytime care responsibility is transferred to another caregiver, and before the patient leaves the preoperative area for the operating room.

Step 2: Marking the operative site. An unambiguous mark must be made using a marker that is sufficiently permanent to be visible after surgical prep and draping on or near the intended surgical incision site. This mark should not be an X, as in “X marks the spot,” but rather a word or line representing the proposed incision. This mark must be made by the surgeon performing the procedure. If possible, the patient should participate when the site is marked.

Step 3: The time out immediately before starting the procedure. A time out must be conducted in the location where the surgical procedure will be done, and all members of the care team—surgeon, nurses, anesthesiologists—must actively participate in verification of correct patient identity, correct side and site of surgery, agreement on the scheduled procedure, and assurance that all of the necessary implants and special equipment are immediately available. This time out must take place before incision. JCAHO requires that the time out be documented in the medical record.

Joint Commission on the Accreditation of Healthcare Organizations: Universal protocol for preventing wrong site, wrong procedure, wrong person surgery. Available at: www.jointcommission.org/patientsafety/universalprotocol. Accessed November 28, 2008.

► The Operating Room

The anesthesiologist must check the equipment in the operating room before helping to transport the patient. Once in the operating room, the patient is transferred to the operating table with the assistance of the nurses and anesthesiologist. It is standard anesthesia practice to apply monitors to measure arterial blood pressure (a-line, blood pressure cuff), heart rate, oxygenation (pulse oximeter), and ventilation (capnography) before induction of anesthesia (Table 11–5).

The anesthesiologist must be certain that a surgeon is present in the room before beginning induction. The final time out should then be performed, confirming site, patient, procedure, and surgical personnel.

► General Anesthesia Management

Patients will be preoxygenated before induction of a general anesthetic. General anesthesia is commonly induced by administration of intravenous drugs (eg, propofol or thio-pental) and, in cases when cardiovascular status is compromised, etomidate or ketamine. Patients receiving propofol may complain of discomfort at the IV sites, and patients receiving etomidate may have some athetoid movements that appear seizurelike. Almost all anesthetics are preceded by the

Table 11–5. Standards for basic anesthesia monitoring.

Parameter	Equipment
<i>Oxygenation:</i> Ensure patient concentration in inspired gas and blood during all anesthetics	<i>Oxygen analyzer:</i> Part of anesthesia machine <i>Pulse oximeter:</i> Continuously audible variable pitch pulse tone
<i>Ventilation:</i> Ensure adequate patient ventilation	<i>Capnography:</i> Continuous monitoring for the presence of end-tidal CO ₂
<i>Circulation:</i> Ensure adequacy of patient circulatory function	<i>EKG:</i> Continuously displayed from the beginning until leaving the room <i>Arterial blood pressure monitor:</i> Measured at least every 5 minutes <i>Measurement of patient heart rate:</i> Usually from EKG or pulse oximeter
<i>Temperature:</i> Aid in maintenance of appropriate patient temperature	Oral, skin, nasal, or bladder temperature probe

administration of an opiate (eg, fentanyl) in a dose that is not intended to induce an anesthetic but that helps reduce the amount of induction agent. Most general anesthetics then include a muscle relaxant to facilitate endotracheal intubation. Tracheal intubation is almost always performed during general anesthesia and is especially important for patients presenting for emergent surgery with presumed full stomach or when positive pressure ventilation is required. The laryngeal mask airway (LMA) can also be used to maintain a patent airway. To minimize the time that the trachea is unprotected, a rapid-sequence induction of anesthesia using rapid administration of induction agent and rapid-acting muscle relaxant (eg, succinylcholine) can be utilized. The “crash induction” is a modification of this rapid-sequence technique with the application of cricoid pressure by a caregiver other than the inducing anesthesia personnel.

General anesthesia may also be induced by mask using an inhalation anesthetic (eg, isoflurane or sevoflurane). This method is commonly used for children. Once adequate depth of anesthesia is assured, a muscle relaxant may be administered to help facilitate endotracheal intubation. Inhalation induction takes longer than rapid-sequence induction, and the airway may be unprotected for a longer time. A combination of inhalation agent and intravenous agent can also be used to induce general anesthesia.

Once an adequate depth of anesthesia and adequate muscle relaxation is attained, the trachea is intubated. Ease of endotracheal intubation can usually be predicted from the careful preoperative airway evaluation.

However, the anesthesiologist occasionally encounters an unexpected difficult intubation and additional maneuvers may be necessary: These can include cricoid manipulation, adjustment of the patient’s head position, or use of a long, stiff catheter (eg, a bougie) or a fiberoptic bronchoscope. The American Society of Anesthesiologists provides an algorithm for the management of the difficult airway. If another provider is placing cricoid pressure, the anesthesiologist must directly state what maneuver would be the most helpful. If the airway cannot be secured after multiple attempts, patients can be awakened and a decision made to proceed with an awake fiberoptic intubation or to cancel the anesthetic until further workup can be performed. The most serious complication of endotracheal intubation, and the most common cause of serious anesthesia morbidity and mortality, is the failure to secure the airway. Other common complications are dental injuries, soft tissue injury to the lips, hypertension and tachycardia, and laryngospasm on extubation.

Following anesthetic induction, the patient must be properly positioned for the procedure. It is the responsibility of both surgeon and anesthesiologist to assure that the patient is positioned to avoid physical or physiologic complications. The American Society of Anesthesiologists’ closed claims study notes that nerve damage from malpositioning during surgery is the second most common anesthetic complication.

Careful attention must be paid to adequately protect all potential pressure and vulnerable areas such as elbows, knees, heels, and eyes. The ulnar nerve is particularly susceptible to injury, as is the brachial plexus when patient’s arms are abducted too far. Hemodynamics may also be compromised by position changes that may result in decreased venous return and resultant hypotension.

American Society of Anesthesiologists: Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anesthesiology*. 2003; 98:1269.

Cheney FW et al: Nerve injury associated with anesthesia: a closed claims study. *Anesthesiology*. 1999;90:1062.

► Maintenance of General Anesthesia

Once the airway is safely secured, anesthesiologists commonly maintain the anesthetic with a combination of an inhalation agent, nitrous oxide, opiate, and muscle relaxant. This “balanced anesthetic” allows for titration of agents to maintain the requirements of anesthesia: analgesia, amnesia (unconsciousness), skeletal muscle relaxation, and control of the hemodynamic responses to surgical stimulation. Drugs with specific pharmacologic profiles are chosen to help satisfy the anesthetic requirements. Analgesia is provided by opiates and inhalational agents; amnesia is provided by benzodiazepines, nitrous oxide, and inhalation agents; and muscle relaxation is provided by neuromuscular blocking drugs, inhaled agents, or local anesthetics. The provision of the right amount of muscle relaxation to facilitate the procedure but not too much to obscure a clinical sign of anesthetic depth or to result in prolonged relaxation postoperatively presents a challenge to the anesthesiologist. A peripheral nerve stimulator can monitor muscle relaxation such that the relaxant is reversible at the end of the case to allow for safe extubation.

► Regional Anesthesia for Surgery

Many operations require no general anesthetic. These include almost any procedure done below the waist, on lower abdomen, and on the upper extremities. Spinal or epidural anesthesia provide excellent muscle relaxation, profound analgesia, and avoidance of airway manipulation, and allows the patient to be conscious. Spinal or epidural anesthesia have additional advantages: decreased blood loss during orthopedic procedures, fewer thrombotic complications, less pulmonary compromise, maintenance of vasodilatation for postoperative vascular surgeries, earlier hospital discharge, and avoidance of immune response compromise.

A. Spinal Anesthesia

Most spinal anesthetics are performed in either the lateral position or with the patient sitting on the operating table.

Following sterile prep and local skin anesthetic, a small 25-27 gauge spinal needle is introduced in the lower lumbar spine, and the subdural space is identified by the presence of cerebrospinal fluid (CSF). Depending on the planned length of surgery, either lidocaine or bupivacaine (with or without epinephrine or an opiate) is injected. Lidocaine spinal anesthesia provides at most 2 hours of anesthesia, while bupivacaine provides up to 5 hours of anesthesia. However, due to patient discomfort from tourniquet break-through pain, the use of orthopedic tourniquets limits the usefulness of spinals no matter which local anesthetic is used to no more than 2 hours. Once the local agent is injected, patients are placed in the supine position for 5-10 minutes to allow for proper spread of the local anesthetic. During this time, blood pressure and heart rate are monitored; both hypotension and bradycardia can be induced by a sympathectomy due to the cephalad spread of the local. During this 5-10 minute period, patient movement should be limited. Once the block has stabilized, the surgical preparation and positioning can proceed. The anesthesiologist monitors the patient in the same manner as for general anesthesia and administers sedation as needed.

Other than expected hemodynamic changes, the most common complication of spinal anesthesia is postspinal headaches. The incidence is very low when smaller-gauge spinal needles are used and are more common in young women. The spinal headache is almost always positional and abates when the patient is recumbent. Severe headaches can result in diplopia because of stretching of the sixth cranial nerve as the brain sinks from loss of CSF. Patients usually complain of the headache a day or two following the operation. Conservative treatment is the maintenance of adequate hydration, remaining recumbent, and an analgesic such as acetaminophen. Severe headache may require a “blood patch” to plug the leak of CSF and is performed by an anesthesiologist.

B. Epidural Anesthesia

Epidural anesthesia has several distinct differences from spinal anesthesia. The epidural space is between the ligamentum flavum and the dural structures; in placing an epidural, the subdural space is not entered, so no CSF leak is created with the potential for a spinal headache. The epidural anesthetic may be continued by insertion of a small catheter into the epidural space. Additional local anesthetic can be added to move the block to higher spinal levels or to maintain the selected level of anesthesia. This continuous epidural technique can be used for postoperative pain control. The catheter can be placed at spinal levels in the midthoracic region for thoracotomy or lower thoracic or lumbar region for abdominal operations or lower extremity procedures. Epidural anesthesia requires the administration of high volumes of local anesthetics. There is the potential for intravascular injection with resultant cardiovascular compromise

or high block. There is also the potential for misplacement of the catheter or epidural needle in the subarachnoid space. Instillation of the larger volumes of local in the subarachnoid space can result in a total spinal or high block with resultant cardiovascular collapse. Therefore, small test doses of local anesthetic are administered to evaluate for signs of intravenous injection or high block. Another potential disadvantage of epidural anesthesia is that the onset is much slower than spinal anesthesia. The same hemodynamic changes observed with epidural can occur with spinal.

A common complication of both spinal and epidural anesthesia is prolonged blockade of parasympathetic fibers that innervate the bladder with resultant urinary retention and the need for a urinary bladder catheter.

C. Peripheral Nerve Block

True regional anesthesia is useful for procedures on the extremities. Useful anesthesia of the upper extremity can be obtained by blockade of the brachial plexus using an interscalene approach, a supraclavicular approach, or an axillary approach. Lower extremity surgery may be performed utilizing blockade of the lumbar plexus and its major branches: femoral nerve, sciatic nerve, lateral femoral cutaneous nerve, obturator nerve, and popliteal nerve. In some instances, a catheter can be placed near the nerve or plexus to allow for continuous blockade and postoperative pain control. The usefulness of these blocks for extremity surgery is limited in time by the use of tourniquets if the patient is to remain awake during the procedure. These blocks are very useful if avoidance of a general anesthetic is desired. Additional advantages of peripheral nerve blocks include earlier discharge from recovery areas and return to home, lack of administration of large doses of opiates, less nausea and vomiting, no instrumentation of patient airway, and earlier ambulation. Intraoperative sedation may be provided, and the anesthesiologist monitors the patient in the standard manner.

▶ Monitored Anesthesia Care

Monitored anesthesia care (MAC) was previously termed local anesthesia with standby. The “standby” is an anesthesia caregiver who monitors the patient’s status while the surgeon performs a procedure under local anesthesia. The anesthesiologist can also provide sedation and analgesia as needed for the patient. This type of anesthesia is usually requested by the surgeon for patients who may be especially frail in health; it provides the option to convert to a general anesthetic if necessary.

▶ Completion of Surgery

At the end of the procedure, most often patients who have been intubated for the surgery have their muscle relaxation reversed and the anesthetic depth decreased to allow them to return to consciousness. Once the return of muscle

function has been assured and the patient is able to respond to commands, the endotracheal tube can be removed and the patient closely observed to ensure adequate ventilation. Patients are then transferred to a stretcher and transported to the PACU, accompanied by a member of the anesthesia care team who monitors the patient's condition during transport. Many institutions require that a member of the surgical team also accompany the patient to the PACU along with the anesthesiologist. Some critically ill patients are transported directly to the intensive care unit (ICU), still intubated, sedated, and ventilated.

▶ Postanesthesia Recovery Room

The PACU, most commonly known as the recovery room, is where most patients are transferred after surgery. The PACU is the designated area in which patients receive postanesthesia monitoring of vital signs as well as the beginning of the nursing care for their surgical recovery. It is the standard of the American Society of Anesthesiologists that all patients, regardless of the type of anesthesia, receive appropriate postanesthesia care, either in a PACU or an equivalent area such as a critical care unit. An exception to this standard can only be made by the anesthesiologist responsible for the patient's care. Once in the PACU, a verbal report is provided to the responsible PACU nurse by a member of the anesthesia care team who is familiar with and who accompanied the patient during transport. The surgeon can also give a report as to the surgical issues that may impact on the patient's recovery.

The PACU is equipped with essentially the same monitors as the operating room and with the drugs and equipment needed for emergency resuscitation. The PACU is a specialized, short-stay ICU. PACUs are staffed with specially trained nurses to monitor patients who are recovering from the anesthetic. Patients are continually monitored in the PACU for approximately 1 hour or until they fulfill specific objective criteria. Discharge from the PACU requires the clinical judgment of the PACU team. Particular attention is focused on the monitoring of oxygenation, ventilation, circulation, level of consciousness, and temperature.

Most PACUs use a discharge scoring system (egg, the Aldrete score) describing objective criteria that must be fulfilled before the patient can be discharged from the PACU. These criteria include quantitative analysis of patient's ability to move extremities in response to verbal commands, adequacy of ventilation (pulse oximetry) circulation (stable vital signs) level of consciousness, and pain control. After outpatient surgery, patients must have an adult to escort them home. Most institutions have policies requiring that anesthesiologists, in conjunction with the PACU nursing team, discharge patients from PACU.

Aldrete JA, Kroulik D: A postanesthetic recovery score. *Anesth Analg*. 1970;49:924.

Awad JT, Chung F: Factors affecting recovery and discharge following ambulatory surgery. *Can J Anaesth*. 2006;53:858.

COMMON POSTOPERATIVE PROBLEMS

There are many reasons why patients have other than a routine stay in the PACU. The three most common PACU problems are hypothermia, nausea and vomiting, and pain control. Hypotension/hypertension, hypoxemia, hypercapnia/hypoventilation, and agitation can also occur.

▶ Hypothermia

A very common complication of anesthesia and surgery is hypothermia. Every effort should be made in the operating room to avoid patients becoming hypothermic, even if this requires that the operating room temperature is maintained at a warmer-than-comfortable level. Patients who are admitted to the PACU and are hypothermic must be rewarmed to avoid the adverse consequence of shivering (ie, increased oxygen consumption). Hypothermia may also have an adverse effect on coagulation parameters and may delay recovery from anesthesia due to decreased drug metabolism. The most effective methods of rewarming are forced-air warming devices or water-jacket devices. Shivering can be actively treated with small doses of meperidine.

Rajagopalan S et al: The effects of mild perioperative hypothermia on blood loss and transfusion requirement. *Anesthesiology*. 2008;108:71.

▶ Postoperative Nausea & Vomiting

According to the Society of Ambulatory Anesthesia (SAMBA), untreated, postoperative nausea and vomiting (PONV) occurs in 20%-30% of the general surgical population and up to 70%-80% in the high-risk surgical population. The increased PACU stays and sometimes hospital admission to control PONV adds to patient discomfort and morbidity and adds a financial burden to the health care system. SAMBA's seven guidelines have been adopted by many health care facilities for the prevention and treatment of PONV.

1. Identify patients at high risk for PONV. The most consistent independent predictors for PONV are female gender, nonsmoking, and a history of PONV or motion sickness, coupled with the anesthesia-related factors of general anesthesia with volatile anesthetics, nitrous oxide, and postoperative opioids.
2. Reduce baseline risk factors for PONV. The most reliable strategy is to use regional anesthesia when possible. Otherwise, propofol used for induction; minimization of intraoperative volatile agents, opioids, and nitrous oxide; and epidurals for postoperative pain management may be the best strategy to reduce PONV.

3. Administer PONV prophylaxis using one or two interventions in adults at moderate risk for PONV. The 5-HT₃ receptor antagonists (ondansetron, dolasetron, granisetron), dexamethasone, and low-dose droperidol are among the most effective first-line antiemetics for PONV prophylaxis: Each independently reduces PONV by 25%. It is recommended that adults who present with moderate risk for PONV receive a combination therapy for prophylaxis with drugs from different classes and different mechanisms. A new drug, aprepitant, a neurokinin-1 (NK-1) receptor antagonist has been shown to significantly reduce PONV given alone or in combination with the 5-HT₃s.
4. For patients at high risk for PONV, SAMBA recommends a multimodal approach to prophylaxis that includes using two or more interventions and trying to reduce the baseline factors (eg, anxiety), minimizing the anesthetic agents chosen, and using the pharmacologic interventions mentioned above.
5. Administer prophylactic antiemetics to children at high risk for PONV. Use the same combination therapy as in adults.
6. Some patients have no risk factors for PONV and therefore receive no prophylaxis but develop PONV postoperatively. Recommended treatment is to begin with low-dose 5-HT₃ antagonist, which is the only class of drugs that has been adequately studied to be effective for the treatment of existing PONV.
7. If rescue therapy for patients who have received prophylaxis is required, it is recommended that the antiemetic(s) chosen should be from a different therapeutic class than the drugs used for prophylaxis.

► Postoperative Acute Pain Management

The management of postoperative surgical pain is the responsibility of both the anesthesiology and surgery services. Other than PONV, inadequate postoperative pain control is a primary cause of unanticipated hospital admission for outpatient surgery. The severity of the pain is usually site dependent (upper abdominal procedures tend to be more painful than lower abdominal procedures; ie, appendectomy is more painful than inguinal hernia, which is more painful than minor chest wall surgery), but the individual patient's response to the pain and efforts to treat it vary widely. What may appear to be a minor incision to some may be very painful to others. The clinical challenge of providing adequate postoperative pain management is also a major mandate by JCAHO and the national media. Thus, almost every anesthesia

department has an acute pain management team that can help with the management of patients in PACU and later in the surgical intensive care or general care unit.

Morphine has been the historical postoperative analgesic, administered either intramuscularly or intravenously. Patient response to a standardized administration protocol is variable, however, and can fail to control pain or cause symptoms of overdose. Every patient is different in the required serum concentration of drug that results in adequate pain control.

There are four common modalities or approaches to postoperative pain management:

Oral medications. For minor procedures, for example, excision of skin lesions, nonsteroidal analgesics may be sufficient. For more intense levels of pain, oral narcotics in combination with acetaminophen are often effective.

Intravenous opioids. Occasionally, one or two intravenous doses of morphine, hydromorphone, or fentanyl may be sufficient to control postoperative pain. However, a more reliable method is the administration of small doses of narcotic given on demand by the patient. Patient-controlled analgesia (PCA) uses the same or even less total narcotic to control pain and is as safe as intramuscular medications. Patients are instructed on how to use the PCA device to administer narcotic on demand. PCA has widespread acceptance by patients, physicians, and nurses because it provides pain control in a timely manner that more closely matches the patient's requirements. Caution must be used when pain control appears to be inadequate and house staff covering the patient are tempted to give an intravenous "boost" of narcotic.

Epidural opiate analgesia. The application of opioids or narcotics at the neuraxial receptor sites via an epidural catheter is probably the modality of choice for severe acute postoperative pain control. An epidural catheter is preferably placed preoperatively at a spinal dermatome level close to the site of incision: midthoracic level for thoracic surgeries, lower thoracic for upper abdominal surgeries, or lumbar for lower abdominal incisions or lower extremity surgeries. This technique utilizes a continuous infusion of a combined solution of a low concentration of local anesthetic (bupivacaine 0.125 mg/cc) and an opioid (morphine, hydromorphone, or fentanyl). This modality does not require patient cooperation but can be used in a PCA mode. Epidural analgesia can be continued for multiple days; it has beneficial effects for maintaining peripheral vasodilatation after vascular procedures and improving respiratory mechanics due to reduced pain when patients are breathing on their own. Patients must be monitored for respiratory depression while receiving epidural analgesia, as respiratory depression is the major complication from this pain control therapy.

Specific nerve or plexus block. Local anesthesia block of single nerves or continuous catheter infusion of local anesthetic around major nerve plexuses is becoming more popular. Examples include single injection or placement of a continuous catheter around the femoral nerve for controlling pain from knee surgery and continuous catheters around the brachial plexus (usually supraclavicular) for controlling pain from upper extremity surgery.

► Complications of Anesthesia

No matter how well patients are prepared for anesthesia and surgery, there is always the possibility of a complication from the delivery of anesthesia. These complications can be minor in nature (eg, intravenous infiltration, hypothermia, or minor ocular injury) or major issues (eg, an unanticipated difficult airway that may result in significant morbidity or death). Many complications are preventable with good preoperative preparation, but some are not preventable (unexpected drug reactions or metabolic crisis, eg, malignant hyperthermia). Four common complications are anesthesia awareness, peripheral nerve injury, malignant hyperthermia, and visual loss.

► Awareness

Many patients are concerned about being aware during the surgical procedure. Intraoperative awareness under general anesthesia is rare with a reported incidence of 0.1%-0.2%. Intraoperative awareness does occur and can lead to significant psychological sequelae and extended disability for the patient. Certain types of surgery have a higher incidence of intraoperative awareness, including cardiac surgery, major trauma, and obstetrics. All are associated with critical or life-threatening situations of hemodynamic compromise that make awareness unavoidable if the caregiver is to achieve other critical anesthetic goals of maintaining cardiac, respiratory, and vascular homeostasis. The Practice Advisory from the American Board of Anesthesiologists defines intraoperative awareness: "When a patient becomes conscious when a surgical procedure is performed under a general anesthetic and subsequently has (explicit) recall of these events." The Advisory notes that the recall does not include the time before the general anesthetic is induced or the time of intentional emergence and return to consciousness.

Strategies suggested to lessen or eliminate the risk of intraoperative awareness include the following:

1. Preoperative evaluation. Patients with a history of previous intraoperative awareness, substance abuse, chronic use of opioids for pain control, and limited hemodynamic reserve have increased risk for intraoperative awareness. Such patients undergoing high-risk operations should be informed of the potential for awareness. There is no consensus that informing all patients about the possibility of intraoperative awareness leads to higher incidence of awareness.

2. Preanesthesia preparation. A strict preoperative equipment checklist involving the anesthesia machine and its components, for example, the volatile anesthesia vaporizer agent levels, is mandatory. Although this strategy does not prevent human errors, it does provide the anesthesiologist a constant reminder that there are preventable components to the complication of awareness.
- 3a. Intraoperative monitoring. The currently accepted strategy is to utilize all the standard anesthesia patient monitors (EKG, blood pressure measurements, heart rate monitors, continuous agent analyzers, and capnography) and to intermittently assess for purposeful or reflex movement to detect intraoperative consciousness. There are instances in which there were no reported changes in vital signs in patients who have reported recall.
- 3b. Monitoring brain electrical activity. Several monitoring devices are claimed to be able to interpret data from the processed, raw electroencephalogram of patients and correlate it to the depth of anesthesia and thus help prevent recall under general anesthesia. The commonest device currently available is known as the bispectral index monitor (BIS; Aspect Medical Systems, Natick, MA). Currently, the use of BIS for patients undergoing general anesthesia has not been shown to offer any advantage over a protocol that uses end-tidal anesthetic agent concentrations in decreasing the incidence of intraoperative awareness.

In conclusion, when awareness occurs, either reported spontaneously by the patient in the postoperative period or elicited during the postoperative visit by the anesthesiologist, the patient's report must be taken seriously. Some patients will require significant counseling and treatment postoperatively, and caregivers should be sensitive to the potential issue and offer any help requested.

Avidan MS et al: Prevention of intraoperative awareness in a high-risk surgical population. *N Engl J Med*. 2011;591-600.

► Peripheral Nerve Injury

Peripheral nerve injury is a known complication of anesthesia and can occur under general anesthesia or a regional technique. These injuries are almost always due to patient positioning and the patient's inability to report and respond to abnormal pressure points or awkward position of an extremity. The ulnar nerve at the elbow is the most common injury and occurs even if the patient has had what was felt to be adequate padding provided for protection. Other peripheral nerves that are less commonly injured include the peroneal nerve at the knee and the radial nerve as it passes through the spiral groove of the humerus. The peroneal nerve

is typically injured by abnormal position against a lithotomy stirrup, and the radial nerve is injured by a blood pressure cuff or abnormal pressure from surgical towels. Patients usually report numbness along the course of the nerve, but some motor weakness may also occur. These injuries usually resolve in a short time period. Abnormal stretching of the brachial plexus from extreme abduction of the arms, improperly placed shoulder braces, or chest wall retractors during cardiac surgery may result in more serious injuries, including not only sensory but motor loss that may not recover as rapidly or completely as the ulnar, radial, or peroneal nerves. More severe injuries that involve motor loss need to have a baseline examination established and therapy started. Since most of these peripheral nerve injuries are due to malpositioning during surgery, it is the responsibility of surgeons, nurses, and anesthesiologists to adequately position patients and provide sufficient padding or other protection.

Welch MB, Brummett CM, Welch TD, et al: Perioperative peripheral nerve injuries: a retrospective study of 380,680 cases during a 10-year period at a single institution. *Anesthesiology*. 2009;111:490-497.

► Malignant Hyperthermia

Malignant hyperthermia is a rare, genetically inherited disease characterized by intense muscle contraction. It results from an uncontrolled release of calcium from the sarcoplasmic reticulum and massive increase of intracellular calcium in skeletal muscle due to the inability of the calcium to be reabsorbed. This intense muscle contraction leads to a hypermetabolic state manifest by hyperthermia, hypercapnia, tachycardia, and metabolic acidosis. It is fatal if untreated. Malignant hyperthermia is commonly triggered by the administration of anesthetic agents; the depolarizing muscle relaxant succinylcholine alone or in conjunction with a volatile agent. The more modern anesthetic vapors sevoflurane and desflurane are less frequently implicated as triggers. Early clinical manifestations of malignant hyperthermia include unexplained tachycardia and metabolic acidosis, but temperature elevation may be a late finding. Although not always reliable, the earliest sign of malignant hyperthermia is sometimes masseter spasm following the administration of succinylcholine during induction. Careful monitoring must always ensue. Relying on temperature elevation alone is dangerous, and arterial blood gases must be monitored for unexplained metabolic acidosis. In some patients, malignant hyperthermia develops insidiously during the surgery, and temperature elevation can be the first manifestation.

Malignant hyperthermia is treatable and preventable. The treatment of choice is intravenous dantrolene. Every operating room must have a malignant hyperthermia protocol and a kit that includes multiple doses of dantrolene. Dantrolene is supplied as a powder and requires several minutes to mix it into a useable intravenous solution. Malignant hyperther-

mia is a true anesthesia emergency, and the anesthesiologist will require assistance from the operative team. The surgical procedure may have to be postponed. Successful treatment of malignant hyperthermia is the usual outcome. Patients should be monitored in a critical care unit for 24 hours or until stable and referred for confirmatory testing.

Malignant hyperthermic reactions can be prevented. Any patient with a personal or family history of malignant hyperthermia should be administered a completely nontriggering anesthetic without relying on succinylcholine or volatile agents.

Hopkins PH: Malignant hyperthermia. *Trends Anaesthes Crit Care*. 2008;19(1):22-33.

► Perioperative Visual Loss

A recently described complication of prolonged (> 6.5 hours) spinal surgical procedures performed in the prone position, associated with large blood losses, is partial or complete visual loss. Vision loss seems to be associated with an ischemic optic neuropathy without any known etiology. There does not seem to be any identifiable pre-op patient characteristic. Intraoperative management for patients undergoing prolonged procedures involving substantial blood loss include continuous blood pressure monitoring and CVP monitoring. There is no consensus on lower limits of hematocrit, limits of vasopressors, or prone positioning. There is no known treatment. The risk of visual loss should be discussed with patients in the preoperative phase of surgery and anesthesia for those operations that require prone positioning.

Apfelbaum JL et al: Practice Advisory for Perioperative Visual Loss Associated with Spine Surgery. An Updated Report by the American Society of Anesthesiologists Task Force on Perioperative Visual Loss. *Anesthesiology*. 2012;116:274-285.

MULTIPLE CHOICE QUESTIONS

- Many patients take over-the-counter herbal remedies. In the perioperative period patients should be advised
 - To continue taking their usual herbal remedies
 - Stop only those remedies that have been approved by their physician
 - Continue taking only those remedies that have been approved by the FDA
 - Stop all over-the-counter herbal remedies
- Regarding the timing of the preoperative anesthesia workup for patients scheduled for a surgical procedure
 - The initial assessment can be done the day of surgery for healthy patients undergoing procedures of high surgical invasiveness.

- B. The initial assessment should be done at a minimum the day before surgery for patients undergoing procedures of high surgical invasiveness.
 - C. The preoperative assessment for healthy patients by an anesthesiologist is not required.
 - D. A note from the patient's primary care physician stating that the patient is "cleared for anesthesia and surgery" will suffice as the preoperative assessment.
3. Regarding patients who have had a recent drug-eluting stent placed and scheduled for an elective surgical procedure with a high risk of bleeding
- A. Surgery may be performed within 4 weeks of stent placement as long as the patient continues taking aspirin and clopidogrel.
 - B. Surgery may be performed within 4 weeks of stent placement with the patient stopping the clopidogrel and continuing on low-dose aspirin.
 - C. Should have the surgical procedure delayed until the procedure can be performed with the patient only taking low-dose aspirin.
 - D. Surgery should be delayed for up to 1 year.
4. Strategies to prevent intraoperative awareness include
- A. Strict monitoring of intraoperative vital signs by the anesthesiologist will always detect intraoperative awareness
 - B. Informing patients during the preoperative workup of the possibility of awareness
 - C. Monitoring brain electrical activity with the BIS monitor
 - D. None of the above
5. The preoperative assessment by an anesthesiologist includes an assessment of a patient's risk for an intraoperative cardiac event. The RCRI factors include all of the following except
- A. A history of ischemic heart disease
 - B. Diabetes mellitus
 - C. Obesity
 - D. Renal insufficiency
 - E. High-risk surgery
 - F. Heart failure

Shock & Acute Pulmonary Failure in Surgical Patients

James W. Holcroft, MD

John T. Anderson, MD

Matthew J. Sena, MD

INITIAL TREATMENT OF SHOCK

Cardiovascular failure, or shock, can be caused by (1) depletion of the vascular volume; (2) compression of the heart or great veins; (3) intrinsic failure of the heart itself or failure arising from excessive hindrance to ventricular ejection; (4) loss of autonomic control of the vasculature; (5) severe untreated systemic inflammation; and (6) severe but partially compensated systemic inflammation. If the shock is decompensated, the mean blood pressure or the cardiac output (more precisely, the product of the pressure and output) will be inadequate for peripheral perfusion. In compensated shock, the perfusion will be adequate but only at the expense of excessive demands on the heart. Depending on the type and severity of cardiovascular failure and on response to treatment, shock can go on to compromise other organ systems. This chapter discusses the cardiovascular and pulmonary disorders associated with shock.

HYPVOLEMIC SHOCK

► Diagnosis

Hypovolemic shock (shock caused by inadequate circulating blood volume) is most often caused by bleeding but may also be a consequence of protracted vomiting or diarrhea, sequestration of fluid in the gut lumen (eg, bowel obstruction), or loss of plasma into injured or burned tissues. Regardless of the etiology, the compensatory responses, mediated primarily by the adrenergic nervous system, are the same: (1) constriction of the venules and small veins in the skin, fat, skeletal muscle, and viscera with displacement of blood from the peripheral capacitance vessels to the heart; (2) constriction of arterioles in the skin, skeletal muscle, gut, pancreas, spleen, and liver (but not the brain or heart); (3) improved cardiac performance through an increase in heart rate and contractility; and (4) increased sodium and

water reabsorption through renin-angiotensin-aldosterone as well as vasopressin release. The result is improved cardiac filling, increased cardiac output (both directly by the increase in contractility and indirectly through increased end-diastolic volumes), and increased blood flow to organs with no or limited tolerance for ischemia (brain and heart).

The symptoms and signs of hypovolemic shock are many and can be caused either by the inadequate blood volume or by the compensatory responses. Some signs manifest themselves early, in mild forms of shock. Some present late and only in severe forms of shock. The goal is to pick up on the early signs. Doing so can save a life.

As early signs of shock, the physician might find it difficult to gain intravenous access. The skin might be cold (a nonspecific sign, but an early sign). But, by far and away, the most important, that is, most sensitive, of all the early signs of hypovolemic shock is diminished blood flow to the skin and subcutaneous tissues. It is a sign that needs to be elicited with care. It can be missed. It is best detected in the skin on the plantar surface of the foot, an area without pigmentation, with the color determined solely by the blood contained in the tissues. One begins by compressing the skin over the plantar surface of a toe with intense pressure, just short of being painful, followed by milking of the blood contained in the compressed area proximally, to the skin over the metatarsal phalangeal joint. The compression is then suddenly released. The previously compressed area will be profoundly pale, but will fill quickly, within a few seconds, if the patient is not in shock (and does not have peripheral vascular disease). In a hypovolemic patient, the refill takes longer. The test is usually done with the foot at the level of the heart, but if the patient is reasonably stable and if the lower extremities are not injured, it is more sensitive if it can be done with the foot raised above the level of the heart, to a height of perhaps 30 cm. Although the toe is usually used, one can also use the skin over the heel. The heel affords a larger surface for observation. One has to use different criteria, however. If the toe

is used, color should begin to return within 4 seconds; if the heel is used, color should return in 2 seconds.

Postural hypotension—a fall in the systolic blood pressure of more than 10 mm Hg that persists for more than 1 minute when the patient sits up—can be a sign of early or mild shock. It is very useful in patients who are suspected of being hypovolemic from either dehydration or occult internal blood loss (eg, in a patient who might have gastrointestinal bleeding). It cannot be used, however, in very ill patients and in injured patients, who might not tolerate changes in position.

Low filling pressures in the right atrium are always present in hypovolemic shock, even in cases of mild shock, assuming there is no accompanying cardiac compression. Filling pressures high enough to distend the neck veins when the patient's head, neck, and torso are elevated 30 degrees, in the absence of cardiac compression, rule out hypovolemic shock. Failure to see the veins suggests, but is not diagnostic of, hypovolemia.

Oliguria is a consistent finding in early shock, in the absence of a hyperosmolar-induced diuresis. A bladder catheter should be inserted in any patient suspected of being hypovolemic. Urine output is considered to be potentially inadequate if it is less than 0.5 mL/kg/h in an adult, less than 1 mL/kg/h in a child, or less than 2 mL/kg/h in an infant. The sign, if present, is both sensitive and specific. One must wait, however, for 30 minutes or so, before one knows that the sign is present.

The hematocrit will fall within minutes in the bleeding patient, or in the patient who has bled, even when the blood loss is mild, if the patient has been given asanguineous fluids. In the absence of fluid administration, however, the fall can take hours—restitution of the intravascular volume from interstitial albumin and water and electrolytes, takes time. One can make an estimate of the blood loss, if the patient has been given asanguineous fluids, by the magnitude of the fall in the hematocrit. A hematocrit fall of 3%-4% indicates that the blood volume was depleted by about 10%; a fall of 6%-8% indicates a depletion of about 20% (or 1 L in an average adult). These calculations assume that the patient has been given enough fluid to correct the hypovolemia. They also assume that the patient was not dehydrated, prior to the hemorrhage, and that the patient did not have large losses of plasma into the extravascular spaces, as in a patient with large burns, prior to a possible hemorrhage. The hematocrit in these patients can be normal in the face of even substantial bleeding.

Hypovolemic shock is easier to recognize when it becomes more severe. In moderate cases (a deficit of 20%-30% of the blood volume), the patient can be thirsty. Hypotension can be present, even in the supine position. A metabolic acidemia, usually with a compensatory rapid respiratory rate, can develop after initial resuscitation. (The acidemia is usually not present before resuscitation. The products of anaerobic

metabolism in the ischemic tissues are only flushed into the circulating blood volume once some degree of reperfusion has been achieved.)

In profound hypovolemic shock (a deficit of more than 30% of blood volume), the blood pressure will always be low, even in the supine position. Cerebral and cardiac perfusion can become inadequate. Signs of the former include changes in mental status, restlessness, agitation, confusion, lethargy, or the appearance of inebriation; signs of the latter include an irregular heartbeat or electrocardiographic evidence of myocardial ischemia, such as ST-T segment depression and, over time, the appearance of Q waves. A metabolic acidemia will always be present, after initial resuscitation.

There are many pitfalls in making the diagnosis of hypovolemic shock, and every clinician will miss the diagnosis on occasion. In some patients, especially children and young adults, strong compensatory mechanisms can maintain the blood pressure at normal levels in the setting of mild to moderate shock. In other patients, one might not know if the observed pressure is abnormally low—a young patient might normally have systolic pressures in the low 100s; the same pressure in a chronically hypertensive patient might precede catastrophe. Pain-producing injuries in the absence of blood loss should produce hypertension; a normal pressure in a patient with a pain-producing injury suggests hypovolemia. Administration of a sedative or narcotic in the face of hypovolemia can produce hypotension but usually has no effect on the pressure in a normovolemic subject—one should not ascribe hypotension to sedatives or narcotics until the possibility of hypovolemia has been ruled out.

The heart rate is notoriously unreliable as a sign of hypovolemic shock. Although it increases in response to graded hemorrhage in anesthetized animals, the correlation between hypovolemia and heart rate in unanesthetized human beings is poor. Unanesthetized hypovolemic human beings often have normal heart rates. Severe hypovolemia can even produce bradycardia, as the cardiovascular system makes a last attempt to allow filling of the ventricles during diastole. A normal heart rate provides no assurance that the patient is not in shock. (A rapid heart rate, however, has to be taken seriously. It might be the only indication of shock. The pitfall is in the assumption that a normal heart rate rules out shock.)

There are at least three other pitfalls that can lead to missing the diagnosis of shock: (1) the cutaneous vasoconstriction of hypovolemic shock can be ablated by the vasodilation induced by alcohol or other pharmacologic agents, both therapeutic and recreational; the patient might have well-perfused skin even when hypovolemic; (2) the oliguria of shock can be overcome by an osmotic diuresis induced by high blood alcohol or glucose levels; and (3) shock can cause alterations in mental status that resemble intoxication with drug use or inebriation. If so, the patient might be in a pre-terminal state, in which the shock is so severe that cerebral

blood flow becomes inadequate. The diagnosis of drug or alcohol use, as the cause of the mental abnormalities, should only be made after shock has been ruled out.

► Treatment

A. Airway and Ventilation

Resuscitation of patients in hypovolemic shock, either hemorrhagic or nonhemorrhagic, begins with ensuring adequacy of the airway. In many patients in shock, especially severe shock, this means preemptive intubation and mechanical ventilation. The physician cannot let uncertainty about the airway interfere with evaluation and resuscitation of other problems in the often confusing picture of shock. A patient who later turns out to need no support for the airway or ventilation can easily be extubated; failure to intubate a patient who later loses control of an airway or who can no longer ventilate means, at the least, an emergency intubation under difficult conditions and, at the worse, anoxic brain damage or death. This approach is different from the approach for medical patients with decompensated chronic obstructive lung disease, in whom intubation can mean prolonged mechanical ventilation and perhaps even failure to ever extubate. Those patients have such severe underlying pulmonary disease that even under baseline conditions they have trouble breathing. The baseline condition in surgical patients is usually perfectly adequate pulmonary function. Once the possible surgical problems are ruled out or dealt with, there is usually no problem with extubation.

If the patient requires mechanical ventilation, and almost all patients intubated for shock do, volume control ventilation, or some variant thereof, is preferable, in the initial phases of resuscitation (in the latter phases, after the dust has settled, we usually use pressure modulated ventilation—see the section in this chapter on Treatment of Acute Pulmonary Failure). The tidal volume is set at 7 mL/kg ideal body weight (IBW); the inspiratory time, at 1 second; the respiratory rate, at 15 breaths/min; and the end expiratory pressure, at 0 cm H₂O, with all of these settings designed to minimize the mean airway pressure. To maintain adequate arterial oxygen saturation, the inspired oxygen concentration is set at 1.00. (The oxygen concentrations can be decreased later, after blood gases come back and the patient is more stable.)

The quick-to-intubate-and-ventilate approach described above pertains to all patients in shock with one exception—patients who present immediately after injury with life-threatening torso hemorrhage. The bleeding can be into the abdomen or **into** the chest or **into** the pericardium. The diagnosis is usually made on the basis of the clinical setting or on sonographic imaging. Some of these patients have to be intubated in the emergency room. If possible, however, one should delay intubation until the patient is in the operating room (which is the immediate destination for all of

these patients, once the problem of exsanguinating cavitory hemorrhage is recognized).

A patient in profound shock from bleeding **into** the torso can suddenly deteriorate, to the point of losing his vital signs, with intubation and initiation of positive pressure ventilation. Positive pressure ventilation has effects on the cardiovascular system. All of them are bad, and all are worsened in the face of hypovolemia. The positive pressure compresses the superior and inferior venae cavae, increasing the time needed to fill the right atrium and right ventricle during diastole. (Normal negative pressure ventilation, spontaneous ventilation, decreases the time needed.) Positive pressure squeezes the thin-walled chambers of the heart (the atria and the right ventricle), making it harder for the chambers to fill during diastole. (Negative pressure ventilation makes it easier for the chambers to fill.) Positive pressure squeezes the pulmonary artery, pulmonary microvasculature, and pulmonary veins, making it hard for the right ventricle to transmit its generated energy into the pulmonary artery. (Negative pressure makes it easier to transmit the energy.) Positive pressure ventilation also compresses the pulmonary veins, mandating longer times for the left atrium to fill during diastole. (Negative pressure allows for quicker filling.)

If the patient loses his vital signs in the operating room, with intubation, the surgeon and anesthesiologist will be ideally situated to deal definitively with the underlying problems of hemorrhage and airway management. In contrast, if the patient is intubated in the emergency department and loses his vital signs, the team will be at a major disadvantage in dealing with the underlying problems. An example is in the patient with a gunshot wound to the abdomen who loses vital signs shortly after intubation in the emergency department. Opening the chest will be done hastily, under suboptimal conditions and it is unlikely to be of help. The maneuver does not deal with the underlying problem—bleeding **into** the abdomen. The patient needs a celiotomy, which cannot be done in the emergency department.

B. Bleeding

Direct pressure should be the first maneuver in controlling external bleeding from any part of the body. Commercially available tourniquets or improvised pneumatic tourniquets can be used for bleeding from extremities. They are easy to apply and are usually safe for up to 2 hours, with the caveat that bleeding should be controlled quickly so as to minimize tourniquet time. Several commercially available, FDA-approved hemostatic agents are available for temporary control of external bleeding. They have been proven to be effective in prehospital and combat environments and can be effective in the hospital setting as well. Blood in the pleural cavities should be drained with a chest tube. Expansion of the lung will decrease further bleeding from the pulmonary

parenchyma through apposition of the visceral and parietal pleurae and will reestablish ventilation through the compressed lung. The tube will also allow monitoring for ongoing bleeding, providing key information that can prompt early operative intervention. Bleeding from pelvic fractures may require temporary binder placement. More definitive control can come later, with angiographic embolization or surgical control. Major long bone fractures should be immobilized. Although it might not be necessary to say, patients with intra-abdominal or intractable intrathoracic bleeding should be prepared for the operating room.

Blind clamping, without direct visualization, in the emergency room, should not be attempted, in the initial control of external bleeding. It can result in target vessel injury or, worse, adjacent venous laceration with increased bleeding.

C. Initial Fluid Resuscitation

Vascular access is best obtained with percutaneously placed, large-bore (ideally 14-gauge or larger) venous catheters. The catheters can be placed in superficial veins in the upper extremities, in central veins at the thoracic outlet, or in the femoral veins; catheters can also be placed in the saphenous veins, by cutdown, or directly into interosseous sites (sternum, tibia, or humerus) using specially designed needle introducer systems (FAST-1, EZ IO), the major advantage of the latter devices being the minimal training required to achieve successful access. Choice of access depends on severity of the shock, pattern of injury, provider experience, and consequences of a complication with the access, should one occur. If veins in the lower extremities are to be used, they must be decannulated within 24 hours to minimize the risk of thrombosis and infection. Gaining central venous access can be dangerous as patients in hypovolemic shock will frequently have collapsed central veins. Urgency of placement predisposes to errors in technique. A pneumothorax or an unintentional arterial puncture in the unstable patient might prove fatal.

Initial fluid resuscitation begins with a warmed crystalloid solution. Either normal saline or lactated Ringer solution can be used. Use of lactate in the resuscitative fluid is reasonable if the shock seems to be severe and if the arterial pH is likely to be less than 7.20. The lactate will buffer the hydrogen ions that are released into the central circulation with the initiation of resuscitation. The resultant lactic acid is then oxidized in the liver to carbon dioxide and water, which are excreted by the lungs and kidneys.

If the arterial pH is not likely to be excessively low, normal saline can be used as the initial resuscitative fluid. A modest hyperchloremic acidemia in the immediate postresuscitative state might favorably change the conformation of albumin molecules, decreasing movement of plasma **into** the interstitium. The acidemia might also increase myocardial contractility.

Blood flow to the liver is not a factor in deciding on lactated Ringer versus normal saline. Even minimal flow, as in severe shock, will be enough to deliver the buffered hydrogen ion to the liver parenchyma. Lactated Ringer should not be used, however, if the patient has preexisting liver disease. Adequate oxidation requires functioning liver cells.

The rate at which the initial crystalloid resuscitation should be given depends on two factors: (1) the severity of the shock and the presence of uncontrolled bleeding. When bleeding has been controlled, resuscitation to normovolemia is the goal. (2) Two L is given as fast as possible, followed by a third liter infused over 10 minutes if necessary. This amount of fluid will resuscitate most patients in whom hemorrhage has been arrested.

If the patient is not resuscitated with this amount of fluid, one should renew the search for bleeding, which might be **into** the chest, abdomen, or retroperitoneum. In addition, one should begin to use blood products, while cutting back on asanguineous fluids.

D. Blood Products

Transfusion therapy can be life saving, but it is not without risk. Transfusion reactions, transmission of blood-borne pathogens, acute lung injury (ALI), and immunomodulation can all arise from the administration of blood products. In the acutely bleeding patient, allogeneic packed red cells should be used when the estimated blood loss exceeds 1.5 L (30% of the blood volume), and possibly earlier if there is the potential for ongoing bleeding or if the patient is at risk for having coronary artery disease (Table 12-1).

In urgent settings, type-O blood should be given to restore circulating blood volume. Rh-positive blood can be given to men and women who are beyond childbearing age; Rh-negative blood has to be used in women of childbearing age. The patient's blood type can be determined within 10 minutes, in most hospitals, and type-specific, uncrossed matched red cells should be used when they become available (except in the case of massive casualties, when type O, Rh-negative universal donor cells should be used, to minimize the chance of giving the wrong type of blood to a misidentified patient). Type specific cells should also be used in the setting of massive transfusion, when cross-matching becomes impossible because of the heterogeneous origin of the circulating cells following rapid blood volume replacement.

If resuscitation is ongoing and if it appears as though the total blood loss is likely to exceed one blood volume in 12 hours, plasma and platelets should be given in amounts sufficient to approximate a 1:1:1 ratio. This should be determined as early as possible to avoid dilutional coagulopathy. "Massive transfusion protocols" can maximize efficient use of blood products through the utilization of predetermined component ratios, bedside refrigeration, and in some cases,

Table 12–1. Hematocrit triggers for transfusion: influence of coronary artery disease (CAD), environment in which the patient is being treated (emergency department vs. intensive care unit), and likelihood of bleeding.

Coronary Artery Disease (CAD)	Environment	Likelihood of Bleeding	Desired Hematocrit (%)
No	ICU	Unlikely	21
No	ICU	Possible	21
No	ED	Unlikely	24
No	ED	Possible	27
Yes	ICU	Unlikely	27 ¹
Yes	ICU	Possible	30 ²
Yes	ED	Unlikely	33 ²
Yes	ED	Possible	36 ²

¹Hematocrit values less than 27 may be sufficient in some patients with treated CAD when there is no risk of bleeding.

²Hematocrit values greater than 30 generally serve as a buffer for unanticipated or unmeasurable bleeding. They are not necessary in all patients with CAD.

protocol-driven laboratory monitoring. Crystalloid infusion can be restricted in the case of massive transfusions—adequate amounts of crystalloids will be infused in conjunction with the blood products.

E. Goals of Fluid Resuscitation

Giving excessive amounts of fluids in an effort to restore the blood pressure to normal or supranormal levels will create edema. Edema in the gut can create an abdominal compartment syndrome, with compression of the inferior vena cava, displacement of the diaphragm **into** the chest, and compression of the heart and lungs; edema in the liver can lead to compression of biliary ductules and inability to excrete bilirubin into the gut; edema in the lungs can hinder ventilation and oxygenation; and edema in wounded tissues can impede healing and the ability to fight off infection. Unnecessarily high blood pressures can also potentially exacerbate bleeding. On the other hand, inadequate resuscitation can leave the patient exposed to the many adverse late effects of prolonged shock, such as multiorgan failure.

The primary goal in fluid resuscitation for all forms of shock is the same: restoration of adequate end organ perfusion, the product of the mean pressure perfusing the organ and the blood flow to the organ. Resuscitating to a brachial systolic pressure of 80 mm Hg or a radial pulse

in the bleeding patient is reasonable until hemorrhage has been controlled. (The treating physician will not know the cardiac output or organ blood flow in the early phases of resuscitation, but he or she can use clinical criteria, such as skin perfusion, urine output, and mental status, in managing the patient, along with the blood pressure.) After the bleeding is controlled, a systolic pressure of 90 mm Hg might be reasonable. In the very old, the blood pressure goal should be higher to ensure a cushion of perfusion for the brain, heart, and other viscera that might be supplied by arteries obstructed by atherosclerosis.

One must keep in mind during the resuscitation, however, that using the blood pressure to define severity of shock or to assess the adequacy of resuscitation can be hazardous. Most patients in hypovolemic shock will be able to constrict the arterioles in their skin, muscle, and visceral organs in response to the hypovolemia (the exception being inebriated patients). They can often maintain a normal pressure even in the face of continued shock. One must consider many variables in assessing adequacy of resuscitation, including peripheral perfusion, urine output, mental status, acid-base balance, and resolution of any signs of myocardial ischemia.

F. Correction of Coagulation Abnormalities

After severe trauma or major sepsis, many patients will demonstrate signs of intravascular coagulation, with prolonged clotting times, low platelet counts, decreased fibrinogen levels, and production of fibrin degradation products or fibrin monomers. Correction requires administration of plasma and platelets, especially to patients who continue to bleed and to those with severe head injuries, in whom intracranial bleeding could be devastating.

Traditional replacement of coagulation factors has been done with thawed frozen plasma. The advantages of frozen plasma are logistical; the disadvantage is that it has to be thawed prior to use, which may take from 30 to 60 minutes. Increasingly, trauma centers are using either prethawed plasma or “liquid” plasma that has never been frozen. The advantage of the former is that the product does not have to be thawed; the major disadvantage is the potential for waste. “Liquid” plasma has the potential advantage of increased factor activity with the disadvantage of waste. Finally, there has been interest in developing freeze dried plasma, particularly by the military. Although the Europeans have extensive experience with the product (it is approved for use in Europe), there is currently no FDA approved formulation in the United States.

Over the last decade, pharmacologic therapy for hemorrhage-related coagulopathy has become a standard adjunct in the setting of hemorrhagic shock. In the recent past, recombinant activated factor VII has been used routinely for severely injured patients with ongoing traumatic coagulopathy. Administration of doses between 80 and

100 mcg/kg is generally recommended for coagulopathy in trauma patients. Smaller doses may be useful for warfarin reversal in the setting of intracranial hemorrhage. Due to the mechanism of action, platelet and fibrinogen levels need to be adequate at the time of administration.

Tranexamic acid (TXA) is an antifibrinolytic agent that has recently been adopted for routine use by the military as a pharmacologic adjunct for hemorrhage control (REF). It is being used with increasing frequency in civilian settings. The impetus for use in trauma originated from a large prospective international trial (CRASH-2) as well as a large retrospective cohort of combat casualties. Although there is no universally recommended monitoring when using the product, it seems reasonable to think that it should be particularly useful in the presence of excessive fibrinolysis, which can be assessed with the use of the thromboelastogram (TEG), a test that is being used more and more often in diagnosing fibrinolysis in the bleeding patient.

Using pharmacologic agents to improve hemostasis can lead to procoagulant side effects. These have been well documented with activated factor VII but are less well known with antifibrinolytic agents such as TXA. If the patient is not bleeding and is not at risk for a devastating consequence of rebleeding, one should not give procoagulant factors—they will only fuel the fire of systemic inflammation and coagulation. As with any intervention, the benefit to risk ratio should be individualized.

G. Hypothermia: Prevention and Treatment

Maintenance of normothermia is critical in the setting of hemorrhagic shock. Patients who have significant blood loss may lose the ability to increase metabolic heat production. In addition, initial fluid replacement is often done using room temperature or cold solutions such as crystalloid administered in the field by paramedics or unwarmed blood products in the hospital. The added stress of environmental or surgical exposure can make it difficult to maintain normothermia. The impact cannot be overstated. The adverse effects of hypothermia on coagulopathy can be profound.

For these reasons, hypothermia prevention and treatment should be an immediate and ongoing management priority during resuscitation from hemorrhagic shock. At the very least, one should keep the environment warm, infuse fluids through warmers, and keep the patient covered, as much as possible. These efforts should commence as soon as possible after the injury or after the onset of illness.

H. Modalities to Be Avoided

There is no role for using colloid solutions in the setting of hypovolemic shock except when size and weight of the crystalloid solutions limit their availability, as in treating mass casualties or under wartime conditions. Under these circumstances, solutions containing hetastarch or hypertonic

saline and dextran can be used. Otherwise, colloids provide no benefit over crystalloid solutions, and they add to cost. Vasopressors should not be used in resuscitating neurologically intact hypovolemic patients, except in desperate situations for short periods while the vascular volume is reexpanded. The idea that vasopressors divert flow from nonessential organs to essential organs is ill-conceived. Although some organs can withstand ischemia for longer periods of time than others, there are very few parts of the body that are not essential. Patients given vasopressors in shock are at risk for ischemic gangrene of the limbs, gut necrosis, liver failure, and acute tubular necrosis. Vasopressors, however, are often indicated in patients in neurogenic shock, because those patients may have lost critical physiological compensatory responses (see section on Neurogenic Shock).

Elevation of the lower extremities above the level of the heart (Trendelenburg position) in a normovolemic subject shifts blood to the heart and increases ventricular end-diastolic volumes. In the hypovolemic patient, however, adrenergically mediated venoconstriction has likely already achieved this shift. Thus the position is of little value in treating hypovolemic shock, and its awkwardness can make evaluation and treatment of other problems more complicated. The position, however, is useful for the treatment of neurogenic shock.

In trauma patients, the pneumatic antishock garment can be useful for temporary compression of bleeding sites that cannot be controlled by other means, for temporary stabilization of pelvic fractures, and as a temporary expedient to increase the blood pressure during transport in patients in neurogenic shock. It has no other uses. It limits the physical examination. It precludes use of the veins in the lower part of the body as sites for venous access. It can hinder filling of the ventricles by compressing the inferior vena cava and the renal and hepatic veins. It can hinder left ventricular ejection by compressing the arterioles in the lower body. It can push the diaphragm into the chest and interfere with ventilation. It is of no use in displacing blood from the periphery to the heart in neurologically intact patients—discharge of the adrenergic system will already have achieved that goal.

CARDIAC COMPRESSIVE SHOCK

► Diagnosis

Cardiac compressive shock can arise from any condition that compresses the heart or great veins, including pericardial tamponade, tension pneumothorax, massive hemothorax, rupture of the diaphragm with encroachment of abdominal viscera into the chest, and distention of the abdomen with compression of the intra-abdominal great veins and elevation of the diaphragm into the chest. All of these conditions are worsened if the patient has to be mechanically ventilated.

The signs of compressive shock are similar to those of hypovolemic shock—postural hypotension, poor cutaneous perfusion, oliguria, hypotension in the supine position, mental status changes, electrocardiographic signs of myocardial ischemia, metabolic acidemia, and hyperventilation—combined with distended neck veins. The only other type of shock that can produce the combination of poor perfusion associated with distended neck veins is cardiogenic shock, which rarely poses a problem in differential diagnosis. Cardiogenic shock usually develops against a background of evident disease that predisposes to primary myocardial dysfunction. Cardiac compression usually follows trauma or occurs in a setting where mechanical compromise of the heart or great veins can arise from imposition of external pressure (as in a possible pericardial tamponade).

The so-called paradoxical pulse is occasionally helpful in diagnosis. A spontaneous breath in a normovolemic subject without cardiac compression produces little effect on systemic blood pressure. If the heart is compressed, the systolic pressure can fall by more than 10 mm Hg. (In contrast, a fall in the blood pressure with positive pressure ventilation is common and nonspecific, especially in hypovolemic patients; the concept of a paradoxical pulse applies only to patients who are breathing on their own.)

The diagnosis of cardiac compression is facilitated if the patient can be monitored in an intensive care unit (ICU) with a pulmonary artery catheter, when small stroke volumes in the face of high filling pressures can be documented by direct measurement. In addition, the catheter can be used to compare pressures in the left and right atria. Under normal circumstances, the pressure in the left atrium is about 5 mm Hg higher than in the right. In tamponade, the pressures are the same.

► Treatment

Infusion of fluid can transiently overcome some of the ill effects of cardiac compression, but the cause of shock in these patients is mechanical, and definitive treatment must correct the mechanical abnormality. Treatment of compressive shock caused by large-volume, high-pressure mechanical ventilation is discussed later in this chapter in the section on mechanical ventilation.

CARDIOGENIC SHOCK

► Diagnosis

Cardiogenic shock can arise from several causes, including arrhythmias, ischemia-induced myocardial failure, valvular or septal defects, systemic or pulmonary hypertension, myocarditis, and cardiomyopathies. Of all the forms of shock, it can be the most resistant to treatment. If the heart cannot pump, there may be nothing that can be done. On the other

hand, in less severe cases, it is possible to improve the efficiency of the pumping capability that remains.

The diagnosis of cardiogenic shock usually depends on recognizing an underlying medical condition predisposing the heart to dysfunction in conjunction with an abnormal electrocardiogram. Given the relative oxygen demands of the left and right ventricles, shock caused by left ventricular failure is much more common in patients with ischemic heart disease and typically presents with chest pain, a third heart sound, rales, ST segment elevation on a 12-lead electrocardiogram, and, on chest film, an enlarged heart or pulmonary edema. Cardiogenic shock may be associated with distended neck veins if the right ventricle has failed, unless the patient is also hypovolemic, as in a bleeding patient with a recent myocardial infarction. In many cases, patients with recent shock or trauma may have mild to moderate forms of right ventricular dysfunction related primarily to the heart's response to systemic inflammation or elevated ventilator pressures. Right-sided dysfunction can be associated with peripheral edema, an enlarged and tender liver, and, on chest film, an enlarged heart. The diagnosis is usually easy, but two common situations may pose a problem.

The first is a ruptured abdominal aortic aneurysm in a patient with coronary artery disease. The patient might have abdominal pain consistent with a myocardial infarction and electrocardiographic signs of ischemia—the ischemia being caused by hypovolemia and shock. The key is to observe the neck veins.

The second is to ascribe shock to myocardial contusion in a patient who has just suffered a blunt injury to the chest. Although blunt chest trauma can damage the heart, the damage is usually either fatal, with death at the scene of the injury, or, more often, of no clinical significance. A contusion that produces failure but not death is rare. Shock after blunt trauma in a patient who survives to reach the hospital is almost never caused by contusion—it is far more likely to be caused by hypovolemia or by a mechanical problem.

► Treatment

A. Initial Management of Dysrhythmias

In the initial treatment of acute dysrhythmias, we use the approach described by Ursic and Harken (ref in the ACS textbook). A bradydysrhythmia in a hypotensive patient with a heart rate less than 50 beats/min deserves treatment, even if the ventricular contractions are well coordinated. One should begin with the intravenous administration of atropine, at a dose of 0.5 mg, repeated at 2-minute intervals for a maximum dose of 2 mg. If the rate remains slow and if the patient is still unstable, the heart should be paced by transvenous or external means.

A tachydysrhythmia can put a patient at risk for myocardial ischemia regardless of origin (sinus vs nonsinus) or etiology (hypovolemic or cardiogenic shock). Thus one has to

decide if the rate is so rapid that it threatens the patient's myocardium. As a first approximation, the goal for most patients should be a ventricular rate between 50 and 100. But the goal can be different for different patients. The maximal ventricular rate, the rate that can be sustained for perhaps 5 minutes, but not longer, declines with age (220—age in years). The maximal aerobic rate, a rate that can be maintained indefinitely, but with strain, is 60%-90% of this value depending on the physical condition of the patient and the presence or absence of ischemic heart disease. For example, a healthy 20-year-old man in good condition should be able to tolerate and sustain a heart rate of 160 (80% of 200) without difficulty (although one should search for the cause of the tachycardia). On the other hand, a 65-year-old man with known coronary stenosis may have a myocardial aerobic threshold of 93 beats/min:

$$(220 - 65) \times 0.6$$

Rates exceeding these limits should be treated.

A moribund patient with a tachydysrhythmia should undergo electrical cardioversion, an intervention that result in full cardiac function with normal blood supply to the brain in a matter of seconds. No other treatment has this potential. Electrical cardioversion is the treatment of choice for coarse ventricular fibrillation, ventricular tachycardia, and for supraventricular dysrhythmias with unsustainably rapid ventricular responses. It is not the treatment of choice for asystole or fine ventricular fibrillation, but no treatment for these dysrhythmias has a chance of achieving resuscitation with full neurological function. Nothing will be gained with cardioversion in the patient in asystole or fine fibrillation, but nothing will be lost.

One hundred joules (J) should be used initially, with rapid escalation to 360 J, as needed. The cardioversion takes precedence over securing the airway, and it takes precedence over obtaining vascular access; it even takes precedence over making a diagnosis of the arrhythmia. Once converted, the patient should be given a single 100-mg dose of lidocaine. Serum electrolytes should be measured and corrected, if needed. One to two grams of magnesium sulfate should be given intravenously over 15 minutes, regardless of initial plasma concentrations. More should be given later if the values are low.

Treatment of any non-moribund patient with a tachydysrhythmia begins with ensuring euolemia and treating other possible extracardiac causes of a tachycardia (such as fever, stress, pain, and anxiety). Dangerously rapid tachydysrhythmias associated with abnormal ventricular conduction should be electrically cardioverted, followed with lidocaine, electrolyte correction, and administration of a single dose of magnesium. In the non-moribund patient with a dangerously rapid tachydysrhythmia and normal ventricular conduction, the initial goal is to slow the rate. Give up to 10 mg of verapamil intravenously over 10 minutes. This will slow the rate in the large majority of the patients. If the initial dose fails to slow

the rate, an additional dose can be given 30 minutes after the initiation of the first dose. If the ventricular response is still too rapid, give digoxin. The digoxin is administered as a loading dose of 0.5 g intravenously, followed by 0.25 g every 6 hours for two additional doses (total of 1.0 g). More might be needed—the goal is to block the AV node enough so that the ventricular response is acceptable. Daily maintenance doses are usually needed, for long-term control, and the serum levels should be measured. Electrolytes should be corrected; magnesium should be supplemented.

For continued control of the rate, we favor digoxin. But one can also continue to use verapamil or add a beta-blocker, for long-term control. All three classes of drugs—calcium channel blockers, digoxin, and beta-blockers—slow AV nodal conduction, but, of the three, only digoxin increases myocardial contractility. Surgical patients need contractility to perfuse wounded or infected tissues.

If more than one drug has to be used, the patient will need to be in a monitored setting. Complete heart block is a potentially disastrous side effect with all of these drugs, especially when used in combination.

If ventricular conduction is normal and the patient is in atrial fibrillation, and if it is thought that the fibrillation is going to be of long duration, and if the physician is sure that the patient needs an "atrial kick," the patient can be converted to a sinus rhythm with amiodarone. This set of conditions is rarely the case, however, in the noncardiac surgical patient. The "atrial kick" provides close to no added energy production from the heart in all but the most extreme cases of myocardial dysfunction. The atria in any reasonably functional heart serve only as reservoirs of energy, as capacitors, like other capacitance elements in the circulation, like the venules and small veins. The atria allow the ventricles to fill evenly under conditions of varying heart rates, but that goal is achieved with or without active contraction of the chambers.

Amiodarone frequently results in conversion of atrial fibrillation to a sinus rhythm, but the disadvantages of the drug, in the noncardiac patient, almost always outweigh the potential benefit. Conversion can lead to embolization of clot from the atrial appendage to the brain. The drug depresses myocardial contractility (potentially impeding wound healing and the ability to fight off infection). It has a long half-life. Its effects can last for weeks.

B. Opioids

Opioids can be especially effective in treating cardiac failure after myocardial infarction. They relieve pain, provide sedation, block adrenergic discharge to the arterioles, block discharge to the venules and small veins, redistribute the blood from the atria and ventricles to the venous capacitance vessels in the periphery, and decrease myocardial oxygen requirements.

C. Diuretics

Diuretics are the keystone of therapy in congestive heart failure with large ventricular end-diastolic volumes. By decreasing vascular volume, diuretics decrease atrial pressures and mobilize peripheral and pulmonary edema. Pulmonary vascular pressures and volumes decrease; effectiveness of right ventricular contraction increases. Coronary blood flow increases as coronary sinus pressure drops. Decreasing pressures in the ventricles during diastole, when the ventricular muscle receives its nutrient blood flow, alleviates compression of the coronary vasculature in the endocardium. Decreasing pressures in the right atrium decreases the stiffness of the coronary vasculature, which decreases the stiffness of the ventricles during diastole (the garden hose effect). The ventricular end-diastolic volumes potentially can increase without much of an associated increase in the end-diastolic pressures.

D. Beta-Blockers

Almost all patients in cardiac failure with ischemia and a rapid heart rate will benefit from a beta-adrenergic blocking agent (eg, esmolol or metoprolol). Decreasing the rate and reducing ventricular stiffness during systole decreases myocardial oxygen requirements. Increasing time in diastole and decreasing ventricular stiffness during diastole augments ventricular filling and increases efficiency of ventricular contraction. All of these effects reduce myocardial oxygen consumption and potentially salvage marginal myocardium. In many patients, the reduced oxygen requirements can be achieved with only minimal loss of energy output from the ventricles. The only contraindication to the use of beta-blockers, beyond the rare development of bronchospasm with administration of the drugs, is hypotension. This latter problem is easily monitored.

E. Vasodilators

Hypertension is unusual but not unheard of in patients with cardiogenic shock. The hypertension is usually associated with inefficient delivery of energy into the aortic root. Treatment should begin with opioids, if the patient is in pain, and then diuresis, if the ventricular end-diastolic volumes are large. Nitroprusside and nitroglycerin are the most useful short-term vasodilators in surgical patients in heart failure (besides opioids). Both drugs act quickly and are easy to monitor; both dilate the systemic arterioles; nitroglycerin also dilates the systemic venules and small veins. For long-term control of pressure, angiotensin-converting enzyme (ACE) inhibitors and calcium channel blockers should be used in place of the nitrates. If the patient has a tachycardia or, as may well be the case, if the patient is at risk for having coronary artery disease or myocardial ischemia, beta-blockade can be used.

Beneficial consequences of controlling the pressure include mobilization of edema, both pulmonary and systemic; enhanced perfusion of the myocardium; reduction of ventricular work and oxygen requirements and, consequently, relief of myocardial ischemia. On the other hand, excessive venous dilation can decrease cardiac filling enough so that stroke volumes and blood pressures fall; excessive arteriolar dilation can make the pressures fall further.

F. Inotropic Agents

Inotropic agents, such as dobutamine or milrinone, can increase cardiac output in some, but not all, patients in cardiogenic shock. Inotropic agents almost always result in increased myocardial oxygen requirements, but this is not usually a problem. Patients receiving the agents should be monitored in an ICU. Development of chest pain or ischemic electrocardiogram changes suggest that oxygen demand is exceeding supply. If it is necessary to use inotropic agents for more than 1 hour, a pulmonary artery catheter should be inserted. Systemic arterial pressures, atrial filling pressures, and cardiac output should be determined at different infusion rates. If any question remains about the adequacy of volume resuscitation, cardiovascular parameters should be measured before and after a fluid bolus is given.

Digitalis compounds should not be used in acute cardiac failure except to control ventricular rates in patients with supraventricular tachydysrhythmias. Toxicity may develop, especially when pH and electrolyte changes are unpredictable. The inotropic actions of digitalis are no different from those of dopamine and milrinone.

G. Chronotropic Agents

Although uncommon in the surgical setting, patients with cardiac failure and a low heart rate (< 70 beats/min) may temporarily benefit from the administration of a chronotropic agent, such as dopamine. (Isoproterenol is almost never used nowadays.) When using dopamine, the heart rate should be increased only to levels that can be tolerated comfortably. A 60-year-old patient with normal coronary arteries gains little with a heart rate that exceeds 120 beats/min; the limit is about 90 beats/min in the presence of coronary artery disease. In most cases, however, the price to be paid for using a chronotropic agent exceeds the potential benefit. Chronotropic agents increase myocardial work and oxygen requirements and shorten the time during diastole for coronary blood flow and ventricular filling. They should be used only as a temporary expedient. If they are used for more than 30 minutes, a pulmonary arterial catheter should be inserted. The goal of therapy is a normal or slightly supranormal cardiac output that provides adequate end-organ perfusion and reverses shock. Trying to achieve more than that only increases the risk of myocardial ischemia.

H. Vasoconstrictors

A vasoconstrictor is occasionally useful to increase coronary perfusion pressure in the setting of coronary stenoses. To be effective, the agent must increase aortic pressure enough so that the increased myocardial perfusion compensates for the increase in the myocardial oxygen requirements.

The major untoward effect of these agents is ischemic necrosis of noncardiac organs, such as the extremities or intestine. They will not increase perfusion to the brain in the setting of cardiogenic shock, assuming that the carotid arteries are open and that the patient has a functioning adrenergic nervous system. The endogenous adrenergic nervous system is ideally suited for ensuring adequate blood flow to the brain. Constrictors should be used only when absolutely necessary and for no more than 60 minutes unless a pulmonary arterial catheter is in place.

I. Transaortic Balloon Pump

The transaortic balloon pump decreases the hindrance that the left ventricle faces when it ejects its blood into the aortic root and can be very effective in resuscitating selected patients with severe reversible left ventricular dysfunction (eg, after cardiopulmonary bypass or acute myocardial infarction). It should be used only if a pulmonary arterial catheter is in place.

J. Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation is most often used in conditions in which one can expect cardiac function to recover within a matter of a few days. Bleeding complications make it impractical for periods exceeding that time.

K. Operative Correction

Although listed last, surgically correctable cardiac conditions should be identified and corrected early, prior to the development of irreversible organ dysfunction. Ruptured valves, occluded arteries, aneurysmal ventricular walls, and certain arrhythmias are examples of potentially correctable lesions. In these cases, early cardiac surgical consultation should be the rule.

NEUROGENIC SHOCK

► Diagnosis

Shock caused by failure of the autonomic nervous system can arise from regional or general anesthetics, injuries to the spinal cord, or administration of autonomic blocking agents. The venules and small veins lose tone, worsened by paralysis of surrounding skeletal muscles. Blood pools in the periphery, ventricular end-diastolic volumes decrease, and stroke volumes and blood pressure fall. Loss of arteriolar

tone in the denervated areas makes the pressure fall further. If the lesion is below the midthoracic sympathetic outflow (approximately T3), activation of the cardiac adrenergic nerves will increase the heart rate and augment ventricular systolic function; if the lesion is more cephalad, the heart will not be able to compensate. Cardiovascular decompensation in neurogenic shock can be profound.

The diagnosis rests on knowledge of the circumstances preceding the onset of shock and on the physical examination. The patient will always be hypotensive, and the skin will be warm and flushed in the denervated areas. The cause is usually obvious.

Nonfatal head injury—in contrast to spinal cord injury—does not produce neurogenic shock or any other kind of shock. In fact, increased intracranial pressure typically increases blood pressure and slows the heart rate (Cushing reflex). Hypotension and tachycardia should never be attributed to head injury—even severe head injury with cerebral dysfunction—until hypovolemia has been ruled out. It is a tragedy to ascribe shock to a head injury when the problem is bleeding from a ruptured spleen.

► Treatment

Trendelenburg position, if it does not complicate other aspects of care, is useful. Intravenous fluids to fill the dilated venules and small veins should be given. Vasoconstrictors should be used if fluids and Trendelenburg position are not enough. Norepinephrine and phenylephrine are good choices if the heart rate is rapid. Dopamine is a good choice if the heart rate is slow.

The primary purpose of vasoconstricting agents in this setting is to restore tone in the venules and small veins; a secondary goal is to constrict dilated arterioles. The blood pressure should be increased to the point that coronary perfusion is sustained—as judged by normal ST-T segments on electrocardiography and absence of chest pain—and to the point that perfusion to the brain and spinal cord is supported. The pressure also has to be high enough to perfuse organs with preexisting obstructing proximal arterial lesions. These patients should be placed in the ICU for both neurologic and hemodynamic monitoring. If vasoconstrictors are used for more than several hours, or if the patient is at high risk for bleeding from multisystem trauma, central venous pressure monitoring or a pulmonary arterial catheter should be used to ensure adequate cardiac filling and function.

LOW-OUTPUT INFLAMMATORY SHOCK

► Diagnosis

Bowel perforation, intestinal necrosis, abscesses, gangrene, and soft tissue infections can produce low-output inflammatory shock, as can ischemia-reperfusion and inadequate resuscitation of massive injuries or large burns.

The cytokinemia arising from the systemic inflammation can disrupt the microvascular endothelium and prompt the loss of plasma into the interstitium. The shock mimics the clinical picture of severe hypovolemic shock, with signs of adrenergic discharge, oliguria, obtundation, and metabolic acidemia. The EKG may show signs of ischemia. Hyperthermia or hypothermia may be present. The diagnosis is usually clear from the clinical circumstances.

► Treatment

Treatment consists of administration of intravenous fluids and antibiotics, correction of gastrointestinal leaks, debridement of dead tissue, and drainage of pus. The patient should be transferred to an ICU. Vasoconstrictors can be given for very short periods of time if the hypotension is so profound that it threatens the brain, the heart, or an organ with an obstructed arterial supply. Inotropes can be used more liberally, while the vascular volume is being replenished, but even then they should be used judiciously until additional physiologic data confirms a euvoletic state. This is easily obtained through the use of a central venous or pulmonary artery catheter. Alternatively, newer, noninvasive measurements of ventricular filling may prove useful. Successful volume expansion will convert the low-output inflammatory shock into a high-output state.

HIGH-OUTPUT INFLAMMATORY SHOCK

► Diagnosis

High-output inflammatory shock can precede low-output inflammatory shock or can be the result of successful treatment of low-output shock. The shock usually, but not always, is associated with a fever. The patient is hypotensive with warm, well-perfused extremities, as the body attempts to control its core temperature by off-loading heat to the environment. If a pulmonary arterial catheter is placed, the cardiac output is found to be high, assuming that the ventricular end-diastolic volumes have been brought back to normal levels. The outputs will remain high, occasionally as high as twice normal, as long as the inflammatory state persists. The oxygen consumption may be increased by a factor of 1.5.

► Treatment

Treatment consists of control of the underlying cause and fluid administration. Inotropes may be useful. If large amounts of fluids are necessary for the resuscitation and if inotropes are being considered, an assessment of ventricular end-diastolic volume should be made to ensure the heart is adequately filling and to assess the impact of the intervention. The most accurate means to accomplish this is through the use of a pulmonary artery catheter. As this

is not always possible, other, less invasive monitoring techniques include the measurement of central venous pressure and serial echocardiography. All have advantages, disadvantages, and in some cases, complications. Regardless, the goal is to perfuse the inflamed tissues with adequate power so that the product of the cardiac output and the mean arterial pressure is normal. In many patients, the result will be a cardiac output that is increased by a factor of 1.5 with a blood pressure that is decreased to a value that is two-thirds of normal. As in other forms of shock, the pressure has to be high enough to perfuse the heart and brain and organs with potentially obstructed arteries, but it does not have to be normal. Vasoconstrictors can be dangerous, potentially leading to necrosis of the limbs, the gut, and the kidneys, especially if there is any degree of hypovolemia. They should not be used unless the clinician is positive that both the right and left ventricular end-diastolic volumes are normally expanded.

INITIAL TREATMENT OF ACUTE PULMONARY FAILURE

DIAGNOSIS OF PULMONARY FAILURE IN SURGICAL PATIENTS

Most causes of pulmonary failure in the surgical patient can be ascribed to one or more of nine causes: the pulmonary failure of shock, trauma, and sepsis; mechanical failure caused by deranged respiratory system mechanics; atelectasis; aspiration; pulmonary contusion; pneumonia; pulmonary embolism; cardiogenic pulmonary edema; and, rarely, neurogenic pulmonary edema.

The pulmonary failure of shock, trauma, and sepsis arises from extrapulmonary trauma, infection, or ischemia-reperfusion in the setting of shock. Products of coagulation and inflammation are washed out from the damaged tissues and carried to the lungs (or to the liver, in the case of the splanchnic circulation, and from there to the lungs), where they set up an acute inflammatory reaction. The extrapulmonary causes are many and range from necrotizing infections to noninfective inflammatory responses (such as pancreatitis) to reperfusion of ischemic limbs to soft tissue injury to broken bones (and embolism of fat and clot from the bone marrow—the so-called fat embolism syndrome, now an outdated term).

The concept of pulmonary failure secondary to extrapulmonary ischemia-reperfusion, coagulation, and inflammation, which is common in surgical patients, can be subsumed into a broader category of pulmonary failure, known as the acute respiratory distress syndrome (ARDS). ARDS is defined by the sudden onset of hypoxemia with bilateral infiltrates, a $\text{Pao}_2/\text{Fio}_2$ less than 200 and the absence of left atrial hypertension (a pulmonary arterial wedge pressure < 18 if measured). A less severe form, ALI requires a $\text{Pao}_2/\text{Fio}_2$ less than 300 with the other criteria.

The causes of ARDS include those that are responsible for the pulmonary failure of shock, trauma, and sepsis and also include severe pneumonia and aspiration. The end result in all of these conditions is activation of macrophages and other inflammatory cells in the lungs. The mediators

disrupt the microvascular endothelium, increasing its permeability. Plasma extravasates into the interstitium and, in the case of the lungs, into the alveoli. The resultant pulmonary edema impairs both ventilation and oxygenation; the microembolization to the lungs impairs perfusion. Arterial oxygen saturation decreases and carbon dioxide content increases—assuming that no compensatory mechanisms come into play. Lastly, to make things worse, the inflammatory process in the lungs releases mediators into the systemic circulation that can lead to inflammation and dysfunction in the liver, gut, and kidneys.

A number of different mediators of coagulation and inflammation have been implicated as causes of the increased permeability. Proteases, kinins, complement, oxygen radicals, prostaglandins, thromboxanes, leukotrienes, lysosomal enzymes, and other mediators are released from aggregates of platelets and white cells or from the endothelium or plasma as a consequence of the interaction between the aggregates and the vessel wall. Some of these substances are chemoattractants of more platelets and white blood cells, and a vicious cycle of inflammation develops that worsens the disruption of the vascular endothelium.

Pathologically, ARDS (and the pulmonary failure of shock, trauma, and sepsis) is characterized by diffuse alveolar damage and a nonspecific inflammatory reaction, with the loss of alveolar epithelium and hyaline membrane formation. Monocytes and neutrophils invade the interstitium. Edema appears within a few hours, alveolar flooding is florid within 1 day, and fibrosis begins in 1-2 weeks. If the process is unchecked, the lungs become sodden and resemble liver tissue on gross inspection; scar tissue appears within a week, and function-limiting fibrosis begins to develop within 2 weeks. If early treatment is effective, the lungs return to normal, both grossly and microscopically.

Mechanical failure can arise from chest wall trauma, pain and weakness after surgery and anesthesia, debility caused by the catabolic metabolism of long-term illness, or bronchopleural fistula. Massive trauma to the chest with multiple fractures of multiple ribs or bilateral disruption of the costochondral junctions can result in a free-floating segment of chest wall known as a *flail chest*. Expansion and relaxation of the chest wall during spontaneous breathing results in paradoxical motion of the free segment in response to changes in intrathoracic pressure; ventilation becomes compromised; and the partial pressure of arterial carbon dioxide (Paco_2) increases. In addition, hypoventilation leads to progressive atelectasis and hypoxemia. Lesser degrees of chest wall injury can lead to hypoventilation secondary to pain with similar results. Prolonged mechanical ventilation with loss of muscle mass and power in the diaphragm and the accessory muscles of respiration can require ventilatory support until muscle function returns to normal. A bronchopleural fistula—a communication from the airway to the pleural cavity to the atmosphere, either through a chest

tube or through a hole in the chest wall—can develop after pulmonary surgery, trauma, or infection. Large air leaks can compromise ventilation to the uninvolved lung as well as to the diseased side because insufflated air preferentially goes to the side with the fistula.

Atelectasis—localized collapse of alveoli—can develop with prolonged immobilization, as during anesthesia or in association with bed rest. The problem is usually full-blown within a few hours after the initiating event. Only mechanical failure (to which it is related), aspiration, cardiogenic pulmonary edema, and pulmonary embolism can produce equivalent levels of hypoxemia so soon, and no other cause of hypoxemia can respond so quickly to therapy. The diagnosis is supported by auscultation of bronchial breath sounds at dependent portions of the lung and occasionally, if severe enough, by x-ray confirmation of plate-like collapse of pulmonary parenchyma. The most reliable confirmation of the diagnosis, however, comes with response to therapy, which can include pain control when necessary and encouragement of deep breathing, coughing, and ambulation when practical. When the hypoxia is severe and refractory to conservative measures, intubation and mechanical ventilation may be necessary, particularly if the underlying etiology (pain and immobility) cannot be reversed easily (eg, high spinal cord injury). Rarely, flexible bronchoscopy may be useful if the lung parenchymal volume loss is due to proximal bronchial obstruction. In general, most forms of atelectasis respond within a few hours to conservative therapy.

Aspiration of gastric contents or blood can occur in any patient who cannot protect the airway. Shock, severe brain injury, or pharmacologic depression (anesthesia, narcotics, or benzodiazepines) can result in a depressed level of consciousness and loss of airway protective reflexes. Gastric acid or particulate matter in the airways leads to disruption of the alveolar and microvascular membranes, causing interstitial and alveolar edema. The resultant hypoxemia is usually evident within a few hours and is associated with a localized infiltrate on x-ray. Recovery of gastric contents by suctioning from the endotracheal tree confirms the diagnosis.

Pulmonary contusion arises from direct trauma to the chest wall and the underlying lung parenchyma. Hypoxemia associated with a localized infiltrate on x-ray develops over 24 hours as the injured lung becomes edematous.

Pneumonia can arise primarily or may be superimposed on aspiration, pulmonary contusion, or the pulmonary failure of shock, trauma, and sepsis. The diagnosis is made by recovery of bacteria and purulent material from the endotracheal tree, hypoxemia, signs of systemic inflammation, and a localized infiltrate on x-ray. The Clinical Pulmonary Infection Score (CPIS), which is derived from these parameters, can be used to quantify the clinical, radiographic, and laboratory findings of pneumonia. It is useful both for diagnosis and for determining the length of treatment. Bronchoalveolar lavage and quantitative culture may

occasionally be used to assist in distinguishing pneumonia from ARDS and other causes of pulmonary inflammation.

Pulmonary embolism typically presents with sudden deterioration of pulmonary function after an event—such as an operation, injury, or the beginning of immobilization—that can stimulate deposition of clot in a large systemic vein. Patients with cancer are at particularly high risk, and in any patient the greater the magnitude of operation or injury, the greater the chance of venous thrombosis and embolization. Clot emboli must be organized to be clinically significant; embolism to the lung of fresh soft clot rarely causes any difficulty. The pulmonary endothelium contains potent fibrinolytics that can break up any poorly organized embolus. Although uncommon in the initial 72 hours following an acquired risk factor (injury, surgery), early postinjury and postsurgical pulmonary embolism is well documented and has to be considered in the differential diagnosis of abrupt-onset hypoxemia.

The chest film is usually nonspecific. A definite diagnosis can be made by high-definition contrast enhanced computed tomograms of the pulmonary vasculature. Modern imaging is extremely sensitive. A negative study rules out an embolism. The CT can also identify atelectasis, infiltrates, and effusions that may not be readily apparent using a standard anterior-posterior radiograph done in the ICU. The major risk involves the physical movement of the patient to the radiology suite. The risk of contrast nephropathy is very low in a euvolemic patient, even in the setting of mild baseline renal disease.

Pulmonary arteriography, with right heart catheterization, can also be used to make the diagnosis of embolism but is seldom used nowadays, with one exception. The study can be very useful in hemodynamically unstable patients in whom a large “saddle embolus” is suspected. The catheter can be left in place, if an embolus is found, and used for catheter-directed thrombolysis.

Cardiogenic pulmonary edema arises from high left atrial and pulmonary microvascular hydrostatic pressures. Patients who have suffered an acute myocardial infarction can present this way, as can patients with underlying myocardial or coronary artery disease when faced with fluid shifts and surgical stress. Occasionally, the rapid administration of intravenous fluid—especially in elderly patients with poor myocardial performance—will outstrip the heart’s ability to pump, and pulmonary edema will result. Acute valvular disease, though rare after injury or cardiac surgery, is another possible cause of inability of the left heart to pump effectively.

The diagnosis is made on the basis of hypoxemia, rales, a third heart sound, perihilar infiltrates, Kerley lines, and cephalization of blood flow on x-ray along with elevated pulmonary arterial wedge pressures on pulmonary arterial catheterization. A wedge (or left atrial) pressure of 24 mm Hg can produce cardiogenic pulmonary edema even in the

presence of an intact endothelium in the pulmonary microvasculature. Pulmonary arterial wedge pressures less than 24 mm Hg will generally not produce edema if the pulmonary vascular endothelium is intact; pressures exceeding 16 mm Hg can worsen the edema associated with increased permeability (such as ARDS). The goal for the wedge pressure in a patient with uncomplicated cardiogenic pulmonary edema in the absence of an inflammatory process in the lungs should be 20 mm Hg or less; the goal in a patient with an inflammatory process should be 12-16 mm Hg.

Neurogenic pulmonary edema is associated both experimentally and clinically with head injury and increased intracranial pressure. The exact mechanism by which this occurs is unknown, but it is probably related to sympathetic discharge with postmicrovascular vasoconstriction in the lungs and a resultant increase in pulmonary microvascular hydrostatic pressure. This form of pulmonary edema and oxygenation defect is rare. In the great majority of patients with a head injury and pulmonary edema, the edema will be caused by some other mechanism, such as ARDS.

INDICATIONS FOR INTUBATION & USE OF MECHANICAL VENTILATION

The indications for intubation and mechanical ventilation are related but often assessed separately. Patients who have primary airway compromise—caused by stridor, maxillofacial trauma, facial and airway burns with edema, or a depressed mental status—may need intubation to protect the airway. In these cases, early intervention is the rule as rapid clinical deterioration can convert a semiurgent procedure into an emergency. In some cases, intubation should be performed before the patient shows evidence of airway compromise. In severe cases, such as massive facial edema, early cricothyroidotomy should be performed.

Intubation of the airway is also indicated if mechanical ventilation is needed for the treatment of established pulmonary failure or for prophylaxis against potential failure or for pulmonary toilet in the face of aspiration. The decision to intubate and initiate mechanical ventilation should be made on the basis of clinical criteria. A respiratory rate exceeding 36 breaths/min, labored ventilation, use of accessory muscles of ventilation, and tachycardia are all indications for intervention. Finally, intubation and mechanical ventilation should be considered in anticipation of treatment that can compromise the airway or worsen the pulmonary status. These include the need for excessive sedation or narcotics, massive fluid resuscitation, and the manipulation of fractures.

Arterial blood gas (ABG) measurements are of no value in making decisions about intubation and mechanical ventilation in patients in extremis. These patients should be intubated regardless of the blood gas results. ABG measurements, however, can assist in the decision to intubate

less severely stressed patients. In the setting of hypoxemia, intubation should be considered if the P_{aO_2} is less than 60 mm Hg and the patient's supplemental oxygen exceeds an O_2 concentration of 50%. For hypercapnic patients, a P_{aCO_2} greater than 45 mm Hg in the setting of acidemia should prompt intubation, especially if serial measurements demonstrate a worsening respiratory acidosis. Regardless of the laboratory values, these guidelines should always be put in the clinical context. A P_{aCO_2} of 40 mm Hg in a patient breathing 40 breaths/min is as alarming as a P_{aCO_2} of 60 mm Hg in a patient with a respiratory rate of 10 breaths/min. A P_{aO_2} of 60 mm Hg on room air in a patient with chronic lung disease may be acceptable; the same value in a patient who is tensing the sternocleidomastoid and intercostal muscles with each breath, making excessive or disorganized use of the abdominal musculature, and who seems to be struggling to draw in enough air, mandates immediate intubation.

The indications for intubation should be more liberal for a surgical patient than for a medical patient. The medical patient with an exacerbation of chronic obstructive lung disease can be poorly served by placement of a foreign body in the trachea. Airway resistance increases, coughing becomes less effective, and opportunistic organisms obtain a foothold on and near the tube. The benefit from intubation may be minimal and noninvasive ventilation techniques, such as bilevel positive airway pressure (BiPAP), may be all that is needed. This support can be given simultaneously with other treatments—such as administration of bronchodilators, antibiotics, and diuretics—in order to avoid intubation and its potential complications.

Circumstances for the seriously ill surgical patient are usually different. The patient who has multiple injuries, for example, can temporarily tolerate the increased airway resistance, loss of cough, and increased likelihood of tracheobronchial infection. What cannot be tolerated is respiratory arrest during trauma resuscitation or during preparation for an operation.

The indications for intubation in the patient with a suspected or known injury to the cervical spine are the same as those in patients with no likelihood of injury. Under no circumstances should concern about the cervical spine lead to procrastination about securing the airway. The consequences of respiratory arrest and anoxic brain damage are as tragic as those of exacerbating a cervical spine injury.

► Types of Intubation

The trachea can be intubated via the mouth, the nose, the cricothyroid membrane (cricothyroidotomy), or directly (tracheostomy). The tubes used for intubation used to come with either high pressure cuffs or low pressure cuffs. Because of problems with compromise of tracheal blood supply, and the subsequent problems of tracheomalacia, erosion into the innominate artery or the esophagus, and tracheal stenosis,

the high pressure cuffs are no longer used. All modern tubes come with low pressure cuffs.

Of the four methods available for intubation, the orotracheal route is usually the easiest. Nasotracheal intubation requires the presence of spontaneous ventilation in order to guide tube placement; cricothyroidotomy and tracheotomy require surgical exposure. Orotracheal intubation allows for passage of a larger tube than the nasotracheal route and avoids the problems of sinusitis and necrosis of the nares, which can occur with nasotracheal intubation. On the other hand, nasotracheal intubation can be accomplished in the awake patient with minimal sedation, and some patients seem to find long-term presence of a nasotracheal tube more comfortable than that of an orotracheal tube. Neither nasotracheal nor orotracheal intubation requires neck flexion or axial rotation. Either approach can be used in patients with suspected injuries to the cervical spine, assuming that axial traction is maintained during the intubation.

Cricothyroidotomy is indicated when an urgent surgical airway is needed. Extensive maxillofacial trauma can make intubation by the orotracheal or nasotracheal route impossible. Translaryngeal intubation can also be difficult because of poor patient cooperation, altered anatomy, or airway or laryngeal swelling. If the patient is in extremis and respiratory collapse is imminent, attempts at orotracheal or nasotracheal intubation should not be prolonged. As a rule, if translaryngeal intubation is not successful after one or two attempts, cricothyroidotomy should be done. The cricothyroid membrane in the midline is bounded superiorly by the lower border of the thyroid cartilage. It is located by palpation and is incised by a stab incision. After the hole has been enlarged with the knife handle, a size 6 or 6.5 endotracheal tube should be inserted. After the airway is secured, the tube can be trimmed (without cutting the balloon tubing) to prevent accidental dislodgement. Alternatively a no. 4 or no. 6 tracheostomy tube can be used if available.

There are several advantages to using the endotracheal tube during an urgent cricothyroidotomy. These include increased tube compliance which facilitates insertion and, perhaps most importantly, universal availability. They are typically found in every airway kit or crash cart. A 6.5 tube will usually accommodate a bougie introducer which may facilitate insertion, particularly when the anatomy is difficult (obese or short neck) and the field is bloody. Larger endotracheal or tracheostomy tubes should not be used as they may not always pass easily through the cricothyroid space. In the short term, these smaller tubes are more than adequate as a rescue treatment and can easily be changed under more controlled circumstances.

Once the airway is secured and the patient stable, a more definitive airway can be planned as needed. The need to convert to a tracheotomy is not absolute. In some cases, the patient may no longer require airway protection. In others, endotracheal intubation may be a reasonable option. In the

past, concerns over subglottic stenosis necessitated conversion of the cricothyroidotomy within several days. This has not been uniformly supported by the literature and should be individualized based on anticipated continued need for airway protection and mechanical ventilation.

Conversion of either an endotracheal airway or cricothyroidotomy to a tracheostomy should be done under controlled conditions. A transverse incision overlying the upper trachea is developed by separating the strap muscles of the neck in the midline. Often the thyroid isthmus must be either displaced or divided to allow for adequate exposure of the anterior surface of the trachea. The tracheostomy tube is placed through the second or third tracheal ring.

Tracheostomy placement is frequently performed for patients who require long-term mechanical ventilation. There are advantages and disadvantages to both the endotracheal tube and the tracheostomy. As a result, there are few absolute diagnostic or time standards for conversion beyond airway control.

One of the theoretical advantages of continued endotracheal intubation is the ease of tube repositioning, which allows distributing pressure on the tracheal mucosa over a larger area, compared with the balloon on the end of a tracheostomy tube, which is fixed in place. The result is a much lower incidence of late tracheal stenosis and tracheoinnominate artery and tracheoesophageal fistulas, compared with a tracheostomy. In addition, because the opening of a translaryngeal tube is well away from the neck and chest, intravenous catheters in these areas can be kept sterile. Finally, the cuffs on translaryngeal tubes usually lie in a more axial position in the trachea than those on a tracheostomy tube and are better able to maintain a seal in patients with poor pulmonary compliance and high inspiratory pressures.

On the other hand, for long-term care, airway resistance with a tracheostomy is lower, nursing care is simpler, suctioning is more direct, and the tubes do not damage the vocal cords or larynx. In addition and perhaps most importantly, accidental extubation is less serious. A well-established tracheostomy tract can be easily reintubated while the patient continues to breathe through the stoma. Tracheostomy is also of benefit when weaning from mechanical ventilation is slow and the patient has failed extubation on multiple occasions. The presence of a tracheostomy allows for prolonged periods off the ventilator without the need for reintubation. If the patient develops respiratory distress off the ventilator and a tracheostomy is present, the ventilator can simply be reconnected to the tracheostomy tube.

The timing of conversion from a translaryngeal intubation to a tracheostomy is controversial. Recommendations as short as 3 days have been made, but large numbers of patients have been intubated for months by the orotracheal or nasotracheal route without serious sequelae. Patients should be converted when airway protection, pulmonary toilet, or any of the other indications outlined above are

present. If, in addition, the need for more than 2-3 weeks of intubation is obvious, the threshold for performing tracheostomy should be lowered.

► Modes of Mechanical Ventilation

Once the airway is controlled, the ventilator should be set up beginning with the mode of ventilation. There are three primary variables used to describe the mode of mechanical ventilation: trigger, limit, and cycle (Table 12-2). The trigger can be patient or time triggered with the latter often referred to as “machine triggered.” This is the variable that determines when a patient receives a breath (starts inspiration). The second is the limit variable and refers to the setting that, when reached, is maintained constant throughout the inspiratory cycle (ie, the “upper limit”). Limit variables are either pressure or flow. When flow is the limit variable, the ventilator is said to be in volume control or volume limited because of the relationship $flow \times time = volume$. Finally, the cycle variable is that which, once reached, terminates the inspiratory cycle and allows passive expiration. Using these three variables, different modes of ventilation have been created. Some are mostly of historical interest, and others are newer, combination modes designed to maximize patient physiology, safety, and comfort.

Machine triggers are time functions based on the set rate, inspiratory time, and inspiratory to expiratory ratio (I:E ratio). Two of the three can be set, and the third is determined. A rate of 20 breaths/min and an inspiratory time of 1 second results in an I:E ratio of 1:2 (1 s inspiration + 2 s expiration = 3 s for a complete cycle; 20 cycles/min).

Patient triggers for delivery of an assisted breath can be either pressure-based or “flow by” depending on the ventilator model. A pressure trigger requires the patient to

generate negative pressure at the onset of inspiration—the pressure in the ventilator tubing falls below a preset value and the ventilator detects this fall in pressure and responds by delivering a breath. The time involved in generating and delivering the breath to the patient, however, can make this form of breathing uncomfortable for the patient. Modern ventilators avoid this problem of triggering by using a flow-by circuit. The ventilator delivers a constant flow of air through the ventilator tubing during expiration, usually at a low level of approximately 5 L/min. The ventilator compares the expiratory and inspiratory flow rates. If the patient is making no inspiratory effort, the flow rates will be the same. If the patient begins to take a breath, the expiratory rate will fall below the inspiratory rate. The ventilator is programmed to trigger a breath when the difference in the flow rates reaches a preset value, usually around 2 L/min, or when the expiratory flow rate falls to 3 L/min. The patient is rewarded with the free flow of at least some air as soon as the effort is initiated. The great majority of patients prefer flow-by over pressure triggering.

A. Volume Control Ventilation

Volume control ventilation is most often used today in situations in which the ventilation needs to be kept simple and the efforts made by the patient need to be minimized, as in the acutely injured or ill patient. The assist-control mode is the most commonly used mode of volume ventilation. It is designed to assist any ventilatory effort made by the patient by delivering a machine breath. Whenever the patient begins to inspire, the ventilator is triggered and the preset machine tidal volume is given. A machine backup rate is also set to ensure a minimal number of machine breaths in the absence of spontaneous ventilatory efforts.

Table 12-2. Characteristics of five commonly used modes of mechanical ventilation.

Mode	Trigger	Limit	Cycle	Notes
Intermittent mandatory ventilation (IMV)	Time (machine)	Flow (volume) or pressure	Time	Volume control IMV or pressure control IMV Can be synchronized to patient's effort (SIMV) and/or used in conjunction with pressure support
Assist control (AC)	Patient and/or time	Flow (volume) or pressure	Time	Assist control volume control (AC VC) or Assist control pressure control (AC PC)
Pressure support (PS)	Patient	Pressure	Flow	Purely spontaneous mode and often referred to as a form of continuous positive airway pressure (CPAP) on the ventilator controls
Inverse ratio	Time	Pressure	Time	PC IMV mode with prolonged inspiratory phase to increase mean airway pressure and functional residual capacity
Pressure-regulated volume control	Patient and/or time	Pressure	Time	Variation of pressure control that limits pressure but adjusts between breaths to ensure preset tidal volume

B. Pressure Control Ventilation and Pressure Support Ventilation

In pressure control ventilation, the inspiratory pressure, inspiratory time, and I:E ratio are selected, and the ventilator automatically adjusts the gas flow rate to maintain a constant pressure during inspiration. The main advantage of this over volume control is that gas flow more closely matches the change in lung compliance that occurs during inspiration. This has the theoretical benefit of a more even distribution of inspired gas and possibly a lower risk of regional alveolar overdistention. It is also more comfortable for the awake patient. Although this can be achieved through manipulating the flow pattern in more advanced volume control ventilators, it is automatic in pressure control ventilation. Physiologic inspiratory times and I:E ratios are usually chosen to improve patient comfort. An inspiratory time of 1 second with an expiratory time of 2-3 seconds is typical. Longer inspiratory times with shorter expiratory times (inverse ratio ventilation) can be used if the physiologic times prove inadequate to provide enough support. The long inspiratory times, along with the short expiratory times, result in air trapping and increase the mean airway pressure. The net result is an increase in functional residual capacity (FRC), similar to that accomplished with high positive end-expiratory pressure (PEEP) levels.

Pressure support ventilation is also a pressure-limited form of ventilation and in most cases, can be considered a distinct mode of ventilation (Table 12-2). It differs from pressure control in that it is always patient triggered and the inspiratory time is determined by the patient and not set by the ventilator. As in pressure control ventilation, the ventilator adjusts the flow to maintain a constant pressure during inspiration. The inspiratory time, however, is determined by the interaction of the gas flow with the patient's inspiratory effort. To do this, the ventilator measures the peak inspiratory flow rate during inspiration. The flow rate usually reaches a maximum value early in the inspiration and then tapers off as the patient's inspiratory effort decreases. When the flow rate decreases to a predetermined fraction of the maximal flow (generally 25% of maximum), gas flow is terminated, and the patient is allowed to exhale. Pressure support can also be used in conjunction with the intermittent mandatory ventilation (IMV) mode (see next section).

The level of the pressure support is set so that the patient breathes comfortably at a reasonable rate, usually less than 24 breaths/min. The goal of the support is to ensure adequate oxygenation and a pH greater than 7.30. The tidal volume generated under these circumstances is generally unimportant.

The mode has many advantages. It is usually comfortable for the patient. It overcomes resistance to inspiratory flow in the endotracheal tube and in the ventilatory apparatus and decreases the work of breathing. It makes it impossible for the ventilator to deliver excessively high pressures. The flow

is maintained for as long as the patient continues to make an inspiratory effort, so the patient can sigh at will. This minimizes the development of atelectasis. It is also ideally suited for preparing the patient for weaning and extubation.

C. Intermittent Mandatory Ventilation & Assist Control Ventilation

With IMV, all aspects of breathing are controlled including the rate, inspiratory time, and expiratory time (and as a result, I:E ratio). The limit variable can be either pressure (PC IMV) or volume (VC IMV). The breaths are generally synchronized (SIMV) if the patient has spontaneous respiratory effort. In this mode, any attempt to breathe at a greater frequency than the set rate is unsupported unless additional pressure support is added. In this case, the patient receives two different modes during mechanical ventilation. The first is the mandatory, machine-triggered breath at the set rate and inspiratory time. The second is a spontaneous, patient-triggered breath at a rate equal to the total minus the set rate with an inspiratory time determined by the patient (see previous discussion of pressure support ventilation). These two breaths will have different waveform characteristics on the ventilator display.

Assist control mode was originally set up to "assist" the patient's spontaneous effort with a completely supported mechanical breath. It can be used with a volume or pressure limit (VC or PC) and set up with a backup rate when spontaneous effort is minimal or absent. The main distinction from SIMV is that all of the patient's inspiratory efforts are completely supported (not just those at the set rate). This has the small disadvantage of air trapping when the patient's respiratory rate is excessively high (> 30-35 breaths per minute) and should be used with caution in patients at risk for hyperinflation (severe emphysema). There is no role for pressure support ventilation in this mode as all breaths are completely assisted.

D. Hybrid Modes

Over the past 15 years, it has become possible to ventilate patients with even more sophisticated hybrid modes. Some ventilators can be set up to deliver constant pressure during the inspiration in such a way that the tidal volume delivered falls in a preset range (pressure-limited volume control, PRVC). Some ventilators can be set up to deliver a preset tidal volume but without exceeding a preset pressure. Some ventilators can be set up with gradually decreasing ventilatory support with algorithms built into the system to minimize the need for physician adjustment of the ventilator during weaning.

▶ Setting Up the Ventilator

After choosing the mode (AC, SIMV, or PS; PC or VC), five parameters remain to be determined: the backup ventilatory

rate, the goal tidal volume of the machine-delivered breaths, the inspiratory time, the inspired oxygen concentration ($F_{I_{O_2}}$), and the PEEP level. The first two of these parameters determine ventilation; the latter three are important in determining oxygenation.

Ventilation has three components: minute ventilation (V_E), alveolar ventilation (V_A), and dead space ventilation (V_D). Although V_A is most closely related to P_{aCO_2} , at steady state, the relationship with V_E and V_D is roughly constant, and therefore, V_E , which is easily quantified, can be used as a surrogate. In patients with uncomplicated pulmonary failure, the respiratory rate can be set at 12-15 breaths/min and the tidal volume set to 7 mL/kg IBW. This produces a V_E of 6-7.5 L/min and a V_A of 4-5 L/min (assuming V_D of 33% in a 70 kg patient). In the absence of significant pulmonary dysfunction, this will result in a P_{aCO_2} of approximately 40 mm Hg and is a good starting point from which adjustments can be made.

If the P_{aCO_2} is elevated, increases in the respiratory rate will often correct the problem. Although this is less efficient than increasing the tidal volume (due to the increased dead space ventilation that occurs with higher respiratory rates), it is a reasonable first step when the respiratory rate is less than 25 breaths/min. Excessively high respiratory rates (> 30 breaths/min) can result in air trapping, especially in patients with expiratory air flow obstruction (chronic obstructive pulmonary disease or severe asthma). On the other hand, excessively high volumes may be associated with elevated airway pressures and can result in barotrauma (pneumothorax), volutrauma (alveolar overdistention), or both. Except in certain circumstances (intracranial hypertension), it is better to accept a mild respiratory acidosis than to ventilate the patient using excessively large tidal volumes (> 10 mL/kg IBW) or excessively high airway pressures (plateau pressure > 30 cm H_2O). When the pH is less than 7.20, very high rates or volumes may be necessary until the pH can be brought into the normal range either through renal compensatory mechanisms or administered bicarbonate. Very high rates or volumes may also be necessary when a bronchopleural fistula is present, to compensate for the volume lost through the fistula.

The inspired oxygen concentration should be kept high enough so that, in most cases, the oxygen saturation of arterial blood exceeds 92%. Patients with chronic obstructive pulmonary disease and long-standing CO_2 retention are an exception. Such patients have lost the ability to increase their respiratory drive in response to increases in P_{aCO_2} and rely instead on their response to hypoxemia. Increasing the arterial oxygen saturation by adding exogenous oxygen takes away this hypoxic ventilatory stimulus and makes weaning from ventilatory support more difficult.

All of the nonoxygen volume of ventilator gas is made up of nitrogen, which, unlike oxygen, is not absorbed from alveoli. Nitrogen can be of great value in stenting open the

alveoli. When it is replaced by increasing concentrations of oxygen, increased atelectasis caused by oxygen absorption can occur. In addition, high concentrations of oxygen can cause chronic pulmonary fibrosis. Ideally, the inspired oxygen concentration should be kept at 0.50 or less.

Keeping the inspired oxygen levels at acceptably low levels is frequently facilitated by the use of PEEP. The pressure is generated by closure of a valve in the expiratory circuit of the ventilator to keep the airway pressure above a preset level during expiration and to minimize alveolar collapse. Placement of an endotracheal tube bypasses the normal physiologic PEEP present during spontaneous ventilation from closure of the glottis at the end of expiration. In addition, supine patients may have a lower FRC due to increased intra-abdominal pressure and cephalad displacement of the diaphragm into the chest. This can be overcome through the use of low levels of "physiologic" PEEP (5 cm H_2O). Increasing the PEEP should be considered when the respiratory system compliance is low or when adequate oxygenation requires an $F_{I_{O_2}}$ that exceeds 0.50.

Low levels of PEEP (< 10 cm H_2O) are well tolerated by most patients. The consequences of excessive PEEP are barotrauma and decreased cardiac output. First, the high pressure can compress the superior and inferior vena cava and the pulmonary veins, compromising diastolic filling of the ventricles (in contrast with a spontaneous inspiration, which augments filling). Second, the high pressures can compress the thin-walled atria and right ventricle, further compromising end-diastolic volumes (also in contrast with a spontaneous inspiration). Finally, the high pressures can compress the pulmonary microvasculature, making it difficult for the right ventricle to push blood through the pulmonary vasculature. The remedy for the decreased cardiac output is usually fluid infusion. The potential problem with this remedy is worsening of the pulmonary failure that prompted the use of the PEEP in the first place. Accounting for all of these factors, PEEP levels greater than 10-12 cm H_2O should generally be used with a pulmonary arterial catheter in place. Titrating to the optimal oxygen delivery, and not arterial PaO_2 , will ensure a balance between the risks and benefits of high PEEP levels. Monitoring the mixed venous oxygen saturation serves as a reasonable method to achieve this goal. Even with invasive monitoring, PEEP levels greater than 15-20 cm H_2O are rarely of benefit.

► Ventilator Safety & Alarms

As can be inferred, modern ventilators are complex, and they should, in general, be used only in the setting of continuous cardiopulmonary monitoring to include electrocardiography and pulse oximetry. In addition, the ventilators themselves have alarms for early warning of apnea, changes in tidal volume or minute ventilation, and excessive inspiratory pressures. These should be individualized to each patient so

that nurses, respiratory therapists, and physicians are notified early in the course of the physiologic derangement. In many cases, the ventilator alarm will precede changes in the pulse oximeter or electrocardiogram. All personnel taking care of the patient should be knowledgeable with both the equipment and the mode of ventilation.

► Discontinuing Mechanical Ventilation

Patients who seem to be doing well and who have required mechanical ventilation for less than 24 hours can frequently be extubated quickly after undergoing a trial of spontaneous ventilation. Patients must be able to maintain their own airway, and their acute illness should be resolving. They should be able to maintain adequate oxygenation with an inspired oxygen concentration of 0.40 or less and with a PEEP of 8 cm water or less.

The majority of ventilated patients are most effectively weaned with daily spontaneous breathing trials. The breathing trial can be given with T-piece ventilation in which the endotracheal tube is attached to a length of tubing connected to a blow-by oxygen source. Alternatively, the trial can be accomplished with a low level (typically 5 cm of water) of pressure support with PEEP or with PEEP alone. In either case, the patient is asked to support his or her own breathing for 30 minutes. If the patient is breathing comfortably at the end of the trial, the patient can be extubated. If a question arises as to the degree of comfort, arterial blood should be drawn for gases, and the patient should be put back on the ventilator while waiting for the results of the blood gas analysis. If the patient was reasonably comfortable at the end of the 30-minute trial and if the pH comes back at a normal value, the patient can be extubated. Note that at the conclusion of the 30-minute trial, full ventilator support should be resumed pending the laboratory results. The patient needs to be well rested when the endotracheal tube is removed. If the patient fails the 30 minute trial, full support is resumed for the remainder of the day, and the trial is repeated the following day. In some cases, the duration of the breathing trial can be extended to up to 2 hours. Although the ability to predict successful extubation is not significantly different, the increased duration may be appropriate for patients who have already required reintubation following completion of a 30 minute SBT. There is generally no role for breathing trials of longer duration when the patient is endotracheally intubated. In fact, this may serve to unnecessarily fatigue the patient making successful extubation, less likely.

Weaning from mechanical ventilation can also be achieved with IMV. Although generally inferior to the once-daily spontaneous breathing trial, patients who are severely debilitated and have required mechanical ventilation for prolonged periods (> 2-3 weeks) can be successfully weaned using this technique when combined with a gradual

reduction in pressure support. The IMV rate is gradually decreased, requiring the patient to contribute increasingly to the maintenance of adequate minute ventilation. The patient's overall clinical status, respiratory rate, and arterial PCO_2 are used as guidelines to determine the rate of weaning. When an IMV of 4/min or less is well tolerated for long periods, the patient is placed on pressure support, which is weaned daily until mechanical support is no longer needed. As noted above, patients with an endotracheal tube in place (vs tracheostomy) should only undergo brief periods where the pressure support is less than 5-8 cm H_2O (30-120 minutes). This amount of PS is required to mitigate the increased resistance of the endotracheal tube. Patients who repeatedly fail extubation or are severely deconditioned benefit from a more deliberate and gradual weaning of the ventilator. Frequently, these patients benefit from tracheostomy and optimization of nutritional status as adjuncts to weaning. Factors that increase the work of breathing such as reactive airway disease, large pleural effusions, and chest wall or visceral edema should be treated and minimized.

► Extubation

The decision to extubate the patient depends both on the assessment for the need for airway protection as well as the need for mechanical ventilation. As mentioned previously, the latter can be determined based on the result of a 30-minute trial of spontaneous breathing. The former should be based on several factors, including the patient's level of consciousness, the presence of airway injury or edema, the need for ongoing endotracheal suctioning, and the possible need for further operative procedures within the next 24 hours. Finally, a subjective determination of a patient's ability to tolerate extubation and spontaneous ventilation should be made. An alert and communicative patient who can lift her head off the pillow is a good candidate for extubation; a lethargic, diaphoretic patient is not. For patients who require continued airway protection but no longer require mechanical ventilatory support, a tracheostomy should be considered.

ADJUVANT DIAGNOSTIC & THERAPEUTIC MEASURES

► Chest Radiographs

Chest x-rays should be obtained daily in patients being treated with mechanical ventilation. A review of the film should confirm the placement of all lines and tubes, including the endotracheal tube, central venous catheters, pleural tubes (thoracostomies), and nas/orogastric or nas/oroenteric tubes. A search for specific pulmonary and pleural processes should be performed. Local infiltrates such as pneumonia or patchy/diffuse processes such as the ARDS should be identified.

In addition to a daily chest radiograph, a stat chest x-ray should be obtained whenever a patient's cardiopulmonary status rapidly deteriorates. Tubes or lines might be displaced; new problems with a reversible etiology such as pneumothorax, a lobar collapse, or a new infiltrate suggesting aspiration might be identified.

► Sedation & Muscle Relaxants

Mechanically ventilated patients frequently require sedatives and/or analgesia to ameliorate the agitation and pain associated with their disease and treatment. Narcotic analgesia in the form of intermittent or continuous opiate infusion may be sufficient. Narcotics, however, should not be used to treat agitation and anxiety that is thought to be caused by the ventilator. Sedating agents, including propofol and benzodiazepines, should be used instead. In addition, haloperidol and risperidone may be useful adjuncts, either alone or in combination with benzodiazepines. As a general rule, intermittent dosing is preferred to continuous infusions. When the latter is used, the agent should be stopped at least once daily—giving the patient a so-called sedation holiday—to assess neurologic status and determine the need for continuing sedation.

Neuromuscular blocking agents add an additional level of patient control and can greatly simplify ventilatory management in patients with severe pulmonary insufficiency. These agents should be reserved for severe patient-ventilator dyssynchrony, a situation in which the patient's spontaneous respiratory efforts result in disorganized and inadequate ventilation by the mechanical ventilator. This may have the untoward effect of life-threatening hypoxemia in a patient with little physiologic reserve.

Nonphysiologic ventilatory methods, such as inverse ratio or high-frequency oscillatory ventilation, may also require the use of neuromuscular blocking agents. Major side effects include a potential increased risk of ventilator-associated pneumonia (VAP), through loss of cough mechanism, and an association with late polyneuropathy of critical illness. As a result, they should be used only when absolutely necessary and for the shortest possible time.

► Antibiotics

Ventilator-associated pneumonia is the most common nosocomial infection in the ICU. The risk of acquiring VAP is directly related to the duration of mechanical ventilation. There is no gold standard for VAP diagnosis. Possible criteria include a new or progressive infiltrate on chest radiograph, worsening hypoxemia, increased sputum quantity, new onset of purulent sputum associated with abundant white cells and organisms on Gram-stained smears, or positive sputum cultures with known pathogenic organisms. Signs of systemic sepsis with increased temperature, leukocytosis, increasing fluid requirements, and glucose intolerance are also common findings in VAP.

If all of these are present, antibiotics should be started. If only one or two are present, antibiotics are probably best withheld to avoid overgrowth of resistant organisms that could later cause fatal pneumonia. Exceptions to this approach include older, severely debilitated patients, immunocompromised patients, and those who are critically ill in whom delayed antibiotic therapy might result in irretrievable deterioration. Thus, an 80-year-old patient with flail chest and a new infiltrate should probably be given antibiotics early; a 20-year-old patient who was hospitalized for a gunshot wound involving the colon and who develops questionable pneumonia 2 weeks later is more likely to tolerate a delay in the initiation of antibiotics until the diagnosis is more definite. In addition, the latter patient may have an alternative explanation for his fever and leukocytosis, such as an intra-abdominal abscess. In this case, the wrong diagnosis might delay appropriate source control (abscess drainage). The CPIS can be useful to guide the diagnosis. The goal is to avoid overtreatment with the risk of antimicrobial resistance and superinfection. Antibiotics can safely be discontinued in patients empirically started on antibiotics for suspected pneumonia who have a CPIS value of 6 or less at 72 hours.

TREATMENT OF THE MORE CHALLENGING PATIENT

This discussion of shock and pulmonary failure in the surgical patient has concentrated on making a clinical diagnosis and directing treatment on the basis of that diagnosis. This approach works well in many patients, but in some it is not sufficient. Effective treatment in the more seriously ill patient frequently has to take into account the underlying physiological abnormalities if the treatment is to work. With this approach, the clinical diagnosis becomes less important. Dealing with the underlying physiological problem becomes paramount.

COMMON PHYSIOLOGICAL RESPONSES TO SEVERE SHOCK

The body responds to the shock state with compensatory responses. These responses help the patient deal with the initial abnormalities of the shock but can contribute to

the later consequences of cardiac and pulmonary failure. Understanding these responses can help the physician in managing the consequences.

► Neurohumoral Responses

The neurohumoral responses to shock include discharge of the cardiovascular nerves and release of vasoactive, metabolically active, and volume-conserving hormones. The responses can be lifesaving before therapy begins and serve to maintain homeostasis once therapy has started.

Adrenergic discharge constricts the arterioles, venules, and small veins in all parts of the body except the brain and heart and augments myocardial systolic function. The result is increased cardiac output and blood pressure and diversion of flow to the brain and heart.

The vasoactive hormones angiotensin II and vasopressin act in concert with discharge of the cardiovascular adrenergic nerves. Angiotensin II constricts the vasculature in the skin, kidneys, and splanchnic organs and diverts blood flow to the heart and brain. It also stimulates the adrenal medulla to release aldosterone, resulting in reabsorption of sodium ions from the glomerular filtrate. Vasopressin, like adrenergic discharge and angiotensin II, constricts the vascular sphincters in the skin and splanchnic organs (it does not constrict the renal vasculature) and diverts blood flow to the heart and brain. It also stimulates reabsorption of water from the distal tubules.

► Metabolic Responses

In all severe shock states, intracellular hydrogen ion concentrations increase. To compensate, extracellular sodium flows down its electrochemical gradient into the cells, along with chloride and water, in exchange for intracellular hydrogen ion. Intracellular pH increases back toward normal, but the cells swell, with perhaps an increase of 3 L in the intracellular volume.

Hypovolemia, hypotension, pain, and other stresses of critical illness stimulate the release of cortisol, glucagon, and epinephrine—all of which increase extracellular glucose concentrations. Thus, glucose should not be used in the initial fluid resuscitation of the patient in shock—it is not necessary and can even induce an osmotic diuresis, worsening hypovolemia and confusing the clinical picture. Glucose-containing solutions should be reserved for those patients who might be in insulin shock.

On the other hand, the endogenously produced glucose generated by the physiological release of the counter-regulatory hormones provides fuel for nervous system function, metabolism of blood cells, and wound healing. The modest increase in extracellular osmolality also helps replenish vascular volume by drawing water out of the cells and by increasing the interstitial hydrostatic pressure. The increased pressure drives interstitial protein into the lymphatics and

from there into the vascular space. Interstitial oncotic pressure falls, and plasma oncotic pressure rises. The augmented oncotic gradient between the vascular and interstitial spaces draws water, sodium, and chloride into the vascular space from the interstitial space. This replenishment of vascular volume will continue as long as interstitial hydrostatic pressures are maintained and as long as interstitial protein stores, which constitute more than half of the total extracellular protein content, can be recruited. A certain degree of hyperglycemia might be beneficial in the postresuscitative phase. Once the patient has recovered, however, it appears that it is best to aggressively keep the blood glucose levels low, at 120 mg/dL or less.

Other hormones with potential metabolic actions, including insulin and growth hormone, are also released during critical illnesses. They have little effect, however, compared with cortisol, glucagon, and epinephrine. Indeed, infusion of cortisol, glucagon, and epinephrine in normal subjects can produce most of the metabolic changes of critical illness.

► Microvascular Responses

In severely ill patients, three responses—dilation of systemic arterioles, failure of cell membrane function, and disruption of the vascular endothelium—serve to worsen the patient's condition. In decompensated shock, the systemic arterioles lose their ability to constrict, while the postcapillary sphincters remain constricted. Microvascular hydrostatic pressure rises. Water, sodium, and chloride are driven out of the vascular space and into the interstitium. The process is limited, however, because the oncotic gradient, which increases as fluid is lost from plasma, prevents further fluid losses.

Trauma and sepsis activate coagulation and inflammation, which can disrupt microvascular endothelial integrity in severely ill patients. Platelet and white cell microaggregates that form in injured or infected tissues embolize to the lungs or liver, where they lodge in the microvasculature. The microaggregates, endothelium, and plasma in the regions of embolization release kinins, platelet-activating factors, fibrin degradation products, thromboxanes, prostacyclin, prostaglandins, complement, leukotrienes, lysosomal enzymes, oxygen radicals, and other toxic factors, which damage the endothelium and dilate the vasculature in the region of the emboli and distally. Protein, water, sodium, and chloride extravasate into the interstitium. The amount of extravasation is limited by the increases in interstitial hydrostatic pressure that arise from interstitial flooding and by dilution of interstitial protein concentrations. The edema that results can be massive and can involve any tissue in the body.

PULMONARY ARTERY CATHETER (SWAN-GANZ CATHETER)

The pulmonary arterial catheter can be useful in evaluating the cardiovascular consequences associated with the physiological responses described above, and it can be invaluable

in directing treatment in selected, seriously ill patients. The modern pulmonary arterial catheter is equipped with a thermistor and an oximeter on its tip. It permits measurement of the cardiac output; right atrial, pulmonary arterial, and pulmonary arterial wedge pressures; and mixed venous oxygen contents. Knowledge of the cardiac output and filling pressures can be used to assess ventricular function as fluid is administered or withheld. The mixed venous oxygen saturation reflects the adequacy of oxygen delivery to the periphery; a value less than 60% indicates inadequate peripheral oxygenation and can be used to evaluate adequacy of the cardiac output and of systemic arterial oxygen content. It can also be used to determine oxygen consumption, which is calculated as the cardiac output multiplied by the difference of the oxygen contents of blood in the systemic and pulmonary arteries. Oxygen consumption can fall in severely ill patients, and measurements of consumption can help assess the patient's response to resuscitation. All of this information can help in dealing with the physiological abnormalities of the shock state and the pulmonary failure that can arise from the shock.

The catheter is particularly useful when treatment of one organ system might harm another. For example, fluid administration might be needed to treat septic shock, but excess fluid might contribute to pulmonary failure; a diuretic might be indicated in an oliguric patient in congestive heart failure, but excessive diuresis might decrease the cardiac output to the point that the kidneys fail; and fluid might be needed for cardiovascular resuscitation in a patient with multiple injuries, but too much fluid might exacerbate cerebral edema. The pulmonary arterial catheter can be extremely helpful in these situations.

Data obtained from the Swan-Ganz catheter can be misleading, however, if mistakes are made in performing the measurements. The cardiac output, as measured by thermodilution, is obtained by creating a temperature differential in the blood in the right atrium and analyzing the change in temperature in the blood over time as it flows past a thermistor on the end of the pulmonary arterial catheter. The greater the area under the temperature curve, the smaller the flow through the right heart. If injections of cold saline are used to create the temperature differential, they should be made at random times during the respiratory cycle to give the best indication of the output available to the patient, but some prefer to make the injections at a consistent time in the cycle to minimize variability in the cardiac output—associated heart-lung interactions. If a heater coil in the catheter is used to create the temperature differential, the changes are made randomly by a program in the equipment used with the catheter. All calculations are made by a computer in the equipment.

When one is obtaining pulmonary arterial or mixed venous blood, the balloon on the end of the catheter should be deflated, and the blood should be withdrawn slowly. If the

blood is withdrawn too quickly, the walls of the pulmonary artery will collapse around the end of the catheter, and the specimen will be contaminated by blood that is pulled back, in a retrograde manner, past ventilated and nonperfused alveoli. The oximeter on the tip of the catheter has to be calibrated frequently by comparing the oxygen saturations of blood obtained from the pulmonary artery with the saturations readout by the oximeter. One must be certain that the blood that is to be used for calibration is truly representative.

The pressures measured with the pulmonary arterial catheter are displayed on an oscilloscope and include a mean pressure that is calculated by computer circuitry in the monitoring equipment. These mean pressures can be used in patient management. They have the advantage that they represent the pressures throughout the respiratory cycle and thus average in the variability associated with heart-lung interactions. Some clinicians prefer to read the end-expiratory pressures from the oscilloscope screen and use those values in patient management. Those pressures are relatively independent of heart-lung interactions, but they can be difficult to interpret, even by the most experienced ICU nurse or physician.

Of the five pressures obtained from the catheter, only two—the right atrial and the mean pulmonary arterial pressures—can be taken at face value; the other three—the pulmonary arterial systolic, diastolic, and wedge pressures—are subject to errors of measurement and interpretation. The pulmonary arterial wedge pressure usually is the same as the left atrial pressure. The wedge pressure will not reflect left atrial pressure; however, if the catheter is in a portion of the vasculature occluded by inflated alveoli. If the wedge pressure varies by more than 10 mm Hg with cycles of mechanical ventilation, one should assume that the tip of the catheter is facing the pressure in the alveoli rather than the pressure in the left atrium.

To account for variations in size of the patient, the cardiac output can be indexed to the calculated body surface area. Alternatively, however, one can use the patient's desirable body weight, calculated on the assumption that a desirable weight is one that is associated with longevity and freedom from diabetes. A body mass index (BMI) of 21 is convenient to use for both men and women. Making a rough approximation of the patient's height, to the nearest half-foot, the desirable weights associated with that height, assuming a BMI of 21, are indicated in Table 12-3. The cardiac outputs associated with that weight are also indicated, assuming that the subjects are supine, nonstressed, resting, fasting, and in a thermoneutral environment. The resting oxygen consumptions under these conditions are

$$3.5 \text{ mL} \times \text{weight} (-1) \times \text{min} (-1)$$

The outputs and the consumptions for patients older than 50 years are adjusted with the assumption that metabolic activity decreases by 10% per decade after age 50.

Table 12–3. Approximate desirable weight, cardiac output, and oxygen consumption in young resting, supine, fasting individuals of varying heights, in a thermoneutral environment.

Height (ft, in)	Desirable Weight ¹ (kg)	Cardiac Output ² (L/min)	Oxygen Consumption ³ (mL/min)
5'0"	49	5	170
5'6"	59	6	205
6'0"	70	7	245
6'6"	83	8	290

¹Calculated with assumption that the desirable weight is that which gives a BMI of 21.

²Calculated as $100 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$.

³Calculated as $3.5 \text{ mL} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$.

Thus, for a 70-year-old person who is 6 feet tall, a normal cardiac output is 7 L/min multiplied by 0.8, or 5.6 L/min. The oxygen consumption is 245 mL/min multiplied by 0.8 or 195 mL/min.

OXYHEMOGLOBIN DISSOCIATION

The amount of oxygen contained in the blood and the amount of oxygen available to be delivered to the tissues can be expressed as a concentration, a saturation, or a partial pressure. All three have their value. Understanding their relationships can help in understanding the cardiac and pulmonary pathophysiology of the critically ill surgical patient.

The concentration of oxygen in the blood, or oxygen content, is expressed as milliliters of O_2 /dL of blood, or vol%. The oxygen content can be measured directly, but the measurement is time consuming, and the content is usually calculated on the basis of the other two measures of blood oxygenation, the oxygen saturation (So_2) and the Po_2 . The oxygen content is related to these other quantities by the following formula:

$$\text{Co}_2 = 1.34 \times [\text{Hb}] \times \text{So}_2 + 0.0031 \times \text{Po}_2 \quad (1)$$

where [Hb] is expressed as g/dL and the Po_2 as mm Hg.

Thus, for example, the oxygen content of a blood specimen with a [Hb] of 12 g/dL, an So_2 of 90%, and a Po_2 of 60 mm Hg is 14.7 vol%.

The first term in the equation represents the O_2 carried by the hemoglobin molecule; the second, the O_2 dissolved in the blood water. This second term is small compared with the first as long as the [Hb] is greater than, say, 7 g/dL and the Po_2 is less than, say, 100 mm Hg. Omitting the second term then simplifies the formula to read as follows:

$$\text{Co}_2 = 1.34 \times [\text{Hb}] \times \text{So}_2 \quad (2)$$

For the previous set of blood gases, this would give a Co_2 of 14.5 vol%.

The formula can be made even simpler by substituting the fraction $4/3$ for the decimal 1.34:

$$\text{Co}_2 = 4/3 \times [\text{Hb}] \times \text{So}_2 \quad (3)$$

Because [Hb] and the So_2 can usually be approximated by integers with little loss of accuracy, the calculation frequently allows cancellation of the three and can be done mentally. For the previous example, the oxygen content would be 14.4 vol%.

Calculation of the oxygen content requires knowledge of the So_2 . Many pulmonary arterial catheters are now equipped with sensors mounted on their tips that directly measure the saturation of the blood in the pulmonary artery. Alternatively, blood can be withdrawn from the tip of the catheter and sent to the laboratory, where the So_2 can be easily measured by an instrument known as a co-oximeter. Most laboratories will make this measurement by specific request, but some will calculate the So_2 from the Po_2 . This calculation is frequently inaccurate for mixed venous specimens but is usually accurate for arterial blood. The calculation is made from equations that are based on the oxyhemoglobin dissociation curve (Figure 12–1), an empirically derived relationship between the So_2 of nonfetal human blood and its Po_2 . The saturation for a given Po_2 depends on blood temperature, $[\text{H}^+]$, and Pco_2 and on the red cell concentration of 2,3-diphosphoglycerate (2,3-DPG). The laboratory should be told the temperature, and it will measure the $[\text{H}^+]$ and Pco_2 . It will then calculate the So_2 .

▲ Figure 12–1. Oxyhemoglobin dissociation curve for human blood at 37°C with a Pco_2 of 40 mm Hg, a pH of 7.40, and a normal 2,3-DPG red cell concentration. Approximate values from Table 12–4 fall close to the idealized curve.

Table 12–4. Approximate correlations for partial pressures of oxygen and oxygen saturation in blood at 37°C with a pH of 7.4, a P_{CO_2} of 40 mm Hg, and a normal 2,3-DPG red cell concentration.

P_{O_2} (mm Hg)	SO_2 (%)
0	0
25	50
40	75
60	90
80	95

from the P_{O_2} with the assumption that the 2,3-DPG concentration is normal.

It is helpful, however, to have some guidelines for converting back and forth between SO_2 and PO_2 . Five approximations for points on the dissociation curve for a patient with normal temperature, $[H^+]$, P_{CO_2} , and 2,3-DPG levels are given in Table 12–4. The P_{50} of human hemoglobin—the PO_2 at which the molecule is half-saturated—is 27 mm Hg (approximated as 25 mm Hg in the table). The PO_2 and SO_2 for mixed venous blood in a person with a $[Hb]$ of 15 g/dL and a normal O_2 consumption and cardiac output are 40 mm Hg and 75%, respectively. A PO_2 of 60 mm Hg—a value that should be exceeded by most patients in an ICU—corresponds to a SO_2 of 90%. A PO_2 of 80 mm Hg corresponds to a SO_2 of 95%. Remembering the values in the table allows construction of a dissociation curve and facilitates conversion from one measure of oxygenation to the other. For example, in a patient with a normal temperature, $[H^+]$, P_{CO_2} , and 2,3-DPG, and a $[Hb]$ of 10 g/dL, a PO_2 of 60 mm Hg in the systemic arterial blood would create an oxygen content of 12 vol% (from Equation 1), a value that would be adequate if the patient had normal coronary arteries and a good heart. Such a value would be inadequate, however, in the face of underlying heart disease.

CAUSES OF ELEVATED P_{aco_2}

The patient in pulmonary failure will frequently have an elevated arterial carbon dioxide tension. The arterial P_{CO_2} is proportionate to CO_2 production divided by alveolar ventilation—defined as the volume of air exchanged per unit time in functioning alveoli. Since CO_2 production is usually fairly constant in adequately perfused patients, the P_{aco_2} comes to be inversely proportionate to alveolar ventilation. An elevated P_{aco_2} in the presence of normal CO_2 production means inadequate alveolar ventilation. Ventilation should be assessed with respect to how much work is required to generate the P_{aco_2} . In the case of spontaneous ventilation,

this assessment involves the frequency and depth of breathing; in the case of mechanical ventilation, the frequency of the machine-generated breaths and the tidal volume of those breaths.

The P_{aco_2} also gives an indication of dead space ventilation—the ventilation of nonperfused airways. Since minute or total ventilation is dead space ventilation plus alveolar ventilation, a normal P_{aco_2} combined with a normal minute ventilation implies a normal dead space ventilation. A normal P_{aco_2} that must be generated by a supranormal minute ventilation implies increased dead space ventilation. Normal dead space ventilation is one-third of total ventilation, but many critically ill surgical patients will have dead space ventilation that is up to two-thirds of total ventilation. Increased dead space ventilation can be caused by hypovolemia with poor perfusion of nondependent alveoli, ARDS, pulmonary emboli, pulmonary vasoconstriction, and mechanical ventilation-induced compression of the pulmonary vasculature. Hypovolemia should be treated by expansion of the vascular volume. Emboli should be treated by anticoagulation or by elimination of their source. Dead space generated by mechanical ventilation should be minimized by adjustment of the ventilator, usually by decreasing tidal volumes or end-expiratory pressures, while at the same time maintaining enough mechanical support to generate a normal P_{CO_2} and alveolar ventilation.

CAUSES OF LOW P_{aO_2}

Almost all surgical patients with pulmonary failure will have systemic arterial hypoxemia. There are five physiological causes: low inspired O_2 concentration, diffusion block between alveolar gas and capillary blood, subnormal alveolar ventilation, shunting of blood through completely nonventilated portions of the lung or bypassing of blood past the lung, and perfusion of parts of the lung that have low ventilation/perfusion ratios. In addition, any process that decreases the mixed venous oxygen content in the presence of any of the above can lower the arterial PO_2 even further. Low mixed venous oxygen content can be caused by a low arterial oxygen content, low cardiac output, or high O_2 consumption.

Arterial hypoxemia in the surgical patient is usually caused by shunting, low ventilation/perfusion ratios, low mixed venous oxygen content, or a combination of these factors. Low inspired O_2 concentrations at sea level are impossible so long as the ventilator is functioning properly. (This must be checked, however, as the first step in diagnosing and correcting the cause of a low P_{aO_2} .) Diffusion block is exceedingly rare in surgical patients. Subnormal alveolar ventilation can be ruled out with a normal arterial P_{CO_2} assuming CO_2 production is not depressed. Thus, shunting and areas of low ventilation/perfusion ratios, along with low mixed venous oxygen content, remain as causes for almost all cases of hypoxemia in the surgical patient. Shunting and

low ventilation/perfusion ratios do not need to be distinguished from each other very often, but the distinction can be made by increasing the inspired O_2 concentration to 100%: Hypoxemia caused by areas of low ventilation/perfusion ratios will be at least partially corrected by 100% O_2 ; hypoxemia caused by shunting will not. The mixed venous oxygen content can be measured with the pulmonary arterial catheter.

ACID-BASE BALANCE

Acid-base abnormalities can arise from the hypoventilation of pulmonary insufficiency or from the metabolic abnormalities of shock. The former has already been discussed. The latter can become more involved.

The hydrogen ion, carbon dioxide gas, and bicarbonate equilibrate with one another in the plasma water, and if two of the quantities are known, the third can be calculated. In practice, the PCO_2 and $[H^+]$, which are measured directly with the blood gas apparatus, will be known. The $[HCO_3^-]$ can then be calculated by the Henderson-Hasselbalch equation, which can be written in the following form:

$$[HCO_3^-] = \frac{24 \times P_{CO_2}}{[H^+]} \quad (4)$$

where $[HCO_3^-]$ is expressed as mmol/L, P_{CO_2} as mm Hg, and $[H^+]$ as nmol/L. This form of the equation requires conversion of pH, the more common expression of $[H^+]$, into nmol/L, the more logical expression, but the conversion is not difficult (Table 12-5). The values in the table are easy to remember if one notes that each value in the column under $[H^+]$ is 80% of the value immediately above, with the exception of 80 and 63, which are off by 1. Thus, by Equation 4, if the P_{CO_2} is 60 mm Hg and the pH is 7.30, the $[HCO_3^-]$ is 29 mmol/L.

The $[HCO_3^-]$ calculated by this equation is the amount of bicarbonate ion dissolved in the plasma water and can be obtained only from a specimen of blood that is obtained and processed without exposure to the atmosphere. The “ CO_2 combining power” that is typically measured along with electrolyte concentrations in blood that is not processed anaerobically includes not only the $[HCO_3^-]$ but any CO_2 gas and carbonic acid that is dissolved in the plasma as well. The CO_2 combining power is usually about 2 mmol/L greater than the calculated (and actual) $[HCO_3^-]$.

The base deficit or excess is determined by comparing the calculated $[HCO_3^-]$ with the $[HCO_3^-]$ that might be expected in a patient with a given P_{CO_2} and $[H^+]$. These expected values have been determined by analyzing blood obtained from patients with a wide variety of pulmonary disorders. For example, the kidneys in a patient with chronic respiratory acidemia can usually compensate to the extent that a chronic elevation in P_{CO_2} of 10 mm Hg will generate an increase in $[HCO_3^-]$ of 3 mmol/L. A patient with

Table 12-5. Conversion of pH to hydrogen ion concentration.

pH	Hydrogen Ion Concentration (mol/L)
7.0	100
7.1	$100 \times 0.8 = 80$
7.2	$80 \times 0.8 = 63$
7.3	$63 \times 0.8 = 50$
7.4	$50 \times 0.8 = 40$
7.5	$40 \times 0.8 = 32$
7.6	$32 \times 0.8 = 25$

Values not indicated in the table can be derived by interpolation. For example, a pH of 7.35 corresponds to a hydrogen ion concentration of approximately 45.

chronic obstructive lung disease and a chronically elevated P_{CO_2} of 60 mm Hg would be expected to have a $[HCO_3^-]$ of 30 mmol/L—6 mmol/L more than a normal value of 24. If such a patient had a pH of 7.30, the actual $[HCO_3^-]$ would be 29 mmol/L (from Equation 4; see the example in the preceding paragraph). That is, the observed value would be 1 mmol/L less than predicted, and the patient would be said to have a base deficit of 1 mmol/L.

The difficulty with the concept of base deficit and excess is that it rests on historically determined values, which may not be applicable to the patient at hand. For example, if a surgical patient with previously normal lungs lost his or her airway after an operation and began to hypoventilate, one would expect the $[HCO_3^-]$ to be normal—24 mmol/L—because the kidneys would not have had time to compensate for the hypercapnia. If the P_{CO_2} was 60 mm Hg and the pH 7.30, the physician should be concerned because the $[HCO_3^-]$ is 29 mmol/L (these values are the same as in the preceding paragraphs). A value of 29 mmol/L should alert the physician to the fact that the $[HCO_3^-]$ is too high, perhaps because $NaHCO_3$ had been given unnecessarily. The base deficit, however, would be 1 mmol/L, suggesting that the patient's $[HCO_3^-]$ was appropriate. The base deficit would be misleading.

The use of base deficit and excess is enshrined in the literature, and the terms are used in this chapter. However, the concept of $[HCO_3^-]$ may be preferable. Errors in patient evaluation are more likely to be minimized if the physician interprets that value in the light of a particular patient's situation. If a chronically ill patient in the ICU has severe ARDS and a P_{CO_2} of 60 mm Hg with a pH of 7.30, no attempt should be made to change the accompanying $[HCO_3^-]$ of 29 mmol/L—that value represents the expected renal compensation for such a

chronic hypercapnia (though the impaired alveolar ventilation should be of concern). Alternatively, if the patient's PCO_2 is 60 mm Hg and the pH is 7.45, the patient has an inappropriately high $[HCO_3^-]$ of approximately 40 mmol/L (calculated from Equation 4), perhaps because of unreplaced losses of hydrogen ion from the stomach, chronic use of a loop diuretic, or administration of excessive amounts of acetate in the patient's parenteral nutrition. In this situation, the $[HCO_3^-]$ should be brought down into the low 30s. The excessively high $[HCO_3^-]$ and its resultant alkalemia may be blunting the patient's ventilatory drive.

Thus, in dealing with acid-base disorders, the calculation of the bicarbonate concentration in arterial plasma can be taken from the blood gas laboratory or calculated by the clinician. In the case of a metabolic acidemia, the underlying abnormality should be corrected and then, if the pH remains less than 7.20, sodium bicarbonate can be used, but only after resuscitation has been initiated and only with the intent of bringing the pH up to a modestly higher level, such as a pH of 7.30. The bicarbonate produces carbon dioxide and water locally, in the interstitial fluid at the sites where the hydrogen ions are being produced. In the absence of resuscitation, the locally generated carbon dioxide can cross back into the cell, worsening intracellular acidosis. There is no problem with bicarbonate if it is given after some local flow has been achieved. The generated carbon dioxide will be washed centrally into the pulmonary vasculature, where it will be eliminated by the lungs.

Metabolic alkalemia in the surgical patient is usually easy to recognize and treat. Contraction alkalemia is treated with fluid expansion. Hypokalemic, hypochloremic metabolic alkalemia caused by unreplaced loss of gastric fluid (continuous nasogastric suction or protracted vomiting), is treated with normal saline supplemented with potassium chloride. Hypokalemic hypochloremic alkalemia caused by use of loop diuretics is treated by withholding diuresis. In situations where continued diuresis is warranted, the addition of acetazolamide to the diuretic regimen is helpful. Although the administration of 0.1 N hydrochloric acid can reverse severe alkalemia, it is rarely necessary and should only be given as a slow central intravenous drip over a period of 48 hours. The amount of acid to be given is calculated on the basis of the presumed extracellular chloride deficit, with the assumption that the interstitial chloride concentration is the same as the plasma concentration, that is, with the assumption that the Donnan factor for chloride is 1.

RISK ASSESSMENT

Predicting the likelihood of survival in critically ill surgical patients is best accomplished by evaluating clinical and laboratory findings. Computation of a severity of illness score is usually unnecessary. Nonetheless, several scoring systems have been developed with the intention of increasing the

precision of the estimate. All such systems assign a mathematical probability for survival in groups of patients, and many are useful for research purposes because they allow comparisons of patients among different institutions. None of them, however, are accurate enough to predict survival for an individual patient, though some are still clinically useful for assessing the effects of therapy.

The APACHE II score, in which clinical data and 14 measured variables are entered into a formula to assess the probability of survival, takes about 30 minutes to calculate by hand—less by computer. The score can predict survival in critically ill medical patients; it has not been found to be of value in the usual surgical patient, and in any case, it is too cumbersome unless one has a particular interest in this kind of methodology.

Methods for predicting survival in trauma patients are well established, though most trauma systems are designed to evaluate all trauma patients and not the specific subset of critically ill trauma patients. The Injury Severity Score, the Revised Trauma Score, and the ASCOT score have proved to be most reliable. The Glasgow Coma Score is quite accurate for predicting survival in patients with head injuries. Combining the Glasgow Coma Score with a simple measurement of fluid requirement has also proved to be accurate in critically injured trauma patients.

MULTIPLE CHOICE QUESTIONS

- Shock can be caused by
 - Depletion of intravascular volume
 - Loss of autonomic control of the vasculature
 - Severe untreated systemic inflammation
 - Both A and C
 - All of A, B, and C
- Hypothermia in hemorrhagic shock
 - Is of limited risk in the initial 24 hours after injury
 - Can contribute to coagulopathy
 - Is unusual in the trauma population outside of cold-weather or water-immersion injuries
 - Is best treated by warming the ambient room temperature
 - Is a secondary concern that can be addressed after the care of injuries
- Cardiac or great vessel compressive shock
 - Can be caused by pericardial tamponade
 - May accompany tension pneumothorax
 - Is worsened by the need for positive pressure ventilation
 - Cannot be caused by intra-abdominal injury
 - All of A, B, and C

4. The pulmonary failure of shock, trauma, and sepsis
 - A. Can be related to products of coagulation and inflammation that are washed out from the damaged tissues
 - B. Can be effectively treated with a combination of antibiotics and corticosteroids
 - C. Is always related to systemic infection
 - D. Is caused by a decrease in pulmonary vascular permeability
 - E. Both A and C

5. All of the following are true about pressure support ventilation, except
 - A. PSV is a pressure-limited ventilator mode
 - B. PSV includes a set inspiratory time
 - C. PSV breaths are patient-triggered
 - D. Inspiratory flow is adjusted to maintain airway pressure
 - E. PSV can be combined with IMV

Management of the Injured Patient

EPIDEMIOLOGY OF TRAUMA

As a “disease,” trauma is a major public health problem. In the United States, it is the leading cause of death among people aged 1-45. For persons under age 30, trauma is responsible for more deaths than all other diseases combined. Because trauma adversely affects a young population, it results in the loss of more working years than all other causes of death. Presence of alcohol is a significant contributor to trauma fatalities, and one-third of all traffic deaths are alcohol related. The financial costs of injury are astounding and exceed \$400 billion annually. Regrettably, nearly 40% of all trauma deaths could be avoided by injury prevention measures (50% of passenger vehicle occupants killed were unrestrained), alcohol cessation, and by the establishment of regional trauma systems that would expedite the evaluation and treatment of seriously injured patients.

Trauma deaths have been described as having a trimodal distribution (Figure 13-1), with peaks that correspond to the types of intervention that would be most effective in reducing mortality. The first peak, the **immediate deaths**, represents patients who die of their injuries before reaching the hospital. The injuries accounting for these deaths include major brain or spinal cord trauma and those resulting in rapid exsanguination. Few of these patients would have any chance of survival even with access to immediate care because almost 60% of these deaths occur at the same time as the injury. Prevention remains the major strategy to reduce these deaths.

The second peak, the early deaths are those that occur within the first few hours after injury. Half are caused by internal hemorrhage, and the other half, by central nervous system injuries. Almost all of these injuries are potentially treatable. However, in most cases, salvage requires prompt and definitive care of the sort available at a trauma center, which is a specialized institution that can provide immediate resuscitation, identification of injuries, and access to

a ready operating room 24 hours a day. Development of well-organized trauma systems with rapid transport and protocol-driven care can reduce the mortality in this time period by 30%.

The third peak, the late deaths, consists of patients who die days or weeks after injury. Ten percent to 20% of all trauma deaths occur during this period. Mortality for this period has traditionally been attributed to infection and multiple organ failure. However, development of trauma systems has changed the epidemiology of these deaths. During the first week, refractory intracranial hypertension following severe head injury is now responsible for a significant number of these deaths. Improvements in critical care management continue to be essential in reducing deaths during this phase. It is paramount that surgeons caring for trauma patients have genuine expertise in surgical critical care.

TRAUMA SYSTEMS

The terrorist attacks of September 11, 2001, highlighted the need for national and state trauma systems that can handle both routine events and mass casualty situations. The purpose of a trauma system is to provide timely, organized care in order to minimize preventable morbidity and mortality following injury. The system includes prehospital care designed to identify, triage, treat, and transport victims with serious injuries. Criteria for staging patients with major trauma consist of standardized scoring systems based on readily discernible anatomic and physiologic variables. These criteria are designed to identify not only the more severe and complex single injuries but also combinations of injuries that require tertiary care. Trauma centers that are part of a larger trauma system are already organized to respond to unexpected multiple casualty events. Regional trauma centers have established links with emergency medical service

▲ **Figure 13-1.** Periods of peak mortality after injury. (Modified from Hoyt DB, Coimbra R: Trauma: introduction. In: Greenfield LJ, Mulholland MW, Oldham KT, et al. *Surgery, Scientific Principles and Practice*, 3rd ed. Lippincott Williams & Wilkins, 2001; p. 271.)

providers and participate in systemwide patient triage and quality improvement. Gaps remain, however, in areas of the country not served by trauma systems, and a wide range in the degree of disaster preparedness exists at all levels of trauma care.

The American College of Surgeons (ACS) defines four levels of institutional trauma care. Level I is the highest designation a trauma center can receive. It indicates that the hospital has committed itself to the care of trauma patients and offers the highest level of skill available in trauma care. A level I trauma center is directed by a board-certified surgeon specializing in trauma care and is staffed by a team of board-certified trauma care specialists available 24 hours a day—including emergency room physicians, trauma surgeons, neurosurgeons and neurologists, orthopedic surgeons, plastic surgeons, anesthesiologists, and radiologists. Level II trauma centers provide 24-hour care by in-hospital and on-call physicians. They can deliver the same quality of care as a level I center but without the same teaching and research obligations. The level III trauma center provides prompt assessment, resuscitation, and stabilization followed by surgical treatment or interhospital transfer as appropriate. Level III centers serve a valuable function in less populated areas where resuscitation and stabilization before transport may be lifesaving. Level IV centers are designed to provide advanced trauma life support (ATLS) prior to patient transfer in remote areas in which no higher level of care is available.

Determining if a victim of a vehicle crash requires care at a trauma center is a decision for emergency medical responders. The Centers for Disease Control (CDC) has sponsored

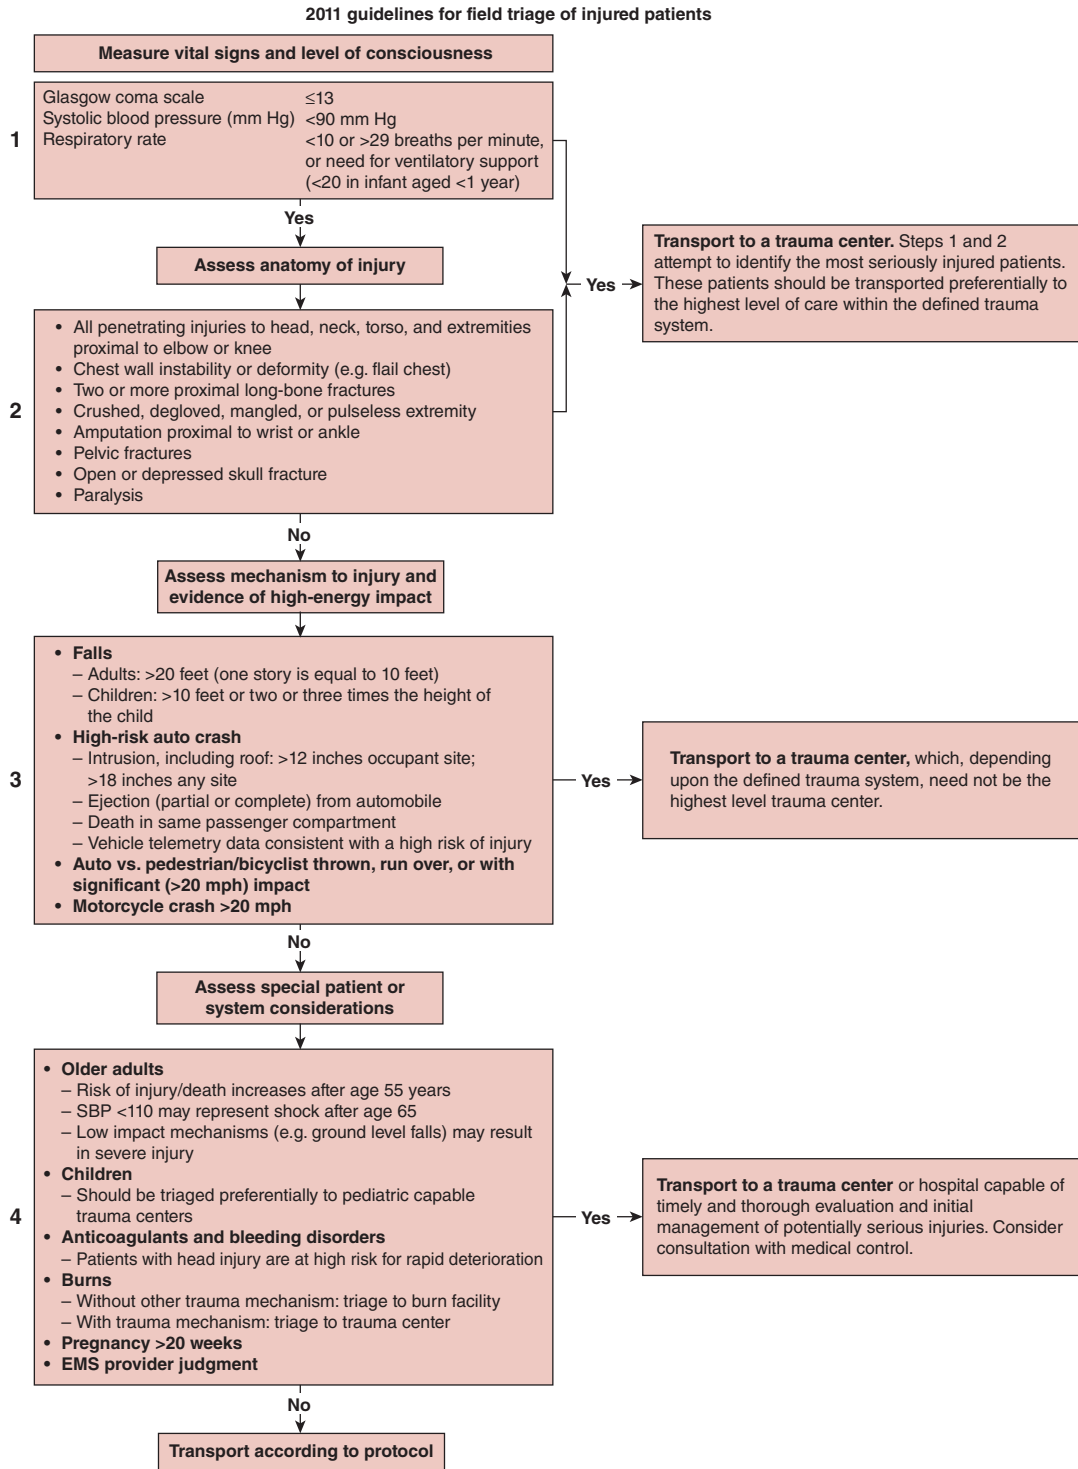

research and policy making aimed at providing guidance to answer this question. It is established that care at a level 1 trauma center reduces the risk of death by 25% for severely injured patients, when compared to treatment at a hospital which does not have verified trauma center resources. The CDC has undertaken two initiatives based on research and expert panel findings: (1) guidelines for the field triage of injured patient and (2) advanced automatic collision notification and triage of the injured patient (AACN). The published guidelines for the field triage of injured patients provides a rapid easily understood algorithm which allows for determination of where to triage trauma patients based upon findings at the scene taking into account assessment of vital signs/level of consciousness, anatomic evidence of injury, and mechanism of injury with regard to the level of energy involved (Figure 13-2). Partnering with the automotive industry has allowed for development of sophisticated sensors and vehicle telematics that allow early notification of a crash, prediction of the likelihood of serious injury among the occupants, and assistance with the field triage decision making. In combination, the AACN system and the field triage algorithm are expected to decrease the time that it takes for a seriously injured patient to receive appropriate and definitive trauma care.

PREHOSPITAL CARE & IMMEDIATE MEASURES AT A CRASH SITE

At first glance, the trauma victim may not appear to be badly injured. Sometimes there may be little external evidence of injury; however, when the mechanism of trauma is sufficient to produce severe injury, the victim must be handled as if a severe injury has occurred. It is critical at the scene that the injured person be protected from further trauma; likewise, rescue personnel need to take precautions to avoid injury to themselves. First aid at the scene of an accident should be administered by trained personnel whenever possible.

Whether the patient is first seen on the battlefield, beside a road, in the emergency ward, or in the hospital, the basic principles of initial management are the same:

1. Is the victim breathing? If not, provide an airway and establish bag-mask ventilation.
2. Is there a pulse or heartbeat? If not, begin closed-chest compression.
3. Is there gross external bleeding? If so, elevate the part if possible and apply enough external pressure to stop the bleeding. A tourniquet when utilized by trained providers is acceptable in circumstances of extreme bleeding.
4. Is there any question of injury to the spine? If so, protect the neck and spine before moving the patient.
5. Splint obvious fractures.

▲ **Figure 13–2.** CDC 2011 guidelines for field triage of injured patients.

As soon as these steps have been taken, the patient can be safely transported.

EVALUATION OF THE TRAUMA PATIENT

In most situations, a brief history is obtained from prehospital personnel via radio communication or when the patient arrives at the hospital. In the case of motor vehicle crashes, for example, it is important to determine the circumstances of the injury, including the speed of impact, the condition of the vehicle, the position of the patient at the scene, type of restraint systems present, evidence of blood loss, and the condition of other passengers. The time that the injury occurred and the treatment rendered while en route is recorded. Knowing the mechanism of injury often gives a clue to concealed trauma. Information regarding serious underlying medical problems should be sought from Medic Alert bracelets or wallet cards. If the patient is conscious and stable, the examiner should obtain a complete history and use this information to direct the examination in order to avoid unnecessary tests.

Trauma victims require a precise, rapid, systematic approach to initial evaluation in order to ensure their survival. The ATLS system developed by the ACS Committee on Trauma represents the best current approach to the severely injured patient. The sequence of evaluation includes primary survey, resuscitation, secondary survey, and definitive management. The primary survey attempts to identify and treat immediate life-threatening conditions. Resuscitation is performed, and the response to therapy is evaluated. The secondary survey includes a comprehensive physical examination designed to detect all injuries and establish a treatment priority for potentially life-threatening and/or limb-threatening ones. During the primary and secondary surveys, appropriate laboratory and imaging studies are performed to aid in the identification of injuries and prepare the patient for definitive care.

1. PRIMARY SURVEY

The ATLS manual and provider course published by the ACS Committee on Trauma is the accepted guideline for the primary survey. The primary survey is a rapid assessment to detect life-threatening injuries following the ABCDE: airway, breathing, circulation, disability, and exposure/environment.

AIRWAY

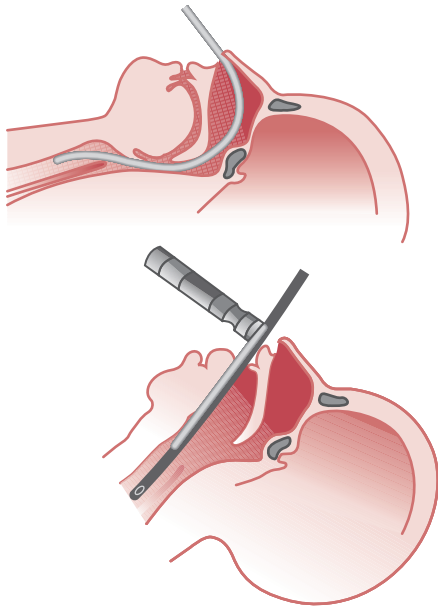

The establishment of an adequate airway has the highest priority in the primary survey. Oxygen by high-flow nasal cannula (10-12 L/min), 100% nonrebreather mask, or bag-mask ventilation with pulse oximetry should be started if not already in place. Maneuvers used in the trauma patient

▲ Figure 13-3. Relief of airway obstruction.

to establish an airway must consider a possible cervical spine injury. Any patient with multisystem trauma, especially those with an altered level of consciousness or blunt trauma above the clavicles, should be assumed to have a cervical spine injury. The rapid assessment for signs of airway obstruction should include inspection for foreign bodies and facial, jaw, or tracheal/laryngeal fractures that may result in acute loss of airway patency. Techniques that can be used to establish a patent airway while protecting the cervical spine include the chin lift or jaw thrust maneuvers (Figure 13-3).

Patients who can communicate verbally without difficulty are unlikely to have an impaired airway. Repeated assessment of airway patency is always prudent. Those patients with severe head injury, altered level of consciousness, or Glasgow Coma Scale (GCS) score 8 or less usually require placement of a definitive airway. Orotracheal or nasotracheal intubation can be attempted with cervical spine precautions if a second person maintains axial immobilization of the head to prevent destabilization of the spine (Figure 13-4). If ventilatory failure occurs and an adequate airway cannot be obtained readily by orotracheal or nasotracheal intubation, surgical cricothyroidotomy should be performed as rapidly as possible (Figure 13-5).

▲ **Figure 13-4.** A. Nasotracheal intubation. B. Orotracheal intubation.

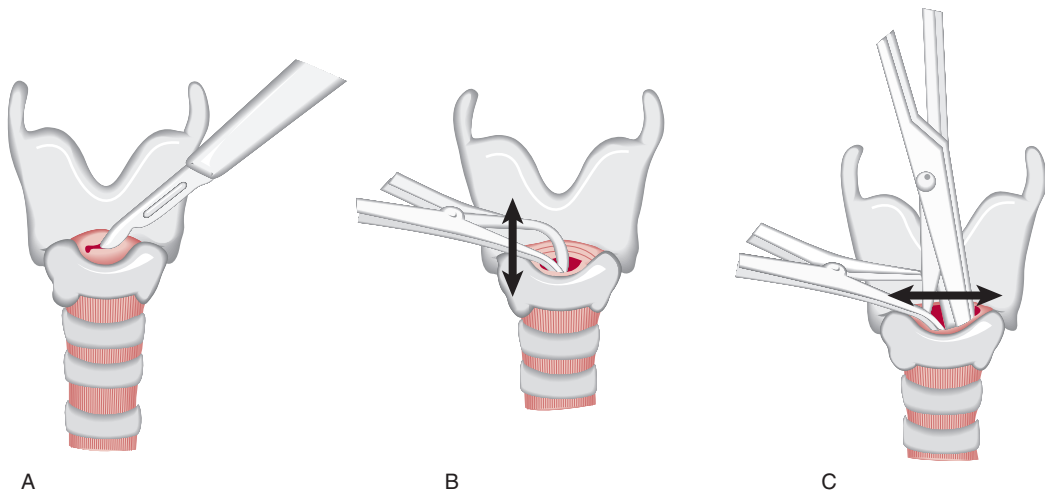

BREATHING

Once the airway has been established, it is necessary to ensure that oxygenation and ventilation is adequate. Examine the patient to determine the degree of chest expansion, breath sounds, tachypnea, crepitus from rib fractures, subcutaneous emphysema, and the presence of penetrating or open wounds. Immediately life-threatening

pulmonary injuries that must be detected and treated promptly include tension pneumothorax, open pneumothorax, flail chest, and massive hemothorax. Chest injury has the second highest case fatality rate in the trauma patient. The following are examples of life-threatening pulmonary injuries and their treatment:

1. Tension pneumothorax—This condition occurs when air becomes trapped in the pleural space under pressure. The harmful effects result primarily from shift of the mediastinum, impairment of venous return, and potential occlusion of the airway. Tension pneumothorax is difficult to diagnose even when the patient reaches the hospital. The clinical findings consist of hypotension in the presence of distended neck veins, decreased or absent breath sounds on the affected side, hyperresonance to percussion, and tracheal shift away from the affected side. These signs may be difficult to detect in a hypovolemic patient with a cervical collar in place. Cyanosis may be a late manifestation. Emergency treatment consists of insertion of a large-bore needle or plastic intravenous cannula (angiocath) through the chest wall into the pleural space in the second intercostal space along the midclavicular line to relieve the pressure and convert the tension pneumothorax to a simple pneumothorax. The needle or cannula should be left in place until a thoracostomy tube is inserted for definitive management (Figure 13-6).

2. Open pneumothorax—This condition results from an open wound of the chest wall with free communication between the pleural space and the atmosphere. The resulting impairment of the thoracic bellows, and its ability to expand the lung results in inadequate ventilation. With chest expansion during a breath, air moves in and out of the chest wall opening instead of through the trachea, producing

▲ **Figure 13-5.** Surgical cricothyroidotomy.

▲ **Figure 13-6.** Relief of pneumothorax. Tension pneumothorax must be immediately decompressed by a needle introduced through the second anterior intercostal space. A chest tube is usually inserted in the midaxillary line at the level of the nipple and is directed posteriorly and superiorly toward the apex of the thorax. The tube is attached to a “three-bottle” suction device, and the rate of escape of air is indicated by the appearance of bubbles in the second of the three bottles. Cessation of bubbling suggests that the air leak has become sealed.

hypoventilation that can be rapidly fatal. Emergency treatment consists of sealing the wound with an occlusive sterile dressing taped on three sides to act as a flutter-type valve or with any material if nothing sterile is available. Definitive treatment requires placement of a chest tube to reexpand the lung and surgical closure of the defect. Airway intubation with positive-pressure mechanical ventilation can be helpful in massive open pneumothorax.

3. Flail chest—Multiple rib fractures resulting in a free-floating segment of chest wall may produce paradoxical motion that impairs lung expansion (Figure 13-7). In patients with flail chest, injury-associated pulmonary contusion is common and is often the major cause of respiratory failure. The injury is identified by careful inspection and palpation during physical examination. Patients with large flail segments will almost always require endotracheal intubation and mechanical ventilation both to stabilize the flail segment and to optimize gas exchange.

▲ **Figure 13-7.** Flail chest.

Smaller flail segments may be well tolerated if supplemental oxygen and adequate analgesia are provided. The work of breathing is increased considerably, and many patients who initially appear to be compensating well may suddenly deteriorate a few hours later. Therefore, most patients with flail chest require monitoring in an intensive care unit (ICU).

CIRCULATION

► Hemorrhage

Free hemorrhage from accessible surface wounds is usually obvious and can be controlled in most cases by local pressure and elevation of the bleeding point. Firm and precise pressure on the major artery in the axilla, antecubital space, wrist, groin, popliteal space, or at the ankle may suffice for temporary control of arterial hemorrhage distal to these points. When all other measures have failed, a tourniquet may be necessary to control major hemorrhage from extensive wounds or major vessels in an extremity. Failure to manage a tourniquet properly may cause irreparable vascular or neurologic damage. For this reason, the tourniquet should be used only when necessary and must be kept exposed and loosened at least every 20 minutes for 1 or 2 minutes while the patient is in transit. Transport to definitive care where the tourniquet can be safely removed and treatment rendered should be a top priority. It is wise to write the time of tourniquet application in military time on the patient’s forehead with a skin-marking pen or on adhesive tape.

► Vascular Access & Resuscitation

All patients with significant trauma should have large-caliber peripheral intravenous catheters inserted immediately for administration of crystalloid fluids as needed. If any degree of shock is present, at least two 14-16 gauge peripheral intravenous lines should be established usually in the antecubital fossa. If venous access cannot be obtained by percutaneous peripheral or central venous cannulation, an intraosseous line in the tibia or other uninjured site should be placed. A venous cutdown of the saphenous vein at the ankle using an angiocath or intravenous extension tubing with the tip cut off can be performed, but is a difficult procedure in the field. A blood sample for type and cross-match should be sent from the venous line, if not already drawn.

As soon as the first intravenous line is inserted, rapid crystalloid infusion should begin. Adult patients should be given 2 L of Ringer lactate or normal saline. For children, the initial administered crystalloid volume should be 20 mL/kg. Patients who experience a transient response should receive an additional infusion of 2 L of crystalloid. Patients in hemorrhagic shock for whom there is no improvement in blood pressure from initial crystalloid infusion or who transiently respond but fail a second crystalloid bolus should be switched to resuscitation with blood products. Beyond the administration of the first two units of packed red blood cells (PRBC), it is important to also administer fresh plasma or thawed fresh frozen plasma (FFP) to avoid coagulopathy in the massively transfused patient. Massive transfusion is defined as at least 10 units of PRBC. The exact ratio of FFP to PRBC is still under active investigation, but a target range of 1:1 or 2:3 is considered acceptable. Military data has shown that the early use of plasma can reduce mortality by up to 50% in the massively transfused trauma patient. Giving platelets as part of the massive transfusion protocol is also supported by military data demonstrating a 20% reduction in mortality for patients who received platelets as fresh whole blood or apheresis platelets in conjunction with PRBC. The exact platelet-to-PRBC ratio for optimal treatment of the hemorrhaging trauma patient is not known, but giving a unit of platelets for every five units of PRBC is a reasonable ratio. Type O, Rh-negative PRBC should be immediately available in the emergency department for any patient with impending cardiac arrest or massive hemorrhage. Some high-volume trauma centers now also stock fresh or "prethawed" AB plasma as well. Type-specific blood should be available within 15-20 minutes of patient arrival to the hospital.

Tranexamic acid is an antifibrinolytic agent which inhibits the breakdown of clotted blood. It does not promote new blood clot formation. Two large clinical trials, one in the military setting and another in civilian population, have demonstrated the efficacy of tranexamic acid when utilized as part of a blood product resuscitation strategy in patients

with traumatic hemorrhage. The survival benefit is greatest in patients who received massive transfusion and those in whom early treatment was accomplished (≤ 1 hour after injury). Tranexamic acid started greater than 3 hours after injury increased the risk of death due to bleeding and is likely ineffective. Dosing is typically 1 g intravenously over 10 minutes, followed by a drip infusion of an additional 1 g over 8 hours.

Transfusion of blood products is not without risk. Despite rigorous screening programs, transmission of viral blood-borne diseases can occur. The current incidence of blood-borne pathogen transmission following red blood cell transfusion are hepatitis B, 1:350,000; hepatitis C 1:400,000; and HIV, 1:2 million. Transfusion of blood products is also associated with transfusion-related immunomodulation and transfusion-related acute lung injury. Both of these problems can increase morbidity and mortality. The storage age of blood transfused can also contribute to problems. Transfusion of a patient with older units of PRBC has been shown to cause generation of systemic proinflammatory mediators and increase the risk of wound infection.

► Monitoring

As intravenous access is obtained, electrocardiogram leads for continuous cardiac monitoring should be placed. Noninvasive blood pressure measurements should be acquired with a time-cycled blood pressure cuff. Pulse oximetry is valuable in ensuring that adequate hemoglobin oxygen saturation is present in the injured patient. Temperature is a crucial vital sign, and it should be measured and recorded along with the first pulse and blood pressure in the emergency department.

NEUROLOGIC DISABILITY

A brief neurologic examination should be documented to assess patients' degree of neurologic impairment. Many factors may contribute to altered levels of consciousness and should be considered in addition to central nervous system injury in all trauma patients. Other than the direct trauma, the most common contributing causes of altered mental status for trauma patients are alcohol intoxication, other central nervous system stimulants or depressants, diabetic ketoacidosis, cerebrovascular accident, and hypovolemic shock. Less common causes are epilepsy, eclampsia, electrolyte imbalances associated with metabolic and systemic diseases, anaphylaxis, heavy metal poisoning, electric shock, tumors, severe systemic infections, hypercalcemia, asphyxia, heat stroke, severe heart failure, and hysteria. These uncommon causes of coma or diminished mental status should be considered if routine testing such as blood alcohol and glucose level, urine toxicology, and head computerized tomography (CT) scanning are unrevealing as to the etiology of mental

Table 13–1. Glasgow Coma Scale score.

impairment. In such cases, further laboratory and diagnostic testing may be warranted.

The differential diagnosis depends upon a careful history and complete physical examination, with particular attention to the neurologic examination with documentation of the patient's GCS score (Table 13–1), and an urgent head CT scan. The GCS score is useful in monitoring acute changes in neurologic function and is used for prognosticating outcomes after severe head injury. The motor component of the GCS score is the most accurate for predicting outcome and has a linear relationship with mortality. Lateralizing signs may also suggest evidence of an intracranial mass effect or carotid or vertebral artery injury, while loss of distal motor and/or sensory function may help localize potential spinal cord injuries.

EXPOSURE/ENVIRONMENT

All clothing should be removed (cut off with trauma shears, usually) from the seriously injured patient, with care taken to avoid unnecessary movement. The removal of helmets or other protective clothing may require additional personnel to stabilize the patient and prevent further injury. All skin surfaces should be examined to identify occult injuries that may not be readily apparent, such as posterior penetrating trauma or open fractures. After inspecting all surfaces, warm blankets or warming devices should be placed to avoid hypothermia in the seriously injured patient.

▲ **Figure 13–8.** Emergency thoracotomy and open cardiac massage.

EMERGENCY ROOM THORACOTOMY

Certain injuries are so critical that operative treatment must be undertaken as soon as the diagnosis is made. In these cases, resuscitation is continued as the patient is being operated on. For cardiopulmonary arrest that occurs in the emergency room as a direct result of trauma, external cardiac compression is rarely successful in maintaining effective perfusion of vital organs. An emergency left anterolateral thoracotomy should be performed in the fourth or fifth intercostal space, and the pericardium should be opened anterior to the phrenic nerve (Figure 13–8). Open cardiac massage, cross-clamping of the descending thoracic aorta, repair of cardiac injuries, and internal defibrillation can be performed as appropriate. Wounds of the lung producing severe hemorrhage or systemic air embolus may require pulmonary hilar cross-clamping.

Emergency room thoracotomy is most useful for cardiac arrest due to penetrating thoracic trauma, particularly in patients with pericardial tamponade from stab wounds. This extreme procedure is ineffective for most patients with cardiac arrest due to blunt trauma and for all patients who have no detectable vital signs in the field (< 1% survival). If vital signs are present in the emergency room but arrest appears imminent, the patient should be transferred rapidly to the operating room if at all possible, since conditions in the operating room are optimal for surgical intervention.

RESUSCITATION PHASE

► Shock

Shock is defined as inadequate end-organ tissue perfusion. Some degree of shock accompanies most severe injuries and

Table 13–2. Classification of hypovolemic shock.

	Class I	Class II	Class III	Class IV
Blood loss (mL)	Up to 750	750–1500	1500–2000	> 2000
Blood loss (% BV)	Up to 15%	15–30%	30–40%	> 40%
Pulse rate (beats/min)	< 100	> 100	> 120	> 140
Blood pressure	Normal	Minimal decrease	Decreased	Significantly decreased
Pulse pressure	Normal	Narrowed	Narrowed	Unobtainable or very narrow
Hourly urine output	≥ 0.5 mL/kg	≥ 0.5 mL/kg	< 0.5 cc/kg	Minimal
CNS/mental status	Slightly anxious	Mildly anxious	Anxious & confused	Confused or lethargic

is manifested initially by pallor, cold sweat, weakness, light-headedness, tachycardia, hypotension, thirst, air hunger, and, eventually, loss of consciousness. Patients with any of these signs should be presumed to be in shock and evaluated thoroughly. All patients determined to be in any degree of shock should be reexamined at regular intervals. The degree of shock has been categorized to guide resuscitation and help caregivers recognize the severity of symptoms (Table 13–2).

A. Hypovolemic Shock

Hypovolemic shock is due to loss of whole blood or plasma. Blood pressure may be maintained initially by vasoconstriction. Tissue hypoxia increases when hypotension ensues, and shock may become irreversible if irreparable damage occurs to the vital organs. Massive or prolonged hemorrhage, severe crush injuries, major fractures, and extensive burns are the most common causes. The presence of any of these conditions is an indication for prompt intravenous fluid infusion.

In mild or class 1 shock (< 15% blood volume loss), compensatory mechanisms may preserve adequate perfusion, and no skin or physiologic changes may be apparent. In moderate or class 2 shock (15%–30% blood loss), the skin on the extremities becomes pale, cool, and moist as a result of vasoconstriction and release of epinephrine. Systolic blood pressure is often maintained at near-normal levels, but urine output will usually decrease. With severe or class 3 shock (30%–40% blood volume loss), these changes—particularly diaphoresis—become more marked, and urine output declines significantly. Hypotension ensues. In addition, changes in cerebral function become evident consisting chiefly of agitation, disorientation, and memory loss. A common error is to attribute uncooperative behavior to intoxication, drug use, or brain injury when in fact it may be due to cerebral ischemia from blood loss. With class 4 shock (> 40% blood volume loss), profound hypotension is typically accompanied by loss of consciousness and anuria.

In this situation, rapid resuscitation with crystalloid and blood products is necessary to prevent imminent death.

With any degree of shock, intravenous balanced salt solution (eg, lactated Ringer solution) should be given rapidly until the signs of shock abate and urine output returns to normal. If shock appears to be due to blood loss, blood transfusion should be given, starting with two units of uncross-matched O-negative blood if cross-matched blood is unavailable. Additional resuscitation with crystalloid and/or blood products is guided by the cause of volume loss and response to fluid administration. Successful resuscitation is indicated by warm, dry, well-perfused skin, a urine output of 30–60 mL/h, and an alert sensorium. Improvement in pH toward normal, correction of lactic acidosis, and minimization of base deficit as measured on an arterial blood gas sample are also indicators of successful resuscitation.

As a general principle, measurements of blood pressure and pulse are less reliable than changes in urine output in assessing the severity of shock. Young and athletic older patients may have compensatory mechanisms which maintain adequate blood pressure even with moderate volume loss. Older patients and those taking cardiac or blood pressure medications often do not exhibit tachycardia even with extreme volume loss. Therefore, a Foley catheter should be inserted into the bladder to monitor urine output in any patient with major injuries or shock. Oliguria is the most reliable sign of moderate shock, and successful resuscitation is indicated by a return of urine output to 0.5–1 mL/kg/h. Absence of oliguria is an unreliable index of the absence of shock if the patient has an osmotic diuresis due to alcohol, glucose, mannitol, or intravenous contrast material.

A patient who is receiving intravenous fluids at a high rate may not exhibit signs of shock even in the setting of ongoing hemorrhage. If a patient continues to require high volumes of fluid after initial resuscitation in order to maintain urine output, mental status, and blood pressure, further investigation must be performed to rule out occult hemorrhage. The patient must be kept recumbent and given

reassurance and analgesics as necessary. If opioids are necessary for pain relief, they are best administered intravenously in small doses.

B. Neurogenic Shock

Neurogenic shock is due to the pooling of blood in autonomically denervated venules and small veins and is usually due to spinal cord injury. Neurogenic shock is not caused by an isolated head injury, and in those patients, other causes of shock should be sought. A patient exhibiting signs of neurogenic shock (warm and well-perfused distal extremities in the presence of hypotension) should be given a 2 L crystalloid fluid bolus—followed by an additional bolus if the response is suboptimal. If neurogenic shock persists with fluid resuscitation, phenylephrine or another vasopressor should be given as a drip with the dosage adjusted until the blood pressure is maintained at a satisfactory level. If the patient does not improve quickly, other kinds of shock must be considered. Patients with neurogenic shock may require central venous pressure monitoring to ensure an optimal volume status.

C. Cardiac Compressive Shock

Cardiac compressive shock is caused by compression of the thin-walled chambers of the heart—the atria and the right ventricle—or by compression or distortion of the great veins entering the heart. The usual causes of this type of shock in the trauma patient are pericardial tamponade, tension pneumothorax, massive hemothorax, diaphragmatic rupture with herniation of abdominal contents into the chest, and an elevated diaphragm from massive abdominal hemorrhage. Treatment consists of urgent decompression depending on the specific cause. In severe cases, emergency thoracotomy may be necessary to restore adequate cardiac function.

D. Cardiogenic Shock

Cardiogenic shock is caused by decreased myocardial contractility and is most commonly caused by myocardial infarction or arrhythmia. Older trauma patients may develop a myocardial infarction as a complication of their injuries. On occasion an acute myocardial infarction may precede a traumatic event and be a cause of injury or loss of consciousness. Rarely, a severe myocardial contusion may lead to cardiogenic shock. Treatment is supportive, with volume replacement guided by hemodynamic monitoring and administration of inotropic agents to augment cardiac output as necessary to maintain adequate end-organ perfusion. Unfortunately, patients with traumatic injuries are not usually candidates for anticoagulant or lytic therapy, and treatment of their acute myocardial ischemia is sometimes hindered by concerns about bleeding. Echocardiography is helpful for assessment of wall motion abnormalities from severe cardiac contusion.

► Laboratory Studies

Immediately after intravenous catheters are placed, a blood sample should be drawn for blood typing and cross-matching. If the patient has a history of renal, hepatic, or cardiac disease or is taking diuretics or anticoagulants, serum electrolytes and coagulation parameters should be measured. In most patients with serious injuries, an arterial blood gas provides rapid data about acidosis and base deficit, both of which are markers of under-resuscitation in addition to oxygenation (PaO_2) and ventilation (PaCO_2). Gross blood in the urine indicates the need for further diagnostic testing with abdominal CT scan or, in selected cases, a cystogram and urethrogram. Patients with obvious severe head injury, where intracranial pressure monitoring may be indicated, should have coagulation studies and a platelet count performed. Measurement of blood alcohol level and urine toxicology screen may be useful in patients with altered mental status.

► Imaging Studies

Radiographic plain films of the chest and pelvis are required in all major injuries. Lateral C-spine films have been supplanted by formal CT scanning of the neck in patients with suspicion of or mechanism for cervical spine injury. Bedside focused assessment with sonography for trauma (FAST) is the preferred triage method for determining the presence of hemoperitoneum in blunt trauma patients or cardiac tamponade in blunt and penetrating trauma patients. The presence of hemoperitoneum in an unstable patient on FAST may be an indication for exploratory laparotomy. Presence of hemoperitoneum in a stable patient or a negative FAST in a patient with abdominal pain is indication for further evaluation with abdominal CT scan.

Patients who have an abnormal chest radiograph with a mechanism for blunt aortic injury should undergo further screening with either helical chest CT done at the time of abdominal imaging or with aortography, if necessary. Cervical spine CT scans should be obtained for patients who are unconscious, have pain in the cervical region, have neurologic deficits, or have painful or distracting injuries. CT scanning of the head should be performed in all patients with loss of consciousness or more serious neurologic impairment. Radiographs of the long bones and noncervical spine can usually be deferred until the more critical injuries of the thorax and abdomen have been delineated and stabilized.

2. SECONDARY SURVEY & PATTERNS OF INJURY

A rapid and complete history and physical examination are essential for patients with serious or multiple injuries. Progressive changes in clinical findings are often the key to

correct diagnosis, and negative findings that change to positive may be of great importance in revising an initial clinical evaluation. This is particularly true in the case of abdominal, thoracic, and intracranial injuries, which frequently do not become manifest until hours after the trauma.

Recognition of injury patterns is also important in identifying all injuries. For example, fractures of the calcaneus resulting from a fall from a great height are often associated with central dislocation of the hip and fractures of the spine and of the skull base. A crushed pelvis is often combined with laceration of the posterior urethra or bladder, vagina, or rectum. Crush injuries of the chest are often associated with lacerations or rupture of the spleen, liver, or diaphragm. Penetrating wounds of the chest may involve not only the thoracic contents but also the abdominal viscera. These combinations occur frequently and should always be suspected.

TREATMENT PRIORITIES

In all cases of patients with multiple injuries, there must be a “captain of the team” who directs the resuscitation, decides which x-rays or special diagnostic tests should be obtained, and establishes priority for care by continuous consultation with other surgical specialists and anesthesiologists. A trauma surgeon or a general surgeon experienced in the care of injured patients usually has this role.

After controlling the airway if necessary, resuscitation and blood volume replacement have first priority. Deepening stupor in patients under observation should arouse suspicion of an expanding intracranial lesion requiring serial neurologic examinations and head CT. Too often, obvious signs of acute alcohol intoxication have been assumed to be the cause of unconsciousness, and intracranial hemorrhage has been overlooked.

Cerebral injuries take precedence in care when there is rapidly deepening coma. Extradural bleeding is a critical emergency, requiring operation for control of bleeding and cerebral decompression. Subdural bleeding may produce a similar emergency. If the patient’s condition permits, CT scanning should be performed for localization of the bleeding within the cranium prior to other operative interventions being initiated. In many cases of combined cerebral and abdominal injury with massive bleeding, laparotomy and craniotomy should be performed simultaneously.

Most urologic injuries are managed at the same time as associated intra-abdominal injuries. Pelvic fractures present special problems and are discussed in Chapter 40. Unless there is associated vascular injury with threatened ischemia of the limb, fractures of the long bones can be splinted and treated on an urgent basis. Open contaminated fractures should be cleansed and debrided as soon as possible. Injuries of the hand run the risk of infection that may result in a lifelong handicap without early effective treatment.

Early treatment of the hand at the same time as treatment of any life-threatening injuries avoids infection and preserves the means of livelihood. Tetanus prophylaxis should be given in all instances of open contaminated wounds, puncture wounds, and burns.

Patients with a severe burden of trauma and shock may not be candidates for definitive treatment of all injuries in the immediate setting. Three physiological derangements comprise the “lethal triad” in the trauma literature: hypothermia, acidosis, and coagulopathy. These are boundaries of a patient’s physiologic envelope beyond which the patient will develop irreversible shock and eventual death. Bailing out of the abdomen with damage control maneuvers in a patient headed for the lethal triad is not a sign of defeat; instead it is usually the intelligent option. Early warning signs of physiologic compromise that could lead to the lethal triad are edema of the small bowel, midgut distension, dusky serosal surfaces, tissue that is cool to the touch, noncompliant swollen abdominal wall, diffuse oozing from surgical or raw surfaces, and lack of obvious clot formation. Successful packing relies on clot formation, so employing a strategy of early packing is recommended rather than turning to it as a last resort.

Details of definitive management of injuries are discussed in the sections on trauma that follow and in the various organ system chapters of this book.

NECK INJURIES

All injuries to the neck are potentially life threatening because of the many vital structures in this area. Injuries to the neck are classified as blunt or penetrating, and the treatment is different for each. The patient must be examined

closely for associated head and chest injuries. The initial level of consciousness is of paramount importance; progressive depression of the sensorium may signify intracranial bleeding or cerebral ischemia and requires neurosurgical evaluation. Trauma to the base of the neck may lacerate major blood vessels or have associated pneumothorax. Hemorrhage into the pleural cavity may occur suddenly as contained hematomas rupture.

► Clinical Findings

Injuries to the larynx and trachea can be asymptomatic or may cause hoarseness, laryngeal stridor, or dyspnea secondary to airway compression or aspiration of blood. Subcutaneous emphysema in the neck can be present if the wall of the larynx or trachea has been disrupted.

Esophageal injuries are rarely isolated and by themselves may not cause immediate symptoms. Severe chest pain and dysphagia are characteristic of esophageal perforation. Hours later, as mediastinitis develops, progressive sepsis may occur. Mediastinitis results because the deep cervical space is in direct continuity with the mediastinum. Esophageal injuries can be recognized promptly if the surgeon is alert to the possibility and seeks out early diagnosis. Exploration of the neck, radiographic examination of the esophagus with contrast medium, and in selected cases flexible esophagoscopy confirms the diagnosis.

Cervical spine fractures and spinal cord injuries should always be suspected in deceleration injuries or following direct trauma to the neck. If the patient complains of cervical pain or tenderness or if the level of consciousness is depressed, the head and neck should be immobilized (eg, with a rigid cervical collar or sandbags) until cervical radiologic imaging can be performed to rule out a cervical fracture or ligamentous injury.

Injury to the great vessels (subclavian, common carotid, internal carotid, and external carotid arteries; subclavian, internal jugular, and external jugular veins) may follow blunt or penetrating trauma. Fractures of the clavicle or first rib may lacerate the subclavian artery and vein. With vascular injuries, the patient typically presents with visible external blood loss, neck hematoma formation, and in varying degrees of shock. Occasionally, bleeding may be contained and the injury may go undetected for a short time. Auscultation may reveal bruits that suggest arterial injury.

► Types of Injuries

A. Penetrating Neck Injuries

Penetrating injuries of the neck are divided into three anatomic zones (Figure 13-9). Zone I injuries occur at the thoracic outlet, which extends from the level of the cricoid cartilage to the clavicles. Included in this area are the proximal carotid arteries, the subclavian vessels, and the major

▲ **Figure 13-9.** Zones of the neck.

vessels of the chest. Proximal control of injuries to vascular structures in this zone often requires a thoracotomy or sternotomy. Zone II injuries occur in the area between the cricoid and the angle of the mandible. Injuries here are the easiest to expose and evaluate. Zone III injuries are between the angle of the mandible and the base of the skull. Exposure is much more difficult in this zone and in some cases may require disarticulation of the mandible. High injuries can be inaccessible, and control of hemorrhage may require ligation of major proximal vessels or angiographic embolization.

Penetrating trauma to the posterior neck may injure the vertebral column, the cervical spinal cord, the interosseous portion of the vertebral artery, and the neck musculature. Penetrating trauma to the anterior and lateral neck may injure the larynx, trachea, esophagus, thyroid, carotid arteries, subclavian arteries, jugular veins, subclavian veins, phrenic and vagus nerves, and thoracic duct.

With any penetrating cervical trauma, the likelihood of significant injury is high because there are so many vital structures in such a small space. Any patient with shock, expanding hematoma, or uncontrolled hemorrhage should be taken to the operating room for emergency exploration. The location of the injury suggests which structures may be involved. Vascular injuries at the base of the neck require thoracotomy or sternotomy to obtain proximal control of injured blood vessels before the site of probable injury is exposed. If the patient is stable after resuscitation, additional diagnostic testing may be considered.

Conventional angiography or computed tomography angiography is usually recommended for patients with stable injuries in zones I and III because precise identification of the location and extent of injury may alter the operative approach. If possible, angiography should be performed before exploration of any injury in which blood vessels

may be damaged below the level of the cricoid cartilage or above a line connecting the mastoid process with the angle of the jaw. Arterial injuries above this line are practically inaccessible. If injury to the carotid artery at the base of the skull is confirmed by angiography, repair may not be possible and ligation may be required to control bleeding, or angiographic intervention may be required. Injured carotid arteries that have produced a neurologic deficit should be repaired if possible. The morbidity and mortality of patients undergoing carotid artery repair are significantly lower than those who have ligation of the carotid artery (15% vs 50%). Carotid artery ligation is indicated in the patient who presents with uncontrollable hemorrhage or coma with no prograde flow in the carotid artery.

Since exposure of injuries in zone II is relatively easy to obtain, a policy of mandatory exploration was the traditional recommendation for all injuries penetrating the platysma muscle. Although this approach is safe, reliable, and time-tested, studies have demonstrated that a selective approach is as safe provided that diagnostic testing does not detect a major injury and the patient is stable. High-resolution helical CT scanning of the neck can also be used to guide surgical decision making in zone II penetrating injuries. Invasive studies such as endoscopy and conventional angiography can often be eliminated if CT demonstrates a trajectory remote from vital structures such as blood vessels or the aerodigestive tract.

In the absence of an obvious vascular injury on clinical examination, ultrasound with color-flow Doppler has been demonstrated to be reliable in ruling out carotid artery injuries. Computed tomography angiography can also be used in this setting and may offer the advantage of identifying an unsuspected vertebral artery injury. Vertebral artery injuries should also be suspected when bleeding from a posterior or lateral neck wound cannot be controlled by pressure on the carotid artery or when there is bleeding from a posterolateral wound associated with fracture of a cervical transverse process. Flexible or rigid endoscopy can be used to evaluate the trachea and esophagus. A contrast study of the upper esophagus should be performed to identify esophageal injuries that might not be readily apparent on endoscopy. These injuries can be difficult to detect and are occasionally missed on surgical exploration. In either case, repeated, careful examinations should be performed.

B. Blunt Neck Injuries

The most important injuries resulting from blunt cervical trauma are: (1) cervical fracture, (2) cervical spinal cord injury, (3) vascular injury, and (4) laryngeal and tracheal injury. Radiographic examination of the cervical spine and soft tissues is essential. Careful neurologic examination can differentiate between injuries to the spinal cord, brachial plexus, and brain.

The diagnosis of a cervical spine fracture is reliant on the history, physical examination, and confirmatory studies. The use of plain radiographs has been supplanted by non-contrast computed tomography of the cervical spine. Awake, unimpaired patients with a negative physical examination are unlikely to have a clinically significant cervical spine injury. Obtunded patients with a negative CT scan and no clinical signs of cervical spine injury are also unlikely to have an injury. Following a negative CT scan, the cervical collar is typically removed once the patient is no longer obtunded and the examination can be repeated, or immediately if the patient is likely to remain obtunded/intubated in the ICU. The pediatric patient with an unreliable physical examination often requires additional imaging to clear the spine. Adult patients with a negative CT scan and pain often require flexion and extension views or a MRI to rule out ligamentous injury. Cervical fractures are often managed with external immobilization using rigid collars or a halo/vest apparatus. In some cases, unstable cervical spine fractures require reduction and internal fixation.

Vascular injuries may occur in cases of severe or localized blunt neck trauma. The common or internal carotid arteries can be torn or sustain intimal disruption and require intervention. Imaging of the cervical vessels is recommended in blunt trauma patients with lateralizing neurologic symptoms or GCS less than 8 with head CT findings that do not explain the neurologic symptoms. Screening should also be considered in patients with mandible or facial fractures, complex skull fractures, traumatic brain injury with thoracic injuries, scalp degloving, and thoracic vascular injuries. While four-vessel arteriography of bilateral carotid and vertebral arteries was the previous gold standard, newer imaging techniques such as a dedicated cervical CT-angiogram or MR-angiogram are the preferred screening tools. Formal arteriograms are reserved for patients who may have injuries amenable to angiographic intervention or if the diagnosis cannot be made by other means and would alter treatment. Most blunt carotid injuries are not amenable to operative intervention due to the location or extent of injury. The use of endovascular stent techniques to repair or control blunt carotid artery injuries is also an option. Patients with blunt carotid or vertebral artery injuries should be considered for anticoagulation or antiplatelet therapy. The value of anticoagulation continues to be debated due to associated bleeding complications, and antiplatelet therapy is a reasonable alternative to full systemic anticoagulation.

► Complications

The complications of untreated neck trauma are related to the individual structures injured. Injuries to the larynx and trachea can result in acute airway obstruction, late tracheal stenosis, and sepsis. Cervicomedial sepsis can result from esophageal injuries. Carotid artery injuries can

produce death from hemorrhage, stroke or cerebral ischemia, and arteriovenous fistula with cardiac decompensation. Major venous injury can result in exsanguination, air embolism, and arteriovenous fistula formation if there is concomitant arterial injury. Cervical fracture can result in paraplegia, quadriplegia, or death.

Prevention of these complications depends upon immediate resuscitation by intubation of the airway, prompt control of external hemorrhage and blood replacement, protection of the head and neck when cervical fracture is possible, accurate and rapid diagnosis, and prompt operative treatment when indicated.

► Treatment

Control of the airway with early intubation is the first key maneuver to successful management of severe neck injuries. Any wound of the neck that penetrates the platysma requires prompt surgical exploration or diagnostic workup to rule out major vascular injury. In patients with zone II injuries, color-flow Doppler imaging may provide a reliable way to assess for vascular injury and can be a safe alternative to contrast angiography. Arteries damaged by high-velocity missiles require debridement. End-to-end anastomosis of the mobilized vessels is preferred, but if a significant segment is lost, an autogenous vein graft can be used. Vertebral artery injury presents a formidable technical problem because of the interosseous course of the artery shortly after it arises from the subclavian artery. Although unilateral vertebral artery ligation has been followed by fatal midbrain or cerebellar necrosis, because of inadequate communication to the basilar artery, only 3% of patients with left vertebral ligation and 2% of patients with right vertebral ligation develop these complications. Therefore, in the face of massive hemorrhage from a partially severed vertebral artery, ligation with surgical clips applied to the vessel between the transverse processes above and below the laceration is accepted.

Subclavian artery injuries are best approached through a combined cervicothoracic incision. Proper exposure is the key to success in the management of these difficult and too-often fatal injuries. Ligation of the subclavian artery is relatively safe, but primary repair is preferable. Care should be taken to avoid phrenic nerve and thoracic duct injury when operating in this region of the neck. If the patient is stable and a subclavian injury is identified at arteriography, an endovascular stent is another therapeutic option.

Venous injuries are best managed by ligation. The possibility of air embolism must be kept constantly in mind. A simple means of preventing this complication is to lower the patient's head using the Trendelenburg position until bleeding is controlled.

Esophageal injuries should be sutured closed primarily and drained. Use of muscle flaps using omohyoid or sternocleidomastoid muscles to cover the repair can be helpful.

Drainage is the mainstay of treatment. Extensive injury to the esophagus is often immediately fatal because of associated injuries to the spinal cord. Systemic antibiotics should be administered routinely to patients with esophageal injuries.

Minor laryngeal and tracheal injuries do not require treatment, but immediate tracheostomy should be performed when airway obstruction exists. If there has been significant injury to the thyroid cartilage, a temporary laryngeal stent (Silastic) should be employed to provide support. Mucosal lacerations should be approximated before insertion of the stent. Conveniently located small perforations of the trachea can be utilized for tracheostomy. Otherwise, the wounds can be closed after they are debrided and a distal tracheostomy performed. Extensive circumferential tracheal injuries may require resection and anastomosis or reconstruction using synthetic materials.

Cervical spinal cord injury should be managed in such a way as to prevent further damage. When there is cervical cord compression from hematoma, vertebral fractures, or foreign bodies, decompression laminectomy is necessary.

► Prognosis

Severe laceration of the cervical spinal cord often results in paralysis. Injuries to the soft tissues of the neck, trachea, and esophagus have a good to excellent prognosis if promptly treated. Major vascular injuries have a good prognosis if promptly treated before the onset of irreversible shock or neurologic deficit. The overall death rate for major cervical injuries is about 10%.

THORACIC INJURIES

Thoracic trauma accounts directly for or is a contributing factor in 50% of deaths from trauma. Early deaths are commonly due to: (1) airway obstruction, (2) flail chest, (3) open pneumothorax, (4) massive hemothorax, (5) tension pneumothorax, and (6) cardiac tamponade. Later deaths are due to respiratory failure, sepsis, and unrecognized injuries/complications. The majority of blunt thoracic injuries are the result of automobile accidents. Even what appears to be a minor blunt thoracic injury leading to rib fractures and pulmonary contusions can have a profound effect on patients. Near-side collisions are responsible for a higher incidence of blunt aortic injury among older adults and are associated with lower delta V forces compared to those in younger patients. Penetrating chest injuries from knives, bullets, etc, are deadly and can result in complex patterns of injury. The mortality rate in hospitalized patients with isolated chest injury is 4%-8%; it is 10%-15% when one other organ system is involved and rises to 35% if multiple additional organs are injured.

Combined injuries of multiple intrathoracic structures are typical. There are often other injuries to the abdomen, head, or skeletal system. When performing an operation on the chest for trauma, it is often necessary to operate on the abdomen as well. Therefore, when trauma patients are brought to the operating room for a laparotomy or thoracotomy, both body regions should be prepped into the operative field. Eighty-five percent of chest injuries do not require open thoracotomy, but immediate use of lifesaving measures is often necessary and should be within the competence of all surgeons.

A rapid estimate of cardiorespiratory status and possible associated injuries from the physical examination gives the physician a valuable overview of a patient who has sustained thoracic injuries. For example, patients with upper airway obstruction appear cyanotic, ashen, or gray; examination reveals stridor or gurgling sounds, ineffective respiratory excursion, constriction of cervical muscles, and retraction of the suprasternal, supraclavicular, intercostal, or epigastric regions. The character of chest wall excursions and the presence or absence of penetrating wounds should be observed. If respiratory excursions are not visible, ventilation is probably inadequate. Severe paradoxical chest wall movement in flail chest is usually located anteriorly and can be seen immediately. Sucking wounds of the chest wall should be obvious. A large hemothorax may be detected by percussion, and subcutaneous emphysema is easily detected on palpation as crepitus. Both massive hemothorax and tension pneumothorax may produce absent or diminished breath sounds and a shift of the trachea to the opposite side, but in massive hemothorax the neck veins are usually collapsed. If the patient has a thready or absent pulse and distended neck veins, the main differential diagnosis is between cardiac tamponade and tension pneumothorax.

In moribund patients, diagnosis must be immediate, and treatment may require chest tube placement, pericardiocentesis, or thoracotomy in the emergency room. The first priority of management should be to provide an airway and restore circulation. One can then reassess the patient and outline definitive measures. A cuffed endotracheal tube and assisted ventilation are required for apnea, ineffectual breathing, severe shock, deep coma, airway obstruction, flail chest, or open sucking chest wounds. Persistent shock or hypoxia due to thoracic trauma may be caused by any of the following: massive hemopneumothorax, cardiac tamponade, tension pneumothorax or massive air leak, or air embolism. If hemorrhagic shock is not explained readily by findings on chest x-ray or external losses, it is almost certainly due to intra-abdominal bleeding.

▶ Tube Thoracostomy

If time permits, the chest is prepared and draped in a sterile fashion. In awake patients, local anesthetic (1% lidocaine) is injected in the skin and surrounding tissues at the planned site of tube insertion. In an unconscious patient, this step is usually unnecessary. The location of the chest tube insertion site is the interspace between the fourth and fifth ribs in the **midaxillary** line. A 2- to 3-cm skin incision is created with a #10 scalpel and carried down into the subcutaneous tissue. Using a large hemostat, a soft tissue tunnel is created just superior to the cephalad edge of the fifth rib. A finger or blunt clamp is used to penetrate the parietal pleura and enter the pleural space. The wound is explored with an index finger to confirm entry into the pleural cavity and check for pulmonary adhesions. A 36F straight thoracostomy tube is inserted and directed posteriorly toward the apex of the lung. The tube is anchored to the skin with stitches and connected to a Pleur-Evac device set at 20 cm H₂O suction with a water seal.

▶ Types of Injuries

A. Chest Wall

Rib fracture, the most common chest injury, varies across a spectrum from simple fracture to fracture with hemothorax to severe multiple fractures with flail chest, pulmonary contusion, and internal injuries. With simple fractures, pain on inspiration is the principal symptom; treatment consists of providing adequate analgesia. In cases of multiple fractures, intercostal nerve blocks or epidural analgesia may be required to ensure adequate ventilation. Multiple fractures can be associated with decreased ventilation and subsequent pneumonia, particularly in the elderly patient.

Flail chest occurs when a portion of the chest wall becomes isolated by multiple fractures and paradoxically moves in and out with inspiration and expiration with a

potentially severe reduction in ventilatory efficiency. The magnitude of the effect is determined by the size of the flail segment and the amount of pain with breathing. The rib fractures are usually anterior, and there are at least two fractures of the same rib. Bilateral costochondral separation and sternal fractures can also cause a flail segment. An associated lung contusion may produce a decrease in lung compliance not fully manifest until 12-48 hours after injury. Increased negative intrapleural pressure is then required for ventilation, and chest wall instability becomes apparent. If ventilation becomes inadequate, atelectasis, hypercapnia, hypoxia, accumulation of secretions, and ineffective cough occur. Arterial PaO_2 is often low before clinical findings appear. Serial blood gas analysis is the best way to determine if a treatment regimen is adequate. For less severe cases, intercostal nerve block or continuous epidural analgesia may be adequate treatment. However, more severe cases require ventilatory assistance for variable periods of time with a cuffed endotracheal tube and a mechanical ventilator.

Most rib or sternal fractures will heal without treatment. In selected patients, internal fixation may be useful; however, determining the patient population who would most benefit is still under investigation. Commercially produced, implantable rib and sternal fracture plating systems are now available. A system with bioabsorbable plates has been described which allows fixation of fragments during the healing process and metabolism by the body within 24 months. Patients who would potentially benefit from an open reduction internal fixation procedure are those with nonunion, severely displaced rib fractures with overriding fragments, severe pain with respiratory compromise (eg, difficulty in being weaned off the mechanical ventilator), multiple unstable rib fractures, and those undergoing thoracotomy for other intrathoracic indication. Because of the peristomal bacterial burden associated with a tracheostomy, this procedure should be used with caution in patients with a prior tracheostomy and need for a surgical incision high on the chest wall.

B. Trachea and Bronchus

Blunt tracheobronchial injuries are often due to compression of the airway between the sternum and the vertebral column in decelerating or high-velocity crush accidents. The distal trachea or main stem bronchi are usually involved, and 80% of all injuries are located within 2.5 cm from the carina. Penetrating tracheobronchial injuries may occur at any location. Most patients have pneumothorax, subcutaneous emphysema, pneumomediastinum, and hemoptysis. Cervicofacial emphysema may be dramatic. Tracheobronchial injury should be suspected when there is a massive air leak or when the lung does not readily reexpand after chest tube placement. In penetrating injuries of the trachea or main stem bronchi, there is usually massive

hemorrhage and hemoptysis. Systemic air embolism resulting in cardiopulmonary arrest may occur if a bronchovenous fistula is present. If air embolism is suspected, emergency thoracotomy should be performed with cross-clamping of the pulmonary hilum on the affected side. The diagnosis is confirmed by aspiration of air from the heart. In blunt injuries, the tracheobronchial injury may not be obvious and may be suspected only after major atelectasis develops several days later. Diagnosis may require flexible or rigid bronchoscopy. Immediate primary repair with absorbable sutures is indicated for all tracheobronchial lacerations.

C. Pleural Space

Hemothorax (blood within the pleural cavity) is classified according to the amount of blood: minimal, 350 mL; moderate, 350-1500 mL; or massive, 1500 mL or more. The rate of bleeding after evacuation of the hemothorax is clinically even more important. If air is also present, the condition is called *hemopneumothorax*.

Hemothorax should be suspected with penetrating or severe blunt thoracic injury. There may be decreased breath sounds and dullness to percussion, and a chest x-ray should be promptly obtained. In experienced hands, ultrasound can diagnose pneumothorax and hemothorax, but this technique is not widely employed at this time. Tube thoracostomy should be performed expeditiously for all hemothoraces. In 85% of cases, tube thoracostomy is the only treatment required. If bleeding is persistent, as noted by continued output from the chest tubes, it is more likely to be from the chest wall and an intercostal artery rather than a pulmonary artery. The use of positive end-expiratory pressure can help tamponade pulmonary parenchymal bleeding in trauma patients who are intubated. When the rate of bleeding shows a steady trend of greater than 200 mL/h or the total hemorrhagic output exceeds 1500 mL, thoracoscopy or thoracotomy should usually be performed. The trend and rate of thoracic bleeding is probably more important than the absolute numbers in deciding to perform surgical intervention. Thoracoscopy has been shown to be effective in controlling chest tube bleeding in 82% of cases. This technique has also been shown to be 90% effective in evacuating retained hemothoraces. In most of these cases, the chest wall is the source of hemorrhage. Thoracotomy is required for management of injuries to the lungs, heart, pericardium, and great vessels.

Pneumothorax occurs in lacerations of the lung or chest wall following penetrating or blunt chest trauma. Hyperinflation (eg, blast injuries and diving accidents) can also rupture the lungs. After penetrating injury, 80% of patients with pneumothorax also have blood in the pleural cavity. Most cases of pneumothorax are readily diagnosed on chest x-ray. In some cases, an occult pneumothorax will be identified on a chest or abdominal CT scan. Pneumothorax or hemothorax may be identified on the lateral scans

performed as part of the FAST examination of the abdomen for trauma (see section on abdominal trauma). Most cases of traumatic pneumothorax should be treated with immediate tube thoracostomy; however, small occult pneumothoraces in stable patients can be observed.

Tension pneumothorax develops when a flap-valve leak allows air to enter the pleural space but prevents its escape; intrapleural pressure rises, causing total collapse of the lung and a shift of the mediastinal viscera to the opposite side, interfering with venous return to the heart. It must be relieved immediately to avoid impairment of cardiac function. Immediate treatment involves placement of a large-bore needle or plastic angiocath in the pleural space with care being taken to avoid injury to the intercostal vessels. After this emergency measure has been instituted, tension pneumothorax should be treated definitively by tube thoracostomy.

Sucking chest wounds, which allow air to pass in and out of the pleural cavity, should be promptly treated by a three-sided occlusive dressing and tube thoracostomy. The pathologic physiology resembles flail chest except that the extent of associated lung injury is usually less. Definitive management includes surgical closure of the defect in the chest wall.

D. Lung Injury

Pulmonary contusion due to sudden parenchymal concussion occurs after blunt trauma or wounding with a high-velocity missile. Pulmonary contusion happens in 75% of patients with flail chest but can also occur following blunt trauma without rib fracture. Alveolar rupture with fluid transudation and extravasation of blood are early findings. Fluid and blood from ruptured alveoli enter alveolar spaces and bronchi, and produce localized airway obstruction and atelectasis. Increased mucous secretions and overzealous intravenous fluid therapy may combine to produce copious secretions and further atelectasis. The patient's ability to cough and clear secretions effectively is weakened because of chest wall pain or mechanical inefficiency from fractures. Elasticity of the lungs is decreased, resistance to air flow increases, and as the work of breathing increases, blood oxygenation and pH drop and Paco_2 rises. The cardiac compensatory response may be compromised, because as many as 35% of these patients have an associated myocardial contusion.

Treatment is often delayed because clinical and x-ray findings may not appear until 12-48 hours after injury. The clinical findings are copious, thin, blood-tinged secretions; chest pain; restlessness; apprehensiveness; and labored respirations. Eventually, dyspnea, cyanosis, tachypnea, and tachycardia develop. X-ray changes consist of patchy parenchymal opacification or diffuse linear peribronchial densities that may progress to diffuse opacification ("white-out") characteristic for acute respiratory distress syndrome.

Mechanical ventilatory support permits adequate alveolar ventilation and reduces the work of breathing. Blood gases should be monitored and arterial saturation adequately maintained. There is some controversy over the best regimen for fluid management, but excessive hydration or blood transfusion should be avoided. Serial measurement of central venous pressure, mixed venous oxygen saturation, and cardiac output help avoid over- or underresuscitation. Despite optimal therapy, about 15% of patients with pulmonary contusion die. Use of protective mechanical ventilator strategies is essential in these patients to avoid progressive ventilator induced lung injury. Use of low-tidal volumes (6 mL/kg) and avoidance of plateau pressures greater than 35 cm H_2O are recommended.

Most lung lacerations are caused by penetrating injuries, and hemopneumothorax is usually present. Tube thoracostomy is indicated to evacuate pleural air or blood and to monitor continuing leaks. Since expansion of the lung tamponades the laceration, most lung lacerations do not produce massive hemorrhage or persistent air leaks. Should a pulmonary laceration require operative intervention, lung-sparing techniques rather than formal anatomic lung resection should be employed when feasible to reduce morbidity and mortality.

Lung hematomas are the result of local parenchymal destruction and hemorrhage. The x-ray appearance is initially a poorly defined density that becomes more circumscribed a few days to 2 weeks after injury. Cystic cavities occasionally develop if damage is extensive. Most hematomas resolve adequately with expectant treatment.

E. Heart and Pericardium

Blunt injury to the heart occurs most often from compression against the steering wheel in automobile accidents. This injury is in decline with the increasing prevalence of airbag technology in motor vehicles. The injury varies from localized contusion to cardiac rupture. Autopsy studies of victims of immediately fatal accidents show that as many as 65% have rupture of one or more cardiac chambers, and 45% have pericardial lacerations. The incidence of blunt myocardial injury in patients who reach the hospital is unknown but is probably higher than generally suspected. The clinical relevance of this diagnosis is widely debated. Most trauma surgeons advocate the diagnosis and treatment of the actual clinical problem such as acute heart failure, valvular injury, cardiac rupture, or dysrhythmia.

Early clinical findings include friction rubs, chest pain, tachycardia, murmurs, dysrhythmias, or signs of low cardiac output. Patients with risk factors for blunt myocardial injury should undergo evaluation with a 12-lead electrocardiogram (EKG). If the EKG is normal and the patient is asymptomatic, the work up is complete. An abnormal EKG should prompt further evaluation with an echocardiogram.

Patients with proven injury on echocardiogram and/or hemodynamic instability should be admitted to the ICU and managed appropriately for the diagnosed injury. An abnormal EKG with a normal echocardiogram merits at least 24 hours of monitoring in a telemetry unit and daily repeat EKGs until stable or the dysrhythmia resolves. Standard measurement of cardiac enzymes is not useful and has no role in the diagnosis of blunt myocardial injury. If the patient is suspected of having a myocardial infarction or acute myocardial ischemia, then cardiac enzymes should be obtained and a cardiology consultation arranged.

Management of symptomatic blunt myocardial injury should be the same as for acute myocardial infarction. Hemopericardium may occur without tamponade and can be treated by pericardiocentesis. Tamponade in blunt cardiac trauma is often due to myocardial rupture or coronary artery laceration. Tamponade produces distended neck veins, shock, and cyanosis. Immediate thoracotomy and control of the injury are indicated. If cardiopulmonary arrest occurs before the patient can be transported to the operating room, emergency room thoracotomy with relief of tamponade should be performed. Treatment of injuries to the valves, papillary muscles, and septum must be individualized; and when tolerated, delayed repair is usually recommended.

Pericardial lacerations from stab wounds tend to seal and cause tamponade, whereas gunshot wounds frequently leave a sufficient pericardial opening for drainage. Gunshot wounds produce more extensive myocardial damage, multiple perforations, and massive bleeding into the pleural space. Hemothorax, shock, and exsanguination occur in nearly all cases of cardiac gunshot wounds. The clinical findings are those of tamponade or acute blood loss. Use of ultrasound and the FAST examination technique can reveal the presence of clinically significant blood in the pericardial space.

Treatment of penetrating cardiac injuries requires prompt thoracotomy, pericardial decompression, and control of hemorrhage. Most patients do not require cardiopulmonary bypass. The standard approach has been to repair the laceration using mattress sutures with pledgets while controlling hemorrhage with a finger on the heart. Suture control of cardiac lacerations may be technically difficult when working with a beating heart or in patients with large or multiple lacerations. Several studies have demonstrated that in most cases, emergency temporary control of hemorrhage from cardiac lacerations can be achieved with the use of a skin stapler (Figure 13–10). Following stabilization of the patient, the staples can be removed after definitive suture repair is performed in the operating room. Hemostatic sealants such as FloSeal offer significant promise as additional tools in the surgical armamentarium when dealing with lacerations to the heart or great vessels. Regardless of the approach utilized, care must be taken to avoid injury to the coronary arteries.

▲ **Figure 13–10.** Technique of cardiac stapling. Finger pressure (not shown) is used to maintain hemostasis during stapling. (Reproduced, with permission, from Macho JR, Markison RE, Schechter WP: Cardiac stapling in the management of penetrating injuries of the heart: rapid control of hemorrhage and decreased risk of personal contamination. *J Trauma*. 1993;34:711.)

Pericardiocentesis or creation of a pericardial window is reserved for selected cases when the diagnosis is uncertain or in preparation for thoracotomy. In approximately 75% of cases of stab wounds and 35% of cases of gunshot cardiac wounds, the patient survives the operation. However, it is estimated that 80%-90% of patients with gunshot wounds of the heart do not reach the hospital.

F. Esophagus

Anatomically, the esophagus is well protected, and perforation from external penetrating trauma is relatively infrequent. Blunt injuries are exceedingly rare. The most common symptom of esophageal perforation is pain; fever develops within hours in most patients. Hematemesis, hoarseness, dysphagia, or respiratory distress may also be present. Physical findings include shock, local tenderness, subcutaneous emphysema, or Hamman sign (pericardial or mediastinal “crunch” synchronous with cardiac sounds). Leukocytosis occurs soon after injury. X-ray findings on plain chest films include evidence of a foreign body or missile and mediastinal air or widening. Pleural effusion or

hydropneumothorax is frequently seen, usually on the left side. Contrast x-rays of the esophagus should be performed but are positive in only about 70% of proven perforations.

A nasogastric tube should be passed to evacuate gastric contents. If recognized within 24-48 hours after injury, the esophageal perforation should be closed and pleural drainage instituted with large-bore catheters. Repair of these perforations requires special techniques that include buttressing of the esophageal closure with pleural or pericardial flaps; pedicles of intercostal, diaphragmatic, or cervical strap muscles; and serosal patches from stomach or jejunum. Illness and death are due to mediastinal and pleural infection.

G. Thoracic Duct

Chylothorax and chylopericardium are rare complications of trauma but are difficult to manage when they occur. Penetrating injuries of the neck, thorax, or upper abdomen can injure the thoracic duct or its major tributaries.

Symptoms are due to mechanical effects of the accumulations (eg, shortness of breath from lung collapse or low cardiac output from tamponade). The diagnosis is established when the fluid is shown to have characteristics of chyle.

The patient should be maintained on a fat-free, high-carbohydrate, high-protein diet and the effusion aspirated. Chest tube drainage should be instituted if the effusion recurs. Lipid-free total parenteral nutrition with no oral intake may be effective in treating persistent leaks. Three or 4 weeks of conservative treatment usually are curative. If daily chyle loss exceeds 1500 mL for 5 successive days or persists after 2-3 weeks of conservative treatment, the thoracic duct should be ligated via a right thoracotomy. Intraoperative identification of the leak may be facilitated by preoperative administration of fat-containing a lipophilic dye.

H. Diaphragm

Penetrating injuries of the diaphragm outnumber blunt diaphragmatic injuries by a ratio of at least 6:1. Diaphragmatic lacerations occur in 10%-15% of cases of penetrating wounds to the chest and in as many as 40% of cases of penetrating trauma to the left chest. Injuries to the right diaphragm are more common than previously thought. The injury is rarely obvious. Wounds of the diaphragm must not be overlooked because they rarely heal spontaneously and because herniation of abdominal viscera into the chest can occur with catastrophic complications either immediately or years after the injuries.

Associated injuries are usually present, and as many as 25% of patients are in shock when first seen. There may be abdominal tenderness, dyspnea, shoulder pain, or unilateral breath sounds. The diagnosis is often missed. Although chest radiography is a sensitive diagnostic tool, it may be entirely normal in 40% of cases. The most common finding is ipsilateral hemothorax, which is present in about

50% of patients. Occasionally, a distended, herniated stomach is confused with a pneumothorax. Passage of a nasogastric tube before x-rays will help to identify an intrathoracic stomach. CT scan or contrast x-rays may be necessary to establish the diagnosis in some cases. Newer generation helical CT scanners that allow sagittal reformatting can be helpful in definitively diagnosing diaphragmatic injury. Laparoscopy is a useful but invasive technique for detecting occult diaphragmatic injuries in patients who have no other indications for formal laparotomy.

Once the diagnosis is made, a transabdominal surgical approach should be used in cases of acute rupture. Laparoscopic suturing for repair of the injury may be possible in selected cases. The diaphragm should be reapproximated and closed with interrupted or running non-absorbable sutures. Chronic herniation is associated with adhesions of the affected viscera to the thoracic structures and should be approached via thoracotomy, with the addition of a separate laparotomy when indicated. These cases can be quite challenging and appropriate preoperative planning is recommended.

ABDOMINAL INJURIES

The specific type of abdominal injury varies according to whether the trauma is penetrating or blunt. Blunt injuries predominate in rural areas, while penetrating injuries are more common in urban areas. The mechanism of injury in blunt trauma is rapid deceleration, and noncompliant organs such as the liver, spleen, pancreas, and kidneys are at greater risk of injury due to parenchymal fracture. Occasionally, hollow viscous organs may be injured, with the duodenum and urinary bladder being particularly susceptible. The small bowel occupies a large portion of the total abdominal volume and is more likely to be injured by penetrating trauma. Most blunt abdominal injuries are related to motor vehicle accidents. Although the use of restraints

has been associated with a decrease in the incidence of head, chest, and solid organ injuries, their use may be associated with pancreatic, mesenteric, and intestinal injuries due to organ compression against the spinal column. These injuries should be considered in patients who have signs of seat belt-related contusions of the abdominal wall. Internal abdominal injury may be present in as many as 30% of these cases. In any abdominal trauma, hemoperitoneum may not manifest clinical signs of peritoneal irritation, particularly in patients with other distracting injuries or depressed mental status. Retroperitoneal injury may be more subtle and difficult to diagnose during the initial evaluation.

Deaths from abdominal trauma result largely from early severe hemorrhage and coagulopathy or from later sepsis. Most deaths from abdominal trauma are preventable. Patients at risk of abdominal injury should undergo prompt and thorough evaluation. In most trauma centers, after physical examination, the initial diagnostic evaluation includes bedside FAST and portable radiographs of the pelvis and chest to assess for other potential sites of bleeding. In unstable patients who cannot be adequately evaluated with FAST due to size, technical problems, or subcutaneous air, diagnostic peritoneal lavage is warranted. After the initial FAST examination, patients who are stable or who respond to initial fluid resuscitation should have a CT scan of the abdomen and pelvis to evaluate for intra-abdominal and retroperitoneal injuries. Patients with persistent hypotension requiring fluid and blood resuscitation in the face of a positive FAST or diagnostic peritoneal lavage should be transported to the operating room emergently for exploratory laparotomy.

In some cases, dramatic physical findings may be due to abdominal wall injury in the absence of intraperitoneal injury. If the results of diagnostic studies are equivocal, diagnostic laparoscopy or exploratory laparotomy should be considered, since they may be lifesaving if serious injuries are identified early. Evaluation always includes a comprehensive physical examination with pelvic and rectal examinations included and may require specific laboratory and radiologic tests (eg, retrograde urethrogram or cystogram, rigid sigmoidoscopy, abdominal CT). Serial physical examinations may be necessary to detect subtle findings.

► Types of Injuries

A. Penetrating Trauma

Penetrating injuries to the abdomen that present with shock or ongoing resuscitation require prompt exploration. Lacerations of major blood vessels or the liver can cause severe and early shock. Penetrating injuries of the spleen, pancreas, or kidneys usually do not bleed massively unless a major vessel to the organ (eg, the renal artery) is damaged. Bleeding must be controlled promptly with packing and appropriate clamping for vascular control. A patient in

shock with a penetrating injury of the abdomen who does not respond to 2 L of crystalloid fluid resuscitation should be operated on immediately following chest x-ray and switched blood product resuscitation.

Patients with hollow visceral injuries may have very few physical signs initially but will progress to sepsis if the injuries are not recognized. Increasing abdominal tenderness demands surgical exploration. White blood cell count elevations and fever appearing several hours following injury are keys to early diagnosis.

The treatment of hemodynamically stable patients with penetrating injuries to the lower chest or abdomen varies. All surgeons agree that patients with signs of peritonitis or hypovolemia should undergo surgical exploration, but operative treatment is less certain for patients with no signs of peritonitis or sepsis who are cardiovascularly stable.

Most stab wounds of the lower chest or abdomen should be explored, since a delay in treatment of a hollow viscous perforation can result in severe sepsis. Some surgeons recommend a selective policy in the management of these patients. When the depth of injury is in doubt, local wound exploration may rule out peritoneal penetration. Laparoscopy has a role in the evaluation of penetrating injuries in experienced hands, but requires considerable diligence to avoid missed injuries. All gunshot wounds of the lower chest and abdomen should be explored, unless there is a likely superficial scything wound, because the incidence of injury to major intra-abdominal structures exceeds 90% in such cases.

B. Blunt Trauma

A major advance in management of blunt trauma has been the FAST examination. Ultrasound has proven to be an ideal modality in the immediate evaluation of the trauma patient because it is rapid and accurate for the detection of intra-abdominal fluid or blood and is readily repeatable. It provides valuable information that augments the surgeon's diagnostic capabilities. Since its introduction in North America in 1989, ultrasonography has become commonplace, and a recent survey reports that 78% of United States trauma centers routinely use the FAST examination in the evaluation of patients.

The goal of the FAST examination is the identification of abnormal collections of blood or fluid. In this regard, it obviates the need for diagnostic peritoneal lavage. The primary focus is on the peritoneal cavity, but attention is also directed to the pericardium and to the pleural space. Unclothed blood or fluid allows transmission of ultrasound waves without echoes and thus appears black (Figure 13-11). In the standard FAST examination, four areas are scanned: the right upper quadrant, the subxiphoid area, the left upper quadrant, and the pelvis (Figure 13-12). Most surgeons recommend scanning initially in the right upper quadrant because

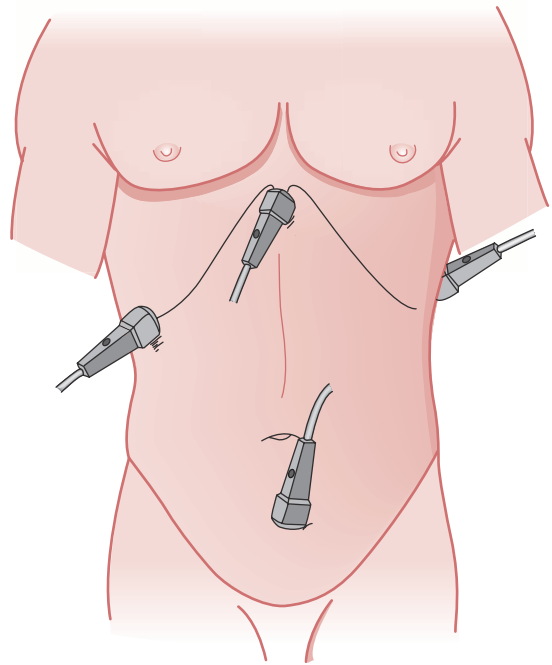

▲ **Figure 13-11.** A. Normal ultrasound of the right upper quadrant. B. Right upper quadrant ultrasound revealing blood between the liver and the kidney and between the liver and the diaphragm. (Courtesy of San Francisco General Hospital.)

more than half of the positive tests will reveal blood or fluid in this area. Unstable patients with a positive FAST examination should undergo urgent exploratory laparotomy.

The other diagnostic procedures most commonly used in patients without obvious indications for immediate laparotomy include diagnostic peritoneal lavage, CT scanning, and diagnostic laparoscopy.

► Diagnostic Peritoneal Lavage

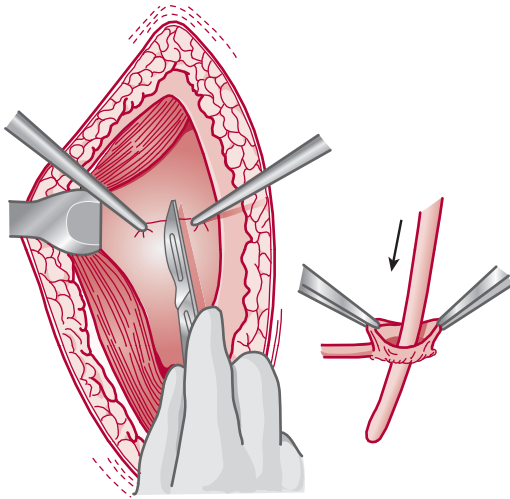

Diagnostic peritoneal lavage is designed to detect the presence of intraperitoneal blood. Although its use has decreased to virtually nil at many centers with the use of the FAST examination, it is still an important test in certain circumstances because of its high sensitivity for the presence

▲ **Figure 13-12.** Transducer positions for FAST. Pericardial area, right and left upper quadrants, and pelvis. (Reproduced, with permission, from Rozycki GS et al. Surgeon-performed ultrasound for the assessment of truncal injuries: lessons learned from 1540 patients. *Ann Surg.* 1998;228:557.)

of blood. Additional determinations of leukocytes, Gram stain, particulate matter, or amylase in the lavage fluid may indicate the presence of a bowel injury. Drainage of lavage fluid from a chest tube or urinary catheter may indicate a lacerated diaphragm or bladder. Lavage can be performed easily and rapidly, with minimal cost and morbidity. It is an invasive procedure that will affect the findings on physical examination and should be performed by a surgeon.

The procedure is neither qualitative nor quantitative. It cannot identify the source of hemorrhage, and relatively small amounts of intraperitoneal bleeding may result in a positive study. It may not detect small and large injuries to the diaphragm and cannot rule out injury to the bowel or retroperitoneal organs. The overall indications for diagnostic peritoneal lavage include abdominal pain or tenderness, low abdominal rib fractures, unexplained hypotension, spinal or pelvic fractures, paraplegia or quadriplegia, and assessment hampered by altered mental status due to neurologic injury or intoxication. Despite the many potential indications, FAST followed by abdominal pelvic CT scanning has replaced the need for most diagnostic

▲ **Figure 13-13.** Diagnostic peritoneal lavage.

peritoneal lavages. The only contraindication is a need for emergency laparotomy.

The procedure may be performed with careful technique on patients with prior abdominal surgery and in pregnant patients. It should usually be performed through a small infraumbilical incision with placement of the catheter under direct vision (Figure 13-13). In pregnant patients and those with pelvic fractures, a supraumbilical approach is indicated. Closed techniques of catheter placement utilizing trocars or guidewires have been shown to be almost as safe as the open technique, but the rate of failure with the closed technique is higher, thus eliminating most of the potential advantage. After placement of the catheter, 1 L of normal saline solution is instilled into the peritoneal cavity and then allowed to drain by gravity. At least 200 mL of lavage fluid should be recovered to allow for accurate interpretation. A portion of the recovered fluid is sent for laboratory analysis of cell counts, the presence of particulate matter, and amylase. Criteria for evaluation of results are summarized in Table 13-3.

► **Computed Tomography**

Computed tomography (CT) is noninvasive, qualitative, sensitive, and accurate for the diagnosis of intra-abdominal and retroperitoneal injuries. Modern multi-slice spiral scanners have greatly decreased the time required for obtaining high-quality images. However, CT scanning remains expensive, involves the use of intravenous contrast administration, exposes the patient to radiation, and requires an experienced radiologist for proper interpretation of the scans. CT scanning also involves transport from the acute care area and should not be attempted in the unstable patient.

Table 13-3. Criteria for evaluation of peritoneal lavage fluid.

Positive
= 100,000 red cells/ μ L
= 500 white cells/ μ L
= 175 units amylase/dL
Bacteria on Gram-stained smear
Bile
Food particles
Intermediate
Pink fluid on free aspiration
50,000–100,000 red cells/ μ L in blunt trauma
100–500 white cells/ μ L
75–175 units amylase/dL
Negative
Clear aspirate
< 100 white cells/ μ L
< 75 units amylase/dL

Computed tomography scanning has a primary role in defining the location and magnitude of intra-abdominal injuries related to blunt trauma. It has the advantage of detecting most retroperitoneal injuries, but it may not identify all gastrointestinal injuries. The information provided on the magnitude of injury allows for potential nonoperative management of patients with solid organ injuries. Nonsurgical therapy is now used in more than 80% of blunt liver and spleen injuries. Detection of high-grade solid organ injuries or bleeding pelvic fractures by CT in relatively stable patients can also lead to other minimally invasive interventions, such as angiographic embolization, which increases the success of nonoperative management. Table 13-4 compares the time, costs, advantages, and disadvantages of nonoperative methods used for evaluation of the injured abdomen.

► **Diagnostic Laparoscopy**

Laparoscopy has an important diagnostic role in stable patients with penetrating abdominal trauma. It can quickly establish whether peritoneal penetration has occurred and thus reduce the number of negative and nontherapeutic trauma laparotomies performed. In selected patients, therapeutic laparoscopy has been used to repair injuries to the bowel and diaphragm. This approach offers all the advantages and disadvantages of minimally invasive surgery. Laparoscopy has also been applied safely and effectively as a screening tool in stable patients with blunt abdominal trauma. However, its use in this context requires further study. Concerns regarding the use of laparoscopy in trauma include the possibility of missed injuries, air embolism, hemodynamic instability related to the pneumoperitoneum, and complications related to trocar placement.

Table 13–4. Comparison of diagnostic methods for abdominal trauma.

Methods	Time/Cost	Advantages/Disadvantages
Physical examination	Quick/no cost	Useful for serial examinations, very limited by other injuries, coma, drug intoxication, poor sensitivity and specificity.
Diagnostic peritoneal lavage (DPL)	Quick/inexpensive	Rapid results in unstable patient but invasive and may be overly sensitive for blood and not specific for site of injury; requires experience and may be limited if previous surgery.
Focused assessment with sonography for trauma (FAST)	Quick/inexpensive	Rapid detection of intra-abdominal fluid and pericardial tamponade; may be limited by operator experience, large body habitus, subcutaneous air; poor for detection of bowel injury. Fairly sensitive but not highly specific.
Helical computerized abdominal tomography (CT)	Slower/expensive	Most specific for site of injury and can evaluate retroperitoneum; very good sensitivity but may miss bowel injury; risk of reaction to contrast dye.

► Exploratory Laparotomy

The three main indications for exploration of the abdomen following blunt trauma are peritonitis, ongoing intra-abdominal hemorrhage, and the presence of other injuries known to be frequently associated with intra-abdominal injuries. Peritonitis after blunt abdominal trauma is rare and can arise from rupture of a hollow organ, such as the duodenum, bladder, intestine, or gallbladder; from pancreatic injury; or occasionally from the presence of retroperitoneal blood.

Emergency abdominal exploration should be considered for patients with profound hypovolemic shock and a normal chest x-ray unless extra-abdominal blood loss is sufficient to account for the hypovolemia. In most cases, a rapidly performed FAST examination or peritoneal lavage will confirm the diagnosis of intraperitoneal hemorrhage. Patients with blunt trauma and hypovolemia should be examined first for intra-abdominal bleeding even if there is no overt

evidence of abdominal trauma. For example, hypovolemia may be due to loss of blood from a large scalp laceration, but it may also be due to unsuspected rupture of the spleen. Hemoperitoneum may present with no signs except hypovolemia. The abdomen may be flat and nontender. Patients whose extra-abdominal bleeding has been controlled should respond to initial fluid resuscitation with an adequate urine output and stabilization of vital signs. If signs of hypovolemia (tachycardia, hypotension, low urine output, metabolic acidosis) recur, intra-abdominal bleeding must be considered to be the cause.

Other injuries frequently associated with abdominal trauma are rib fractures, pelvic fractures, abdominal wall injuries, and fractures of the thoracolumbar spine (eg, 20% of patients with fractures of the left lower ribs have a splenic laceration).

► Treatment

A. Splenic Injuries

The spleen is the most commonly injured organ in cases of blunt abdominal trauma. Splenic injuries in children are typically managed without surgery. Currently, 50%-88% of adults with blunt splenic injuries are also treated nonoperatively. Patients must be monitored closely and immediate availability of an operating room is essential. Patients should be evaluated frequently for the possibility of other missed injuries or recurrent bleeding. Stable patients who have high-grade splenic injuries on CT scan or have evidence of ongoing bleeding on CT scan may be candidates for angiographic embolization. Unstable patients with splenic injuries should undergo splenectomy or attempts at splenic repair if appropriate.

Associated injuries are uncommon for patients in whom nonoperative management is attempted. In unstable patients, emergent celiotomy should be performed. Splenic salvage procedures such as splenorrhaphy, partial resection, wrapping with Vicryl mesh, or topical therapy with hemostatic agents should be attempted if the patient's condition permits and there are a limited number of concomitant abdominal injuries. In the face of multiple injuries, ongoing cardiovascular compromise, or vascular avulsion of the spleen, total splenectomy is indicated. Following splenectomy, immunizations against *Pneumococcus* species, *Meningococcus* species, and *Haemophilus influenzae* are recommended postoperatively to reduce the risk of overwhelming postsplenectomy sepsis.

B. Liver Injuries

Approximately 85% of all patients with blunt hepatic trauma are stable following resuscitation. In this group, nonoperative management has been proven to be superior to open

operation in avoiding complications and decreasing mortality. The primary requirement for nonoperative therapy is continued hemodynamic stability. Patients are monitored in the ICU with frequent assessment of vital signs and serial hematocrits. If transfusion with more than two units of PRBC is required, arteriography with possible embolization of bleeding vessels should be considered.

Nonoperative management of blunt hepatic trauma is successful in more than 90% of cases. With more severe injuries, repeat CT scanning may be necessary to evaluate for possible complications such as parenchymal infarction, hematoma, or biloma. Extrahepatic bile collections should generally be drained percutaneously. Intrahepatic collections of blood and bile usually resolve spontaneously over the course of several months. Patients with high-grade liver injuries have up to a 40% chance of developing bile leaks from the injured liver bed. Nuclear medicine scanning to delineate biliary flow with derivatives of iminodiacetic acid is useful in detection of bile leaks and should be done in the first few days after injury to reduce complications. Laparoscopic washout and placement of drains is an option for patients found to have evidence of extrahepatic bile leakage on HIDA scan. In addition, 1%-4% of patients with blunt liver injury will have injuries to other abdominal organs, which should prompt the clinician to consider the possibility of missed injury in patients who develop abdominal sepsis after injury.

Severe liver injury may result in exsanguinating hemorrhage with hypotension that does not respond to fluid resuscitation. For these patients, operative exploration is warranted. At laparotomy, immediate efforts should be directed to control of hemorrhage and stabilization of the patient by restoration of circulating blood volume. The initial techniques for the control of hepatic hemorrhage include manual compression, perihepatic packing, and the Pringle maneuver. Manual compression or perihepatic packing with laparotomy pads will control hemorrhage in most cases. The Pringle maneuver—clamping of the hepatic pedicle—should be performed when life-threatening hemorrhage is unresponsive to packing; it will control all hepatic bleeding except that from the hepatic veins or the intrahepatic vena cava. In most cases, the Pringle maneuver should not be maintained for more than 1 hour in order to prevent ischemic damage to the liver. Hepatic bleeding can be controlled by suture ligation or application of surgical clips directly to the bleeding vessels. Electrocautery or the argon beam coagulator can be used to control bleeding from raw surfaces of the liver. Microfibrillar collagen or hemostatic gelatin foam sponges soaked in thrombin can be applied to bleeding areas with pressure to control diffuse capillary bleeding. Fibrin glue has been used in treating both superficial and deep lacerations and appears to be the most effective topical agent but reports of fatal anaphylactic reactions have limited its use. When injury

has already resulted in massive blood loss, packing of the abdomen with laparotomy pads and planned reexploration should be considered. Avoidance of the lethal triad of hypothermia, acidosis, and coagulopathy are paramount to successful surgical treatment of a major liver injury and may require further resuscitation in the ICU prior to return to the operating room. At the time of reexploration in 24-48 hours, hemorrhage is usually well controlled and can be managed with individual vessel ligation and debridement. Evidence of persistent hemorrhage should prompt earlier reexploration. Angiographic embolization may be a useful adjunct to surgical packing if arterial hemorrhage is still present or not well controlled. Rarely, selective hepatic artery ligation, resectional debridement, or hepatic lobectomy may be required to control hemorrhage. The raw surface of the liver may then be covered with omentum. Drains should always be used. Decompression of the biliary system is contraindicated, though sutures or clips should be used to control intraparenchymal bile ducts.

Hepatic vein injuries frequently bleed massively. Hepatic venous or intrahepatic vena caval injury should be suspected immediately when the Pringle maneuver fails to control bleeding. Several techniques have been described for isolation of the intrahepatic cava prior to attempted repair of these injuries. Unfortunately, even with the use of these techniques, mortality remains very high.

C. Biliary Tract Injuries

Biliary tract injuries are relatively uncommon, particularly for blunt trauma. Injury to the gallbladder should be treated in most cases by cholecystectomy. Minor injuries to the common bile duct can be treated by suture closure and insertion of a T-tube. Avulsion of the common bile duct or in combination with duodenal or ampullary trauma may require choledochojejunostomy in conjunction with total or partial pancreatectomy, duodenectomy, or other diversion procedures. Segmental loss of the common bile duct is best treated by choledochojejunostomy and drainage.

D. Pancreatic Injuries

Pancreatic injuries may present with few clinical manifestations. Injury should be suspected whenever the upper abdomen has been traumatized, especially when serum amylase and lipase levels remain persistently elevated. The best diagnostic study for pancreatic injury (other than exploratory celiotomy) is CT scan of the abdomen. Peritoneal lavage is usually not helpful. Upper gastrointestinal studies with water-soluble contrast material may suggest pancreatic injury by demonstrating widening of the duodenal C-loop. Endoscopic retrograde cholangiopancreatography may be used in selected cases to evaluate for injuries to the major ducts.

The treatment of pancreatic injury depends on its grade and extent. Minor injuries not involving a major duct may be treated nonoperatively. Moderate injuries usually require operative exploration, debridement, and the placement of external drains. More severe injuries, including those with major duct injury or transection of the gland, may require distal resection or external drainage. Traumatic injuries to the head of the pancreas often include associated vascular injuries and carry a high mortality rate. Efforts should be directed at controlling hemorrhage, and drains can be placed in the area of the pancreatic injury. In most cases, pancreaticoduodenectomy should not be attempted in the setting of an unstable patient with multiple injuries.

The late complications of pancreatic injuries include pseudocyst, pancreatic fistula, and pancreatic abscess. Patients treated without resection may require reoperation for resection or Roux-en-Y internal gastrointestinal drainage.

E. Gastrointestinal Tract Injuries

Most injuries of the stomach can be repaired. Large injuries, such as those from shotgun blasts, may require subtotal or total resection. Failure to identify posterior stomach wall injuries by opening the lesser space is a pitfall to guard against.

Duodenal injuries may not be evident from the initial physical examination or x-ray studies. Abdominal films will reveal retroperitoneal gas within 6 hours after injury in most patients. CT performed with a contrast agent will frequently identify the site of perforation. Most duodenal injuries can be treated with lateral repair. Some may require resection with end-to-end anastomosis. Occasionally, pancreaticoduodenectomy or duodenal diversion with gastrojejunostomy and pyloric closure is required to manage a severe injury. A duodenostomy tube is useful in decompressing the duodenum and can be used to control a fistula caused by an injury. Jejunal or omental patches may also aid in preventing a suture line leak. A distal jejunostomy feeding tube is helpful in the long-term recovery from these injuries.

Duodenal hematomas causing high-grade obstruction usually resolve with nonoperative management. Patients may require total parenteral nutrition. In some cases, a small-bore enteral feeding tube can be passed beyond the area of obstruction utilizing interventional radiology techniques. Large hematomas may require operative evacuation, particularly when the obstruction lasts for more than 10-14 days and a persistent hematoma is seen on CT scan.

Most small bowel injuries can be treated with a two-layer sutured closure, though mesenteric injuries leading to devascularized segments of small bowel will require resection. The underlying principle is to preserve as much small bowel as possible.

For injuries to the colon, the past approach has been to divert the fecal stream or exteriorize the injury. However,

more recent studies have shown a higher complication rate with colostomy formation than with primary repair. Wounds should be considered for primary repair if the blood supply is not compromised. Primary repair is more likely to be associated with complications in patients with ongoing shock, in those requiring multiple transfusions, if more than 6 hours elapse between injury and operation, or if there is gross contamination or peritonitis. Small, clean rectal injuries may be closed primarily if conditions are favorable. The treatment of larger rectal wounds involving pelvic fracture should include proximal diversion. Insertion of presacral drains is optional. In this latter case, direct repair of the rectal injury is not mandatory but should be performed if it can be readily exposed. Irrigation of the distal stump should be performed in most cases unless it would further contaminate the pelvic space.

F. Abdominal Wall Injuries

Abdominal wall injuries from blunt trauma are most often due to shear forces, such as being run over by the wheels of a tractor or bus. The shearing often devitalizes the subcutaneous tissue and skin, and if debridement is delayed, a serious necrotizing anaerobic infection may develop. The management of penetrating abdominal wall injuries is usually straightforward. Debridement and irrigation are appropriate surgical treatments. Every effort must be made to remove foreign material, shreds of clothing, necrotic muscle, and soft tissue. Abdominal wall defects may require insertion of absorbable mesh or coverage with a myocutaneous flap.

G. Genitourinary Tract Injuries

The most commonly injured genitourinary tract organs are the male genitalia, the uterus, the urethra, the bladder, the ureters, and the kidneys. The workup for these injuries consists primarily of radiologic examinations, which may include abdominal CT scan, cystogram, or retrograde urethrogram. In unstable patients with associated injuries, it may not be possible to obtain these studies prior to emergency laparotomy. In these patients, an intraoperative single-shot intravenous urogram is safe and of high quality in most cases. This study often provides important information that facilitates rapid and accurate decision making. It can confirm function in the noninjured kidney and help in identifying blunt renal injuries that may be safely observed.

1. Bladder injuries—Rupture of the bladder, like urethral disruption, is frequently associated with pelvic fractures. Seventy-five percent of ruptures are extraperitoneal and 25% intraperitoneal. Intraperitoneal bladder ruptures should be repaired through a mid-line abdominal incision. Rupture of the anterior wall of the bladder can be repaired by direct suture; rupture of the posterior wall can be repaired from inside the bladder after an opening has been made in the

anterior wall. Care should be taken to avoid entering a pelvic hematoma. Retroperitoneal injuries can often be treated with urinary drainage, depending on the size of injury. Postoperatively, urine should be diverted for at least 7 days.

2. Urethral injuries—Membranous prostatic urethral disruption is often associated with pelvic fractures or deceleration injuries. Blood at the urethral meatus associated with scrotal hematoma and high-riding prostate on digital rectal examination are the classic signs of injury to the male urethra. The prostate may be elevated superiorly by the pelvic hematoma and will be free-riding and high on rectal examination. If these signs are present, a retrograde urethrogram should be performed before attempts at catheter placement, which may convert an incomplete injury to a complete disruption. If an injury is present, urethrography will demonstrate free extravasation of contrast from the urethra into the preperitoneal space.

Penetrating injuries are best treated with primary repair. Suprapubic bladder drainage and delayed reconstruction of blunt urethral disruption injuries are safe and effective in most cases. Immediate realignment with cystourethroscopy and placement of a urethral catheter is an attractive, minimally invasive alternative. In cases of partial disruption, it has been shown to result in stricture-free outcomes.

Major injuries to the bulbous or penile urethra should be managed by suprapubic urinary diversion. A voiding cystourethrogram may later reveal a stricture, but operative correction or dilation is usually not necessary.

3. Renal injuries—Advances in the imaging and staging of renal trauma as well as in treatment strategies have decreased the need for operation and increased renal preservation. More than half of renal injuries can be treated nonoperatively. Management criteria are based on radiographic, laboratory, and clinical findings. Nonoperative treatment of penetrating renal lacerations is appropriate in hemodynamically stable patients without other injuries. Small to moderate injuries can be treated nonoperatively, but severe injuries are associated with a significant risk of delayed bleeding if treated expectantly. Stable patients may be candidates for angiographic procedures to control bleeding, revascularize a dissection or injuries leading to vessel thrombosis. Renal exploration should be considered if laparotomy is indicated for associated injuries. A mid-line transabdominal approach is preferred. The renal artery and vein are secured before the Gerota fascia is opened. The injury should be managed by suture repair, partial nephrectomy, or, rarely, total nephrectomy. Pedicle grafts of omentum or free peritoneal patch grafts can be used to cover defects. Renal vascular injuries require immediate operation to save the kidney. Meticulous attention to reconstructive techniques in renal exploration can ensure an excellent renal salvage rate. Adherence to the principles of early proximal vascular control, debridement of devitalized tissue, hemostasis, closure of the collecting

system, and coverage of the defect will maximize the salvage of renal function while minimizing potential complications.

Perirenal hematomas found incidentally at celiotomy should be explored if they are expanding, pulsatile, or not contained by retroperitoneal tissues or if a preexploration urogram shows extensive urinary extravasation.

4. Injuries to the male genitalia—Injuries to the male genitalia usually result in skin loss only; the penis, penile urethra, and testes are usually spared. Skin loss from the penis should be treated with a primary skin graft. Scrotal skin loss should be treated by delayed reconstruction; an exposed testis can be temporarily protected by placing it in a subcutaneous tissue pocket in the thigh.

5. Uterine injuries—Injuries of the female reproductive organs are infrequent except in combination with genitourinary or rectal trauma. Injuries to the uterine fundus usually can be repaired with absorbable sutures; drainage is not necessary. In more extensive injuries, hysterectomy may be preferable. The vaginal cuff may be left open for drainage, particularly if there is an associated urinary tract or rectal injury. Injuries involving the uterus in a pregnant woman usually result in death of the fetus. Bleeding may be massive in such patients, particularly in women approaching parturition. Cesarean section plus hysterectomy may be the only alternative.

6. Ureteral injuries—Ureteral injuries are easily missed because urinalysis and imaging studies can be unreliable. Most such injuries can be successfully reconstructed by primary repair over stents, ureteral reimplantations, or ureteroureterostomy depending on the level of injury.

VASCULAR INJURIES

► Historical Perspective

Much of our knowledge of blood vessel injuries was developed during the course of military conflicts in the 20th century. Although techniques for the management of vascular injuries were in use prior to World War I, arterial ligation to save a life rather than arterial repair to salvage a limb was generally employed, and amputation frequently resulted after vascular injury.

The current mortality rate for lower extremity arterial injury is low in both civilian and recent military series: 2%-6%. Limb salvage rates in civilian series are 85%-90%, with best results obtained for interposition vein grafts. Ligation, need for reoperation, and failed revascularization are associated with worse outcomes and higher amputation rates. Low mortality and improved limb salvage is a result of more rapid transport of injured people, improved blood volume replacement, selective use of arteriography and shunts, and better operative techniques.

► The Epidemiology of Vascular Trauma

The epidemiology of vascular trauma has been studied in three different settings: military conflicts, large urban locations, and, to a lesser extent, rural areas. The types of injuries seen in civilian vascular trauma, once much different from military settings, are now more similar to military wounds. The incidence is increasing as a result of the rise in urban violence, motor vehicle crashes, and iatrogenic injuries owing to more frequent use of minimally invasive diagnostic and therapeutic procedures.

Peripheral vascular trauma typically occurs in young men between the ages of 20 and 40 years. In both urban and rural environments, penetrating mechanisms dominate, accounting for 50%-90% of vascular injuries. Because many vascular injuries of the head, neck, and torso are immediately fatal, most patients with vascular injuries surviving transport have extremity trauma. This is especially true in the military experience where extremity vascular injuries account for approximately 90% of all arterial trauma. In the urban civilian experience, extremity vascular injuries comprise about 50% of arterial injuries. In rural vascular trauma, blunt injuries occur more frequently than in urban populations.

Mortality and utilization of medical resources is higher among patients with vascular injuries than among patients

who do not have blood vessel injuries. Vascular injuries from automobile accidents or falls from heights and crush injuries account for up to half of all noniatrogenic vascular injuries in US hospitals. The likelihood of vascular injury after blunt trauma correlates with the overall severity of the injury and the presence of specific orthopedic injuries; for example, up to 45% of patients with posterior knee dislocations or severe instability from high-velocity blunt trauma sustain popliteal artery injury.

The number of iatrogenic vascular injuries has risen dramatically in recent decades. Most involve diagnostic and therapeutic procedures utilizing the femoral (less frequently the brachial or axillary) vessels, which serve as percutaneous access routes. In order of decreasing frequency, injuries include hemorrhage and hematoma, pseudoaneurysm, arteriovenous fistula formation, vessel thrombosis, and embolization. Rates of injury range from 0.5% for diagnostic procedures to as high as 10% for therapeutic procedures involving large catheters. Increasing age, female gender, use of anticoagulation, and the presence of atherosclerosis increase the risk of these complications. Complications remote from the puncture site include vessel rupture and dissection. Operative procedures (especially hepatic and pancreaticobiliary surgery) are associated with iatrogenic vascular trauma. In addition, anterior and retroperitoneal approaches to the lumbar spine and other orthopedic procedures such as total joint replacement and arthroscopy can produce vascular injuries.

► Types of Injuries

A. Penetrating Trauma

The local and regional effects of penetrating wounds are determined by the mechanism of vessel injury. Stab wounds, low-velocity (< 2000 ft/s) bullet wounds, iatrogenic injuries from percutaneous catheterization, and inadvertent intra-arterial injection of drugs produce less soft tissue injury and disrupt collateral circulation less than injuries from sources with greater kinetic energy. The high-velocity missiles responsible for war wounds produce more extensive vascular injuries, which involve massive destruction and contamination of surrounding tissues. The temporary cavitation effect of high-velocity missiles causes additional trauma to the ends of severed arteries and may produce arterial thrombosis due to disrupted intima even when the artery has not been directly hit. This blast effect can also draw material such as clothing, dirt, or pieces of skin along the wound tract, which contributes to the risk of infection. Associated injuries are often major determinants of the eventual outcome.

Shotgun blasts present special problems. Although muzzle velocity is low (about 1200 ft/s), the multiple pellets produce widespread damage, and shotgun wadding entering the wound enhances the likelihood of infection. Similar to

high-velocity injuries, the damage is often much greater than might be anticipated from inspection of the entry wound. Moreover, the multiplicity of potential sites of arterial damage often mandates diagnostic arteriography even in the presence of obvious arterial insufficiency.

B. Blunt Trauma

Motor vehicle accidents are a major cause of blunt vascular trauma. Multiple injuries include fractures and dislocations; and while direct vascular injury may occur, in most instances the damage is indirect due to fractures. This is especially likely to occur with fractures near joints, where vessels are relatively fixed and vulnerable to shear forces. For example, the popliteal artery and vein are frequently injured in association with posterior dislocation of the knee. Fractures of large heavy bones such as the femur or tibia transmit forces that have cavitation effects similar to those caused by high-velocity bullets. There is extensive damage to soft tissues and neurovascular structures, and edema formation interferes with evaluation of pulses. Delay in diagnosis and the presence of associated injuries decrease the chances of limb salvage. Contusions or crush injuries may result in complete or partial disruption of arteries, producing intimal flaps or intramural hematomas that impede blood flow.

Blunt thoracic aortic injury (BTAI) is a serious traumatic injury that continues to have a high initial mortality and is associated with modern high-speed methods of transportation or significant falls. Autopsy data from cases of fatal BTAI demonstrated that 57% of patients were dead at the scene or on arrival to the hospital, 37% died during the first 4 hours at the hospital, and only 6% died after 4 hours in the hospital. The disruption generally occurs at the aortic isthmus (between the left subclavian artery and the ligamentum arteriosum) due to a deceleration injury in which the heart, the ascending aorta, and the transverse arch continue to move forward while movement of the isthmus and the descending aorta is limited by their posterior attachments. Clinical findings associated with traumatic rupture of the thoracic aorta are listed in Table 13-5 and radiographic

Table 13-5. Clinical features of traumatic aortic rupture.

History of high-speed deceleration injury
Flail chest
Fractured sternum
Superior vena cava syndrome
Multiple or first or second rib fractures
Upper extremity hypertension or pulse deficits
Hematoma in the carotid sheaths
Interscapular bruits
Hoarseness with normal larynx

Table 13-6. Radiographic features of traumatic aortic rupture.

Widening of mediastinum
Fractured sternum
Multiple or first rib or second rib fractures
Esophageal deviation to the right
Tracheal deviation to the right
Apical cap
Depression of left main stem bronchus
Obliteration of the aortic knob
Obliteration of the descending aorta
Obliteration of the aortopulmonary window
Obliteration of the medial left upper lobe
Widened paravertebral stripe

findings in Table 13-6. Blunt traumatic injury to the abdominal aorta is uncommon, but it has been reported from lap seat belt trauma.

Almost any vessel can be injured by blunt trauma, including the extracranial cerebral and visceral arteries. Blunt carotid arterial injuries are associated with mortality rates of 20%-30%, with over 50% of survivors having permanent, severe neurologic deficits. Whereas in the past vertebral artery injuries were considered innocuous, recent studies have reported devastating complications related to these injuries, including a 70% incidence of coexistent cervical spine injuries. Traumatic injury to the superior mesenteric artery is associated with a 50% mortality rate. The brachial and popliteal arteries, which cross joints and are exposed to direct trauma, are particularly susceptible to injury as a result of fractures and dislocations.

► Clinical Findings

A. Hemorrhage

When pulsatile external hemorrhage is present, the diagnosis of arterial injury is obvious, but when blood accumulates in deep tissues of the extremity, the thorax, abdomen, or retroperitoneum, the only manifestation may be shock. Peripheral vasoconstriction may make evaluation of peripheral pulses difficult until blood volume is restored. If the artery is completely severed, thrombus may form at the contracted vessel ends and a major vascular injury may not be suspected. The presence of arterial pulses distal to a penetrating wound does not preclude arterial injury; as many as 20% of patients with injuries of major arteries in an extremity have palpable pulses distal to the injury, either because the vessel has not thrombosed or because pulse waves are transmitted through soft clot. Conversely, the absence of a palpable pulse in an adequately resuscitated patient is a sensitive indicator of arterial injury.

B. Ischemia

Acute arterial insufficiency must be diagnosed promptly to prevent tissue loss. Ischemia should be suspected when the patient has one or more of the “five Ps”: pain, pallor, paralysis, paresthesia, or pulselessness. The susceptibility of different cells to hypoxia varies (eg, sudden occlusion of the carotid artery results in brain damage within minutes unless collateral circulation can maintain adequate perfusion, but a kidney can survive severe ischemia for up to an hour). Peripheral nerves are quite vulnerable to ischemia because they have a high basal energy requirement to maintain ion gradients over large membrane surfaces and because they have few glycogen stores. Hence, interruption of arterial flow for relatively short periods can result in nerve damage due to interrupted substrate delivery. In contrast, skeletal muscle is more tolerant of decreased arterial flow. Muscle can be ischemic for up to 4 hours without developing histologic changes. In general, complete interruption of all arterial inflow (including collateral blood supply) results in neuromuscular ischemic damage after 4-6 hours. Restoration of flow can actually worsen this damage as part of the reperfusion syndrome and can increase the severity of the original ischemic insult.

Prolonged ischemia can produce muscle necrosis and rhabdomyolysis, which releases potassium and myoglobin into the circulation. Myoglobin is an oxygen-transporting protein similar in structure to hemoglobin; it is innocuous unless it dissociates into heme, which is nephrotoxic in an acidic milieu. Precipitation of heme pigment also occurs when urine flow is reduced by hypotension or hypovolemia, obstructing renal tubules and worsening nephrotoxicity. Myoglobinemia can lead to acute tubular necrosis and renal failure, hyperkalemia, and a risk of life-threatening arrhythmias. Thus, in addition to limb loss, acute arterial ischemia can produce organ failure and death.

C. False Aneurysm

Disruption of an arterial wall as a result of trauma may lead to formation of a false aneurysm. The wall of a false aneurysm is composed primarily of fibrous tissue derived from nearby tissues, not arterial tissue. Because blood continues to flow past the fistulous opening, the extremity is seldom ischemic. False aneurysms may rupture at any time. They continue to expand because they lack vascular wall integrity. Spontaneous resolution of pseudoaneurysms larger than 3 cm is unlikely, and operative repair becomes increasingly difficult as the aneurysms increase in size and complexity with time. Symptoms gradually appear as a result of compression of adjacent nerves or collateral vessels or from rupture of the aneurysm—or as a result of thrombosis with ischemic symptoms. Iatrogenic false aneurysms after arterial puncture thrombose spontaneously within 4 weeks when they are less than 3 cm in diameter.

Simple ultrasound follow-up rather than operative therapy is indicated. Color-flow duplex-guided compression of iatrogenic pseudoaneurysms is successful in 70%-90% of attempts, but the procedure is uncomfortable and may take hours of probe pressure. Ultrasound-guided thrombin injection has been effective for thrombosis of large false aneurysms in a matter of seconds, but distal arterial thrombosis has also been described using this technique.

D. Arteriovenous Fistula

With simultaneous injury of an adjacent artery and vein, a fistula may form that allows blood from the artery to enter the vein. Because venous pressure is lower than arterial pressure, flow through an arteriovenous fistula is continuous; accentuation of the bruit and thrill can be detected over the fistula during systole. Traumatic arteriovenous fistulas may occur as operative complications (eg, aortocaval fistula following removal of a herniated intervertebral disk). Iatrogenic femoral arteriovenous fistulas after arteriograms and cardiac catheterization are seen with increasing frequency. Long-standing large arteriovenous fistulas may result in high-output cardiac failure. Similar to iatrogenic pseudoaneurysms occurring after arteriography, spontaneous resolution of acute arteriovenous fistulas usually occurs.

► Diagnosis

Arterial injury must be considered in any injured patient. Patients who present in shock following penetrating injury or blunt trauma should be assumed to have vascular injury until proven otherwise. Any injury near a major artery should arouse suspicion. A plain film may be helpful in demonstrating a fracture whose fragments could jeopardize an adjacent vessel or a bullet fragment that could have passed near to a major vessel. Before the x-ray is taken, entrance and exit wounds should be marked with radiopaque objects such as a paper clip.

Diagnosis is usually established on the basis of physical examination looking for signs of injury (Table 13-7).

Table 13-7. Signs of extremity vascular injury.

Hard signs

- Expanding or pulsatile hematoma
- Limb ischemia
- Bruit or thrill
- Absence of distal pulse

Soft signs

- History of hemorrhage at scene, now stopped
- Deficit of nerve associated with vessel
- Stable, nonexpanding hematoma
- Proximity of wound to major extremity blood vessel
- Ankle brachial index < 0.9

In addition to checking for obvious hemorrhage and the five Ps, the physician should listen for a bruit, palpate for a thrill (eg, of an arteriovenous fistula), and look for an expanding hematoma (eg, of a false aneurysm). Secondary hemorrhage from a wound is an ominous sign that may herald massive hemorrhage. The finding of these “hard” signs reliably reflects the presence of a vascular injury; hard signs mandate immediate exploration in most instances. The presence of “soft” signs (history of bleeding, diminished but palpable pulse, injury in proximity to a major artery, neuroparaxia) requires further tests or serial observation.

Doppler flow studies have gained importance in the diagnosis of arterial trauma. An ankle brachial index (ABI), determined by dividing the systolic pressure in the injured limb by the systolic pressure in an uninjured arm, is highly reliable for excluding arterial injury after both blunt and penetrating trauma. An ABI less than 0.9 has sensitivity of 95%, specificity of 97%, and negative predictive value of 99% for determining the presence of clinically significant arterial injury. Thus, only patients with soft signs and an ABI less than 0.9 require arteriography.

Color-flow duplex ultrasonography combines real-time B mode (brightness modulation) ultrasound imaging with a steerable pulsed Doppler flow detector. This technology can provide images of vessels and velocity spectral analysis. Color-flow duplex scanning of an area of injury is noninvasive, painless, portable, and easily repeated for follow-up examinations. When compared with arteriography and performed by experienced examiners, duplex ultrasound identifies nearly all major injuries that require treatment, potentially at considerable cost savings. In addition to screening for arterial trauma, duplex scanning has been used to detect pseudoaneurysms, arteriovenous fistulas, and intimal flaps. However, potential logistical and resource problems exist. The technology is sophisticated and requires skill in operation and interpretation, which is not always immediately available.

Arteriography is the most accurate diagnostic procedure for identifying vascular injuries (Figure 13-14). Arteriography to exclude vascular injury for soft signs results in a negative exploration rate of 20%-35% and an arteriography-related complication rate of 2%-4%. Proximity as the sole indication for arteriography has an extremely low yield, ranging from 0% to 10%. Patients with unequivocal signs of arterial injury on physical examination or plain films should have urgent operation. The false-negative rate of arteriography is low, and a normal arteriogram precludes the need for surgical exploration. Virtually all arteriographic errors are due to false-positives, which occur in 2%-8% of patients. Technical considerations in performing arteriography include the following: (1) entrance and exit wounds should be marked with a radiopaque marker; (2) the injection site should not be near the suspected injury; (3) an area 10-15 cm proximal and distal to the suspected injury should

▲ **Figure 13-14.** Arteriogram showing traumatic pseudoaneurysm of subclavian/axillary artery from penetrating injury.

be included in the arteriographic field; (4) sequential films should be obtained to detect early venous filling; (5) any abnormality should be considered an indication of arterial injury unless it is obviously the result of preexisting disease; and (6) two different projections should be obtained.

Emergency center arteriography using micropuncture Seldinger technique or cannulating the artery to be studied with an 18-gauge catheter (antegrade in the lower extremity and prograde in the upper extremity arteries) is quick and accurate. The use of fluoroscopy, especially if equipped with subtraction capability, simplifies the timing of contrast injection and x-ray exposure. Fluoroscopy is particularly helpful to visualize distal arteries and minimize the amount of contrast media needed. Arteriography may be particularly useful in differentiating arterial injury from spasm. In general, it is risky to attribute abnormal physical findings in an injured patient to arterial spasm; an arteriogram is indicated in such patients.

Arteriography is also valuable when arterial injuries may have occurred at multiple sites or to localize an injury when a long parallel penetration makes this determination difficult. Complications of arteriography include groin hematomas, iatrogenic pseudoaneurysms, arteriovenous fistulas, embolic occlusions, and delays in diagnosis that may lead to irreversible ischemia in marginally perfused limbs. The availability of CT angiograms with latest generation multidetector contrast-enhanced spiral scanners is a viable alternative to traditional angiography. CT angiograms can diagnose intimal dissections, pseudoaneurysms, arteriovenous fistulas, thrombosis or occlusion, and active bleeding. Metallic foreign bodies can create artifacts that interfere with generation of optimal CT angiogram studies.

For patients suspected of having BTAI based on mechanism of injury, the chest x-ray is a good screening tool to determine the need for further investigation. The most significant radiographic findings for possible BTAI include widened mediastinum, obscured aortic knob, deviation

▲ **Figure 13–15.** Computed tomography scan of the chest showing traumatic disruption of the aorta from blunt injury.

of the left mainstem bronchus or nasogastric tube, and opacification of the aortopulmonary window. Helical chest CT scanning is a useful diagnostic tool for screening and diagnosis of BTAI (Figure 13–15). A negative chest CT scan can obviate the need for further evaluation with a contrast aortogram. Patients with indeterminate CT scans or positive scans should have confirmation and delineation of the extent of BTAI with arteriography or a CT angiogram. In selected instances, cardiothoracic and/or trauma surgeons may consider helical CT scanning alone to be an adequate and complete work-up for BTAI. In addition, a helical CT angiogram with 3D reconstruction guides potential endovascular approach for treatment of BTAI. The use of either transesophageal echocardiography or intraluminal ultrasound in the diagnosis of BTAI continues to evolve, but they are not considered standard diagnostic modalities.

► Management

A. Initial Treatment

A rapid but thorough examination should be performed to determine the complete extent of injury. The physician must establish the priority of arterial injury in the overall management of the patient and should remember that delay in arterial repair decreases chances of a favorable outcome. When repair is performed within 12 hours after injury, amputation is rarely necessary; if repair is performed later, the incidence of amputation is about 50%. Depending on the degree of ischemia, delay in arterial repair will lead to lasting neuromuscular damage after as short a period as 4–6 hours.

Restoration of blood volume and control of hemorrhage are done simultaneously. If exsanguinating hemorrhage precludes resuscitation in the emergency room, the patient should be moved directly to the operating room. External bleeding is best controlled by firm direct pressure or packing. Probes or fingers should not be inserted into the wound

because a clot may be dislodged, causing profuse bleeding. Tourniquets occlude venous return, disturb collateral flow, and further compromise circulation and should not be employed unless exsanguinating hemorrhage cannot be controlled by other means. Atraumatic vascular clamps may be applied to accessible vessels by trained surgeons, but blind clamping can increase damage and injure adjacent nerves and veins.

After hemorrhage has been controlled and general resuscitation accomplished, further assessment is possible. The extent of associated injuries is determined and a plan of management made. Large-bore intravenous catheters should be placed in extremities with no potential venous injuries. It is prudent to preserve the saphenous or cephalic vein in an uninjured extremity for use as a venous autograft for vascular repair.

B. Nonoperative Treatment

Some arterial injuries remain asymptomatic and heal. Data supporting the practice of observation of small or asymptomatic arterial injuries have emerged from experimental animal studies and clinical reports showing resolution, improvement, or stabilization of arterial injuries. In well-defined settings, this strategy has proved safe in follow-up reports covering periods of up to 10 years. Thus, a nonoperative approach may be appropriate for compliant patients willing to return for follow-up who have: (1) no active hemorrhage; (2) low-velocity injuries (particularly stab wounds or iatrogenic punctures); (3) minimal arterial wall disruptions (< 5 mm); (4) small (< 5 mm) intimal defects; and (5) intact distal circulation.

Follow-up must include frequent physical examinations and carefully performed noninvasive studies, and patients should be asymptomatic and the strategy must be reconsidered if symptoms develop. Adjuvant therapy with antiplatelet agents is usually recommended to improve patency in patients with intimal flaps.

Endovascular management has assumed a greater role in the treatment of arterial trauma in recent years. Transcatheter embolization with coils or balloons has been successful in managing selected arterial injuries such as pseudoaneurysms, arteriovenous fistulas, and active bleeding from nonessential arteries. Coils are made of stainless steel with wool or polyester tufts. They are extruded at the site of vessel injury through 5F or 7F catheters. After deployment, the coils expand and lodge at the extrusion site and the tufts promote thrombosis. Catheter-based intra-arterial infusion of vasodilators has also been used to treat vasospasm in small distal arteries.

The recent popularity of endovascular grafting in elective vascular surgery (Chapter 34) has been applied to the treatment of arterial trauma. A fixation device such as a stent is attached to a graft, and the Stent graft is inserted

endoluminally from a remote site and deployed at the site of injury to repair false aneurysms or arteriovenous fistulas. The indications for endovascular grafting are likely to change as technology advances, but the most frequent application currently is in stable patients with delayed presentations who have complex false aneurysms or arteriovenous fistulas. Use of Stent grafts in the acute setting requires the availability of a wide variety of sizes and lengths of grafts and advanced catheter skills.

Endovascular repair of BTAI can be performed either electively or even emergently (Figure 13–16). In a recent American Association for the Surgery of Trauma (AAST) multicenter study, two-thirds of patients underwent endovascular Stent graft repair as compared to one-third who underwent traditional open repair. When adjusted for confounding variables, the endovascular approach was

associated with reduced mortality (odds ratio 8.42, 95% confidence interval 2.76-25.69) and fewer blood transfusions. Further study is needed to determine the long-term outcome using endovascular techniques to repair BTAI. Commercial grafts have yielded better results than the noncommercial “homemade” grafts. Thoracic aorta lacerations of more than 1.5 cm resulting in graft apposition length less than 2 cm or those near or in the curvature of the aortic arch are associated with an increased risk of endoleak. Endoleak occurred in 14% of the AAST BTAI trial patients, with half being successfully managed with the deployment of additional stent grafts.

In selected cases of BTAI repair, whether it is operative or endovascular, treatment is delayed because treatment and recovery from other more life-threatening injuries has priority (eg, severe pulmonary contusion, brain injury). This is acceptable, and the incidence of aortic rupture after 4 hours in the hospital is low. Systemic blood pressure and heart rate should be controlled with a beta-blocker and other pharmacologic agents as necessary to minimize the risk of rupture while waiting for definitive repair of the injured aorta.

C. Operative Treatment

General anesthesia is preferable to spinal or regional anesthesia. When vascular injuries involve the neck or thoracic outlet, endotracheal intubation must be performed carefully to avoid dislodging a clot and to protect the airway. Moreover, care is necessary to avoid neurologic damage in patients with associated cervical spine injuries. At least one uninjured extremity should also be prepared for surgery so that saphenous or cephalic vein conduit may be obtained if a vein graft is required. Provision should also be made for operative arteriography.

Incisions should be generous and parallel to the injured vessel. Meticulous care in handling incisions is essential to avoid secondary infections; all undamaged tissue should be conserved for use in covering repaired vessels. Preservation of all arterial branches is important in order to maintain collateral circulation. Atraumatic control of the vessel should be achieved proximal and distal to the injury so that the injured area may be dissected free of other tissues and inspected without risk of further bleeding. When large hematomas and multiple wounds make exposure and clamping of vessels difficult, it is wise to place a sterile orthopedic tourniquet proximal to the injury that can be inflated temporarily if needed.

The extent of arterial injury must be accurately determined. Arterial spasm generally responds to gentle hydraulic or mechanical dilation. Local application of warm saline or drugs such as papaverine, tolazoline, lidocaine, or nitroglycerin is occasionally effective in relieving spasm. Intra-arterial injection of nitroglycerin or papaverine is also very effective in alleviating spasm. If spasm persists, however, it is best to assume that it is caused by an intramural injury, and the

▲ **Figure 13–16.** Aortogram and placement of aortic stent graft to repair a blunt aortic disruption.

vessel should be opened for direct inspection. An old adage is that spasm is spelled “c-l-o-t.”

All devitalized tissue, including damaged portions of the artery, must be debrided. One should resect only the grossly injured portion of the vessel. The method of reconstruction depends on the degree of arterial damage. In selected instances, the ends of injured vessels can be approximated and an end-to-end anastomosis created. If the vessels cannot be mobilized well enough to provide a tension-free anastomosis, an interposition graft should be used. Early experience with prosthetic interposition grafts was disappointing since postoperative infection, thrombosis, and anastomotic disruption were common. These problems have decreased considerably with the use of grafts made of expanded polytetrafluoroethylene (PTFE). Proponents of synthetic graphs focus on the fact that they fail well (eg, infected pseudoaneurysm), whereas a vein graft will disintegrate and result in a sudden blow-out type hemorrhage. Nevertheless, most surgeons still prefer to use an autogenous graft (ie, vein or artery) in severely contaminated wounds. Saphenous vein grafts should be obtained from the noninjured leg to avoid impairment of venous return on the side of the injury. Patch angioplasty using saphenous vein is performed when closure of a partially transected vessel would result in narrowing. Suturing should be done with fine 5-0 or 6-0 monofilament material.

In the unusual circumstance of isolated vascular injury, 5000-10,000 units of intravenous heparin can be given to prevent thrombosis. Otherwise, a small amount of dilute heparin solution (100 units/mL) may be gently injected into the proximal and distal lumen of the injured vessel before clamps are applied. Proximal and distal thrombi are removed with a Fogarty embolectomy catheter. Backbleeding from the distal artery is not a sure indication that thrombus is absent. A completion operative arteriogram is indicated to determine distal patency and to check on the adequacy of the reconstruction—even when distal pulses are palpable.

It was formerly taught that fractures should be stabilized before vascular injuries were repaired so that manipulation of bones would not jeopardize vascular repair. The disadvantages of this dictum were delay in restoration of flow to ischemic tissue and interference with vascular reconstruction and subsequent arteriographic study of the completed repair by the fixation device. It is currently recommended that vascular repair be performed first, followed by careful application of external traction devices that allow easy access to the wound for observation and dressing changes. Another alternative is to place an intraluminal shunt temporarily across the vascular injury to decrease ischemia while fractures or other injuries are treated. Once the fracture is stabilized, the temporary shunt can be removed and definitive vascular repair completed. Improved outcomes similar to civilian lower extremity vascular trauma have been

attributed to the use of temporary vascular shunts and damage control techniques in the current Iraq War.

Repaired vessels must be covered with healthy tissue. If left exposed, they invariably desiccate and rupture. Skin alone is inadequate, because subsequent necrosis of the skin would leave the vessels exposed, greatly endangering the reconstruction. Generally, an adjacent muscle (eg, sartorius muscle for coverage of the common femoral artery) can be mobilized and placed over the repair. Musculocutaneous flaps can be constructed by plastic surgeons to cover almost any site. In an extensive or severely contaminated wound, a remote bypass may be routed through clean tissue planes to circumvent difficult soft tissue coverage problems.

D. Venous Injuries

Venous injuries commonly accompany arterial injuries. In order of decreasing frequency, the most common extremity venous injuries are the superficial femoral vein, the popliteal vein, and the common femoral vein. The relative importance and timing of venous repair in an injured extremity is controversial. Advocates of routine venous repair contend that ligation is associated with significant postoperative morbidity, including more frequent failure of arterial repairs due to compromised outflow, venous insufficiency, compartment syndrome, and limb loss. Proponents of venous ligation argue that venous repairs are difficult (requiring interposition, compilation, and spiral grafting), time consuming (dangerous in the multiply-injured patient), and likely to cause occlusion (patency rates are only about 50%). The presence of postoperative edema after combined arterial and venous injuries is not reliably reduced by attempted venous repair. It seems reasonable to recommend repair of venous injuries when the repair is not too technically difficult (lateral venorrhaphy) and the patient is hemodynamically stable. Complex repair with autologous vein or ringed PTFE can yield good short-term patency in experienced hands (77% primary repair, 67% vein graft, 74% PTFE). Thus, the decision to repair the vein depends on the condition of the patient and the condition of the vein. When venous ligation is necessary, postoperative edema can be controlled by elevation of the extremity and use of compression stockings or wraps. In patients undergoing venous repair, patency should be monitored using duplex scanning. If thrombosis of the repair is detected and there are no contraindications, anticoagulation should be instituted and maintained for at least 3 months postoperatively.

E. Fasciotomy

Fasciotomy is an important adjunctive treatment in many cases of arterial trauma. Indications include the following: (1) combined arterial and venous injury; (2) massive soft tissue damage; (3) delay between injury and repair (4-6 hours); (4) prolonged hypotension; and (5) excessive swelling or

high tissue pressure measured by one of several techniques. Whenever compartment pressures (measured with a needle and manometer) approach 25–30 mm Hg, fasciotomy should be considered. Fasciotomies must be performed through adequate skin incisions because when edema is massive, the skin envelope itself can compromise neurovascular function.

Fasciotomies are not benign procedures. They create large open wounds, and chronic venous insufficiency is a recognized late complication even in the absence of venous reflux or obstruction. The chronic swelling is thought to be related to loss of integrity of the ensheathing fascia of the calf muscles, reducing the efficiency of the calf muscle pump. Thus, some authorities recommend against routine use of fasciotomies at the initial operation. This approach is dependent on the ability to conduct frequent serial physical examinations and the ready availability of an operating room should problems arise. In the postoperative period, compartmental pressures can be measured using a handheld solid-state transducer as often as clinically indicated. Normal intracompartment pressure is less than 10 mm Hg. In general, a pressure of 25–30 mm Hg requires either fasciotomy or continuous monitoring. When the pressure exceeds 30 mm Hg, fasciotomy is mandatory. In patients who are obtunded or who cannot cooperate with serial physical examination, earlier fasciotomy should be considered.

F. Immediate Amputation

High-energy or crush injuries of the extremities are associated with high morbidity and a poor prognosis for useful limb function—there is a high late amputation rate despite initial limb salvage. Vascular injuries are now repaired with a high rate of success, but associated orthopedic, soft tissue, and nerve injuries are the critical factors that determine long-term function. A number of scoring systems or indices have been proposed to help determine when to amputate immediately and thus reduce the number of protracted reconstructive procedures that ultimately fail. Management of the mangled extremity is particularly difficult, and none of the scoring systems are universally accepted. Evaluation and management of these patients should be multidisciplinary, and the decision to amputate emergently should be made by two independent surgeons whenever possible.

BLAST INJURY

Blast injuries in civilian populations occur as a result of fireworks, household explosions, or industrial accidents. Urban guerrilla warfare or terrorist tactics may take the form of letter bombs, suitcase bombs, vehicle bombs, and suicide bombers. Injuries occur from the effects of the blast itself, propelled foreign bodies, or, in large blasts, from falling objects. Military blast injuries may also involve personnel submerged in water. Water increases energy transmission and the possibility of injury to the viscera of the thorax or abdomen. The pathophysiology of blast injuries involves two mechanisms. Crush injury results from rapid displacement of the body wall and may result in laceration and contusion of underlying structures. Minor displacements may produce serious injury if the body wall velocity is high. In addition, the motion of the body wall generates waves that propagate within the body and transfer energy to internal sites.

► Clinical Findings

A. Symptoms and Signs

The injury is dependent upon proximity to the blast, space confinement, and detonation size. Large explosions cause multiple foreign body impregnations, bruises, abrasions, and lacerations. Gross soilage of wounds from clothing, flying debris, or explosive powder is common. About 10% of all casualties have deep injuries to the chest or abdomen. Blast-induced circulatory shock may be caused by immediate myocardial depression without a compensatory vasoconstriction.

Lung damage usually involves rupture of the alveolus with hemorrhage. Air embolism from bronchovenous fistula may cause sudden death. The mechanisms of lung injury are thought to be due to spalling effects (splintering forces produced when a pressure wave hits a fluid-air interface), implosion effects, and pressure differentials. Hypoxia may result from a ventilation-perfusion mismatch caused by the pulmonary hemorrhage. Patients with pulmonary blast injury may die despite intensive respiratory support.

Blast injury causing pneumatic disruption of the esophagus or bowel has been reported. Tension pneumoperitoneum is a known although rare complication of barotrauma. Letter bombs cause predominantly hand, face, eye, and ear injuries. Energy transmission within the fluid media of the eye can cause globe rupture, dialysis of the iris, hyphema of the anterior chamber, lens capsule tears, retinal rupture, or macular pucker. Ear injuries may consist of drum rupture or cochlear damage. There may be nerve or conduction hearing deficit or deafness. Tinnitus, vertigo, and anosmia are also seen in letter bomb casualties.

B. Imaging Studies

Chest x-ray may initially be normal or may show pneumothorax, pneumomediastinum, or parenchymal infiltrates. In mass casualty situations it may be necessary to reserve the use of CT scans for those patients with acute changing neurologic examinations during the immediate intake period. Patients with multiple penetrating injuries from shrapnel may benefit from full-body CT scanning following initial stabilization and evaluation. Correlation of radiologic imaging studies with clinical examination is useful in guiding which injuries may need operative intervention when the number of skin surface wounds is high and it is impractical to explore all of these wounds.

► Treatment

Severe injuries with shock from blood loss or hypoxia require resuscitative measures to restore perfusion and oxygenation. Penetrating injuries of the brain may require neurosurgical intervention along with intracranial pressure monitoring. The usual criteria for exploring penetrating wounds of the thorax or abdomen are employed. Perforation of hollow organs should be suspected in patients with appropriate histories, particularly those who were submerged at the time of injury. Respiratory insufficiency may result from pulmonary injury or may be secondary to shock, fat embolism, or other causes. Tracheal intubation and prolonged respiratory care with mechanical ventilation may be necessary. In cases of tension pneumoperitoneum, surgical decompression may dramatically improve respiratory and hemodynamic functions. Shrapnel is the main cause of abdominal injury following terrorist bombings. Surgical treatment of extremity injuries requires wide debridement of devitalized muscle,

thorough cleansing of wounds, and removal of foreign materials. The possibility of gas gangrene in contaminated muscle injuries may warrant open treatment. Eye injuries may require immediate repair. Ear injuries are usually treated expectantly.

MULTIPLE CHOICE QUESTIONS

1. A 31-year old man with a stab wound to the left neck over the sternocleidomastoid at the level of the lower pole of the thyroid gland
 - A. Has a wound in an area that is easily explored in the operating room as most injuries here can be identified and controlled directly
 - B. Has a penetrating injury in zone 3
 - C. Should have an initial assessment including airway, breathing, and circulation
 - D. Should be taken to angiography if unstable
 - E. Has little risk of vascular injury
2. All of the following are correct about a patient with a systolic blood pressure of 75 torr after a roll-over automobile accident that resulted in the death of another passenger except
 - A. Should be transported to a trauma center as expeditiously as possible
 - B. Can have shock due to hypovolemia, cardiac failure, or neurogenic causes
 - C. Should have an algorithmic approach to his care in the prehospital and trauma resuscitation phases of care
 - D. Should bypass the trauma room and go directly to the operating room
 - E. Has a mechanism of injury that places him at substantial risk of being severely injured
3. Thoracic injuries
 - A. Are unusually contributors to the death of a trauma patient
 - B. Can cause late deaths due to respiratory failure or sepsis
 - C. Can include acceleration/deceleration as common mechanism of a severe aortic injury

- D. Carry a similar mortality in older and younger patients
 - E. A, B, and C are all correct
4. Abdominal injuries
- A. Can only be reliably assessed by CT scan or laparotomy
 - B. Require laparotomy and repair for all identified liver parenchyma injuries
 - C. Can routinely be evaluated by laparoscopy
 - D. Can be evaluated by diagnostic peritoneal lavage primarily to identify intraperitoneal bile
 - E. From gunshot wounds below the nipple line typically require laparotomy for evaluation and management
5. Peripheral vascular injuries
- A. Are common in young men
 - B. Are more likely from penetrating than blunt injury
 - C. Are not often evaluated by CT scan
 - D. Can commonly be iatrogenic from medical procedures
 - E. All are correct

Burns & Other Thermal Injuries

Robert H. Demling, MD

14

BURNS

A severe thermal injury is one of the most devastating physical and psychological injuries a person can suffer. Over 2 million injuries due to burns require medical attention each year in the United States, with 14,000 deaths resulting. Fires in the home are responsible for only 5% of burn injuries but for 50% of burn deaths—most due to smoke inhalation. About 75,000 patients require hospitalization every year, and 25,000 of those remain hospitalized for over 2 months—evidence of the severity of illness associated with this injury.

ANATOMY & PHYSIOLOGY OF THE SKIN

The skin is the largest organ of the body, ranging in area from 0.25 m² in the newborn to 1.8 m² in the adult. It consists of two layers: the epidermis and the dermis (corium). The outermost cells of the epidermis are dead cornified cells that act as a tough protective barrier against the environment, including bacterial invasion and chemical exposure. The inner cells of the epidermis are metabolically active, producing compounds like growth factor, which help the ongoing replication process every 2 weeks. The second, thicker layer, the dermis (0.06-0.12 mm), is composed chiefly of fibrous connective tissue. The dermis contains the blood vessels and nerves to the skin and the epithelial appendages of specialized function like sweat glands. The nerve endings that mediate pain are found in the dermis.

The dermis is a barrier that prevents loss of body fluids by evaporation and loss of excess body heat. Sweat glands help maintain body temperature by controlling the amount of water that evaporates. The dermis is also interlaced with sensory nerve endings that mediate the sensations of touch, pressure, pain, heat, and cold. This is a protective mechanism that allows an individual to adapt to changes in the physical environment.

The skin produces vitamin D, which is synthesized by the action of sunlight on certain intradermal cholesterol compounds.

DEPTH OF BURNS

The depth of the burn (Figure 14–1) significantly affects all subsequent clinical events. The depth may be difficult to determine and in some cases is not known until after spontaneous healing has occurred or when the eschar is surgically removed or separates, exposing the wound bed.

Traditionally, burns have been classified as first-, second-, and third-degree, but the current emphasis on burn healing has led to classification as partial-thickness burns, which can heal spontaneously, and full-thickness burns, which require skin grafting, although deep partial-thickness burns are usually excised and grafted as well.

A first-degree burn involves only the epidermis and is characterized by erythema and minor microscopic changes; tissue damage is minimal, protective functions of the skin are intact, skin edema is minimal, and systemic effects are rare. Pain, the chief symptom, usually resolves in 48-72 hours, and healing takes place uneventfully. In 5-10 days, the damaged epithelium peels off in small scales, leaving no residual scarring. The most common causes of first-degree burns are overexposure to sunlight and brief scalding.

Second-degree or partial-thickness burns are deeper, involving all of the epidermis and some of the corium or dermis. The systemic severity of the burn and the quality of subsequent healing are directly related to the amount of undamaged dermis. Superficial burns are often characterized by blister formation, while deeper partial-thickness burns have a reddish appearance or a layer of whitish, nonviable dermis firmly adherent to the remaining viable tissue. Blisters, when present, continue to increase in size in the postburn period as the osmotically active particles in the blister fluid attract water. Complications from superficial

▲ **Figure 14–1.** Layers of the skin showing depth of first-degree, second-degree, and third-degree burns.

second-degree burns are mainly severe pain related. These burns usually heal with minimal scarring in 10–14 days unless they become infected.

Deep dermal burns heal over a period of 4–8 weeks with only a fragile epithelial covering developing that arises from the residual uninjured epithelium of the deep dermal sweat glands and hair follicles. Severe hypertrophic scarring occurs when such an injury heals; the resulting epithelial covering is prone to blistering and breakdown. Evaporative losses after healing remain high compared with losses in normal skin. Conversion of a partial thickness injury to a full-thickness burn by the actions of wound bacteria is common. Skin grafting of deep dermal burns, when feasible, improves the biologic quality and appearance of the skin cover.

Full-thickness (third-degree) burns have a characteristic white, dry, waxy appearance and may appear to the untrained eye as unburned skin. Burns caused by prolonged exposure to heat, with involvement of fat and underlying tissue, may be brown, dark red, or black. The diagnostic findings of full-thickness burns are lack of sensation in the burned skin, lack of capillary refill, and a leathery texture that is unlike normal skin. All dermal epithelial elements are destroyed, leaving no potential for reepithelialization.

DETERMINATION OF SEVERITY OF INJURY

Illness and death are related to the size (surface area) and depth of the burn, the age and prior state of health of the victim, the location of the burn wound, and the severity of associated injuries, particularly lung injuries caused by smoke inhalation.

The total body surface area involved in the burn is most accurately determined by using the age-related charts designed by Lund and Browder (Figure 14–2). A set of these charts should be filled out for every burn patient on admission and when resuscitation is begun.

A careful calculation of the percentage of total body burn is useful for several reasons. First, there is a general clinical tendency to both underestimate and overestimate the

size of the burn and thus its severity. The American Burn Association has adopted a severity index for burn injury (Table 14–1). Second, prognosis is directly related to the extent of injury both size and depth. Third, the decision about who should be treated in a specialized burn facility or managed as an outpatient is based on the estimate of burn size and depth.

Patients under age 2 years and over age 60 years have a significantly higher death rate for any given extent of burn. The higher death rate in infants results from a number of factors. First, the body surface area in children relative to body weight is much greater than in adults. Therefore, a burn of comparable surface area has a greater physiologic impact on a child. Second, immature kidneys and liver do not allow for removal of a high solute load from injured tissue or the rapid restoration of adequate nutritional support. Third, the incompletely developed immune system increases susceptibility to infection. Associated conditions such as cardiac disease, diabetes, or chronic obstructive pulmonary disease significantly worsen the prognosis in elderly patients.

Burns involving the hands, face, feet, or perineum are at risk for severe complications if not properly treated. Patients with such burns should always be admitted to the hospital, preferably to a burn center. Chemical and electrical burns or those involving the respiratory tract are invariably far more extensive than is evident on initial inspection. Therefore, hospital admission is also necessary in these cases.

PATHOLOGY & PATHOPHYSIOLOGY OF THERMAL INJURIES

The microscopic pathologic feature of the burn wound is principally surface coagulation necrosis. Burned tissue has three distinct zones. The first is the zone of “coagulation,” or necrosis with irreversible cell death and no capillary blood flow. Surrounding this is a zone of injury or stasis, characterized by sluggish capillary blood flow and injured cells. Although damaged, the tissue is still viable. Further tissue injury can be caused by products of inflammation such as oxidants and vasoconstrictor mediators. Environmental insults such as hypoperfusion, desiccation, or infection can also cause the injured tissue to become necrotic. This process is called **wound conversion**. The third zone is that of “hyperemia,” which is the usual inflammatory response of healthy tissue to nonlethal injury. Vasodilatation and increased capillary permeability is typically present.

A rapid loss of intravascular fluid and protein occurs through the heat-injured capillaries. The volume loss is greatest in the first 6–8 hours, with capillary integrity returning toward normal by 36–48 hours. A transient increase in vascular permeability also occurs in nonburned tissues, probably as a result of the initial release of vasoactive mediators. However, the edema that develops in nonburned tissues during resuscitation appears to be due in large part to

Relative percentages of areas affected by growth

Area	Age		
	10	15	Adult
A = half of head	5 1/2	4 1/2	3 1/2
B = half of one thigh	4 1/4	4 1/2	4 3/4
C = half of one leg	3	3 1/4	3 1/2

Relative percentages of areas affected by growth

Area	Age		
	0	1	5
A = half of head	9 1/2	8 1/2	6 1/2
B = half of one thigh	2 3/4	3 1/4	4
C = half of one leg	2 1/2	2 1/2	2 3/4

▲ **Figure 14–2.** Table for estimating extent of burns. In adults, a reasonable system for calculating the percentage of body surface burned is the “rule of nines”: Each arm equals 9%, the head equals 9%, the anterior and posterior trunk each equal 18%, and each leg equals 18%; the sum of these percentages is 99%.

the marked hypoproteinemia caused by protein loss into the burn itself. A systemic inflammatory response occurs in response to a large body burn, resulting in the release of oxidants and other inflammatory mediators into unburned tissues. A generalized decrease in cell energy and membrane potential occurs as a result. This leads to a shift of extracellular sodium and water into the intracellular space. This process is also corrected as hemodynamic stability is restored but will return if the systemic inflammation is amplified. Smoke inhalation markedly increases the hemodynamic instability, fluid requirements, and mortality rates by adding another source of intense inflammation leading to local lung and systemic tissue damage.

METABOLIC RESPONSE TO BURNS & METABOLIC SUPPORT

The initial metabolic response appears to be activated by proinflammatory cytokines and in turn oxidants. The secretion of catecholamines, cortisol, glucagon, renin-angiotensin,

antidiuretic hormone, and aldosterone is also increased. Early in the response, energy is supplied by the breakdown of stored glycogen and by the process of anaerobic glycolysis.

Profound hypermetabolism and catabolism occur in the postburn period, characterized by an increase in metabolic rate that approaches doubling of the basal rate in severe burns and a rapid loss of the components of lean body mass with muscle loss exceeding a pound a day. The degree of response is proportionate to the degree of injury, with a plateau occurring when the burn involves about 70% of the total body surface. The initiating and perpetuating factors are the mediators of inflammation, especially the cytokines and endotoxin. Added environmental stresses such as pain, cooling, and sepsis syndrome increase the obligatory hypermetabolism and catabolism.

During the first postburn week, the metabolic rate (or heat production) and oxygen consumption rise progressively from the normal level present during resuscitation and remain elevated until the wound is covered and no other sources of inflammation remain. The specific pathophysiologic

Table 14–1. Summary of American Burn Association burn severity categorization.

Major Burn Injury

Second-degree burn of > 25% body surface area in adults
 Second-degree burn of > 20% body surface area in children
 Third-degree burn of > 10% body surface area
 Most burns involving hands, face, eyes, ears, feet, or perineum
 Most patients with the following:
 Inhalation injury
 Electrical injury
 Burn injury complicated by other major trauma
 Poor-risk patients with burns

Moderate Uncomplicated Burn Injury

Second-degree burn of 15%–25% body surface area in adults
 Second-degree burn of 10%–20% body surface area in children
 Third-degree burn of < 10% body surface area

Minor Burn Injury

Second-degree burn of < 15% body surface area in adults
 Second-degree burn of < 10% body surface area in children
 Third-degree burn of < 2% body surface area

mechanism remains undefined, but increased and persistent catecholamine and cortisol secretion are major factors, as is increased circulating endotoxin absorbed from wound or gut and proinflammatory cytokines.

The evaporative water loss from the wound may reach 300 mL/m²/h (normal is about 15 mL/m²/h). This produces a heat loss of about 580 kcal/L of water evaporated. Covering the burn with an impermeable membrane, such as skin substitute, reduces the heat loss. Similarly, placing the burn patient in a warm environment, where convection and radiant loss of heat are minimized, also modestly reduces the heat loss and the metabolic rate. The persistently elevated circulating levels of catecholamines and cortisol stimulate an exaggerated degree of gluconeogenesis and protein breakdown. Protein catabolism, glucose intolerance, and marked total body weight loss result.

Aggressive nutritional support along with rapid wound closure and control of pain, stress, and sepsis will help control the hypermetabolic catabolic state. Controlled use of a beta-blocker has been shown to decrease catabolism. In addition, insulin, growth hormones, and testosterone analogues have been shown to both decrease catabolism and increase anabolism.

IMMUNOLOGIC FACTORS IN BURNS

A number of immunologic abnormalities in burn patients predispose to infection. Serum IgA, IgM, and IgG are frequently depressed, reflecting depressed B-cell function.

Cell-mediated immunity or T-cell function is also impaired, as demonstrated by prolonged survival of homografts and xenografts.

Polymorphonuclear (PMN) chemotactic activity is suppressed. A decrease in chemotaxis predates evidence of clinical sepsis by several days. Decreased oxygen consumption and impaired bacterial killing have also been demonstrated in PMNs. Depressed killing is probably due to decreased production of hydrogen peroxide and superoxide; this has been demonstrated by decreased PMN chemiluminescent activity in burn patients.

BURN MANAGEMENT

ACUTE RESUSCITATION

The burn patient should be assessed and treated like any patient with major trauma. The first priority is to ensure an adequate airway. If there is a possibility that smoke inhalation has occurred—as suggested by exposure to a fire in an enclosed space or burns of the face, nares, or upper torso—arterial blood gases and arterial oxygen saturation of hemoglobin and carboxyhemoglobin CoHgb levels should be measured, and 100% oxygen should be administered. If CoHgb is elevated, 100% oxygen should be administered until levels return to normal.

Endotracheal intubation is indicated if the patient is semicomatose, has deep burns to the face and neck, or is otherwise critically injured. Intubation should be done early in all doubtful cases, because delayed intubation will be difficult to achieve in cases associated with facial and pharyngeal edema or upper airway injury, and an emergency tracheostomy may become necessary later under difficult circumstances. Respiratory support is necessary for severe smoke damage to the lower airways. If the burn exceeds 20% of body surface area, a urinary catheter should be inserted to monitor urine output. A large-bore intravenous catheter should be inserted, preferably into a large peripheral vein. There is a significant complication rate with the use of central lines in burn patients owing to the increased risk of infection.

Severe burns are characterized by large losses of intravascular fluid, which are greatest during the first 8–12 hours. Fluid loss occurs as a result of the altered capillary permeability, severe hypoproteinemia, and the shift of sodium into the cells. Both fluid shifts diminish significantly by 24 hours postburn. The lung appears to be reasonably well protected from the early edema process, and pulmonary edema is uncommon during the resuscitation period unless there is a superimposed inhalation injury. Increasing perfusion rather than infusion of bicarbonates is the appropriate approach.

Initially, an isotonic crystalloid salt solution is infused to counterbalance the loss of plasma volume into the extravascular space and the further loss of extracellular fluid into the intracellular space. Lactated Ringer solution is commonly

used, the rate being dictated by urine output, pulse (character and rate), state of consciousness, and, to a lesser extent, blood pressure. Urine output should be maintained at 0.5 mL/kg/h and the pulse at 120 beats/min or slower. Base deficit has been shown to be an excellent marker, with an increasing deficit indicating inadequate perfusion.

Swan-Ganz catheters and central venous pressure lines are seldom needed except in the case of severe smoke inhalation injury or unless the patient has sufficient cardiopulmonary disease that accurate monitoring of volume status would be difficult without measurement of filling pressures or unless a persistent base deficit is present, indicating continued impaired perfusion. The amount of lactated Ringer necessary in the first 24 hours for adequate resuscitation is approximately 3-4 mL/kg of body weight per percent of body burn, which is the amount of fluid needed to restore the estimated sodium deficit. At least half of the fluid is given in the first 8 hours because of the greater initial volume loss. Dextrose-containing solutions are not used initially because of early stress-induced glucose intolerance.

Although the importance of restoring colloid osmotic pressure and plasma proteins is well recognized, the timing of colloid infusion remains somewhat varied. Plasma proteins are ordinarily not infused until after the initial plasma leak begins to decrease. This usually occurs about 4-8 hours postburn. The addition of a protein infusion to the treatment regimen after this period will decrease the fluid requirements and—in very young or elderly patients and in patients with massive burns (in excess of 50% of body surface)—will improve hemodynamic stability.

After intravenous fluids are started and vital signs stabilized, the wound should be debrided of all loose skin and dirt. To avoid severe hypothermia, debridement is best done by completing one body area before exposing a second. An alternative is to use an overhead radiant heater, which will decrease net heat loss. Cool water is a very good analgesic on a small superficial burn; however, it should not be used for larger burns because of the risk of hypothermia. Pain is best controlled with the use of intravenous rather than intramuscular narcotics. Tetanus toxoid, 0.5 mL, should be administered to patients with any significant burn injury.

POSTRESUSCITATION PERIOD

Treatment should aim to decrease excessive catecholamine stimulation and provide enough calories to offset the effects of the hypermetabolism. Hypothermia, pain, and anxiety all need to be aggressively controlled. Hypovolemia should be prevented by giving enough fluid to make up for the body losses.

Ongoing management of any smoke inhalation injury will be necessary using vigorous pulmonary toilet to avoid airway plugging and hypoxia. Nutritional support should begin as early as possible in the postburn period to maximize

wound healing and minimize immune deficiency. Patients with moderate body burns may be able to meet nutritional needs by voluntary oral intake. Patients with large burns invariably require calorie and protein supplementation to reach a goal of 30 cal/kg body weight for calories and 1.5 g/kg body weight for protein. This can usually be accomplished by administering a formula diet through a small feeding tube. Parenteral nutrition is also occasionally required, but the intestinal route is preferred if needs can be met this way. Early restoration of gut function will also decrease gut bacterial translocation and endotoxin leak.

Vitamins A, E, and C and zinc should be given until the burn wound is closed. Low-dose heparin therapy may be beneficial, as with other immobilized patients with soft tissue injury.

CARE OF THE BURN WOUND

In the management of superficial partial or second-degree burns, one must provide as aseptic an environment as possible to prevent infection. However, superficial burns generally do not require the use of topical antibiotics. Occlusive dressings are used to minimize exposure to air, increase the rate of reepithelialization, and decrease pain. The exception is the face, which can be treated open with an antibacterial ointment. If there is no infection, burns will heal spontaneously.

The goals in managing deep partial-thickness or full-thickness (third-degree) burns are to prevent invasive infection (ie, burn wound sepsis), to remove dead tissue, and to cover the wound with skin or skin substitutes as soon as possible.

All topical antibiotics retard wound healing to some degree and therefore should be used only on deep second- or third-degree burns or wounds, which have a high risk of infection.

▶ Topical Antibacterial Agents

Topical agents have definitely advanced the care of burn patients. Although burn wound sepsis is still a major problem, the incidence is lower and the death rate has been markedly reduced, particularly in burns of less than 50% of body surface area. A silver-containing product is the treatment of choice because silver has superior antimicrobial properties. Silver sulfadiazine is the most widely used preparation. Mafenide, silver nitrate, povidone-iodine, and gentamicin ointments are also used. Silver release dressings are now very popular. A secondary dressing is placed over the silver release dressing to retain heat and optimize the wound environment.

Silver sulfadiazine, a cream that is effective against a wide spectrum of gram-positive and gram-negative organisms, is only moderately effective in penetrating the burn eschar. A transient leukopenia secondary to bone marrow suppression

often occurs with the use of silver sulfadiazine in large burns, but the process is usually self-limiting, and the agent does not have to be discontinued.

Silver release dressings are available in a slow-release form that release silver ions for several days, decreasing dressing changes and improving patient comfort.

► Exposure Versus Closed Management

There are two methods of management of the burn wound with topical agents. In exposure therapy, no dressings are applied over the wound after application of the agent to the wound twice or three times daily. This approach is typically used on the face and head. Disadvantages are increased pain and heat loss as a result of the exposed wound and an increased risk of cross-contamination.

In the closed method, an occlusive dressing is applied over the agent and is usually changed twice daily. The disadvantage of this method is the potential increase in bacterial growth if the dressing is not changed twice daily, particularly when thick eschar is present. The advantages are less pain, less heat loss, and less cross-contamination. The closed method is generally preferred.

► Temporary Skin Substitutes

Skin substitutes are another alternative to topical agents for the partial-thickness burn or the clean excised wound. A number of synthetic and biologically active temporary skin substitutes are in use. Reepithelialization is accelerated. Also, pain is better controlled. Homografts (human skin) work better for this purpose on large excised wounds but are difficult to obtain. Other alternatives include a number of tissue engineered skin substitutes, which contain bioactive matrix components.

► Hydrotherapy

The use of immersion hydrotherapy for wound management has substantially decreased. A number of studies have shown that the infection rate is actually increased when patients are immersed in a tub because of the generalized inoculation of burn wounds with bacteria from what was previously a localized infection. Hydrotherapy, on a slant board, is a very useful approach once the wounds are in the process of being debrided and closed. Showering is also effective for wound cleansing in the more stable patient.

► Debridement & Grafting

Burn wound inflammation, even in the absence of infection, can result in multiple organ dysfunction and perpetuation of the hypermetabolic catabolic state. Early wound closure would be expected to control this process more effectively. Surgical management of burn wounds has now become much more aggressive, with operative debridement

beginning within the first several days postburn rather than after eschar has sloughed. More rapid closure of burn wounds clearly decreases the rate of sepsis and significantly decreases the death rate. The approach to operative debridement varies from an extensive burn excision and grafting within several days of injury to a more moderate approach of limiting debridements to less than 15% of the burned area. Excision can be carried down to fascia or to viable remaining dermis or fat. Excision to fascia is more commonly used when the burn extends well into the fat. A meshed skin graft can be covered with a biologic dressing to avoid desiccation of the uncovered wound. Excision to viable tissue, referred to as tangential excision, is advantageous because it provides a vascular base for grafting while preserving remaining viable tissue, especially dermis. Tourniquets can be used to decrease blood loss. Blood loss is substantial in view of the vascularity of the dermis.

A number of permanent skin substitutes could further facilitate wound closure, particularly in large burns with insufficient donor sites. Autologous cultures of epithelium have been applied with some success. Permanent skin substitutes composed of both dermis and epidermis have been designed to maintain coverage and improve skin function.

► Maintenance of Function

The maintenance of functional motion during the evolution of the burn wound is necessary to avoid loss of motion at joints. Wound contraction, a normal event during healing, may result in extremity contracture. Immobilization will produce joint stiffness. Contracture of the scar, muscles, and tendons across a joint causes loss of motion, which can be diminished by traction and early motion.

The scar is a metabolically active tissue, continually undergoing reorganization. The extensive scarring that frequently occurs after burns can lead to disfiguring and disabling contractures, but it may be avoided by the use of splints and elevation to maintain a functional position. Following application of the skin graft, maintenance of proper positioning with splints is indicated along with active motion exercises.

If reinjury does not occur, the amount of collagen in the scar tends to decrease with time (usually over a year). Stiff collagen becomes softer, and on flat surfaces of the body, where reinjury and inflammation are prevented, remodeling may totally eliminate contracture. However, around joints or the neck, contractures can persist, and surgical reconstruction is necessary. The sooner the burn wound can be covered with skin grafts, the less likely is contracture formation.

MANAGEMENT OF COMPLICATIONS

Infection remains a critical problem in burns, though the incidence has been reduced by modern therapy with the combination of early excision and grafting along with

Table 14–2. Diagnosis of burn wound infection.

Systemic Changes	Colonized or Clean	Wound Infection
Body temperature	Increased	Variable
White blood cell count	Increased Mild left shift	High or low Severe left shift
Wound appearance	Variable—may appear purulent or benign	Purulence may be present, or wound surface may appear dry and pale
Bacterial Content		
Surface	Scant to large amount	Variable
Quantitative	Usually < 10 ⁵ /g	Usually > 10 ⁵ /g
Biopsy	No invasion of normal tissue	Invasion of normal tissue by organisms

topical antibacterial agents. An infection is present when a quantitative culture of the burn indicates a concentration of 10⁵ organisms; a semiquantitative swab culture is used more commonly. The cultures also show the sensitivity of the bacteria, and when the bacterial concentration passes 10⁵ organisms per gram, systemic administration of specific antibiotics should be instituted (Tables 14–2 and 14–3).

Sepsis syndrome occurs in all major burns. Fever, hypermetabolism, catabolism, and often leukocytosis are typical characteristics, the result of local burn and total body inflammation. Infection is often not present as this process can be attributed to an autodestructive response to inflammation. This intense inflammatory response can lead to death from multisystem organ failure and hemodynamic parameters comparable to sepsis shock.

Any significant infection can further perpetuate this response. Continued deterioration of a wound is likely due to invasive infection. A more common cause of infection today is a pulmonary complication—either a chemical or bacterial insult leading to pneumonia. Catheter sepsis is the third most common cause of infection. If infection is found, an aggressive antibiotics regime is indicated. Early excision and wound closure is the best way to avoid later development of burn wound sepsis.

Circumferential burns of an extremity or of the trunk pose special problems. Swelling beneath the unyielding eschar may act as a tourniquet to blood and lymph flow, and the distal extremity may become swollen and tense. More extensive swelling may compromise the arterial supply. Escharotomy, or excision of the eschar, may be required. To avoid permanent damage, escharotomy must be performed before arterial ischemia develops. Constriction involving the chest or abdomen may severely restrict ventilation and may require longitudinal escharotomies. Anesthetics are rarely required, and the procedure can usually be performed in the patient’s room.

Acute gastroduodenal (Curling) ulcers were at one time a frequent complication of severe burns, but the incidence is now extremely low, largely as a result of the early and routine institution of antacid and nutritional therapy and the decrease in the rate of sepsis.

A complication unique to children is seizures, which may result from electrolyte imbalance, hypoxemia, infection, or drugs; in one-third of cases, the cause is unknown. Hyponatremia is the most frequent cause. Systemic hypertension occurs in about 10% of cases in the postresuscitation period.

RESPIRATORY INJURY IN BURNS

Today the major cause of death after burns is respiratory failure or complications in the respiratory tract. The problems include inhalation injury, aspiration in unconscious

Table 14–3. Most common pathogens in burn infections.

	<i>Staphylococcus aureus</i>	<i>Pseudomonas aeruginosa</i>	<i>Candida albicans</i>
Wound appearance	Loss of wound granulation	Surface necrosis; patchy, black	Minimal exudate
Course	Slow onset over 2-5 days	Rapid onset over 12-36 hours	Slow (days)
CNS signs	Disorientation	Modest changes	Often no change
Temperature	Marked increase	High or low	Modest changes
White blood count	Marked increase	High or low	Modest changes
Hypotension	Modest	Often severe	Minimal change
Mortality rate	5%	20%-30%	30%-50%

Table 14–4. Carbon monoxide poisoning.

Carboxyhemoglobin Level	Severity	Symptoms
< 20%	Mild	Headache, mild dyspnea, visual changes, confusion
20%-40%	Moderate	Irritability, diminished judgment, dim vision, nausea, easy fatigability
40%-60%	Severe	Hallucinations, confusion, ataxia, collapse, coma
> 60%	Fatal	

patients, bacterial pneumonia, pulmonary edema, and post-traumatic pulmonary insufficiency. Smoke inhalation markedly increases mortality from burn injury.

Smoke inhalation injuries, caused by incomplete products of combustion and which predispose to other complications, are divided into three categories: carbon monoxide poisoning (Table 14–4), upper airways injury, and inhalation of noxious compounds in the lower airways (Table 14–5).

Carbon monoxide poisoning must be considered in every patient suspected of having inhalation injury on the basis of having been burned in a closed space and physical evidence of inhalation. Arterial blood gases and carboxyhemoglobin levels must be determined. Levels of carboxyhemoglobin above 5% in nonsmokers and above 10% in smokers indicate carbon monoxide poisoning. Carbon monoxide has an affinity for hemoglobin 200 times that of oxygen, displaces oxygen, and produces a leftward shift in the oxyhemoglobin dissociation curve (P_{50} , the oxygen tension at which half the hemoglobin is saturated with oxygen, is lowered). Calculations of oxyhemoglobin saturation may be

Table 14–5. Sources of toxic chemicals in smoke.

Wood, cotton	Aldehydes (acrolein), nitrogen dioxide, CO
Polyvinylchloride	Hydrochloric acid, phosgene, CO
Rubber	Sulfur dioxide, hydrogen sulfide, CO
Polystyrene	Copious black smoke and soot—CO ₂ , H ₂ O, and some CO
Acrylonitrile, polyurethane, nitrogenous compounds	Hydrogen cyanide
Fire retardants may produce toxic fumes	Halogens (F ₂ , Cl ₂ , Br ₂), ammonia, hydrogen cyanide, CO

misleading because the hemoglobin combined with carbon monoxide is not detected and the percentage saturation of oxyhemoglobin may appear normal.

Mild carbon monoxide poisoning (< 20% carboxyhemoglobin) is manifested by headache, slight dyspnea, mild confusion, and diminished visual acuity. Moderate poisoning (20%-40% carboxyhemoglobin) leads to irritability, impairment of judgment, dim vision, nausea, and fatigability. Severe poisoning (40%-60% carboxyhemoglobin) produces hallucinations, confusion, ataxia, collapse, and coma. Levels in excess of 60% carboxyhemoglobin are usually fatal.

Various toxic chemicals in inspired smoke produce tracheobronchial respiratory injuries. Inhalation of kerosene smoke, for example, is relatively innocuous. Smoke from a wood fire is extremely irritating because it contains aldehyde gases, particularly acrolein. Direct inhalation of acrolein, even in low concentrations, irritates mucous membranes and causes severe airway damage. Smoke from some plastic compounds, such as polyurethane, is the most serious kind of toxic irritant, and some plastics give off poisonous gases such as chlorine, sulfuric acid, and cyanides. Cyanide absorption can be lethal. Oxidants are released after all smoke exposures, causing mucosal and alveolar injury.

Inhalation injury causes severe mucosal edema followed soon by sloughing of the mucosa. The destroyed mucosa in the larger airways is replaced by a mucopurulent membrane. The edema fluid enters the airway and, when mixed with the pus in the lumen, may form casts and plugs in the smaller bronchioles. Terminal bronchioles and alveoli contain carbonaceous material. Acute bronchiolitis and bronchopneumonia commonly develop within a few days. Sputum smears should be examined daily to detect early bacterial tracheobronchial infection.

When inhalation injury is suspected, early endoscopic examination of the airway with fiberoptic bronchoscopy is helpful in determining the area of injury (ie, the extent of upper and lower airway involvement). Unfortunately, the severity of the injury cannot be accurately quantified by bronchoscopy—it can only be shown that an injury is present. Direct laryngoscopy probably gives as much information.

After several days, small bronchi become obstructed by inflammation and mucin plugs, leading to severe atelectasis and resulting hypoxia. This process is typically confined to the airways; in severe cases, alveolar edema will be present.

The most common cause of respiratory failure is a chemical tracheobronchitis due to the inhalation injury. Airway clearance is impeded due to ciliary damage and denuded airways. Alteration of oropharyngeal normal flora with colonization by pathogens then leads to bronchopneumonia.

Pulmonary insufficiency is associated with systemic sepsis. Differentiating acute respiratory distress syndrome (ARDS) from bacterial pneumonia may be difficult in severe cases of inhalation of sepsis. There is damage to the

pulmonary capillaries and leakage of fluid and protein into the interstitial spaces of the lung, resulting in loss of compliance and difficulty in oxygenation of the blood. Modern methods of ventilatory support and vigorous pulmonary toilet have significantly reduced the death rate from pulmonary insufficiency.

► Treatment

Management of a burn patient should include frequent evaluation of the lungs throughout the hospital course. All patients who initially have evidence of smoke inhalation should receive humidified oxygen in high concentrations. If carbon monoxide poisoning has occurred, 100% oxygen should be given until the carboxyhemoglobin content returns to normal levels and symptoms of carbon monoxide toxicity resolve. With severe exposures, carbon monoxide may still be bound to the cytochrome enzymes, leading to cell hypoxia even after carboxyhemoglobin levels have returned to near normal. Continued oxygen administration will also reverse this process. Hyperbaric oxygen is often used in these cases.

The use of corticosteroids for inhalation injuries is no longer controversial and is clearly contraindicated with the exception of chronic bronchiolitis obliterans. The exception is the patient with a relative steroid insufficiency.

Bronchodilators by aerosol or aminophylline given intravenously may help if wheezing is due to the reflex bronchospasm typically present. Chest physical therapy is also required.

When endotracheal intubation is used without mechanical ventilation (eg, for upper airway obstruction), mist and continuous positive pressure ventilatory assistance should be included. The humidity will help loosen the secretions and prevent drying of the airway; the continuous positive pressure will help prevent atelectasis and closure of lung units distal to the swollen airways. Tracheostomy is indicated in the first several days for patients who are expected to require ventilatory support for a few weeks or more. If the neck is burned, excision and grafting followed by tracheostomy is indicated in order to improve pulmonary toilet.

Mechanical ventilation should be instituted early if a significant pulmonary injury is anticipated. A large body burn with chest wall involvement will result in decreased chest wall compliance, increased work of breathing, and subsequent atelectasis. Tracheobronchial injury from inhaled chemicals is accentuated by the presence of a body burn, with a resultant increase in the potential for atelectasis and infection. Controlled ventilation along with sedation will diminish the degree of injury and also conserve energy expenditure. Early excision of the deep chest wall burn will help remove the constricting component. Wound closure in turn will decrease the excessive CO₂ production caused by the hypermetabolic state.

REHABILITATION OF THE BURNED PATIENT

Plastic surgical revisions of scars are often necessary after the initial grafting, particularly to release contractures over joints and for cosmetic reasons. The physician must be realistic in defining an acceptable result, and the patient should be told that it may take years to achieve. Burn scars are often unsightly, and—although hope should be extended that improvement can be made—total resolution is not possible in many cases.

Skin expansion techniques utilizing a subdermal Silastic bag that is gradually expanded have greatly improved scar revision management. The ability to enlarge the available skin to be used for replacement of scar improves both cosmetic appearance and function. Advances in microvascular flap surgery have also resulted in substantial improvements in outcome.

The patient must take special care of the skin of the burn scar. Prolonged exposure to sunlight should be avoided, and the wound involves areas such as the face and hands, which are frequently exposed to the sun, ultraviolet screening agents should be used. Hypertrophic scars and keloids are particularly bothersome and can be diminished with the use of pressure garments, which must be worn until the scar matures—approximately 12 months. Since the skin appendages are often destroyed by full-thickness burns, creams and lotions are required to prevent drying and cracking and to reduce itching. Substances such as lanolin, vitamin A and D ointment, and Eucerin cream are all effective.

ELECTRICAL INJURY

There are three kinds of electrical injuries: electrical current injury, electrothermal burns from arcing current, and flame burns caused by ignition of clothing. Occasionally, all three are present in the same victim.

Electrical current injury, or “hidden injury,” results from the passage of electrical current through the body. Flash or arc burns are thermal injuries to the skin caused by a high-tension electrical current creating local heat and damaging skin. The thermal injury to the skin is intense and deep, because the electrical arc has a temperature of about 2500°C (high enough to melt bone). Flame burns from ignited clothing are often the most serious part of the injury. Treatment is the same as for any thermal injury.

Once current enters the body, its pathway depends on the resistances it encounters in the various organs. The following are listed in descending order of resistance: bone, fat, tendon, skin, muscle, blood, and nerve. The pathway of the current determines immediate survival; for example, if the current passes through the heart or the brain stem, death may be immediate from ventricular fibrillation or apnea. Current passing through muscles may cause spasms severe enough to produce long-bone fractures or dislocations.

The type of current is also related to the severity of injury with low-voltage (150 V) current. The usual 60-cycle alternating current that causes most injuries in the home is particularly severe. Alternating current causes tetanic contractions, and the victim may become “locked” to the contact. Cardiac arrest is common from contact with low-voltage house current.

High-voltage electrical current injuries are more than just burns. Focal deep burns occur at the points of entrance and exit through the skin. These burns often extend through local muscle, resulting in fourth-degree burn. Once inside the body, the current travels through muscles, causing an injury more like a crush than a thermal burn. This leads to blood and fluid extravasation, increasing interstitial pressure in the muscle compartments. A fasciotomy is often necessary, opening all the muscle compartments involved. Early action is necessary to avoid severe vascular insufficiency or nerve damage. Thrombosis frequently occurs in vessels deep in an extremity, causing a greater depth of tissue necrosis than is evident at the initial examination. The greatest muscle injury is usually closest to the bone, where the highest heat of resistance is generated. The treatment of electrical injuries depends on the extent of deep muscle and nerve destruction more than on any other factor.

Severe myoglobinuria may develop with the risk of acute tubular necrosis as the muscle pigment is released from muscle and precipitates in renal tubules. The urine output must be kept two to three times normal with intravenous fluids. Alkalinization of the urine and osmotic diuretics may be indicated if myoglobinuria is present to more rapidly clear the pigment.

A rapid drop in hematocrit sometimes follows as sudden destruction of red blood cells by the electrical energy occurs. Bleeding into deep tissues may occur as a result of disruption of blood vessels and tissue planes. In some cases, thrombosed vessels disintegrate later and cause massive

interstitial hemorrhage. Increased fluid infusion is required for initial resuscitation compared to extent of external thermal burns alone.

The skin burn at the entrance and exit sites is usually a depressed gray or yellow area of full-thickness destruction surrounded by a sharply defined zone of hyperemia. Charring may be present. The lesion should be debrided to underlying healthy tissue. Frequently, there is deep destruction not initially evident, especially to muscles beneath the skin surface. This dead and devitalized tissue must also be excised as soon as possible. Amputation rate for extremity involved is still high but decreasing. A second debridement is usually indicated 24–48 hours after the injury, because the necrosis is found to be more extensive than originally thought. The strategy of obtaining skin covering for these burns can tax ingenuity because of the extent and depth of the wounds. Microvascular flaps are now used routinely to replace large tissue losses.

In general, the treatment of electrical injuries is complex at every step, and these patients are referred to specialized centers. There are no formulas for determining severity and outcome of high-voltage electrical injuries.

HEAT STROKE & RELATED INJURIES

Heat stroke occurs when core body temperature exceeds 40°C and produces severe central nervous system dysfunction. Two related syndromes induced by exposure to heat are heat cramps and heat exhaustion.

In humans, heat is dissipated from the skin by radiation, conduction, convection, and evaporation. When the ambient temperature rises, heat loss by the first three is impaired; loss by evaporation is hindered by a high relative humidity. Predisposing factors to heat accumulation are dermatitis; use of phenothiazines, beta-blockers, diuretics, or anticholinergics; intercurrent fever from other disease; obesity; alcoholism; and heavy clothing. Cocaine and amphetamines may increase metabolic heat production.

Heat cramps—muscle pain after exertion in a hot environment—are usually attributed to salt deficit. It is probable, however, that many cases are really examples of **exertional rhabdomyolysis**. This condition, which may also be a complicating factor in heat stroke, involves acute muscle injury due to severe exertional efforts beyond the limits for which the individual has trained. It often produces myoglobinuria, which rarely affects kidney function except when it occurs in patients also suffering from heat stroke. Complete recovery is the rule after uncomplicated heat cramps.

Heat exhaustion consists of fatigue, muscular weakness, tachycardia, postural syncope, nausea, vomiting, and an urge to defecate caused by dehydration and hypovolemia from heat stress. Temperature usually exceeds 39°C. Although body temperature is normal in heat exhaustion, there is a continuum between this syndrome and heat stroke.

Heat stroke, a result of imbalance between heat production and heat dissipation, kills about 4000 persons yearly in the United States. Exercise-induced heat stroke most often affects young people (eg, athletes, military recruits, laborers) who are exercising strenuously in a hot environment, usually without adequate training. Heat production exceeds the ability to dissipate the heat; core temperature then rises and hypovolemia is evident. Sedentary heat stroke is a disease of elderly or infirm people whose cardiovascular systems are unable to adapt to the stress of a hot environment and release sufficient heat such that body temperature rises. Epidemics of heat stroke in elderly people can be predicted when the ambient temperature surpasses 32.2°C and the relative humidity reaches 50%-76%.

The mechanism of injury is direct damage by heat to the parenchyma and vasculature of the organs. In addition, there is a marked cytokine-induced activation of inflammation similar to sepsis, leading to inflammation-induced organ damage. The central nervous system is particularly vulnerable, and cellular necrosis is found in the brains of those who die of heat stroke. Hepatocellular and renal tubular damage are apparent in severe cases. Subendocardial damage and occasionally transmural infarcts are discovered in fatal cases even in young persons without previous cardiac disease. Disseminated intravascular coagulation may develop, aggravating injury in all organ systems and predisposing to bleeding complications.

► Clinical Findings

A. Symptoms and Signs

Heat stroke should be suspected in anyone who develops sudden neurological changes in a hot environment. If the patient's temperature is above 40°C (range: 40-43°C), the diagnosis of heat stroke is definitive. Measurements of body temperature must be made rectally. A prodrome including dizziness, headache, nausea, chills, and goose-flesh of the chest and arms is seen occasionally but is not common. In most cases, the patient recalls having experienced no warning symptoms except weakness, tiredness, or dizziness. Confusion, belligerent behavior, or stupor may precede coma. Convulsions may occur.

The skin is pink or ashen and sometimes, paradoxically, dry and hot; dry skin in the presence of hyperpyrexia is virtually pathognomonic of heat stroke. Profuse sweating is usually present in runners and other athletes who have heat stroke. The heart rate ranges from 140 beats/min to 170 beats/min; central venous or pulmonary wedge pressure is high;

and in some cases the blood pressure is low. Hyperventilation may reach 60 breaths/min and may give rise to respiratory alkalosis. Pulmonary edema and bloody sputum may develop in severe cases. Jaundice is frequent within the first few days after onset of symptoms.

Dehydration, which may produce the same central nervous system symptoms as heat stroke, is an aggravating factor in about 50% of cases.

B. Laboratory Findings

There is no characteristic pattern to the electrolyte changes. The serum sodium concentration may be normal or high, and the potassium concentration is usually low on admission or at some point during resuscitation. In the first few days, the aspartate aminotransferase (AST), lactate dehydrogenase (LDH), and creatine kinase (CK) may be elevated, especially in exertional heat stroke. Proteinuria and granular and red cell casts are seen in urine specimens collected immediately after diagnosis. If the urine is dark red or brown, it probably contains myoglobin. The blood urea nitrogen and serum creatinine rise transiently in most patients and continue to climb if renal failure develops. Hematologic findings may be normal or may be typical of disseminated intravascular coagulation (ie, low fibrinogen, increased fibrin split products, slow prothrombin and partial thromboplastin times, and decreased platelet count).

C. Prevention

For the most part, heat stroke in military recruits and athletes in training is preventable by adhering to a graduated schedule of increasing performance requirements that allows acclimatization over 2-3 weeks and increasing fluid replacement using water and some electrolytes, especially sodium. Heat produced by exercise is dissipated by increased cardiac output, vasodilation in the skin, and increased sweating. With acclimatization, there is increased efficiency for muscular work, increased myocardial performance, expanded extracellular fluid volume if hydration is maintained, greater output of sweat for a given amount of work (releasing more heat), a lower salt content of sweat, and a lower central temperature for a given amount of work.

Access to drinking water should be unrestricted during vigorous physical activity in a hot environment. Free water is preferable to electrolyte-containing solutions. Clothing and protective gear should be lightened as heat production and air temperature rise, and heavy exercise should not be scheduled at the hottest times of day, especially at the beginning of a training schedule.

► Treatment

The patient should be cooled rapidly. The most efficient method is to induce evaporative heat loss by spraying the patient

with water at 15°C and fanning with cool air. Immersion in an ice water bath or the use of ice packs is also effective but causes cutaneous vasoconstriction and shivering and makes patient monitoring more difficult. Monitor the rectal temperature frequently. To avoid overshooting the end point, vigorous cooling should be stopped when the temperature reaches 38.9°C. Shivering should be controlled with parenteral phenothiazines. Oxygen should be administered, and if the PaO₂ drops below 65 mm Hg, tracheal intubation should be performed to control ventilation. Fluid, electrolyte, and acid-base balance must be controlled by frequent monitoring. Intravenous fluid administration should be based on the central venous or pulmonary artery wedge pressure, blood pressure, and urine output; overhydration must be avoided. Intravenous mannitol (12.5 g) may be given early if myoglobinuria is present to avoid renal dysfunction. Disseminated intravascular coagulation may require treatment with heparin. Occasionally, inotropic agents (eg, isoproterenol, dopamine) may be indicated for cardiac insufficiency, which should be suspected if hypotension persists after hypovolemia has been corrected.

► Prognosis

Bad prognostic signs are temperature of 42.2°C or more, coma lasting over 2 hours, shock, hyperkalemia, and an AST greater than 1000 units/L during the first 24 hours. The death rate is about 10% in patients who are correctly diagnosed and treated promptly. Deaths in the first few days are usually due to cerebral damage; later deaths may be from bleeding or may be due to cardiac, renal, or hepatic failure.

Leon LR: Heat stroke and cytokines. *Prog Brain Res.* 2007;162:481.

FROSTBITE

Frostbite involves freezing of tissues. Ice crystals form between and in the cells and grow at the expense of intracellular water. The resulting ischemia due to vasoconstriction and increased blood viscosity is the mechanism of tissue injury. Skin and muscle are considerably more susceptible than tendons and bones to freezing damage due to a lower oxygen requirement, which explains why the patient may still be able to move severely frostbitten digits.

Frostbite is caused by cold exposure, the effects of which can be magnified by moisture or wind; for example, the chilling effects on skin are the same with an air temperature of 6.7°C and a 40-mph wind as with an air temperature of -40°C and only a 2-mph wind. Contact with metal or gasoline in very cold weather can cause virtually instantaneous freezing; skin will often stick to metal and be lost. The risk of frostbite is increased by generalized hypothermia, which produces peripheral vasoconstriction as part of the mechanism for preservation of core body temperature.

Two related injuries, trench foot and immersion foot, involve prolonged exposure to wet cold above freezing (eg, 10°C). The resulting tissue damage is produced by tissue ischemia.

► Clinical Findings

Frostnip, a minor variant of this syndrome, is a transient blanching and numbness of exposed parts that may progress to frostbite if not immediately detected and treated. It often appears on the tips of fingers, ears, nose, chin, or cheeks and should be managed by rewarming through contact with warm parts of the body or warm air.

Frostbitten parts are numb, painless, and of a white or waxy appearance. With superficial frostbite, only the skin and subcutaneous tissues are frozen, so the tissues beneath are still compressible with pressure. Deep frostbite involves freezing of underlying tissues, which imparts a wooden consistency to the extremity.

After rewarming, the frostbitten area becomes mottled blue or purple and painful and tender. Blisters appear that may take several weeks to resolve. The part becomes edematous and to a varying degree painful.

► Treatment

The frostbitten part should be rewarmed (thawed) in a water bath at 40-42.2°C for 20-30 minutes. Thawing should not be attempted until the victim can be kept permanently warm and at rest. It is far better to continue walking on frostbitten feet even for many hours than to thaw them in a remote cold area where definitive care cannot be provided. If a thermometer is unavailable, the temperature of the water should be adjusted to be warm but not hot to a normal hand. Never use the frozen part to test the water temperature or expose it to a source of direct heat such as a fire. The risk of seriously compounding the injury is great with any method of thawing other than immersion in warm water.

After thawing has been completed, the patient should be kept recumbent and the injured part left open to the air, protected from direct contact with sheets, clothing, or other material. Blisters should be left intact and the skin gently debrided by immersing the part in a whirlpool bath for about 20 minutes twice daily. No scrubbing or massaging of the injured part should be allowed, and topical ointments, antiseptics, and so on, are of no value. Vasodilating agents and surgical sympathectomy do not appear to improve healing.

The tissue will heal gradually, and any dead tissue will become demarcated and usually slough spontaneously. Early in the course, it is nearly impossible, even for someone with considerable experience in the treatment of frostbite, to judge the depth of injury; most early assessments tend to overestimate the extent of permanent damage. Therefore, expectant treatment is the rule, and surgical debridement should be avoided even if evolution of the injury requires

many months. Surgery may be indicated to release constricting circumferential eschars, but rarely should the process of spontaneous separation of gangrenous tissue be surgically facilitated. Even in severe injuries, amputation is rarely indicated before 2 months unless invasive infection supervenes. Nuclear scans may be useful to delineate tissue viability.

Concomitant fractures or dislocations create challenging and complex problems. Dislocations should be reduced immediately after thawing. Open fractures require operative reduction, but closed fractures should be managed with a posterior plastic splint. Anterior tibial compartment syndrome, which may develop in patients with associated fractures, may be diagnosed by arteriography and treated by fasciotomy.

After the eschar separates, the skin is noted to be thin, shiny, tender, and sensitive to cold; occasionally it exhibits a tendency to perspire more readily. Gradually, it returns toward normal, but pain on exposure to cold may persist indefinitely.

► Prognosis

The prognosis for normal function is excellent if appropriate treatment is provided. Individuals who have recovered from frostbite have increased susceptibility to another frostbite injury on exposure to cold.

Affleck DG et al: Assessment of tissue viability in complex extremity injuries: utility of the pyrophosphate nuclear scan. *J Trauma*. 2001;50:263.

Murphy JV et al: Frostbite: pathogenesis and treatment. *J Trauma*. 2000;48:171.

ACCIDENTAL HYPOTHERMIA

Accidental hypothermia consists of the uncontrolled lowering of core body temperature below 35°C by exposure to cold. The syndrome may be seen, for example, in elderly people living alone in inadequately heated homes, in alcoholics exposed to the cold during a binge, in those engaged in winter sports, and in people who become lost in cold weather. Alcohol facilitates the induction of hypothermia by producing sedation (inhibiting shivering) and cutaneous dilation. Other sedatives, tranquilizers, and antidepressants are occasionally implicated. Diseases that predispose to hypothermia include myxedema, hypopituitarism, adrenal insufficiency, cerebral vascular insufficiency, mental impairment, and cardiovascular disorders.

The heart is the organ most sensitive to cooling and is subject to ventricular fibrillation or asystole when the temperature drops to 21-24°C. Hypothermia affects the oxyhemoglobin dissociation curve, so less oxygen is released to the tissues. Cardiac standstill may cause death in less than 1 hour in shipwreck victims immersed in cold water (6.7°C).

Increased capillary permeability, manifested by generalized edema and pulmonary, hepatic, and renal dysfunction, may develop as the patient is rewarmed. Coagulopathies and disseminated intravascular coagulation are seen occasionally. Pancreatitis and acute renal failure are common in patients whose temperature on admission is below 32°C.

► Clinical Findings

A. Symptoms and Signs

The patient is mentally depressed (somnolent, stuporous, or comatose), cold, and pale to cyanotic. The clinical findings are not always striking and may be mistaken for the effects of alcohol. The core temperature ranges from 21°C to 35°C. Shivering is absent when the temperature is below 32°C. Respirations are slow and shallow. The blood pressure is usually normal and the heart rate slow. When the core temperature drops below 32°C, the patient may appear to be dead. The extremities may be frostbitten or frozen.

B. Laboratory Findings

Dehydration may increase the concentration of various blood constituents. Severe hypoglycemia is common, and unless detected and treated immediately, it may become dangerously worse as rewarming produces shivering. The serum amylase is elevated in about half of cases, but autopsy studies show that it does not always reflect pancreatitis. Diabetic ketoacidosis becomes a management problem in some patients whose amylase values are elevated on entry. The AST, LDH, and CK enzymes are usually elevated but are of no predictive significance. The electrocardiogram shows lengthening of the PR interval, delay in interventricular conduction, and a pathognomonic J wave at the junction of the QRS complex and ST segment.

► Treatment

Hypothermic patients should never be considered dead until all measures for resuscitation have failed, because cardiopulmonary arrest in severe hypothermia is still compatible with some recovery.

Mild hypothermia (body temperature 32-35°C) can be treated in most cases by passive rewarming (heavy clothing and blankets in a warm environment) for a few hours—especially when the patient is shivering. The patient's temperature should be continuously monitored with a rectal or esophageal probe until body temperature reaches normal. Since the volume of intravenous fluids required for resuscitation is often substantial, their temperature can affect the outcome. Consequently, intravenous fluids should be warmed with a heat exchanger during administration.

Active rewarming is indicated for temperature below 32°C, cardiovascular instability, or failure of passive rewarming. The methods include immersion in a warm

water bath, inhalation of heated air, pleural lavage, and blood warming with an extracorporeal bypass machine. Active external rewarming is most often performed by immersion in a warm (40-42°C) water bath, which will raise body temperature at a rate of 1-2 degrees per hour. A disadvantage of this method is that the core temperature may continue to decline after initiation of the rewarming efforts (known as afterdrop), which is associated with worsening cardiovascular function.

Closed pleural irrigation should be performed by flushing the right hemithorax with warm (40-42°C) saline solution through two large thoracostomy tubes, one anterior and the other posterior. Rewarming by peritoneal lavage involves giving warm (40-45°C) crystalloid solutions, 6 L/h, which raises core temperature by 2-4 degrees per hour.

Active core rewarming with partial cardiopulmonary bypass, the most efficient technique, is indicated for patients with ventricular fibrillation and severe hypothermia or those with frozen extremities. At a flow rate of 6-7 L/min, core temperature can be raised by 1-2°C every 3-5 minutes.

In severe cases, endotracheal intubation should be used for better management of ventilation and protection against aspiration, a common lethal complication. Arterial blood gases should be monitored frequently. Bretylium tosylate in an initial dose of 10 mg/kg is the best drug for ventricular fibrillation. Antibiotics are often indicated for coexisting pneumonitis. Serious infections are often unsuspected upon admission, and delay in appropriate therapy may contribute to the severity of the illness. Hypoglycemia calls for intravenous administration of 50% glucose solution. Fluid administration must be gauged by central venous or pulmonary artery wedge pressures, urine output, and other circulatory parameters. Increased capillary permeability following rewarming predisposes to the development of pulmonary edema and compartment syndromes in the extremities. To minimize these complications, the central venous or wedge pressure should be kept below 12-14 cm water. Drugs should not be injected into peripheral tissues, because absorption will not take place while the patient is cold and because drugs may accumulate to produce serious toxicity as rewarming occurs.

As rewarming proceeds, the patient should be continually reassessed for signs of concomitant disease that may have been masked by hypothermia, especially myxedema and hypoglycemia. Any inexplicable failure to respond should suggest adrenal insufficiency.

► Prognosis

Survival can be expected in only 50% of patients whose core temperature drops below 32.2°C. Coexisting diseases (eg, stroke, neoplasm, myocardial infarction) are common and increase the death rate to 75% or more. Survival does not correlate closely with the lowest absolute temperature

reached. Death may result from brain damage pneumonitis, heart failure, or renal insufficiency.

MULTIPLE CHOICE QUESTIONS

- Burn severity can be informed by each of the following except
 - Fraction of body surface area affected
 - Patient's age
 - Death of others in the same incident
 - Accompanying other major trauma
 - Concurrent inhalational injury
- Hypermetabolism after burn injuries
 - Can contribute to coagulopathy
 - Causes a disproportionate loss of muscle mass
 - Can approach a threefold increase in basal metabolic rate after severe burns
 - Can be slowed with beta-adrenergic blockade
 - Is not catabolic and can be limited by decreased caloric intake
- Care of the burn wound may include each of the following except
 - Closed method occlusive dressings with twice daily dressing changes
 - May accompany tension pneumothorax
 - Exposure therapy with topical agents applied to uncovered areas of the face
 - Primary management with bismuth-containing antimicrobial topical agents
 - Temporary coverage with a skin substitute
- Maintenance of functional motion during burn wound healing
 - Benefits from early consideration with functional position splinting and active motion
 - Is benefitted, in general, by the tendency of the wounds to contract
 - Suffers after early skin grafting due to promotion of wound contracture
 - Is easier to maintain around joints due to increased natural motion
 - A and C
- Respiratory compromise after burn wounds is commonly due to
 - Early pulmonary emboli (12-36 hours after injury)
 - Inhalational injury
 - Cardiogenic pulmonary edema
 - Fungal bronchitis
 - Viral pneumonitis

Otolaryngology: Head & Neck Surgery

Paul M. Weinberger, MD
David J. Terris, MD

15

INTRODUCTION

From hearing loss or nasal hemorrhage (epistaxis) to endocrine surgery and expert management of acute airway emergencies, otolaryngology/head and neck surgery is a surgical subspecialty which focuses on the management of a wide range of disorders of the head and neck. As a colleague once put it, “Otolaryngology pretty much covers everything above the clavicles except the eyes, the brain, and the spinal cord.” The limits inherent to a single book chapter preclude covering such a broad field comprehensively. Therefore this chapter will present an overview of selected disease processes in otolaryngology that are of importance to the general surgeon in training. Other important parts of otolaryngology such as surgical endocrine disorders of the neck (eg, thyroid and parathyroid), facial plastic and reconstructive surgery, and facial skeletal trauma are covered in separate chapters.

DISORDERS OF THE EAR, AUDITORY, VESTIBULAR SYSTEMS, AND TEMPORAL BONE

► Anatomy and Physiology

The external ear consists of two parts, the auricle (projecting from the lateral aspect of the head) and the external auditory canal (EAC) projecting medially to the tympanic membrane. Functioning as resonant amplifiers of sound energy, the concha of the auricle (Figure 15–1) has a resonance frequency of approximately 5 KHz, and the EAC has a resonance frequency of approximately 3.5 KHz. Combined, the external ear amplifies sound by approximately 10-15 dB in the 2-5 KHz range.

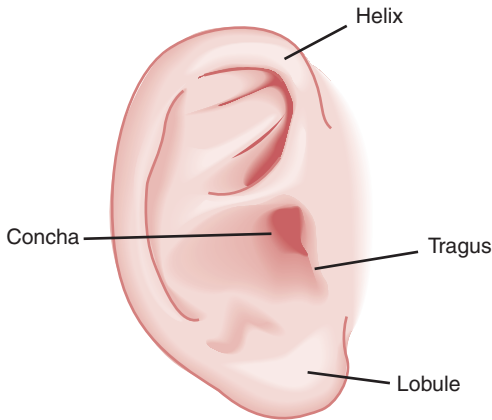

The tympanic membrane is positioned in an oblique plane, separating the EAC from the middle ear. It functions in transforming acoustic energy from sound waves to mechanical energy, which is transmitted via the ossicles—malleus, incus, and stapes to the oval window of the cochlea. The mechanics of the middle ear further amplify sound

energy using two methods. First, the tympanic membrane is approximately 17 times larger than the footplate of the stapes; second, the ossicles act as a lever, providing a mechanical advantage of 1:1.3 from the tympanic membrane to the oval window. Combined, the result is a 25-30 dB gain in amplification.

The temporal bone houses the bony portion of the EAC, the middle, and the inner ear. The otic capsule of the inner ear is the hardest bone in the human body. Other important structures passing through or adjacent to the temporal bone include the carotid artery, the jugular vein, and the facial nerve (seventh cranial nerve). All of these structures are at risk for injury from temporal bone trauma.

The inner ear consists of the cochlea, which is both the auditory and vestibular sense organ. The vestibular system senses both linear acceleration (gravity) and angular acceleration (rotation). The hearing portion of the cochlea is a coiled tube that resembles a snail. Divided into three separate chambers, the scala vestibule and the scala tympani are filled with perilymph (similar in composition to extracellular fluid), while the scala media is filled with endolymph (similar in composition to intracellular fluid). The endolymph composition is maintained by Na⁺/K⁺ ATPase pumps within the stria vascularis found on the lateral walls of the scala media. These different chambers thus have different electrolyte composition, creating an electrical potential between the compartments. The sound energy, once transferred through the ossicles to the oval window of the cochlea, is coupled directly to the perilymph of the scala vestibule.

The resulting traveling wave is in the form of mechanical energy, which is then converted to electrical (neural) impulses within the scala media by the organ of Corti. The organ of Corti consists of inner hair cells (which are the sensory cells) and outer hair cells (which function as modulators of the inner hair cells), support cells and tectorial membrane. These nerve impulses produced by the inner hair cells are transmitted to the brainstem by the eighth cranial nerve,

▲ **Figure 15–1.** Normal external ear anatomy.

which travels from the cochlea through the internal auditory canal (IAC).

The vestibular system consists of the utricle, saccule, and three semicircular canals. Enveloped within the endolymphatic membrane, which is filled with endolymph, they are surrounded by perilymph, and then the very hard bone of the otic capsule. The utricle detects horizontal acceleration while the saccule detects vertical acceleration. Three semicircular canals, situated at right angles to each other, and paired with a semicircular canal on the opposite side of the head, detect angular acceleration.

Simplified, linear or angular motion causes their respective sensory cells to deflect, and the sensory cell body to depolarize. Depending on the direction, each vestibular apparatus will either increase or decrease the discharge rate relative to the basal rate, providing both direction, and speed of acceleration. Vestibular information is transmitted to the brainstem by the vestibular branch of the eighth cranial nerve.

► Urgencies and Emergencies

A. Sudden Sensorineural Hearing Loss

The sudden onset of unilateral (or more uncommonly bilateral) hearing loss occurs at an annual incidence of 5-20 cases per 100,000 persons and can be an extremely unsettling experience for a patient. Most experts use a definition based on at least a 30 dB hearing loss occurring over 3 days or less. The causes of SSHL include viral infection (particularly herpes-family viruses), trauma, vascular compromise from thromboembolic phenomena or vasospasm, autoimmune disease, ototoxic (from chemotherapy, antibiotics, or salicylates), and congenital anatomic defects.

Prompt evaluation and initiation of treatment is critical, and may improve the prognosis for hearing improvement. Because of the multitude of potential mechanisms,

a careful history should be performed. Often, the cause remains unknown. Patients may report an antecedent loud noise exposure such as an explosion (suggesting traumatic perilymphatic fistula), or upper respiratory tract infection symptoms (suggesting possible viral mechanism). Recent heart surgery or thromboembolic phenomenon could suggest a vascular etiology. Patients should be questioned about coincident imbalance or vertiginous symptoms, and tinnitus (ringing in the ears), indicative of vestibular as well as auditory pathology.

Formal pure-tone audiometry testing should be obtained. If the patient reports vestibular or balance symptoms, investigation of the vestibular system should be performed. Dix-Hallpike and Baranay maneuvers test for vertigo in response to specific position changes with respect to gravity. Simple tests of the auditory system (Weber and Rinne tests) can also be performed at the bedside using a 512 KHz tuning fork (Table 15–1). Pneumatic otoscopy should be performed, to evaluate for fistula sign (vertigo on pneumotoscopy insufflation).

Workup should include evaluation for a vestibular schwannoma, as this represents approximately 1%-3% of the sudden sensorineural hearing loss (SSHL). This can be done by the auditory evoked brainstem response (ABR), or a magnetic resonance imaging (MRI) with contrast using IAC protocols. Some experts advocate a less expensive screening MRI without contrast as an acceptable first step, followed by more definitive evaluations if any abnormalities are present. Laboratory studies should include a CBC with differential, ESR, PT/PTT, and cochlear antibodies. Additional studies

Table 15–1. Weber and Rinne tuning fork tests.

Condition	Weber	Rinne
Left sensorineural hearing loss	Louder on <i>right</i>	A>B bilaterally
Left conductive hearing loss	Louder on <i>left</i>	A>B on right A=B or A<B on left
Normal hearing	Midline/no difference	A>B bilaterally

In the **Weber** test, the tuning fork is struck and applied in the midline to the skull or teeth. This stimulates both cochlea by direct bone conduction. The patient is asked whether they hear the sound the same on both sides or louder on one side.

In the **Rinne** test, a tuning fork is struck and held by the auricle (condition "A," air conduction). Sound is conducted through the ossicular chain and to the cochlea. The fork is then applied to the mastoid tip, and acoustic energy transmitted to the cochlea by direct bone conduction (condition "B," bone conduction). The patient is then asked which is louder, A or B. In a normal hearing ear, A (air) is greater than B (bone). In sensorineural hearing loss, A will still be greater than B. In conductive hearing loss, A=B or even B>A.

that may be helpful include syphilis testing (either MHA-TP or FTA-Abs), and thyroid function tests. If there is a family history of sudden hearing loss, a computed tomography (CT) scan looking for enlarged vestibular aqueduct can be obtained.

If the workup reveals a cause for the SSHL, this should be addressed. Unfortunately, the majority remain idiopathic. In this case, unless contraindicated due to comorbidities, initial treatment should be started empirically. Oral corticosteroids, such as a prednisone taper (60 mg daily for 9 days then tapering over 5 days), and antiviral medication (such as acyclovir) should be administered for a minimum of 2 weeks. Other treatments such as hyperbaric oxygen, carbogen inhalation, anticoagulation, and diuretics have been proposed for the treatment of SSHL but results of these therapies have been inconclusive.

The prognosis for spontaneous recovery of function is hopeful, and approximately 60% of patients will recover full or partial hearing. With corticosteroid treatment, this may increase to 80% according to some studies. The addition of acyclovir has not been shown to be effective, but some experts recommend it due to low side effects and a plausible mechanism of action.

B. Acute Facial Nerve Paralysis

The seventh cranial nerve (facial nerve) innervates the muscles of facial expression (as well as special motor afferents to the parotid and lacrimal glands). A careful history will help define the onset of paralysis (eg, acute deterioration over less than 2-3 days, or gradual decline). Antecedent events (temporal bone trauma, acute otitis media [AOM], hearing loss or imbalance, and recent viral illness) should be elicited and can help guide further workup and management.

Potential causes of acute facial nerve paralysis are numerous; however over 50% are idiopathic and termed “Bell Palsy.” Note that Bell Palsy is a diagnosis of exclusion, and therefore a focused but complete workup must be performed. Fully 20% of facial nerve paralyzes are caused by trauma. Other common causes (but by no means an inclusive list) include herpes zoster oticus (Ramsey Hunt syndrome), complications from otitis media and mastoiditis, Lyme disease, cholesteatoma, and neoplasm.

A complete physical examination with emphasis on the neurologic system and cranial nerves is critical. An important consideration in evaluating the patient with acute facial nerve paralysis is distinguishing between central and peripheral lesions. In central lesions, there is sparing of forehead elevation on the affected side due to decussating fibers from the contralateral side. In peripheral lesions the fibers have already crossed and there is no forehead sparing. The degree of facial nerve functional loss should be documented and has important bearing on prognosis. Several grading systems have been proposed; the House–Brackmann scale is the most

Table 15–2. House-Brackmann facial nerve paralysis scale.

Grade	Characteristics
I (Normal)	Normal function in all branches
II (Mild dysfunction)	Slight weakness to visual inspection Normal symmetry and tone at rest Forehead: moderate to good function Eye: complete closure, minimal effort Mouth: slight asymmetry
III (Moderate dysfunction)	Mild difference to gross inspection between sides Normal symmetry and tone at rest Forehead: slight to moderate movement Eye: complete closure, requires effort Mouth: slightly weak, requires effort
IV (Moderately severe dysfunction)	Obvious weakness to gross inspection between sides Normal symmetry and tone at rest Forehead: no motion even with effort Eye: incomplete closure even with effort Mouth: asymmetric with maximum effort
V (Severe dysfunction)	Only barely perceptible motion to gross inspection Asymmetry at rest Forehead: no motion even with effort Eye: incomplete closure even with effort Mouth: slight movement even with maximum effort
VI (Total paralysis)	No movement

widely used and is presented in Table 15–2. Facial nerve function is graded from I (normal) to VI (total paralysis) for each side.

Evaluation should include pure-tone audiometry and electrophysiologic testing. A high-resolution CT of the temporal bone is the imaging study of choice for evaluating bone changes (from mastoiditis, temporal bone trauma, cholesteatoma, or neoplasm) whereas MRI with contrast is helpful when inflammation (eg, herpes zoster oticus) or neoplasm affecting the nerve is suspected. Laboratory studies should include a CBC with differential and ESR or CRP. If these are clinically suspected, autoimmune serologies and Lyme titers can be obtained.

If the facial nerve paralysis is caused by traumatic injury, management depends on the onset of paralysis; immediate and complete paralysis will often benefit from surgical decompression. In delayed or partial dysfunction, spontaneous recovery is likely and surgical intervention may not be beneficial. For idiopathic paralysis (Bell Palsy), initial medical therapy is targeted to reducing inflammation and targeting a possible viral etiology. A corticosteroid course should be initiated, either prednisone or prednisolone. Previous recommendations for the use of acyclovir (or similar antiherpetic

analog) have recently been questioned. A large-scale randomized double blind study by Sullivan et al demonstrated no benefit for acyclovir, but significant benefit for prednisolone in the treatment of Bell Palsy. If the paralysis progresses, surgical decompression may be beneficial. Most experts also argue a significant benefit to performing surgical decompression of the facial nerve if a patient progresses to severe paralysis, provided the decompression is performed within 14 days of the onset of paralysis. Severe paralysis is usually defined as developing greater than 90% degeneration on electroneurography (ENoG) and lacking voluntary motor potentials on EMG.

C. Foreign Body in the External Auditory Canal–Button Batteries

The vast majority of cases of foreign bodies in the EAC occur in children, or mentally impaired adults. Many otologic foreign bodies, if carefully selected, are actually amenable to removal under direct visualization in an emergency department or primary care office setting. In a large series of over 600 cases of ear foreign bodies, Shulze et al found an overall 77% success rate for the removal under direct visualization by emergency physicians. It is important to note that the majority of those foreign bodies successfully removed in this manner fit the category of “soft, irregular” material such as paper or cotton, and “pliable or rubber-like” such as silly putty or erasers. Success with hard objects, and especially spherical objects such as plastic beads was markedly lower. Thus, an argument can be made for a single attempt by the pediatrician or emergency physician under direct visualization, if the object meets the former criteria. This should be tempered, however, with the understanding that complication rates are much higher with removal under direct vision. Complications of foreign body removal most commonly include canal wall lacerations (47%), with tympanic membrane perforations less common (4%). More serious complications such as ossicular chain injury and oval window perforation are possible but rare. When initial foreign body removal is performed instead by the otolaryngologist using binocular otomicroscopy either in the office or operative setting, the complication rate is quite low (6.3%).

Foreign body removal using binocular otomicroscopy is the primary method used by most otolaryngologists. Specific techniques depend on the characteristics of the foreign body. Objects with sharp edges can often be grasped with alligator or duck-bill forceps. Soft objects are often amenable to removal with otologic suction. Removal of spherical and hard, irregular objects requires more finesse. In these cases a 90-degree probe is invaluable. The probe is carefully guided behind the object under binocular otomicroscopic visualization. Then the probe is rotated along its axis to bring the end behind the object. The object is then guided out of the EAC. Another special case is an insect within the EAC, most

commonly cockroaches. This can be quite alarming to the patient if the insect is still alive. The proximity of the insect to the tympanic membrane translates movement of the insect to distressingly loud perceived sound levels. In such cases the external ear canal can be gently irrigated with either mineral oil or lidocaine to suffocate the insect followed by prompt removal.

Some non-otolaryngologists advocate the use of gentle irrigation to attempt dislodgement of EAC foreign bodies. This technique can be used successfully, but requires caution. First, if there is any suspicion of tympanic membrane perforation, irrigation is contraindicated as it could flush debris into the middle ear space. Second, if the foreign body is composed of vegetable material (such as a popcorn kernel) irrigation should be avoided. If the object is not successfully flushed out, subsequent swelling of the vegetable foreign body can result in extreme pain as the EAC skin is compressed against the bony canal. Removal, once this occurs can be problematic, and may require general anesthesia and the use of an operating microscope. For this reason, otologic medications are also contraindicated in vegetable material otologic foreign bodies. The third condition where irrigation (and otologic medications) is specifically contraindicated is in the case of EAC button-batteries.

While the previously described foreign bodies can be managed on an outpatient basis, the finding of a button battery in the EAC is considered an emergent situation, requiring urgent removal by an otolaryngologist. If left in place for any length of time, batteries in the EAC can result in severe complications. In an early description of this problem by Kavanagh et al, 100% of patients experienced multiple, serious sequelae. These included tympanic membrane perforation or total destruction (75%), marked dermal destruction with bone exposure (88%), impairment of hearing (38%), ossicular chain erosion (25%), and even facial nerve paralysis (13%). Both leakage of corrosive battery acid and electrical current discharge resulting in chlorine gas and sodium hydroxide by electrolysis have been hypothesized to contribute to the destructive effects of button batteries. Removal is accomplished under binocular otomicroscopy in the operating room, and sometimes requires piecemeal removal of the battery. Following removal of the battery, the EAC should be flushed with copious amounts of saline, and careful inspection of the external canal and tympanic membrane should be performed.

► Disorders and Diseases

A. Otitis Externa

Otitis externa is an infection of the EAC, usually from bacterial species such as *Pseudomonas*, *Proteus*, *Klebsiella*, *Streptococcus*, and *Enterobacter*. Evaluation and management of a patient with suspected otitis externa includes a complete history and physical examination with emphasis

on the otologic examination. Patients will often give a history of recent water exposure to the external ear, such as from swimming, or other predisposing factors such as chronic hearing aid use. The external pinna should be manipulated gently. In otitis media this should not elicit pain, whereas for patients with otitis externa movement of the pinna is extremely painful. On handheld otoscopy the canal wall will appear edematous and erythematous. Sometimes the edema is severe enough the tympanic membrane cannot be visualized. In this case, insertion of a Pope otowick is indicated to carry ototopical medications the length of the external ear canal past the obstructed site. Severe cases may require frequent suction debridement under microscopic visualization. Patients should be placed on ototopical antibiotic drops containing a topical corticosteroid, such as ciprofloxacin 0.3%/dexamethasone 0.1% suspension (Ciprodex). Some (largely nonotolaryngologist) physicians allow the use of hydrocortisone 1%/polymyxin/neomycin (Cortisporin) as an alternative. This is not recommended for several reasons. First, several authors have demonstrated up to 10% risk of contact dermatitis with polymyxin/neomycin ototopical drops. Second, if a possibility of tympanic membrane perforation exists, these drops carry the possibility of ototoxicity, according to laboratory studies in animals; they are not approved for the middle ear use (unlike fluoroquinolones). Additionally, some studies have demonstrated faster pain relief with Ciprodex compared to Cortisporin. It is essential to note that failure to respond to appropriate therapy within 48-72 hours should prompt the clinician to reassess the patient to confirm a diagnosis of otitis externa.

Of note, patients with a history of diabetes (or any immunocompromising condition) should demand more aggressive therapy targeted toward *Pseudomonas*. This will usually involve an ototopical fluoroquinolone, ototopical corticosteroid, and oral or IV fluoroquinolone therapy. In the past, this subset of otitis externa carried the misnomer “malignant otitis externa” due to the high mortality rate even with surgical debridement and antibiotics. Modern antibiotic therapy and earlier diagnoses and intervention have dramatically improved outcomes, and mortality from this disease is now relatively rare.

Otomycosis is otitis externa due to a fungal infection, usually due to *Aspergillus* or *Candida* species. On otoscopy, there is usually far less edema and erythema than with bacterial infection. The use of ototopical antibiotic solutions will not improve these patients, and usually worsens their condition. Otomycosis can be notoriously difficult to treat, but many cases do respond to suction debridement followed by acidic eardrops and a topical corticosteroid. A commonly used topical preparation is acetic acid 2% with hydrocortisone 1% (Vosol HC). Topical antifungals such as nystatin or amphotericin B are also available but use of these should be reserved for difficult cases under the care of an otolaryngologist.

B. Otitis Media

Classification of common middle ear pathology is often poorly understood by nonotolaryngologists. There are multiple disease processes of the middle ear which include the root term “otitis media.” Additionally, the acronyms used to represent diseases of abnormal middle ear fluid are quite similar.

The first condition, AOM, represents what is commonly referred to as “a middle ear infection.” The typical patient is a young child, with history of upper respiratory tract symptoms, fever, and pulling at one ear. Handheld otoscopy will reveal a bulging, erythematous tympanic membrane. Unlike otitis externa (above) there is no pain with manipulation of the auricle. Several studies from Europe have demonstrated that the majority of AOM cases resolve spontaneously without intervention. Nevertheless, in the United States most parents would be unhappy with a decision not to treat, and antibiotic therapy for AOM is routine. Usual pathogens include bacteria such as *Streptococcus*, *Haemophilus*, and *Moraxella*. The latter two are often resistant to penicillins and thus treatment with amoxicillin may not clear the infection; thus many practitioners recommend a second-generation cephalosporin. Failure to respond to these agents often necessitates a second-line antibiotic such as amoxicillin-clavulanic acid (Augmentin).

Otitis media with effusion (OME) is defined as fluid in the middle ear but no active signs of an infection. OME often results from eustachian tube dysfunction, which predisposes to accumulation of a sterile serous fluid in the middle ear cleft that does not clear. OME is common in young children, with a prevalence approaching 30% according to some reports. Patients with OME present with complaints of muffled or decreased hearing. Examination reveals fluid in the middle ear cleft. Chronic serous otitis media (CSOM) results when middle ear fluid after an episode of AOM fails to clear after a reasonable time span (4-6 weeks).

The most common surgical intervention to treat these problems is myringotomy and tympanostomy (M&T), so-called “ventilation tube” placement. Basic indications for M&T include multiple episodes of AOM (four episodes in 6 months, or six episodes in 12 months), CSOM with hearing impairment present for 3 months or longer, or presence of complications of AOM. Some authors have advocated for a more stratified approach to indications, where patients presenting with problems at an early age warrant surgical intervention with less stringent criteria.

C. Vestibular Schwannoma

Vestibular schwannomas (also sometimes referred to by the misnomer “acoustic neuromas”) represent a nonmalignant but neoplastic proliferation of Schwann cells ensheathing the eighth cranial nerve. These tumors represent nearly 10% of all intracranial tumors, and usually present with a unilateral

high-frequency sensorineural hearing loss, followed later by development of imbalance symptoms. Even a mild degree of hearing loss may be misleading, as sensory processing (as evidenced by speech discrimination scores) are often more impaired than pure-tone averages would predict. Tinnitus and true vertigo are less common symptoms. Interestingly, these tumors arise more often from the vestibular division than the auditory division of cranial nerve eight. The symptoms associated with vestibular schwannomas are associated with compressive effects from the neoplastic growth. In the case of larger tumors, patients can sometimes present with facial nerve weakness. One important syndrome associated with vestibular schwannomas is neurofibromatosis-2 (NF2). Patients with NF2 can present with bilateral vestibular schwannomas, and consideration of hearing preservation strategies thus is extremely important for these patients.

Presumptive diagnosis of vestibular schwannoma is usually made by MRI with gadolinium. Schwannomas enhance brightly on T1 or T2 weighted images with gadolinium. Other diagnostic tests can include auditory brainstem response (ABR), electronystagmography (ENG). All patients with suspected vestibular schwannomas should have audiometric testing (pure-tone averages and speech discrimination scores) performed.

Management of vestibular schwannomas remains controversial. Many authors advocate that small schwannomas confined to the IAC can be successfully watched via serial imaging. Tumors demonstrating no growth (<2 mm) can continue to be watched, while most authors would argue for intervention if more than 2 mm growth occurs. If intervention is elected, treatment can be microsurgical (often involving combined neurosurgical and otologist collaboration) or by stereotactic radiosurgery (gamma knife) for small tumors. The goal of treatment is eradication of the tumor while preserving hearing and facial nerve function when possible. Preservation of facial nerve function (House-Brackman grade 2 or better) is generally successful in up to 70% of patients, regardless of surgical approach used.

D. Benign Paroxysmal Positional Vertigo

Dizziness is an extremely common phenomenon, and has been estimated to affect as many as 30% of patients. An important distinction should be made at this point between various sensations commonly described by patients as “dizziness.” For patients describing dizziness symptoms, an attempt to elicit a more accurate description should always be sought. Vertigo is defined as the illusion of rotation. This should be distinguished from sensations of imbalance or unsteadiness, or of almost losing consciousness (presyncope).

Benign paroxysmal positional vertigo (BPPV) is the most common cause of acute-onset vertigo. Patients will describe sudden onset of intense vertigo lasting seconds rather than

minutes, usually brought on by changes in head or body position relative to gravity. There is sometimes an associated history of head trauma. The etiology is thought to be due to dislocation of micro-crystals of calcium hydroxyapatite (otoconia) from the vestibule into the posterior semicircular canal. Certain head movements cause the otoconia to abnormally trigger copular deflection and thus elicit imbalanced vestibular input to the brainstem triggering intense vertigo. Diagnosis of BPPV can be made by positional testing, such as the Dix-Hallpike maneuver. In this test, the patient’s head is turned to one side and the patient is laid into a recumbent position with the head maintained in the rotated position. Elicitation of vertigo, often accompanied by the expected rotatory nystagmus, essentially confirms the diagnosis. Treatment consists of directed repositioning techniques such as the Epley maneuver. These maneuvers are designed to rotate the otoconia through the semicircular canal, depositing them back in a more physiologic location within the vestibule. Often several treatments are required, and patients can be instructed in the self-application of these maneuvers.

E. Ménière Disease

Ménière disease is characterized by waxing and waning sensorineural hearing loss (typically low frequency more than high), episodes of vertigo, sensation of aural fullness, and tinnitus. Hearing loss typically follows an episodic but slowly progressive course, with times of worse hearing followed by partial recovery. The hearing loss (and vestibular dysfunction) is most commonly unilateral, although bilateral disease can develop. The vertigo attacks associated with Ménière disease can be debilitating, and are often accompanied by nausea, vomiting, and inability to perform normal activities.

Diagnosis of Ménière disease is made based on clinical presence of the tetrad of symptoms, combined with evidence of hearing loss and vestibular dysfunction. The episodic nature of the disease is an important characteristic; a single episode of hearing loss and vertigo should not prompt a diagnosis of Ménière disease. In this case, viral labyrinthitis is a more likely culprit.

First described in 1861 by Prosper Ménière, the pathogenesis of Ménière disease remains essentially unknown. It is thought to relate to dilation of the membranous labyrinth, possibly from dysfunction within the endolymphatic sac. Anatomic cadaver studies have demonstrated endolymphatic hydrops (swelling of the scala media and endolymphatic sac) in patients with Ménière disease. Unfortunately, these anatomic changes have also been demonstrated in presumably normal (or at least asymptomatic) patients.

The mainstay of treatment for Ménière disease remains medical therapy. Patients are typically begun on a low-salt diet initially. Patients are also instructed to avoid caffeine, nicotine, and alcohol. Diuretics can be added, along with

vestibular suppressants such as diazepam. Antihistamines (meclizine, dimenhydrinate, etc) have also demonstrated benefit in ameliorating vertigo symptoms associated with Ménière disease.

Patients suffering from severe, incapacitating vertigo and failing medical therapy can be offered several surgical interventions. Many authors advocate unilateral chemical ablation of the vestibular system. This is most often accomplished by transtympanic injection of gentamycin, and while efficacious for vertigo resolution is associated with sensorineural hearing loss in up to 25% of patients. For patients with intact hearing, many experts feel endolymphatic sac decompression and shunting can offer significant relief with preservation of hearing, although this remains unproven in randomized controlled trials. Similarly unproven, vestibular neurectomy (selective sectioning of the vestibular branch of the eighth cranial nerve) may conserve hearing and provide vertigo relief. For patients with severe hearing loss and vertigo, a total transmastoid labyrinthectomy relieves vertigo in over 90% of patients, at the cost of complete hearing loss on the affected side.

F. Cholesteatoma

A cholesteatoma is a cyst-like, expansile lesion of the temporal bone consisting of stratified squamous epithelium and trapped desquamated keratin. It occurs in the pneumatized temporal bone, most commonly the middle ear and mastoid (Figure 15-2). There are two types of cholesteatoma (acquired and congenital) with the former being the most common. Acquired cholesteatomas arise from either retraction pockets within the tympanic membrane, or secondarily from a tympanic membrane perforation. Congenital cholesteatomas are thought to arise from epithelial cell rests that fail to undergo apoptosis during development. Whatever the origin, once formed cholesteatomas behave in a locally destructive manner. Bone erosion is common, especially of the ossicular chain but also potentially the bone surrounding the inner ear (the otic capsule). If left untreated cholesteatomas can even invade intracranially.

Early cholesteatomas have few if any symptoms, and usually start with a slowly progressive hearing loss. If an infection develops in a cholesteatoma, a foul otorrhea will develop, and this sometimes is the presenting symptom. If a cholesteatoma is suspected, careful inspection under binocular otomicroscopy is essential. All debris must be removed to allow a full visualization of the entire visible portion of the tympanic membrane. Cholesteatomas will appear as a whitish keratin mass. A pneumatic otoscopy test is essential; if vertigo is elicited the surgeon must suspect erosion into the inner ear structures.

The treatment for cholesteatoma is surgery, usually involving removal of the mastoid air cell septations by otologic drill, exposing the middle ear space. This accomplishes two

▲ **Figure 15-2.** Cholesteatoma of the left middle ear. Large arrowhead indicates the external ear canal. Note the soft tissue density (cholesteatoma) in the middle ear space and the absence of any visible ossicular chain. Part of the bony covering of the inner ear semicircular canal (the otic capsule) has also been eroded.

goals—providing safe visualization and access and removal of all cholesteatoma tissue. This procedure is performed under careful microscopic visualization as many important structures (such as the facial nerve and the inner ear) should be preserved. The primary goal of surgery is creation of a safe, dry ear. All other considerations, including preservation of hearing, take second place.

DISORDERS OF THE NOSE AND PARANASAL SINUSES

► Anatomy and Physiology

The nose and paranasal sinuses serve to warm, filter, and humidify inspired air, to modulate vocalizations and speech, and provide for the sense of smell. The external nose consists of soft tissue and skin resting on a largely cartilaginous framework. The internal nose (nasal cavity) begins at the nasal vestibule anteriorly and extends posteriorly to the choana (which forms the boundary between the nasal cavity and the nasopharynx).

The nasal cavity (Figure 15-3) is divided in the sagittal plane in largely symmetric halves by the nasal septum. These cavities are partially filled by the three turbinates (superior, middle, and inferior, and occasionally a fourth supreme

▲ **Figure 15–3.** Sinonasal anatomy. In this coronal plane CT scan, several key sinonasal landmarks can be seen. M, maxillary sinus; IT, inferior turbinate; MT, middle turbinate; im, inferior meatus; mm, middle meatus; arrowhead indicates nasal septum.

turbinate), which arise from the lateral nasal wall. The spaces below each turbinate are called meati (eg, superior meatus, middle meatus, and inferior meatus). These meati are important for localizing the outflow tracts of the various paranasal sinuses, which drain in a characteristic pattern. The nasolacrimal duct drains into the inferior meatus. The maxillary, frontal, and anterior ethmoid sinuses all drain into the middle meatus. The sphenoid sinus and posterior ethmoids drain into the superior meatus. Additionally, the olfactory nerve endings (the end organ for the sense of smell) are located on the superior nasal septum and superior turbinate mucosa.

The paranasal sinuses consist of hollow cavities that derive from pneumatization into the frontal, ethmoid, sphenoid, and maxillary bones of the craniofacial skeleton. They are lined with respiratory epithelium (pseudostratified ciliated columnar epithelium), which serves to circulate and drain mucous along with entrapped particulate matter. They are normally air-filled but can become fluid-filled if the ostia become obstructed by inflammation, anatomic problems, or disease process.

► Urgencies and Emergencies

A. Nasal Foreign Body

As is the case for foreign bodies of the external ear, nasal foreign bodies are typically encountered in children.

Typical presentation is a young child with several day history of *unilateral* foul rhinorrhea. Oftentimes, the offending foreign body was inserted days to weeks before symptom onset, and the patient or parents may not recall a specific event precipitating the symptoms.

Offending foreign bodies can include vegetative, inert (plastic/metal) material and button batteries. Unlike external ear foreign bodies, nasal foreign bodies should always be treated as relative urgencies regardless of the type of object present. This is because of the anatomic relationship of the nose to the upper airway—if the object becomes dislodged, it could easily become an airway foreign body (a true emergency).

For this reason, many otolaryngologists advocate recommend removal of all but the most anteriorly placed nasal foreign bodies under general anesthesia using endoscopic visualization. The threshold for performing retrieval under sedation should likewise be low. In our practice, nasal foreign bodies confined to the nasal vestibule, or easily visible by anterior rhinoscopy can be safely removed without sedation *in a cooperative patient*. Young children, superior or posterior location or difficult visualization all result in removal in the operating room with endoscopic visualization. Another advantage to removing nasal foreign bodies in this manner is that postremoval inspection of the nasal cavity is easily performed. Oftentimes the nasal mucosa can be significantly inflamed and placement of absorbable material can prevent unwanted adhesions between opposing mucosal surfaces.

Nasal button batteries present a similar situation to external ear button batteries (see External Ear Foreign Body, above). The potential for extensive tissue damage from leakage of acid and electrical current discharge usually necessitates removal under general anesthesia. Following removal, extensive flushing with normal saline and careful inspection of the nasal cavity should be performed.

B. Invasive Fungal Sinusitis

Invasive fungal sinusitis is almost always encountered in immunocompromised patients, most often patients undergoing chemotherapy for malignancy, or poorly controlled diabetics. It is caused by uncontrolled infiltrative growth of usually non-pathogenic fungal organisms. Offending agents are ubiquitous in the environment, and are commonly found in the nasal secretions of healthy normal patients. The two most common fungi are *Aspergillus* and *Rhizopus* species. The latter is more aggressive and is termed Mucormycosis. *Rhizopus* tends to preferentially grow in acidic environments, and is thus found more often in the setting of diabetic ketoacidosis. Even with early diagnosis and maximal surgical therapy, and modern antifungal agents, the disease still carries a significant mortality rate. This varies depending on causative agent, from approximately 10% (*Aspergillus*) to 30% (*Rhizopus*).

▲ **Figure 15–4.** Invasive fungal sinusitis. In this patient with invasive fungal sinusitis, the initial finding was a dark area (arrowhead) on the inferior face of the middle turbinate found on bedside nasal endoscopy.

The index of suspicion for invasive fungal sinusitis must be high for any immunocompromised patient, as the symptoms can be subtle and the disease rapidly progressive. Patients are usually ill appearing and complain of facial pain, headache, nasal discharge, and may have mental status changes. Careful inspection of the face, oral cavity, and nasal cavity is mandatory. Dark ulcers (Figure 15–4) may be noted on the anterior face of the middle turbinate, inferior turbinate, lateral nasal wall, septum, or palate. Cranial nerve deficits may be noted in later stages of the disease.

If invasive fungal sinusitis is suspected, biopsies should be taken of the suspicious areas and sent for immediate pathologic examination. The pathologist should be alerted that invasive fungal sinusitis is suspected, so that special fungal stains can be performed. A worrisome finding is lack of bleeding at the biopsy site, as this may signify retrograde tissue infarction secondary to angioinvasive fungus.

Once invasive fungal sinusitis is confirmed, therapy consists of rapid reversal of immunosuppression followed by aggressive surgical debridement of all necrotic tissue (down to healthy, bleeding tissue) and systemic antifungal therapy. Two commonly used agents are voriconazole and amphotericin B. Usually multiple surgical debridements are required. Typically, patients do not recover unless the underlying immunosuppression is resolved; for example absolute neutrophil counts greater than 500 or diabetic ketoacidosis

rapidly reversed. Adjuvant therapy with donor neutrophil transfusion is an emerging treatment addition especially in cases failing to respond to conventional treatment. A multidisciplinary team including otolaryngology, hematology/oncology, and infectious disease specialists should closely follow these patients. Many patients develop metastatic fungal infections and can develop necrotic cavitation at distant sites. This often occurs as the patient's immune system recovers, and can result in lethal pulmonary hemorrhage, strokes, and other serious systemic sequelae.

Invasive fungal sinusitis should not be confused with other forms of fungal disease of the paranasal sinuses. In allergic fungal sinusitis, chronic host immunologic/inflammatory response to noninvasive fungal elements results in tissue eosinophilia, nasal polyps (hyperplastic growth that obstructs normal drainage and airflow), and bony remodeling.

C. Epistaxis

Epistaxis most commonly arises from the anterior portion of the nasal septum, referred to as Little's area. In this region, blood vessels derived from both the internal and external carotid anastomose to form Kiesselbach plexus. This rich blood supply can result in quite dramatic amounts of bleeding which can be distressing for the patient. Fortunately, many of these episodes respond to simple external pressure (pinching the anterior external nose) for 10 minutes.

The etiology of epistaxis is primarily related to disruption of nasal mucosa, thus exposing small blood vessels that can rupture. In children this often relates to nose picking. In adults, the etiology often relates to turbulent nasal airflow, such as from a deviated nasal septum. Other predisposing factors include drying of the nasal mucosa, and hypertension. The latter is particularly important in the acute management of epistaxis; often the bleeding will not be controllable until the accompanying hypertension is dealt with.

Epistaxis not responding to conservative management may require intranasal tamponade. Several different packing devices, including petrolatum gauze, thrombin containing collagen products, sponges, and inflatable balloons can be used to perform anterior packing. Anterior bleeding from Little's area can also sometimes be controlled with topical silver nitrate chemical cauterization, usually under endoscopic visualization.

Another common source of epistaxis is bleeding from branches of the anterior ethmoid or sphenopalatine artery. Epistaxis from these often requires posterior packing (such as with Foley catheter occlusion of the choanae and complete obliteration of the nasal airspace with gauze packing). Patients requiring posterior packing should be hospitalized and placed on pulse oximetry. Of note, nasal packing materials should be covered with topical antibiotics before placement, and all patients with intranasal packing should be

placed on antistaphylococcal antibiotics to prevent possible toxic shock syndrome. Epistaxis recalcitrant to anterior and posterior packing can be managed by surgical ligation of the offending arterial supply (internal maxillary, sphenopalatine, and anterior ethmoid) or by arterial embolization by an interventional radiologist.

Chronic medical management of patients predisposed to epistaxis includes management of hypertension, and promoting moist nasal mucosa. Patients are commonly placed on two to three times daily application of nasal saline spray, and topical petroleum jelly or antibiotic ointment to the anterior septum. Patients with severe, recurrent epistaxis should be evaluated for possible systemic disease (such as hereditary hemorrhagic telangiectasia, Wegener granulomatosis, etc).

► Disorders and Diseases

A. Acute Rhinosinusitis

Rhinosinusitis refers to inflammation of the mucosal lining of the nose and paranasal sinuses. Acute rhinosinusitis is present for less than 3 weeks, and is usually precipitated by a viral upper respiratory tract infection. It is important to emphasize that only a minority of cases of acute rhinosinusitis become complicated by bacterial superinfection (0.5%-2%). Similarly, change in color of nasal discharge is not a specific sign of bacterial rhinosinusitis.

Symptoms initially reflect the precipitating upper respiratory viral infection (cough, sneezing, fever, nasal congestion, facial pain/pressure, rhinorrhea, and sore throat) followed by development of rhinosinusitis symptoms. A set of diagnostic symptoms for rhinosinusitis (both acute and chronic) have been established. Patients must have two major, or one major and two minor criteria. These criteria are outlined in Table 15-3.

Table 15-3. Major and minor criteria for diagnoses of rhinosinusitis.

Major Criteria	Minor Criteria
Facial pain or pressure	Headache
Nasal obstruction	Fever (for chronic rhinosinusitis)
Nasal discharge or purulence	Halitosis
Purulence in nasal cavity	Fatigue
Anosmia or hyposmia	Dental pain
Fever (for acute rhinosinusitis)	Cough
	Ear pain/pressure/fullness

Adapted from Lanza DC, Kennedy DW. *Otolaryngol Head Neck Surg.* 1997; 117(3 Pt 2): S1-S7.

Acute bacterial rhinosinusitis should be suspected if symptoms persist after 10 days, or worsen within 10 days after an initial improvement. Physical examination may reveal purulent nasal secretions, nasal mucosal erythema, and tenderness overlying the sinuses. Nasal endoscopy (with middle meatal cultures) can be very useful, and visualization of purulent secretions emanating from the osteomeatal complex should increase suspicion for bacterial rhinosinusitis.

Treatment of acute rhinosinusitis is largely conservative in nature. Nasal saline lavage helps to eliminate excess mucous and inflammatory mediators, and restore mucociliary clearance. Topical decongestants (such as oxymetazoline) can help reduce mucosal edema and restore sinus ostia drainage. Use should be restricted to 3 days, as tachyphylaxis and dependence can result from overuse of topical decongestants. Mucolytics such as guaifenesin can help thin mucous secretions, allowing easier mucociliary transport. The only therapy tested and confirmed by placebo-controlled trials is intranasal topical steroids (such as mometasone or flunisolide). Topical steroids have been demonstrated to reduce time to symptom resolution, both for bacterial and nonbacterial acute rhinosinusitis. It is important to note that antihistamines have no proven benefit in acute rhinosinusitis, and may actually cause symptom exacerbation by drying mucous secretions. Antibiotics should be reserved for patients suspected of having acute bacterial rhinosinusitis. Current recommendations specify first-line antibiotic therapy should consist of amoxicillin. After 7 days, if a patient fails to improve clinically a broader-spectrum antibiotic such as a fluoroquinolone, trimethoprim/sulfamethoxazole, azithromycin, or amoxicillin/clavulanic acid can be tried. All of these have greater than 80% efficacy in clearing acute bacterial rhinosinusitis.

Patients experiencing multiple episodes of acute rhinosinusitis should be evaluated carefully for predisposing conditions. These may include anatomic obstruction (which may be relieved by septoplasty and/or functional endoscopic sinus surgery), underlying impairment of mucociliary clearance (such as from immotile cilia/Kartagener syndrome, or cystic fibrosis), or immune system dysfunction. Complications of acute bacterial rhinosinusitis can include orbital cellulitis and subperiosteal abscess formation, meningitis, and cavernous sinus thrombosis.

B. Chronic Rhinosinusitis

Chronic rhinosinusitis is extremely common, and affects between 2% and 15% of people in the United States. It is defined as the presence of rhinosinusitis symptoms for greater than 12 weeks (major criteria from Table 15-3) combined with evidence of inflammation. The latter can include findings of purulent mucous in the middle meatus or ethmoid region, nasal polyps or polypoid degeneration of the nasal mucosa. Radiographic findings (Figure 15-5)

▲ **Figure 15–5.** Chronic sinusitis. In this axial plane CT of a patient with chronic sinusitis, radiographic evidence of inflammation can be seen. The right nasolacrimal duct (NL) mucosa is edematous. There is an air-fluid level and opacification of the right maxillary sinus (M).

can also document inflammation, most commonly by CT. Findings can include diffuse mucosal thickening, chronic bony remodeling, and sinus opacification.

Management of chronic rhinosinusitis is primarily by topical and systemic medication. Most otolaryngologists place chronic rhinosinusitis patients on topical nasal steroids for at least 1 month. At this time if symptoms persist, a CT scan may be useful in demonstrating any anatomic abnormalities that may be amenable to surgical correction. Surgery is aimed at removing the obstruction to natural mucous flow from the paranasal sinuses, and most patients will continue to require medication after surgery to prevent return of symptoms.

The etiology of chronic rhinosinusitis is not fully elucidated. Most otolaryngologists feel that there are several disease processes currently described together under the generic heading chronic rhinosinusitis. Tissue eosinophilia may play an important role in differentiating these groups; current molecular evidence supports this distinction. Future research will undoubtedly change our understanding of these disease processes and how they are managed.

C. Rhinitis Medicamentosa

As mentioned above, extended use of topical nasal decongestants (such as oxymetazoline) or other vasoconstrictors (such as intranasal cocaine) can lead to tachyphylaxis and mucosal dependence. The resulting severe mucosal edema, hyperemia, and nasal obstruction are termed *rhinitis*

medicamentosa. Patients will report daily topical vasoconstrictor/decongestant use, and absolute dependence on these medications for any appreciable nasal airflow. It is not unusual for patients suffering from rhinitis medicamentosa to carry their topical vasoconstrictor medication with them due to their frequent use. This is often a telltale sign of dependence. On physical examination the nasal mucosa will be thickened, erythematous and edematous, and lack appreciable decongestion on topical decongestant application.

Treatment requires complete cessation of the offending agent. Patients should be started on nasal saline lavage and nasal topical steroids. Oral decongestants and a course of oral corticosteroids may help hasten symptom resolution and increase patient compliance. Resolution usually takes 3–4 weeks, and may require much more time in the case of long-term vasoconstrictor use, or intranasal cocaine abuse.

Complications of untreated rhinitis medicamentosa include poor healing after nasal surgery, septal perforation, and formation of synechiae. For this reason, it is important to recognize and treat rhinitis medicamentosa preoperatively, before embarking on any nasal surgical treatment.

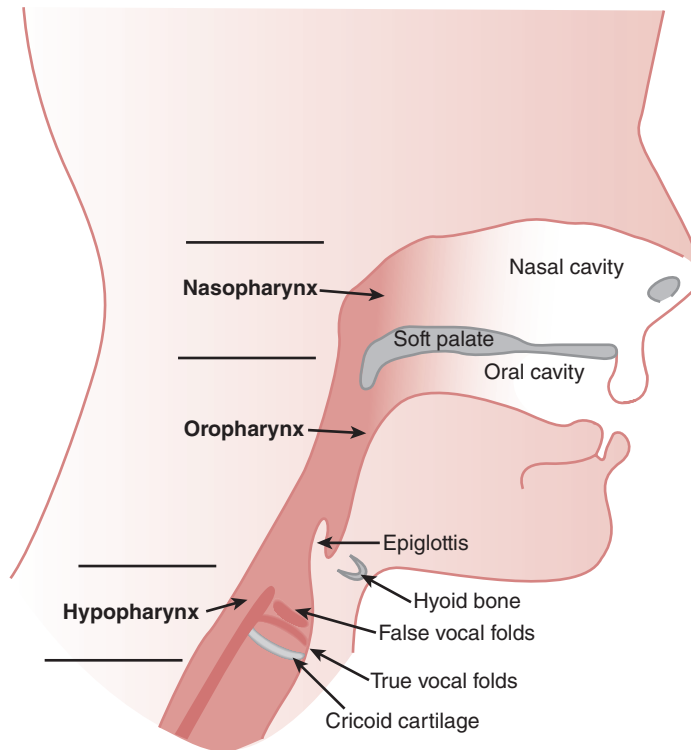

DISORDERS OF THE ORAL CAVITY AND PHARYNX

► Anatomy and Physiology

The oral cavity is bounded anteriorly by the vermilion border of the lips, and posteriorly by the anterior pillars of the palatine tonsils. The superior aspect of the oral cavity includes the hard and soft palate, and inferiorly includes the lingual mucosa and the anterior two-thirds of the tongue. This region of the tongue is bounded by the circumvallate papilla, which lie along the sulcus terminalis and separate the oral tongue from the base of tongue (part of the oropharynx).

The pharynx connects the nasal and oral cavities to the esophagus and larynx. It consists of three segments—the nasopharynx, the oropharynx, and the hypopharynx (Figure 15–6). The nasopharynx begins as an extension from the posterior aspect of the nasal cavity and extends from the nasal choana to the soft palate. The oropharynx extends from the soft palate to the level of the hyoid bone, and is bounded laterally by the tonsillar pillars (the palatoglossal and palatopharyngeal arches). It includes the base of tongue, lateral/posterior pharyngeal wall, and tonsillar fossae. The hypopharynx extends from the level of the hyoid bone to the inferior aspect of the cricoid cartilage, and includes the pyriform sinuses, postcricoid region, and posterior hypopharyngeal wall.

The primary functions of the oral cavity are related to chewing and swallowing (mastication and deglutition) and shaping of phonatory vibrations to produce intelligible speech. Taste buds on the dorsum of the tongue are

▲ **Figure 15–6.** Relationship of the three sections of the pharynx. The nasopharynx extends from the nasal choanae to the soft palate. The oropharynx then extends from the soft palate to the level of the hyoid bone. The hypopharynx extends from the level of the hyoid bone to the level of the cricoid cartilage.

responsible for basic taste perception—sweet, salty, bitter, and sour. This sensory information is transmitted to the facial nerve via the chorda tympani nerve for the anterior two-thirds of the tongue. General sensation of the tongue is carried by the lingual nerve. All sensory information from the posterior one-third of the tongue is carried by the glossopharyngeal nerve. Complex nuances of taste are mediated by olfactory receptors in the superior-most aspect of the nasal cavity and are not directly related to the tongue or oral cavity.

The tongue has four pairs of intrinsic muscles, which interdigitate throughout the tongue. These muscles act to lengthen or shorten the tongue, curl the apex and edges, and flatten or round the dorsal surface. The intrinsic tongue muscles originate and insert within the tongue itself. Extrinsic tongue muscles (genioglossus, hyoglossus, styloglossus, and palatoglossus) also act to protrude, depress, elevate, and retract the tongue. All motor function of the tongue is mediated by cranial nerve XII (the hypoglossal nerve).

The act of swallowing, or deglutition, is complex and consists of three main phases—oral, pharyngeal, and esophageal. The oral phase is under voluntary control, while

the remaining phases proceed under reflex control. The oral phase of swallowing consists of preparation of the food bolus by mastication to soften and shape the bolus. Following this, oral transport ensues and the food bolus is transported to the posterior tongue. The anterior tongue then elevates against the hard palate, contracts and propels the bolus to the oropharynx. Simultaneously, the nasopharynx is sealed off preventing nasal regurgitation. In the pharyngeal phase, several complex actions occur which elevate the larynx, temporarily halt respirations and protect the airway from aspiration, and relax the cricopharyngeus muscle to allow passage of the food bolus. The esophageal phase then propels the food bolus distally by means of sequential peristaltic contractions. Alteration of the timing or execution of any of these phases can result in dysphagia, or difficulty swallowing.

► Urgencies and Emergencies

A. Acute Angioedema and Ludwig Angina

Acute angioedema is characterized by localized swelling of subcutaneous and submucosal tissue of the head and neck.

The swelling may begin with mild facial involvement but may progress to involve the oral cavity, tongue, pharynx, and larynx. It is often self-limited but may present as a medical emergency. Tongue or laryngeal involvement may rapidly lead to airway obstruction and asphyxiation. Angioedema has a rapid onset and with proper medical treatment usually resolves within 24-48 hours. The underlying pathophysiology of angioedema involves vasoactive mediators such as bradykinin and histamine, causing interstitial edema through endothelial-mediated vasodilation of arterioles with subsequent capillary and venule leakage. The three major etiologies are drug-induced, hereditary, and allergic angioedema. Drug-induced and hereditary angioedema appear to be mediated by the kallikrein-kinin system while allergic angioedema appears to be mast cell-mediated.

Initial management of acute angioedema is focused on airway maintenance. Depending on clinical presentation, this may include nebulized epinephrine inhalation, intubation (either oral or transnasal fiberoptic), or tracheotomy. Due to the potentially rapid progression of this disease process, there should be a low threshold for securing an airway by the latter two methods. Many authors advocate the use of glucocorticoids (10 mg dexamethasone IV every 8 hours) combined with histamine receptor antagonists (both an H1 antagonist such as benadryl 25 mg IV every 6 hours, and an H2 antagonist such as ranitidine 50 mg IV every 6 hours) for 24 hours. Recent evidence has shown that the latter therapies may not be beneficial in drug-induced or hereditary angioedema. This should be balanced with the understanding that in clinical practice, rapid differentiation of the exact subtype of angioedema may not be as practical as empiric therapy given the relatively benign nature of these medications compared to the potentially life-threatening threat of airway obstruction.

Drug-induced angioedema has classically been associated with the use of angiotensin-converting enzyme inhibitors (ACE inhibitors), although many other medications can also (less commonly) cause this phenomenon. The incidence of angioedema secondary to ACE inhibitor use has been noted to be 0.4%-0.7%. The pathophysiology of ACE inhibitor-induced angioedema appears to be secondary to a localized increase in bradykinin levels related to the inhibition of ACE. Studies have shown that one-half of all cases of ACE inhibitor-induced angioedema occur within the first week of initiating treatment. However, some patients undergo years of ACE inhibitors therapy without incident before their first attack of acute angioedema. Treatment should begin with emergent airway maintenance with discontinuation of any possible drugs that may be inducing the edema. Other drugs with known complications of angioedema include rituximab, alteplase, fluoxetine, laronidase, lepirudin, and tacrolimus. Studies involving angiotensin II receptor antagonists (ARBs) have revealed a decreased incidence of angioedema in comparison to ACE inhibitors therapy. However, clinicians

should still use caution when initiating an ARB in a patient with known ACE inhibitor-induced angioedema.

Hereditary angioedema involves a deficiency or dysfunction of C1-esterase inhibitor, which leads to increased levels of vasoactive bradykinin. It is autosomally dominant in inheritance and the defect has been mapped to chromosome 11q. Clinically, hereditary angioedema often presents with recurrent episodes of facial and oral swelling, as well as abdominal pain secondary to intestinal wall edema. Studies have revealed that certain drugs (estrogen, ACE inhibitors, ARBs), surgery, and infections may elicit acute angioedema attacks in hereditary angioedema patients. After airway maintenance has been ensured, intravenous C1-esterase inhibitor is the treatment modality of choice. The synthetic steroid danazol has also been used prophylactically to help prevent future acute episodes by increasing the functional levels of C1-esterase inhibitor.

Allergic angioedema is mast cell-mediated and histamine plays the major role in its pathophysiology. In contrast to drug-induced and hereditary angioedema, skin changes including urticaria and pruritis are commonly seen in allergic angioedema. Clinically, the pruritic wheals are spread by scratching and lesions are usually limited to the lips and periorbital areas and less commonly the extremities and genitalia. This form of angioedema is frequently seen in patients who also suffer from atopic dermatitis, allergic rhinitis, and asthma. Triggers of acute attacks of allergic angioedema include certain drugs, infections, food, and plant products.

Ludwig angina is an uncommon life-threatening condition characterized by cellulitis involving the submental, sublingual, and submandibular spaces. The source of the infection is odontogenic and spreads rapidly. The infection is usually polymicrobial with aerobic and anaerobic gram-positive cocci and gram-negative rods. Prior to antibiotics the mortality rate exceeded 50%. Clinically, patients present with painful neck swelling and edema of the floor of mouth often leading to elevation and displacement of the tongue. Patients will have a prominent "hot potato" voice and palpation of the floor of mouth reveals woody edema. The most common cause of death in these patients is airway compromise, and therefore, primary treatment should be centered on airway maintenance with early involvement of anesthesiology and otolaryngology physicians. Intubation is often anatomically difficult and tracheotomy under local anesthesia is often the preferred method of ensuring a patent airway. Recent case studies have shown the benefit of intravenous dexamethasone and nebulized epinephrine to aid with temporizing the airway and transnasal intubation. Airway observation in the intensive care unit may be an option for less severe cases. After the airway has been secured, proper systemic antibiotic therapy should be initiated immediately followed by incision and drainage for most cases. Major complications include extension of the infection posteriorly to involve the parapharyngeal and retropharyngeal spaces as

well as the superior mediastinum. The diagnosis is clinical, but CT may be used to assess the retropharyngeal extension of the infection.

B. Peritonsillar Abscess

Peritonsillar abscess (PTA) is a common infection of the peritonsillar space between the palatine tonsil, tonsillar pillars, and the superior pharyngeal constrictor muscle. Its prevalence in the United States has been estimated at 30 per 100,000 people annually. The infection is suppurative in nature and thought to be secondary to either extension of adjacent acute tonsillitis or obstruction of Weber glands (minor salivary glands) at the tonsillar pole. PTA is seen in both children and adults. The typical patient presents complaining of a 4- to 5-day history of sore throat and fever, with worsening trismus, odynophagia, dysphagia, and inability to tolerate secretions. PTA should be managed acutely, as the infection may progress and spread to the deep neck tissue and compromise the airway.

The gold standard in diagnosis of PTA is physical examination, which reveals bulging soft tissue, tonsillar erythema and exudate, and possible uvular deviation. Needle aspiration or incision and drainage confirms the diagnosis. Recent studies have revealed the benefit of intraoral ultrasound in the diagnosis of PTA. CT may be necessary in patients with severe trismus or young uncooperative patients and can aid in differentiating PTA from retropharyngeal abscess.

The management of PTA is dependent on the patient characteristics. Needle aspiration can be performed quickly, is relatively safe, and can be both diagnostic and therapeutic. Incision and drainage should only be performed by physicians with an understanding of the relevant pharyngeal anatomy, as multiple vital structures including cranial nerves and the carotid artery potentially lie within the surgical field. In cooperative adults, it can usually be performed using local anesthesia but patients with severe trismus may require general anesthesia. In our practice (for adult patients), pre-procedure administration of 900 mg clindamycin, 10 mg dexamethasone, IV fluid hydration, and IV morphine for analgesia can greatly facilitate the procedure by reducing trismus and promoting patient comfort and cooperation. After instillation of local anesthetic, a needle aspiration can be used to confirm the site of incision. A limited mucosal incision is made with a scalpel, taking care not to penetrate the underlying muscular layer. Blunt dissection is then used to penetrate the abscess cavity. Oral suction should be in place before penetration of the abscess cavity to prevent possible aspiration of purulence. Studies have shown both needle aspiration and incision and drainage to be greater than 90% effective but both carry a 10%-15% risk of recurrent PTA. The pediatric patient usually will not tolerate either needle aspiration or incision and drainage under local anesthesia and general anesthesia is often necessary.

Antibiotic therapy against *Streptococcus pyogenes* and oral anaerobes with either penicillin or clindamycin should follow abscess drainage. Most patients with PTA can be treated as outpatients.

Emergent tonsillectomy in the setting of acute infection (“Quincy tonsillectomy”) is usually reserved for cases of PTA that are not successfully drained by simple incision and drainage. While some authors advocate this as a first-line therapeutic option, the increased operative difficulty secondary to acute inflammation, and increased incidence of postoperative hemorrhage make this a less attractive option. It requires general anesthesia and most otolaryngologists would advocate overnight hospitalization postoperatively for observation.

If needle aspiration or incision and drainage of a PTA is performed, it is important to counsel the patient that future risk of PTA is increased. Many otolaryngologists therefore recommend an elective tonsillectomy be performed 2-3 months following a PTA.

C. Deep Neck Space Infections

Although greatly decreased in incidence since the advent of modern antibiotics, deep neck space infections remain a potentially life-threatening condition and require acute recognition and treatment. The source of deep neck space infection is most commonly odontogenic. Other sources of infection include adjacent tonsillar, upper respiratory and salivary infections as well as instrumentation and foreign bodies. These infections are usually polymicrobial, composed predominantly of anaerobes mixed with various streptococcal and staphylococcal species. Drug-resistant bacteria are commonly seen in intravenous drug users who present with deep neck space infections secondary to needle injection disruption of the cervical fascia. Presenting symptoms depend on the exact location of the abscess, but patients commonly present with fever, painful sore throat, decreased neck range of motion, dysphagia, and odynophagia. Physical examination can reveal trismus, a toxic appearance with facial and neck edema, cervical lymphadenopathy, and purulent oral secretions. It is not uncommon for patients to present several days after being discharged on antibiotics for a less severe, local infection. It is important to note that patients on antibiotic or immunosuppression therapy may have more subtle signs of infection and systemic toxicity may be masked.

A thorough understanding of the anatomy of the cervical fascia and deep spaces of neck is paramount in diagnosing and managing these rapidly spreading infections. The cervical fascia is divided into two layers, the superficial cervical fascia and the deep cervical fascia. The deep cervical fascia is further divided into three separate layers—superficial layer of deep cervical fascia, middle layer of deep cervical fascia, and deep layer of deep cervical fascia.

Furthermore, the middle layer of deep cervical fascia is subdivided into muscular and visceral divisions and the deep layer of deep cervical fascia is subdivided into alar and prevertebral layers.

These divisions of the deep cervical fascia separate the neck into numerous potential spaces, which may harbor these life-threatening infections. One easy way of categorizing these spaces is by their relationship to the hyoid bone. Potential spaces that exist entirely above the hyoid bone include the submandibular space and the parapharyngeal space. The pretracheal space exists entirely below the hyoid bone. The prevertebral space, danger space, and retropharyngeal space extend along the entire length of the neck.

Parapharyngeal abscess must be differentiated from PTA, as the former requires external drainage via the submaxillary fossa while the latter is best drained intraorally. Retropharyngeal abscesses are most commonly seen in children and are located between the visceral layer of the middle layer of deep cervical fascia and the alar division of the deep layer of deep cervical fascia. Because of the smaller caliber airway in children, retropharyngeal abscess represents a potential source of airway obstruction and should be managed accordingly. The danger space is the region between the alar and prevertebral layers of the deep cervical fascia, which extends from the base of the skull to the diaphragm. Infection of the danger space usually arises from contiguous spread from retropharyngeal, prevertebral, or pharyngomaxillary infections. The lack of definitive anatomic barriers in the danger space offers very little resistance to spread of infection. The prevertebral space is directly posterior to the danger space between the prevertebral division of deep cervical fascia and the paravertebral fascia. Infection of prevertebral space is usually secondary to penetrating trauma or tuberculosis.

Lateral and anteroposterior neck films have traditionally been used to help localize an abscess, although this has now largely been replaced by CT. Recent studies have shown a potential benefit of MRI in delineating soft tissue and vascular spread of infection, although the time required to obtain MRI imaging makes its use of questionable value. Deep neck space infections can progress rapidly and patients usually require hospitalization under close supervision.

Initial treatment should focus on an evaluation of need for securing an airway with either endotracheal intubation or tracheotomy. Once airway patency has been verified or secured, needle aspiration can sometimes be performed (in the case of easily accessible abscesses) to obtain culture and gram stain. Intravenous antibiotics are started immediately and should cover both aerobic and anaerobic organisms. Ampicillin-sulbactam or clindamycin are commonly used. If methicillin-resistant *Staphylococcus aureus* is suspected, vancomycin should also be initiated. If the patient does not improve clinically on antibiotic therapy after 48 hours, open surgical drainage of the abscess may be necessary.

Major complications of deep neck space infections include mediastinitis, osteomyelitis, Horner syndrome, and cranial nerve deficits. Involvement of the carotid sheath may also lead to suppurative jugular thrombophlebitis (Lemierre syndrome). Early diagnosis and proper treatment may help limit these serious complications.

▶ Disorders and Diseases

A. Oral Cavity Lesions

Inspection and palpation of the oral cavity is an essential part of the head and neck examination. There are numerous lesions that may affect the oral cavity and this review focuses on those which may predispose patients to oral cavity neoplasms. Approximately half of all head and neck cancers occur in the oral cavity.

Leukoplakia is actually a descriptive term rather than a true pathologic term. It represents an asymptomatic white plaque that cannot be scraped off. It is frequently found on the oral and buccal mucosa as well as the tongue. Its prevalence has been estimated from 1% to 5% of the population. Some studies have linked leukoplakia to tobacco use although the true etiology is still uncertain. Leukoplakia represents the clinically evident result of hyperplastic epithelial growth. Many authors recommend a short 1-2 week trial of oral topical steroid preparation (kenalog in orabase) for initial management. Leukoplakia is associated with a malignant transformation rate of approximately 5%, and persistent lesions should be biopsied to assess for premalignant dysplasia or malignancy. The rates of dysplasia are highest for lesions found on the floor of the mouth, tongue, and lower lip. Treatment is aimed at preventing malignant transformation to oral cavity squamous cell carcinoma (OSCC). Surgical excision, KTP laser, and CO₂ laser excision have all been shown to be effective. Recent studies have also revealed potential efficacy of medical treatment with both topical bleomycin in dimethyl sulfoxide and retinoid compounds.

Erythroplakia is categorized as a nonhomogenous leukoplakia and is described as a velvety red plaque that cannot be removed. It is found in similar regions of the oral cavity as leukoplakia and is also usually asymptomatic at presentation. It is less common than traditional homogenous white leukoplakia with prevalence estimated at 0.2%-0.8%. However, it boasts a higher degree of premalignant dysplasia than leukoplakia, with over half of cases having *in situ* or overtly invasive squamous cell carcinoma on histologic examination.

Lichen planus is a common dermatologic lesion that may present in the oral cavity. The skin lesions are classically described as pruritic, planar, purple, polygonal papules, while the oral lesions have several different phenotypic subtypes. Reticular, plaque-like, atrophic, erosive, and bullous forms have all been described in the literature. The oral lesions have a questionable capacity for malignant transformation. The data is controversial but one study has

estimated the rate of malignant transformation to OSCCC between 1% and 5%. The lesions require biopsy to confirm the diagnosis. Treatment includes vigorous oral hygiene, topical steroids, and immunosuppressive agents.

B. Sialadenitis and Sialolithiasis

There are several nonneoplastic and inflammatory conditions that may affect the major and minor salivary glands. Infection of the salivary glands may be either viral or bacterial in etiology. Viral sialadenitis is most commonly secondary to mumps, which presents with a flu-like prodrome followed by parotid gland swelling. Mumps normally affects children and may be complicated by orchitis, oophoritis, aseptic meningitis, and encephalitis. The incidence of mumps has declined significantly since routine vaccination has been instituted. Other viruses known to cause sialadenitis include cytomegalovirus, coxsackievirus A and B, echovirus, Epstein-Barr virus, and influenza A.

Bacterial sialadenitis may be acute or chronic. Acute suppurative sialadenitis occurs most commonly in dehydrated patients who are postoperative, elderly, or those on diuretic therapy. The parotid gland is affected in the majority of cases secondary to the diminished bacteriostatic activity of its serous saliva. Salivary stasis, ductal obstruction, and decreased saliva production appear to be predisposing conditions to acute sialadenitis. Patients usually present with fever, systemic toxicity, and tender swelling and enlargement of the affected glands. The most common organism isolated is *S aureus*, though culture may reveal a polymicrobial infection with both aerobic and anaerobic organisms. Treatment involves ample hydration, warm facial compresses, sialogogues (such as lemon wedges) to stimulate saliva secretion in the affected gland. Antibiotics targeted against *S aureus* should be started immediately and continued for 7-10 days. CT may be necessary to rule out abscess formation or stone (sialolithiasis) in patients who do not improve clinically after several days of appropriate therapy.

Sialolithiasis may occur in the setting of acute or chronic sialadenitis or it may be an incidental finding on routine imaging studies. Salivary calculi affect males more than females and are seen most frequently between ages 30 and 60. In contrast to sialadenitis, sialolithiasis preferentially affects the submandibular glands because of their alkaline, high calcium, mucus-rich environment. Large, solitary, radio-opaque stones are usually found in the submandibular glands, while the parotid glands are more likely to have multiple smaller, radiolucent stones. Calculus formation is believed to be secondary to partial obstruction of the salivary duct combined with calcium-rich stagnant saliva. Salts composed of calcium phosphate, magnesium, ammonium, and carbonate precipitate in this environment. Contributing factors to the development of salivary calculi include underlying acute or chronic sialadenitis, dehydration, and

anticholinergic medications. Uric acid salivary calculi may also be seen in the setting of gout.

Patients with sialolithiasis frequently present with pain and swelling of the affected gland, although many patients have asymptomatic calculi discovered incidentally. Eating usually exacerbates the pain. Physical examination may reveal the location of the calculi by simple palpation. Obstruction of the flow of saliva can be analyzed by massaging the gland. It is important to note that stones are more commonly found in the salivary ductal structures rather than their associated glands. CT is the preferred method of imaging if sialolithiasis is suspected but a calculus is unable to be palpated on physical examination. CT has a 10-fold greater sensitivity than plain films in detecting salivary calculi. Ultrasound may also have benefit in locating calculi when CT is unavailable. Sialography is no longer routinely used and is contraindicated in patients with acute sialadenitis.

Treatment of sialolithiasis should begin conservatively with hydration, salivary gland massage, heating pads applied to the affected gland, and sialogogues. Anticholinergic medications should be discontinued and antibiotics should be initiated if there is concern for acute suppurative sialadenitis. There are several options for more invasive therapy for patients who do not respond to conservative management. Transoral removal of submandibular stones, sialadenectomy, lithotripsy, wire-basket removal, and sialoendoscopy have all been shown to be effective in the appropriate patient.

C. Acute and Chronic (Recurrent) Tonsillitis

Tonsillitis is one of the most common problems encountered by the otolaryngologist. In general, tonsillitis refers to inflammation of the palatine tonsils located on the lateral walls of the oropharynx between the palatoglossal and palatopharyngeal folds. The pharyngeal tonsils or adenoids, while part of Waldeyer's ring of lymphatic tissue are anatomically separate from the palatine tonsils. The adenoids are located on the posterior wall of the nasopharynx in close proximity to the eustachian tube opening.

Acute tonsillitis is primarily a pediatric disease that tends to affect children aged 5-15. It is most commonly caused by group A beta-hemolytic streptococcal species, although anaerobes, *Haemophilus influenzae*, and viruses can also be causative agents. Patients usually present with fever, painful sore throat, halitosis, and dysphagia. It is important to note the distinction in clinical presentation between acute tonsillitis, viral pharyngitis, and infectious mononucleosis (caused by the Epstein-Barr virus). Viral pharyngitis commonly presents with a triad of cough, coryza, and conjunctivitis, while patients with mononucleosis typically present with anterior and posterior cervical lymphadenopathy, odynophagia, and a grayish tonsillar exudate. On physical examination, the acute tonsillitis patient has erythematous tonsils,

purulent tonsillar exudate, and anterior cervical lymphadenopathy.

Tonsillar hyperplasia is measured in the medial-to-lateral plane of the oropharynx and helps in the assessment of upper airway obstruction. They are traditionally rated on a 1–4 scale, with 1+ being confined below the level of the tonsillar pillars, 2+ at the pillars, 3+ extending past the pillars, and 4+ meeting in the midline. Tonsillar hypertrophy in the pediatric population may predispose to the development of sleep-disordered breathing. Patients typically present with heroic snoring, voice changes, observed episodes of sleep apnea, and daytime somnolence. In these cases, elective tonsillectomy (usually combined with adenoidectomy) can often provide resolution of obstructive symptoms.

The diagnosis of acute tonsillitis is clinical although many practitioners rely on a positive streptococcal test or culture. The mainstay in treatment of acute tonsillitis continues to be a 7–10 day course of penicillin or a comparable cephalosporin. However, it is now estimated that failure with penicillin therapy occurs in up to 30% of cases. Following up culture results and adjusting the antibiotic therapy has therefore become an important step in management. Complications from acute tonsillitis include the formation of PTA and neck abscess formation. Antibiotic use has greatly decreased the incidence of rare systemic complications like poststreptococcal glomerulonephritis and rheumatic fever.

Many patients have a solitary episode of acute tonsillitis, which responds favorably to antibiotic treatment, while some patients have recurrent acute tonsillitis with multiple infections over the course of years. Chronic tonsillitis is a state of persistent tonsillar inflammation for greater than 3 months following an episode of acute infection. It is characterized by chronic sore throat and odynophagia with tonsillar enlargement, tonsillolith debris, and cervical lymphadenitis present on physical examination. Recent studies have suggested that polymicrobial infections, drug-resistant organisms, *H influenzae*, *S aureus*, anaerobes, and actinomycetes may all play a role in chronic tonsillar disease. Treatment of chronic tonsillitis, therefore, should begin with the use of broader spectrum antibiotics like amoxicillin-clavulanate or clindamycin, which may target these offending organisms.

The critical question in the treatment of both acute and chronic tonsillitis is whether or not to perform a tonsillectomy. Medical management with antibiotics is always the first-line therapy for acute tonsillitis. Tonsillectomy for acute episodes (also known as “Quincy tonsillectomy”) is usually considered only when complications such as deep neck-space abscess or acute airway obstruction are concurrently present. Tonsillectomy is generally performed for patients with recurrent acute tonsillitis, defined as seven episodes within 1 year, five episodes each year for the past 2 years, or three episodes per year for 3 successive years.

D. Obstructive Sleep Apnea

Obstructive sleep apnea is an intrinsic dyssomnia that affects roughly 15–20 million people in the United States. It is classically described as the presence of hypopneic episodes, apneic episodes, and respiratory effort related arousals that occur during sleep. An apneic event requires 10 or more seconds of cessation of airflow, followed by arousal with restoration of normal ventilation. The definition of hypopnea varies between sleep laboratories, but generally refers to an episode of decreased airflow (>50% reduction) for greater than 10 seconds, associated with decreased oxygen saturation or arousal. Patients usually present with nighttime snoring, daytime hypersomnolence, irritability, morning headaches, cognitive impairment, and often witnessed apneic events with cessation of airflow followed by choking or gasping. When taking a history, it is important to confer with the patient’s bed partner, as the patient may be unaware of his/her nighttime symptoms. Cardiovascular disease, hypertension, metabolic dysfunction, respiratory failure, and cor pulmonale are among the serious long-term effects of obstructive sleep apnea.

The pathophysiology of obstructive sleep apnea appears to be a combination of upper airway collapse and decreased neural output from the respiratory center in the brainstem. During normal inspiration, the pharyngeal muscles are stimulated via a central nervous system reflex pathway to help maintain pharyngeal airway patency. During sleep, however, these neural reflexes are attenuated and the airway becomes more susceptible to collapse. Patients who are predisposed to airway obstruction due to anatomic reasons are at high risk for developing obstructive sleep apnea. Documented anatomic risk factors for obstructive sleep apnea include macroglossia, adenotonsillar hypertrophy, elongation of the soft palate, and retrognathia.

Obstructive sleep apnea is more common in men and the overall incidence appears to increase with age. The most significant risk factor is obesity and the recent increase in prevalence is thought to relate to the current obesity epidemic. Other known risk factors include nasal obstruction, smoking, diabetes mellitus, alcohol consumption, and the previously mentioned anatomic abnormalities. Physical examination may reveal obesity with an increased neck circumference. A thorough head and neck examination should be performed to fully assess airway patency. Oral cavity examination may reveal tonsillar hyperplasia. The nasal cavity and nasopharynx should be examined using a flexible fiberoptic endoscope to rule out nasal obstruction secondary to deviated septum, nasal polyps, or turbinate hyperplasia. The modified Müller maneuver should be performed to assess for site of upper airway collapse during inspiration. Patients are asked to inspire against a closed mouth while their nose is pinched shut, thus creating a column of negative pressure within the upper airway. The airway at the level

of the soft palate, lateral pharyngeal wall, and base of tongue are then observed for luminal collapse and graded on a 1-3 scale.

Polysomnography remains the gold standard in diagnosing obstructive sleep apnea, which can be defined by either the apnea-hypopnea index (AHI) or the respiratory disturbance index (RDI). The AHI includes the number of hypopneas and apneas which occur per hour of sleep, while the RDI is the number of hypopneas, apneas, and respiratory effort related arousals per hour of sleep. The generally accepted guidelines for diagnosis of obstructive sleep apnea are an AHI of 15 or greater in an asymptomatic patient or an AHI of greater than 5 in a symptomatic patient. Imaging studies are usually not required to diagnose obstructive sleep apnea, although they may help assess for upper airway anatomic abnormalities.

Treatment of obstructive sleep apnea should begin with the identification and prevention of risk factors. Behavior modifications such as weight loss, smoking and alcohol cessation, and discontinuation of any CNS depressants may help improve the patient's apneic index. Safety precautions related to daytime hypersomnolence need to be discussed for high-risk patients like pilots and commercial truck drivers.

Continuous positive airway pressure (CPAP) is considered first-line therapy after behavioral modifications. The positive pressure helps keep the airway patent and has been shown to be highly effective in reducing obstructive sleep apnea symptoms. Some patients experience difficulty tolerating CPAP therapy. Breathing against the positive pressure airflow can be difficult to adjust to, and this must be considered when treating the obstructive sleep apnea patient. Bi-level positive airway pressure (BiPAP) is another system that employs a higher inspiratory pressure with a lower expiratory pressure to allow for easier expiration. There are numerous oral appliances, which may help adjust the airway during sleep to improve patency, although studies have shown these appliances to be less effective than CPAP in improving the apneic index.

Several surgical options are available for patients who do not respond well to initial treatment. Routine adenoidectomy and tonsillectomy has been shown to be effective in pediatric patients with isolated adenotonsillar hypertrophy contributing to their obstructive sleep apnea symptoms. For adult patients, more extensive surgery is usually required. Uvulopalatopharyngoplasty (UP3) is the first-line surgical therapy in which the uvula, a small amount of soft palate, and the palatine tonsils are removed. The concept of "multi-level sleep surgery" is important, as UP3 alone is associated with a significant (>50%) failure rate. Most commonly UP3 is combined with additional procedures to address other areas of obstruction. Septoplasty and inferior turbinate reduction can improve nasal airflow. The tongue base can be advanced by suture suspension, hyoid suspension, or genioglossus advancement. Other more invasive surgical

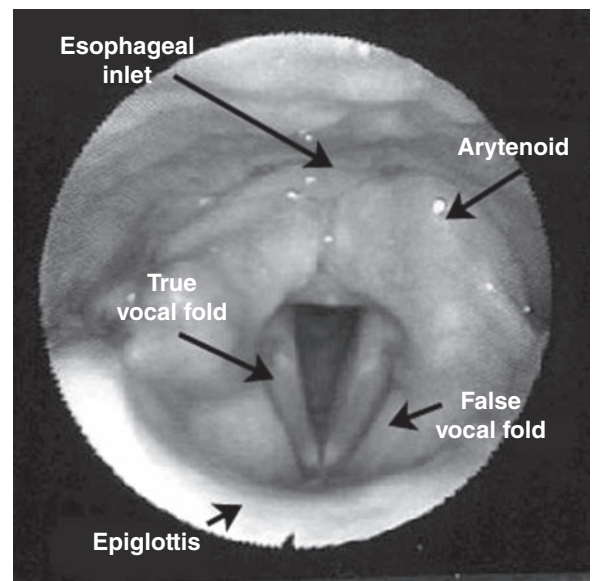

interventions include maxillomandibular advancement. Some authors have advocated less-invasive therapy including palatal stiffening implants and radiofrequency ablation, but the long-term data are lacking. Life-threatening obstructive sleep apnea that does not respond to CPAP/BiPAP or surgical intervention may require permanent tracheostomy. A repeat polysomnogram should be performed in surgical patients 1-3 months postoperatively to monitor for improvements.

DISORDERS OF THE LARYNX AND TRACHEA

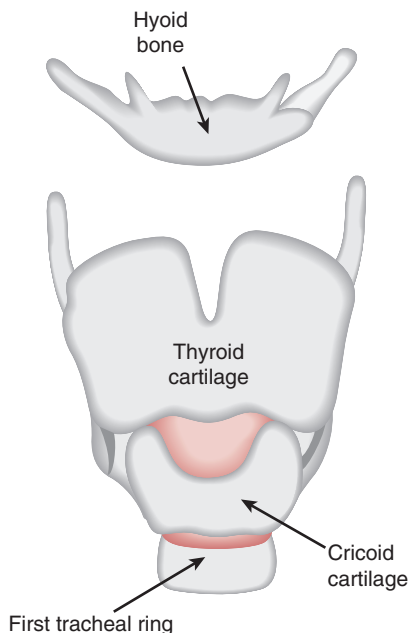

► Anatomy and Physiology

The anatomy of the larynx (Figures 15-7 and 15-8) is best understood in the context of its function. The primary function of the larynx is to protect the airway from aspiration during swallowing. The epiglottis and aryepiglottic folds help direct food and liquids laterally into the pyriform sinuses and away from the midline laryngeal inlet. The paired arytenoid cartilages act as attachment points for most of the intrinsic muscles of the larynx, serving to move the vocal folds together (adduction) and apart (abduction). The false vocal folds and true vocal folds adduct to prevent entry of food or liquids into the airway.

The larynx also functions in respiration. Owing to reflex pathways in the brainstem, the glottis opens just prior to inspiration. Other laryngeal reflexes respond to subglottic

▲ **Figure 15-7.** Internal anatomy of the larynx as seen on endoscopy.

▲ **Figure 15-8.** Cartilaginous and bony laryngeal framework.

pressure and hypercapnea. Additionally, initiation of swallowing causes a reflex period of involuntary apnea.

Phonation is the most uniquely human of the three functions of the larynx. At its most basic description, the glottic larynx produces a fundamental tone by the vibration of the free edge of the true vocal folds. This vibration is due to passive vibration of the vocal folds from air moving past the opposed free edges. Changing the tension within the vocal fold changes the pitch at which the vocal fold vibrates.

Several cartilages comprise the framework of the larynx (Figure 15-8). The thyroid cartilage is the largest laryngeal cartilage. This shield-shaped cartilage is responsible for the anterior neck prominence, sometimes called the “Adam’s apple” in lay terminology, and it provides protection to the internal components of the larynx. The cricoid cartilage lies inferior to the thyroid cartilage and serves as the major support for the larynx. It is the only complete cartilaginous ring within the upper airway. Internally, the paired arytenoid cartilages articulate with the cricoid cartilage, and attach to the vocal folds. Movement of the arytenoids results in abduction or adduction of the vocal folds. The epiglottis is a flexible cartilage located above the larynx. It is not involved in structural support of the larynx, but serves to assist in protecting the airway during deglutition (swallowing).

Innervation to the larynx is provided by the vagus nerve (cranial nerve X). The vagus nerve originates from three nuclei located within the medulla—the nucleus ambiguus,

the dorsal nucleus, and the solitary tract nucleus. All motor fibers (and thus laryngeal motor innervation) originate from the nucleus ambiguus. The dorsal (parasympathetic) nucleus is the origination for efferents to involuntary muscles of the bronchi, esophagus, heart, stomach, and intestine. Sensory innervation from the pharynx, larynx, and esophagus terminates in the solitary tract nucleus. The vagus nerve exits the skull base through the jugular foramen. It descends in the neck behind the jugular vein and carotid artery and sends pharyngeal branches to the muscles of the pharynx and soft palate. The superior laryngeal nerve arises directly from the vagus, and has an internal and external branch. The internal superior laryngeal nerve enters the larynx through the thyrohyoid membrane and supplies sensation to the larynx above the true vocal cords. The external superior laryngeal nerve innervates the cricothyroid muscle, the only muscle of the larynx not innervated by the recurrent laryngeal nerve. The right recurrent laryngeal nerve arises from the vagus and loops around the subclavian artery. The left recurrent laryngeal nerve arises more distally in the thorax, and loops around the aortic arch. Both recurrent laryngeal nerves then ascend in the tracheo-esophageal grooves, and enter the larynx near the cricothyroid joint. The recurrent laryngeal nerves provide motor innervation to all of the intrinsic muscles of the larynx except the cricothyroid. A summary of the laryngeal muscles is provided in Table 15-4.

► Urgencies and Emergencies

A. Pediatric Airway Obstruction

The rapid and accurate evaluation of a child in respiratory distress is one of the most critical skills an otolaryngologist must master. Noisy breathing and respiratory distress have multiple etiologies, and differentiation between acute emergencies and chronic conditions is essential. An important point to learn early on is that not all noisy breathing is stridor.

True stridor may represent an impending airway failure, and thus must be distinguished from other upper airway noises that are sometimes mistakenly referred to as “stridor.” Airway obstruction at the level of the nasopharynx produces snoring sounds, or stertor. Tracheobronchitis can produce a wheezy, barking cough characteristic of croup. Asthma, tracheobronchial foreign bodies, and bronchomalacia can produce wheezing. “Stridor” specifically refers to the noise that is produced by air movement through a partially obstructed airway. Inspiratory stridor usually signifies an obstruction above the level of the vocal cords, while expiratory stridor most often occurs with subglottic obstruction. Biphasic stridor usually signifies an obstruction at the level of the vocal cords or subglottis.

The immediate concern in evaluating a child with stridor is verifying or establishing a stable airway. The initial evaluation should consist of non-invasive examination to

Table 15–4. Major muscles of the larynx.

Muscle	Function	Innervation	Key Point
Posterior cricoarytenoid	Abducts vocal folds, tenses vocal folds	Recurrent laryngeal nerve	ONLY abductor of vocal folds
Lateral cricoarytenoid	Adducts true vocal folds	Recurrent laryngeal nerve	
Interarytenoid	Adducts posterior glottis	Recurrent laryngeal nerve	ONLY laryngeal muscle receiving bilateral innervation
Oblique arytenoids	Closes laryngeal inlet during swallowing	Recurrent laryngeal nerve	
Thyroarytenoid	Adducts, tenses vocal fold	Recurrent laryngeal nerve	
Cricothyroid	Increase vocal fold tension, especially at higher pitches	External branch of superior laryngeal nerve	ONLY muscle not innervated by recurrent laryngeal nerve

avoid exacerbating a potentially unstable airway. If the child is in acute respiratory distress, evaluations such as flexible fiberoptic laryngoscopy should not routinely be performed.

A careful history should be obtained, including the duration of the stridor and relationship to feedings. Parents should be questioned about any change in symptoms with position changes. Presence of any birth or intrauterine complications, history of intubation, as well as congenital anomalies should be determined.

If the child is not in acute distress, flexible fiberoptic laryngoscopy may provide valuable diagnostic information. This can be done with the child awake and restrained, or under general anesthesia with spontaneous ventilations. This allows determination of nasopharyngeal and supraglottic anatomy, as well as vocal cord motion. If available, the examination should be recorded to allow playback and review, as real-time examination can be problematic in an often-uncooperative child.

Other investigations should be based on the presence of suggestive symptoms. Swallowing function is often impaired in children with stridor, and should be evaluated. Vascular rings may produce extrinsic compression of the esophagus and trachea leading to stridor, feeding difficulties and failure to thrive. An altered, weak, or absent cry from birth can suggest neurologic impairment. Recurrent pneumonia or excessive cough with feeding may be present with vocal cord impairment, severe reflux, or tracheoesophageal fistula.

One of the most common causes of pediatric stridor is laryngotracheobronchitis, or croup. This is an acute viral illness, most commonly caused by the parainfluenza virus. The typical patient is an infant or young child with low-grade fever, seal-like barking cough, and occasionally biphasic stridor. The classic radiographic finding is a “steeple” sign visible on AP views, indicative of the characteristic narrowed subglottic airway from edema. The typical course for most patients is resolution over several days and few patients require hospitalization. Signs of respiratory distress

including tachypnea, retractions, and cyanosis may necessitate closer observation such as hospitalization. For these more severe cases, treatment with humidified air, nebulized racemic epinephrine, and systemic steroids may be indicated. Manipulation of the airway may exacerbate the clinical situation, and should be avoided unless clearly indicated.

Epiglottitis is fortunately becoming vanishingly rare in most industrialized countries, owing to nearly universal vaccination of children against *H influenzae* type B. If recognized and managed appropriately (with aggressive airway control) outcomes are usually excellent. If managed conservatively, epiglottitis is associated with up to 6%-10% mortality. Patients present with high fever, drooling, and odynophagia and are usually toxic in appearance. Of note, epiglottitis tends to progress quite rapidly; patients can decompensate clinically in a matter of hours. The characteristic position naturally assumed by patients with epiglottitis is the leaning forward position, to maximize their marginal airway opening. Even oral cavity examination with a tongue blade can precipitate an airway crisis; therefore evaluation and treatment ideally consists of immediate control of the airway in the operating room under general inhalational anesthesia. A cherry-red epiglottitis will be visible on endoscopic examination. Pharyngeal and blood cultures should be obtained, and the child started on broad spectrum IV antibiotics such as ceftriaxone. Once definitive identification of the culprit organism is made antibiotic selection can be narrowed appropriately. Children are left intubated until air leak around the endotracheal tube is evident.

Chronic pediatric stridor is most often due to laryngomalacia. Parents will usually report onset of symptoms shortly after birth. It often worsens initially, but in the vast majority of cases resolves without the need for intervention, usually by 12-18 months. A variety of factors have been hypothesized to contribute to laryngomalacia including neurologic, muscular, and reflux-induced inflammation. The stridor is worsened while crying or in an excited state, and is usually

Table 15–5. Summary of the Cotton grading system for subglottic stenosis.

Grades	Degree of Subglottic Obstruction
Grade 1	Less than 50% obstruction
Grade 2	50%-70% obstruction
Grade 3	71%-99% obstruction
Grade 4	100% obstruction

relieved by placement in the prone position. Flexible fiberoptic laryngoscopy reveals collapse of floppy supraglottic structures such as the epiglottis and aryepiglottic folds. There is a strong association of laryngomalacia with reflux, and presumptive treatment with an acid blocking medication (such as ranitidine) may be beneficial. Surgical treatment of the supraglottis is reserved for severe cases such as patients with cyanosis or failure to thrive. The most common procedure is aryepiglottoplasty, where cold knife or carbon dioxide laser is used to excise redundant mucosa over the arytenoid cartilages. Rarely, tracheostomy may be necessary.

Subglottic stenosis is the second most common cause of chronic pediatric stridor. Causes include both congenital stenosis, and acquired (most often from prolonged intubation). Typically, patients have recurrent “croup” and biphasic stridor. If present in older children, the patient may only become symptomatic periodically, in association with upper respiratory tract infections. Diagnosis requires endoscopic evaluation, and can be defined as a subglottic airway diameter of less than 4 mm in full-term infants and less than 3 mm in premature infants. Pediatric subglottic stenosis is traditionally graded according to the Cotton scale (Table 15–5). Tracheotomy may be required in moderate to severe cases. Treatment of subglottic stenosis can consist of tracheal dilatation (either by rigid serial dilation or controlled radial expansion balloon), debridement by microdebrider or carbon dioxide laser, cricoid split, or laryngotracheoplasty.

B. Foreign Body Aspiration

Airway foreign body typically involves children between 1 and 4 years of age, but can occur in any age group. Children in this age range tend to place objects in their mouths and lack molars for grinding of food. Objects can range from peanuts (most common) to coins, marbles, and toy products. Adult foreign body aspiration is usually associated with food, typically meat. Foreign body aspiration is potentially life threatening and it is recognized as the fifth most common cause of unintentional-injury related mortality in the United States. Pharyngeal foreign body (most

▲ **Figure 15–9.** Airway foreign body in a 4 year old. The patient in question had a history of brief choking while eating dinner three nights earlier, followed by intermittent nonproductive cough. He had a normal chest x-ray and slight wheezing heard on one side only. On rigid bronchoscopy, a soft green bean was found in a right distal bronchus.

commonly in the vallecula) represents a potential impending airway foreign body, and should be treated as such.

The clinical presentation of patients with airway foreign body depends on the anatomic location. Patients with pharyngeal or hypopharyngeal foreign bodies typically present with dysphagia, odynophagia, and occasionally drooling from inability to tolerate secretions. If large objects become lodged in the larynx, patients may present with pain, dysphonia, inspiratory stridor, and dyspnea. Tracheal foreign bodies produce both inspiratory and expiratory stridor. Distally located foreign bodies (Figure 15–9) often lodge in the right bronchus (especially in adults). This is due to the angles at which the left and right mainstem bronchi branch off the trachea, with the right being a less acute angle. Distal foreign bodies typically produce unilateral wheezing and decreased breath sounds. A history of acute choking episode is very common and is 76%-92% sensitive in diagnosing foreign body aspiration.

Acute management of airway foreign body is dictated by patient condition. In a conscious patient who is able to exchange air and cough, an attempt at foreign body removal should not be made immediately. Unconscious patients, or victims unable to cough or move air require immediate intervention. If the means for performing a

cricothyrotomy or tracheotomy are not available, the Heimlich maneuver can be performed as three manual abdominal thrusts to compress the lungs and potentially produce enough airway pressure to dislodge the foreign body. For patients without impending loss of airway, anteroposterior and lateral radiographs of the airway including larynx and chest can be helpful. While only radio-opaque foreign bodies can be visualized, radiographs may demonstrate obstructive emphysema, atelectasis, or consolidation. Additionally, they can provide a baseline study for future comparison.

Definitive removal of an airway foreign body requires general anesthesia, and direct laryngoscopy. Distally located foreign bodies are best addressed with rigid bronchoscopy for removal. A clear history consistent with aspiration often should prompt operative evaluation, even if specific symptoms (stridor, unilateral wheezing, decreased breath sounds) are lacking, as these may be absent in up to 40% of cases. Suspected nut aspiration (common in children) should be treated aggressively. Local tissue reactions to the nut oils and proteins are common, and can be robust. Post removal, patients with peanut aspiration may require intensive care unit observation and ventilatory support while the inflammatory reaction resolves.

C. Laryngeal Trauma

Laryngeal trauma is rare, representing 1 out of every 14,000-42,000 emergency room visits. Quick recognition of laryngeal trauma is essential as it can rapidly lead to death. Up to one-third of laryngeal trauma victims die prior to arrival to a hospital setting.

Laryngeal trauma can be classified as blunt or penetrating. Blunt laryngeal trauma results from crushing of the laryngeal framework against the cervical spine, and usually results from motor vehicle accidents. Other common etiologies include strangulation type injuries, and clothesline injuries. Penetrating laryngeal trauma usually results from projectile injury, such as a gunshot, or knife wounds to the neck.

Every patient with trauma to the neck should be evaluated for potential laryngeal trauma. Patients may report dyspnea, hoarseness, or aphonia. Other less common symptoms include dysphagia, anterior neck pain, and odynophagia. Evaluation should begin with the ABCs of trauma—airway, breathing, circulation. Severe laryngeal trauma (particularly clothesline-type injuries) can result in loss of airway and necessitate the need for immediate tracheotomy. Physical findings common in patients with laryngeal trauma include stridor, subcutaneous crepitance (emphysema), bruising or edema to the anterior neck, loss of palpable landmarks, and hemoptysis. As outlined above (stridor and airway obstruction) the type of stridor can often give an indication of the site of airflow obstruction.

Further evaluation of laryngeal trauma is dictated by the patient's condition. If an adult patient's airway is unstable, most experts would advocate awake tracheostomy or cricothyrotomy under local anesthesia, as endotracheal intubation in the setting of laryngeal trauma can be problematic. For unstable pediatric laryngeal trauma, inhalational anesthetic followed by rigid endoscopic intubation is recommended by many experts. Once a stable airway has been determined or secured, evaluation can proceed.

Flexible fiberoptic laryngoscopy is advocated for awake, stable patients. The airway should be evaluated for vocal cord mobility, edema, laryngeal lacerations, and hematomas. Because the underlying mechanism of injury often results in damage to other adjacent structures, laryngeal trauma patients should undergo complete cervical spine radiography, and evaluation for esophageal or vascular injury should be considered. Some authors recommend fine-cut CT imaging of the larynx to help guide treatment planning. It should be emphasized that CT scanning rarely provides useful information regarding the immediate airway management for patients suspected of having laryngeal trauma, but often provide helpful information regarding surgical planning for repair.

Management of the patient with laryngeal trauma depends on the severity of injury. Patients with small laryngeal hematomas, small lacerations not involving the vocal fold edge or anterior commissure, and nondisplaced stable thyroid cartilage fractures can often be managed without tracheostomy. Most such patients should be hospitalized for 24 hours of airway observation and placed on systemic steroids, humidified air, and proton pump inhibitor (PPI) therapy. If mucosal disruption is present antibiotics should be initiated.

More severe laryngeal traumas often require tracheotomy and direct laryngoscopy or even open laryngeal exploration and repair. This should ideally be performed within 24 hours of the initial injury. Open laryngeal exploration is performed via a midline thyrotomy approach. A horizontal skin incision is made at the level of the cricothyroid membrane. Subplatysmal flaps are elevated, and the strap muscles divided at the midline. The airway is then entered in the midline of the cricothyroid membrane, and a vertical incision through the midline thyroid cartilage extended superiorly. Care must be taken to avoid injury to the underlying endolaryngeal mucosa. Following this, the mucosa is incised allowing inspection of the endolarynx. Once the endolarynx is exposed, all mucosal lacerations should be repaired to cover all exposed cartilage. If the anterior commissure is disrupted, a laryngeal stent may need to be placed, although placement of a stent itself leads to some degree of laryngeal injury. If placed, stents should be removed as soon as possible, usually around 2 weeks.

Outcomes for laryngeal trauma patients are fairly good once initial control of the airway is obtained. Most patients usually achieve a stable airway and undergo decannulation,

which may take from 1 to 6 months or longer depending on the extent of injury. Overall, up to 90% of patients can recover a satisfactory vocal quality if managed appropriately.

► Disorders and Diseases

A. Hoarseness

Hoarseness or *dysphonia* is defined as an alteration in the quality or character of phonation. Patients may describe their voice as breathy, harsh, or rough. Common etiologies of hoarseness include viral illness, vocal fold paralysis, laryngopharyngeal reflux (LPR), laryngeal polyps, allergy, vocal abuse, dysplasia, and cancer.

Patients should be questioned about onset, frequency, and nature of the hoarseness. As previously discussed, the larynx is an essential part of swallowing, and any history of coughing or choking after eating should be elicited. Likewise the patient should be questioned about recurrent episodes of pneumonia. Any history of intubation, head and neck trauma, or previous head and neck surgery should be sought. Patients should be questioned about smoking and alcohol use.

Physical examination begins with a full head and neck examination. It is important to visualize the larynx. Methods of visualization include indirect mirror examination, rigid endoscopy, or transnasal flexible fiberoptic laryngoscopy. Videostroboscopy offers invaluable information about vocal fold motion and can identify adynamic segments and altered areas of mucosal wave propagation.

One common benign cause of hoarseness is vocal polyps. These are due to local tissue inflammation. Vocal nodules are distinct from polyps, and always occur bilaterally. They are most often a result of vocal abuse/misuse and usually respond dramatically to voice therapy. Vocal fold granulomas are usually due to extra-esophageal acid reflux damage.

Hoarseness can also be the presenting symptom for cancer, most often for cancer of the true vocal folds. The vast majority of laryngeal cancer is squamous cell cancer, and smoking is the biggest risk factor for its development. Laryngeal cancer is discussed further in the section Head and Neck Cancer. While early stage laryngeal cancer is highly curable, advanced stage carries a dramatically reduced prognosis. Thus, any patient with hoarseness lasting longer than 2 weeks should be evaluated and undergo visualization of their larynx.

B. Laryngopharyngeal Reflux

LPR impacts hundreds of thousands of patients annually, with some studies estimating as many as 30% of Americans may suffer from some degree of LPR. It is increasingly clear that LPR is a disease separate and distinct from classic gastroesophageal reflux disease (GERD). Patients with LPR typically present with frequent throat clearing, globus

sensation, cough and hoarseness (as opposed to postprandial heartburn with GERD).

Physical examination of patients suspected of LPR should include an examination of the larynx, most commonly by flexible transnasal fiberoptic laryngoscopy. Hoarseness is not pathognomonic for LPR, and can also be present in more serious disorders. Several laryngeal findings are common in patients with LPR. Presence of vocal cord granuloma or pseudosulcus vocalis, although uncommon, is highly suggestive of LPR. Other common laryngoscopic findings consistent with LPR include posterior laryngeal hypertrophy, laryngeal edema and erythema, cobblestoning, or posterior commissure bar.

The diagnosis of LPR relies on a combination of symptoms and physical findings rather than one isolated factor being pathognomonic. Several studies have demonstrated the presence of many of the above symptoms and laryngeal findings in healthy, normal control patients. Many clinicians advocate the use of a metric scale that combines multiple common symptoms or physical findings. Two such instruments are the reflux finding score (RFS) and the reflux symptom index (RSI). In general, an RFS of greater than 8 is suggestive for LPR, and a score of greater than 13 on the RSI is likewise indicative of LPR.

Treatment for LPR currently consists of PPIs as a first-line therapy with surgery (eg, Nissen fundoplication) for selected treatment failures. It should be pointed out that although multiple uncontrolled studies have demonstrated benefit of PPIs for the treatment of LPR, the majority of randomized controlled trials have failed to confirm this. Possible confounding factors include lack of clear “gold standard” for the diagnosis of LPR, and differing treatment regimens. Our current practice is to place patients with LPR on once-daily PPI therapy for a 3- to 6-month period, after which response to treatment is assessed. The extended length of time is critical, as studies have shown that resolution of laryngeal findings can take up to 6 months to resolve once PPI therapy is initiated. If there is no response to once-daily PPI therapy, the patient can be advanced to twice-daily PPI therapy. Disease severity can prompt initiation of PPI therapy at twice-daily dosing; severe laryngeal edema or presence of subglottic stenosis would be two such indications.

It should also be mentioned that if a patient is diagnosed with LPR, some form of evaluation of the esophagus should be undertaken. There is up to a 20% incidence of unsuspected esophageal abnormalities in patients with LPR. This evaluation can take the form of imaging modalities such as barium swallow, or endoscopic examination such as esophagoscopy.

C. Vocal Cord Immobility/Paralysis

Vocal cord mobility problems represent a wide range of etiologies characterized by diverse patient presentation and

prognostic outcomes. The distinction between unilateral and bilateral, and between paretic (hypomobile) versus paralyzed cords is imperative.

Patients with unilateral vocal cord paralysis may be asymptomatic, but often present with a hoarse, breathy voice. Their voice often starts out stronger in the morning and worsens throughout the day as they develop vocal fatigue. Accompanying symptoms can include frequent throat clearing, cough, vague globus sensation, and aspiration. Often patients will report subjective shortness of breath or a feeling of “running out of air” despite normal pulmonary function. This is secondary to glottal incompetence (lack of apposition of the vocal folds) resulting in escaped air during phonation. Thus a patient with unilateral vocal fold paralysis may be able to climb a flight of stairs without difficulty, yet feel short of breath when attempting to carry on a telephone conversation. Patients should be questioned specifically about swallowing, weight loss, recent illnesses or intubations, and surgeries (especially cardiac, cervical spine, and thyroid procedures).

The etiologies of vocal cord paralysis reflect the diverse nature of illnesses and injuries that can result in the final common pathway of vocal cord immobility or paralysis. The vocal cords derive their innervation from the vagus nerve, and any injury along the course of this nerve may result in vocal cord paralysis. Unilateral vocal cord paresis is by far the most common, with bilateral representing less than 20% of all paralysis. Historically, the most common cause of unilateral vocal cord paralysis was malignancy (such as lung cancer or skull base tumors). More recent studies show that iatrogenic surgical injury is now the most common cause. Nonthyroid surgical procedures (including anterior approaches to the cervical spine and carotid endarterectomy) now account for the majority of these iatrogenic injuries. Thyroid surgery remains the most common cause of bilateral vocal cord paralysis. Table 15–6 summarizes the most common causes of vocal fold paralysis. It should be noted that laryngeal manifestations of rheumatoid arthritis can rarely mimic vocal cord paralysis, although the underlying problem in this case is vocal cord immobility secondary to fixation of the arytenoid cartilages.

It is important to note that vocal cord immobility or paralysis is a *sign of pathology* and not a diagnosis. Thus the first concern when evaluating a patient with vocal cord paralysis should be investigation of the etiology. Often the cause is not identifiable, and the vocal cord paralysis is deemed idiopathic. A thorough head and neck examination should be performed, including endoscopic evaluation of the larynx. This most often is by flexible fiberoptic laryngoscopy, with most laryngologists recommending videostroboscopy as well. For unilateral recurrent laryngeal nerve injury, the affected immobile cord will usually lie in a paramedian position. This is due to lack of abduction, with some retained adduction (due to the cricothyroid muscle, which

Table 15–6. Most common causes of vocal cord paralysis.

Unilateral Vocal Cord Paralysis (%)

Trauma	7

is innervated by the superior laryngeal nerve). For more proximal vagal lesions, the affected cord will usually rest in intermediate position, due to loss of both abduction and adduction innervation. There is also loss of sensation to the affected hemilarynx, and aspiration is common.

Diagnostic testing should include a chest radiograph and CT scan following the entire vagus nerve course (ie, neck and chest, from skull base to the mid-chest). More esoteric tests are likely to be low yield and poorly cost-effective, and should be reserved for more selective use. Many laryngologists advocate the use of laryngeal electromyography (EMG). This test is performed percutaneously, and tests the superior laryngeal nerve and recurrent laryngeal nerve by evaluating motor unit electrical activity in the cricothyroid and thyroarytenoid muscles, respectively. Laryngeal EMG can provide useful information regarding the degree and likely site of injury (central vs peripheral), as well as the potential for spontaneous recovery. It is most predictive if performed 6 weeks to 6 months after initial injury.

Initial therapy for unilateral vocal cord paralysis consists of observation and speech therapy. Often the opposing vocal cord can compensate by crossing the midline and closing the glottal gap. This can produce an acceptable vocal quality, usually occurring within a 3-6 months time span.

Patients not obtaining a good result using these conservative measures can be treated by a variety of surgical interventions. The goal of surgical treatment for unilateral vocal cord paralysis is medialization of the affected cord. This reduces the glottic gap and allows the opposing, innervated cord to contact the other vocal fold with less effort. Treatment selection for unilateral vocal cord paralysis depends on the potential for recovery. In cases such as iatrogenic surgical injury with little chance of spontaneous recovery, definitive therapy can be initiated early. For idiopathic causes, a more conservative approach is usually advocated. Overall, up to 60% of patients with idiopathic unilateral vocal cord paralysis will recover to a near-normal voice within 8-12 months. Thus, most experts would recommend waiting at least 1 year before proceeding with definitive therapy. Clear indications for earlier intervention include significant dysphagia and aspiration from glottic incompetence.

Definitive surgical procedures for unilateral vocal fold paralysis include laryngeal framework surgery, injection of longer lasting material, and reinnervation techniques. The thyroplasty technique (a laryngeal framework surgical procedure) is performed through an external skin incision. After exposing the thyroid cartilage, a window is cut in the thyroid ala overlying the position of the vocal fold on the affected side. An implant is then placed in a subperichondrial window, thus pushing the vocal fold toward the midline. Implants can include Silastic, autologous cartilage, and Gore-Tex. Most laryngologists perform this procedure with the patient lightly sedated. A flexible fiberoptic laryngoscope can be suspended in position, and the patient is asked to phonate periodically so that the surgical effects can be evaluated in real time and adjusted accordingly.

Another common surgical intervention is injection medialization. This can be performed as an office-based procedure using only local anesthesia, or in the operating room under general anesthesia. In either case, a variety of injectable materials are placed within the vocal fold lateral to the vocal process, to medialize the cord. In the past, Teflon was commonly used for this purpose, but has now largely fallen out of favor secondary to a high rate of complications. An alternative, long lasting (but not permanent) injectable is calcium hydroxyapatite microspheres in methylcarboxycellulose carrier gel (Radiess Voice). Temporary injectables include gelfoam paste, hyaluronic acid, micronized cadaveric dermis (Cymetra), cross-linked collagen (Zyderm), and methylcarboxycellulose gel (Radiess Voice Gel).

Surgical reinnervation for unilateral vocal cord paralysis is gaining popularity. Approaches can include nerve-muscle pedicle (using the omohyoid and ansa hypoglossi nerve) and direct nerve-nerve reinnervation (ansa cervicalis to recurrent laryngeal nerve). Results from these techniques are generally good, but can take 6 months or longer to be realized. For this reason, many surgeons combine reinnervation with injection medialization using a temporary substance.

For bilateral vocal cord paralysis, treatment approaches have a different perspective. Whereas restoration of voice is the primary goal for unilateral paralysis, resolution of potential or actual airway compromise is of tantamount importance in cases of bilateral paralysis. Most patients are initially treated with a tracheotomy to bypass the glottic obstruction. One common surgical procedure is lateralization of the vocal folds by arytenoidectomy. While this usually provides a patent airway and allows decannulation (reversal of the tracheotomy) the patient's vocal quality usually suffers significantly.

Another surgical approach, partial posterior cordectomy) can often preserve vocal quality to some degree, while providing improved airway. This approach uses a laser through a surgical laryngoscope to remove a c-shaped wedge from the posterior portion of one vocal cord. This preserves a bilateral vibratory margin anteriorly while providing an airway posteriorly. The technique is often best performed as multiple less aggressive procedures to fine-tune vocal quality versus airway, rather than a single definitive procedure.

D. Recurrent Respiratory Papillomatosis

Recurrent respiratory papillomatosis is caused by the human papilloma virus, specifically types 6 and 11. Human papilloma virus is a small nonenveloped virus that infects the nuclei of host cells for replication. Papillomaviruses show a preference for infection of epithelial tissues and are very common in humans. Human papillomavirus (HPV) is responsible for a variety of disease including skin warts, recurrent respiratory papillomatosis, and invasive cancers such as cervical or oropharyngeal carcinoma. Transmission is hypothesized to involve vertical transmission during childbirth; maternal presence of condylomata during the perinatal period confers a 200-fold increase in relative risk for developing respiratory papillomatosis.

Benign, recurrent hyperplastic tissue growth of the upper airway characterizes this disease. It has a bimodal age distribution, with incidence peaks in children (infants to 12 years old), and in adults (30-40 years of age). Patients typically present with dysphonia or aphonia, although advanced disease can cause stridor from impending airway obstruction.

The primary site affected is the larynx, with the glottis being the most common area followed by the supraglottic larynx (Figure 15-10). Respiratory papillomatosis generally remains confined to the larynx but can spread distally to affect the trachea, bronchi, and lungs. Disease recurrence is frequent, and reports of children requiring more than 100 surgical procedures are not uncommon.

The primary therapy for respiratory papillomatosis remains surgical debulking, primarily by microdebrider or carbon dioxide laser ablation. Adjuvant medical treatments include cidofovir, indole-3-carbinol, ribavirin, mumps vaccine, and photodynamic therapy. The role for these adjuvant

▲ **Figure 15–10.** Adult recurrent respiratory papillomatosis. The right true vocal fold is involved with respiratory papillomatosis. In this patient, the disease was confined mostly to the single true vocal fold, although some disease was also present in the anterior portion of the contralateral vocal fold.

therapies in the treatment of respiratory papillomatosis is still being elucidated. Many otolaryngologists advocate avoidance of tracheotomy if possible, because this has been epidemiologically associated with increased risk of spread of papillomas to the lower respiratory tract. It is possible because patients with inherently more aggressive disease are also those who are more likely to require tracheostomy.

HEAD AND NECK CANCER

► Pathophysiology of Head and Neck Squamous Cell Carcinoma

Excluding skin cancer, the vast majority of head and neck cancers are squamous cell cancers. This is the sixth most common malignancy; over 500,000 patients worldwide are diagnosed with head and neck squamous cell carcinoma each year. Head and neck squamous cell carcinoma is a potentially curable malignancy when diagnosed at an early stage. Unfortunately, patients often present with locally advanced disease. Overall, the prognosis is poor in this latter group of patients. For patients with advanced disease, between 60% and 70% develop loco-regional recurrences within 2 years.

Despite numerous advances in our understanding of this disease and in development of improved medical and

surgical therapies, mortality rates have not changed significantly over the last two decades. Additionally, current therapies (both surgical and nonsurgical) carry a high level of treatment-related morbidity; patients with advanced-stage disease often suffer significant speech and swallowing impairment following treatment.

Development of head and neck squamous cell carcinoma is traditionally attributed to the synergistic carcinogenic effects of tobacco and alcohol. Other factors, such as poor oral dentition, gastroesophageal reflux, betel nut chewing, and viral infection may also be important contributors to the development of head and neck squamous cell carcinoma. It is now accepted that high-risk types (eg, 16, 18, and 31) of HPV are a causal agent in the development of some head and neck squamous cell carcinomas, particularly cancers of the oropharynx. While as many as 50% of oropharyngeal cancers have detectable HPV-16 DNA, only 25%-30% of all oropharyngeal cancers are thought to have a viral etiology (as opposed to the usual insults of tobacco and alcohol). In HPV-mediated transformation, oncoproteins (primarily E6 and E7) encoded by the HPV genome are transcribed by infected human epithelial cells, resulting in the degradation and inactivation of host tumor suppressor genes p53 and Rb. This is thought to allow unchecked cell cycle progression and development of genetic instability. Head and neck squamous cell carcinomas with active (eg, transcribed) HPV share a common molecular phenotype, similar to that of HPV-caused cervical cancer. Head and neck squamous cell carcinomas with inactive HPV appear to share a molecular phenotype in common with HPV-negative head and neck squamous cell carcinomas. The role, if any, of HPV in these latter cancers is under investigation.

Head and neck cancers are thought to progress through characteristic stages of premalignancy (dysplasia, carcinoma *in situ*, until finally reaching invasive carcinoma). This progression reflects the accumulation of multiple genetic changes from mutation, gene silencing (via methylation), chromosomal rearrangements, deletions and duplications. Common changes include mutational inactivation of p53 and Rb tumor suppressors, abrogation of the tumor suppressor p16 axis, amplification of the CCND1 locus (the gene encoding the cell cycle mediator cyclin D1), and various changes resulting in overexpression of epidermal growth factor receptor (EGFR), c-Met and transforming growth factor alpha (TGF- α).

Another important concept in head and neck cancer biology is that of *field cancerization*. According to this theory, first described in 1953, the entire mucosa of the upper aerodigestive tract is exposed to the same carcinogenic insults. Thus, premalignant changes are likely in a wide field, not just at the site of the original cancer. Even if that cancer is successfully treated, the patient remains at high risk for developing subsequent malignancies throughout the upper aerodigestive tract. Recent molecular-based investigations

have provided strong support for this concept, and multiple studies have demonstrated genetic alterations in histologically normal tissue from high-risk individuals. For this reason, patients with a history of head and neck squamous cell carcinoma should be closely followed with yearly screening examinations for life.

► Evaluation of the Patient With Head and Neck Cancer

A. History and Physical Examination

Any patient with a significant history of alcohol and tobacco use who presents with complaints related to the upper aerodigestive system should be evaluated with an index of suspicion for head and neck squamous cell carcinoma. Common symptoms of head and neck cancer can be quite subtle. Mechanical obstruction and dysfunction from tumor mass can produce dysphagia. Head and neck cancers are often associated with significant pain, and odynophagia is common for cancers of the oral cavity and oropharynx. Referred pain from neck metastases can result in otalgia, as can cancers arising in the nasopharynx or those affecting the EAC. Cancers of the true vocal cords often produce significant hoarseness early in the course of disease progression. Other symptoms can include hemoptysis, globus sensation, trismus, and weight loss. Sometimes the presenting symptom is a neck mass representing nodal metastases from an asymptomatic primary source.

Patients should be asked about family history of cancers and personal risk factors such as alcohol use and all forms of tobacco—cigarettes, cigars, chewing tobacco, etc. Certain ethnic populations (specifically emigrants from the country of India) may give a history of betel nut chewing. This nut has been found, like tobacco, to have synergistic carcinogenic risk when present in combination with alcohol consumption.

Physical examination should include a comprehensive evaluation of all sites of the head and neck. Inspection of the face and scalp for skin lesions, masses, and asymmetry should be performed. Otoscopy and anterior rhinoscopy allow evaluation of the EAC, tympanic membrane, and nasal cavity. Unilateral serous fluid in the middle ear space in an adult should raise suspicion for a nasopharyngeal lesion. The entire oral cavity should be evaluated, including each gingivo-buccal sulcus. The floor of mouth and base of tongue should be manually palpated for induration, pain on palpation, and asymmetry. Evaluation of the larynx and base of tongue can be performed by headlamp and mirror examination (indirect laryngoscopy). Flexible fiberoptic evaluation often provides additional detail and visualization not possible with the former method. Additionally, the nasal cavity and nasopharynx can easily be evaluated during the same procedure. A complete evaluation of the cranial nerves should be performed. This can often give insight into nerves

affected by tumor mass effect (compression) or direct nerve invasion (perineural spread).

The neck should be carefully palpated for cervical lymphadenopathy. This is most easily accomplished by standing behind the patient and palpating each area of the neck symmetrically using both hands. This allows tactile comparison between sides. The pads of the fingers and thumbs are the most sensitive parts of the hands and should be used instead of the tips of the digits.

B. Imaging

Imaging is an important part of the diagnostic evaluation of a patient with head and neck cancer. Goals of imaging include preoperative identification of site and extent of tumor infiltration, presence of suspicious lymph nodes, and presence of anatomic variations. The imaging modality of choice for most suspected head and neck tumors is CT scan with intravenous contrast. This allows adequate soft tissue and bony detail. Most head and neck cancers will demonstrate enhancement on IV contrast administration, and the contrast additionally makes delineation of soft tissue structures much easier. In some cases contrasted MRI may offer additional information. These cases include evaluation of the skull base, parapharyngeal space and orbit, and evaluation of cranial nerves for signs of perineural spread.

Increasingly, evaluation of head and neck squamous cell carcinoma patients for distant metastases and monitoring for posttreatment disease recurrence or persistence involves the use of tumor imaging by 18F-fluorodeoxyglucose positron emission tomography (FDG-PET) (Figure 15–11). The use of FDG-PET and combined PET/CT modalities is extremely important as early identification of persistent/recurrent disease has the potential to impact survival, especially for patients with advanced nodal disease. While CT and MRI rely on contrast enhancement patterns and differences in tissue attenuation, FDG-PET works somewhat independently of these criteria. FDG follows a cellular uptake pathway similar to glucose and becomes concentrated in cells with elevated glucose utilization. Because changes in tumor metabolism often precede changes discernable on clinical examination this makes FDG-PET potentially valuable in discovering clinically nondetectable tumor spread or recurrence. PET-CT results are generally reported as standardized uptake values (SUV). This is a ratio of tissue FDG uptake normalized to injected dose of FDG, patient body weight, and serum glucose levels. Higher SUV values indicate increased FDG uptake. Multiple tissue metabolic changes can lead to increased FDG uptake, including inflammation, infection, radiation response, and malignancy. While still a matter of debate, general consensus is that SUV greater than 2.5–3.5 should be considered suspicious for malignancy.

▲ **Figure 15-11.** Positron emission tomography (PET scan). PET scan showing uptake in the original primary site (palate, indicated by large arrowhead) as well as new mediastinal uptake indicative of nodal metastases (thin arrow). Note the normal physiologic uptake in the liver (moderate intensity) and heart and brain (high intensity) demonstrating the relatively high glucose utilization of these organs.

C. Staging and Treatment of Head and Neck Squamous Cell Carcinoma: TNM Staging

Staging for head and neck squamous cell carcinoma in the United States uses a TNM system. Staging is important because it allows estimation of prognosis, treatment planning, and expected response to treatment. The TNM system classifies cancers by T—primary tumor size, N—locoregional nodal metastases, and M—distant metastatic spread. The rules for classification vary by subsite within the head and neck. In general cancers of subsites that can be seen directly (ie, oral cavity, oropharynx, etc) are T-staged by size. By comparison, cancers of subsites not visible directly

(ie, larynx, hypopharynx, sinonasal, etc) are T-staged by anatomic spread of disease.

Initial evaluation of the primary site and T-staging is best accomplished by operative direct laryngoscopy and esophagoscopy. This allows examination of the primary site and evaluation of the entire upper aerodigestive tract for simultaneous second primary tumors and biopsy of suspicious areas. Some authors propose trans-nasal esophagoscopy as an acceptable alternative to operative endoscopy. This method allows evaluation (and biopsy) of the most common areas for malignancy with the exception of the postcricoid region and subglottis. Transnasal esophagoscopy has the advantage of being able to be performed as an office-based procedure without the need for sedation.

It should be mentioned that cancers of Waldeyer's ring which includes the palatine tonsil and base of tongue (lingual tonsil), while usually squamous cell cancer, can also be lymphoid in origin (such as lymphoma). If there is a suspicion for lymphoma, biopsy specimens should be sent as fresh material and not placed into formaldehyde. Often, flow cytometry and other pathologic tests useful for evaluation of lymphomas cannot be performed on formaldehyde-fixed specimens.

N-stage is determined by the presence of clinically evident regional lymph node metastases. It is important to point out that for head and neck cancer suspicious lymphadenopathy identified only on CT or MRI scan is included in the clinical staging. Radiologic findings suspicious for malignant lymph node metastases include lymph nodes that are round, heterogeneously enhancing, and larger than 1 cm. The current criteria for N-staging (for subsites other than nasopharynx) is summarized in Table 15-7.

M-stage is determined by the presence of distant metastatic disease. The most common sites of metastases for head and neck squamous cell carcinoma are the liver and the lungs. Therefore part of the initial staging workup for a patient with head and neck cancer includes some method of

Table 15-7. Determination of N-stage for cancers of the oral cavity, oropharynx, hypopharynx, and larynx.

Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastases in a single ipsilateral lymph node, 3 cm or less
N2	Metastases in a single ipsilateral lymph node, > 3 cm but not more than 6 cm
N2a	
N2b	Metastases in multiple ipsilateral lymph nodes < 6 cm
N2c	Metastases in bilateral or contralateral lymph nodes < 6 cm
N3	Metastases in lymph node(s) greater than 6 cm

Table 15–8. Summary of TNM staging for cancers of the oral cavity, oropharynx, hypopharynx, and larynx.

Stage	T-Stage	N-Stage	M-Stage
Stage 0	T-is (<i>in situ</i>)	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3 T1-T3	N0 N1	M0
Stage IVa	T4a T1-T4a	N0-N1 N2	M0
Stage IVb	T4b Any T	N0-N2 N3	M0
Stage IVc	Any T	Any N	M1

evaluating these structures. This most commonly consists of liver function blood tests and a chest roentgenogram, although at some institutions whole-body CT-PET scan is becoming more prevalent. M-stage is reported as Mx (cannot be determined), M0 (no distant metastases) or M1 (distant metastatic disease).

Overall staging is achieved by combining the T, N, and M stages to yield four broad stages (stage I-IV, with I carrying the best prognosis and IV the worst). Stage IV is further split into IV-a (simplified, denoting a surgically treatable cancer) and IV-b and -c (surgically unresectable). The overall staging system (based on the *AJCC Cancer Staging Manual*, sixth edition) for sites other than nasopharynx is summarized in Table 15–8 and Figure 15–12.

	N0	N1	N2	N3
T1	Stage I			
T2	Stage II			
T3	Stage III			
T4a	Stage IVa			
T4b				Stage IVb

▲ Figure 15–12. Summary of staging criteria for cancers of the oral cavity, oropharynx, hypopharynx, and larynx. Carcinoma in situ is stage 0, and presence of distant metastases (M1) is staged as stage IVc regardless of T or N stage.

► Therapy

Traditional therapy for head and neck squamous cell carcinoma depends on the stage of the cancer and varies by subsite. Simplified, early stage cancers are usually treated with single modality therapy, either surgical excision or radiation therapy. Advanced stage (stages III and IV) cancers are best treated by combined modality therapy, either surgery and postoperative radiotherapy, or chemotherapy/radiation therapy. Current research has shown that the latter is best delivered as concurrent chemotherapy-radiation therapy.

One new modality being investigated for head and neck squamous cell carcinoma includes molecularly targeted therapy. These therapies are designed to be specific for cancer cells, and include monoclonal antibodies and small molecule protein inhibitors. The most studied targeted therapy in head and neck squamous cell carcinoma is cetuximab, which targets the EGFR. In the initial randomized controlled clinical trial, researchers found that concurrent cetuximab and radiotherapy improved survival and locoregional disease control compared to radiotherapy alone. Studies have also demonstrated improvement in survival when cetuximab is combined with traditional chemotherapy. The EXTREME (Erbix in First Line Treatment of Recurrent or Metastatic Head and Neck Cancer) trial randomized 442 patients from 17 countries to either chemotherapy (5-fluorouracil plus either cisplatin or carboplatin) or the same chemotherapy plus cetuximab. Patients in the cetuximab arm had 20% reduction in risk of death, and overall survival was increased from a median 7.4 months to 10.1 months. Other targeted therapies currently being studied include bevacizumab (an inhibitor of VEGF receptor, involved in angiogenesis) and various orally administered EGFR small-molecule tyrosine kinase inhibitors. Particularly promising are combination targeted therapies which include agents addressing both the EGF and VEGF pathways.

SPECIFIC HEAD AND NECK SQUAMOUS CELL CANCER SITES

► Cancers of the Oral Cavity

Patients with oral cavity cancer typically present with a painful mass of the tongue, buccal mucosa, floor of mouth, or alveolar ridge. Appearance to visual examination alone can be misleading. While most cancers have either an ulcerative or an exophytic appearance, many can have only subtle visually detectable changes. On palpation, the involved area is usually firm and indurated. A bimanual examination of the floor of mouth is mandatory for a complete examination. The mass should be manipulated to discern mobility. Oral cavity cancers can invade the mandible quite readily, and immobility should raise concern for bone invasion.

As with other head and neck subsites where the primary tumor can be directly visualized, T-staging is assessed by

Table 15–9. T Stage for cancers of the oral cavity.

T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm, but not more than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension
T4	Tumor invades through adjacent structures
T4a	Lip: cortical bone, floor of mouth, facial skin of chin or nose Oral cavity proper: cortical bone, deep muscles of tongue (genioglossus, palatoglossus, hyoglossus, styloglossus), skin.
T4b	Tumor invades masticator space, pterygoid plates, skull base, and/or encases carotid artery

tumor size (summarized in Table 15–9). Cancers which invade adjacent structures are, in general, up-staged to T4 regardless of size. Note that superficial erosion of the bony tooth socket by a gingival primary tumor is not sufficient to upstage to T4.

The nodal drainage patterns of oral cavity cancers are of particular concern, because the incidence of occult metastases can approach 30% depending on T-stage and depth of invasion. Cancers of the upper lip can drain to the parotid bed in addition to level I. When planning treatment of occult metastases, it is important to remember that midline cancers of the oral cavity often drain bilaterally.

Treatment for oral cavity cancer is primarily surgical. Cancers of the lip can often be addressed with simple wedge excision, with 5-mm borders of surrounding normal tissue. If less than one-third of the lip is excised, a reasonable result can be obtained with simple closure. Larger excisions require a reconstructive procedure, often involving transfer of lip tissue from the contralateral lip. Cancers of the tongue, floor of mouth, and buccal mucosa are excised with a margin of 1 cm normal appearing tissue. Often primary closure, with or without a split thickness skin graft, will provide acceptable functional outcomes. Large resections usually require a flap reconstruction, especially if bone is involved, and a segmental mandibulectomy needs to be performed. The flap reconstruction can be either a pedicled flap (such as pectoralis major flap), or a free flap (radial forearm and fibular being common flap harvest sites).

Assuming appropriate treatment, outcomes for patients with oral cavity cancer are generally good. The prognosis for squamous cell carcinoma of the lip is excellent, with 5-year survival of 91% for stage I-II, 83% for stage III-IVb, and 52% for stage IVc. Squamous cell carcinoma of the oral cavity proper carries a reduced, yet still relatively good prognosis. Five-year survival rates are 72% for stage I-II, 44% for stage III-IVb, and 35% for stage IVc.

► Cancers of the Oropharynx

The oropharynx consists of the soft palate, base of tongue, palatine tonsils, and posterior/lateral oropharyngeal walls. Patients with cancer of the soft palate usually present with relatively early stage lesions, which typically remain fairly superficial. They usually arise on the anterior aspect of the palate and patients may report noticing a lump in the palate while swallowing. This contrasts with cancers of the tongue base, tonsillar region and pharyngeal walls, which typically present at advanced stage. These anatomic regions lack the rich supply of pain nerve fibers typical of the oral cavity and soft palate, and cancers can spread significantly before being noticed. Typical presenting symptoms usually are attributable to sequelae from invasion of adjacent structures, and can include dysphagia, cranial nerve defects, referred otalgia, trismus (from pterygoid muscle invasion), or neck mass (from nodal metastases). Because early-stage oropharyngeal cancers often are asymptomatic, any erythroplastic or suspicious lesion in these areas should be biopsied even if no associated symptoms are present.

As is the case for oral cavity cancer, T-staging for squamous cell cancer of the oropharynx is generally determined by tumor size (summarized in Table 15–10). Again, invasion of adjacent structures results in classification as T4 regardless of size. Oropharyngeal cancer N-staging is the same as other head and neck squamous cell carcinoma subsites (except nasopharynx). Nodal metastases from oropharyngeal cancers are common, with 70% of patients with oropharyngeal cancer having ipsilateral cervical nodal metastases at the time of presentation. Bilateral cervical nodal metastases are also relatively common, up to 30%-50%, depending on size and subsite of the primary tumor.

Treatment for oropharyngeal cancer, especially the tongue base and soft palate, is often weighted toward non-surgical therapy. This is because surgical resection can result in extensive morbidity in terms of velopharyngeal insufficiency (for palate) and dysphagia (for tongue base).

Table 15–10. T stage for cancers of the oropharynx.

T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm, but not more than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension
T4	Tumor invades through adjacent structures (larynx; deep muscles of tongue such as genioglossus, palatoglossus, hyoglossus, styloglossus; medial pterygoid, hard palate, mandible)
T4b	Tumor invades masticator space, pterygoid plates, lateral nasopharynx, skull base, and/or encases carotid artery

Because of interruption of the blood supply to the remainder of the tongue, large base of tongue cancers usually require total glossectomy even if the anterior tongue is spared. Surgical resections of all but the smallest oropharyngeal cancers usually require flap reconstruction; in the modern era this is most often in the form of a free flap with microvascular anastomoses. A tracheotomy is usually performed during the initial surgical resection for maintenance of adequate airway. As collective experience with robot-assisted oropharyngeal surgery advances, surgical treatment is likely to become more common as this approach appears to have decreased morbidity compared to open techniques.

As with other head and neck squamous cell carcinomas, early stage (I-II) cancers are treated with single modality therapy, and advanced stage (III-IV) cancers require multiple modalities. It should be noted that nonsurgical modalities have their own set of consequences, and there is some evidence demonstrating worse swallowing outcomes following chemotherapy-radiation compared to surgery and postoperative radiotherapy for advanced stage oropharyngeal lesions.

The association between HPV and oropharyngeal cancers deserves special mention. HPV is the accepted etiologic cause of greater than 95% of cervical cancer. Since the first demonstration of HPV in a head and neck squamous cell carcinoma tumor in 1985, numerous studies have found HPV DNA in head and neck squamous cell carcinomas from various subsites, most commonly the oropharynx. It now appears that of oropharyngeal squamous cell carcinomas, approximately 50% have no association with HPV, 25% are likely to be caused by HPV (similar to cervical cancer), and 25% have HPV DNA but an unclear relationship between the virus and the cancer. Future studies assessing the role of HPV in this latter group are currently being developed.

Survival for oropharyngeal cancer is generally worse than that of oral cavity cancer. Five-year survival for stage I-II oropharyngeal cancer is 58%, stage III-IVb is 41%, and stage IVc only 20%.

► Cancers of the Larynx

Interestingly, laryngeal cancer was an extremely rare disease until the 20th century. Mass-produced cigarettes came into vogue in the 1900s; soon after this a dramatic rise in the incidence of laryngeal cancer began to be noted. Tobacco exposure is now accepted as the primary etiologic agent responsible for laryngeal cancer. Other possible additive factors include laryngo-pharyngeal reflux and possibly certain viruses such as herpes simplex or HPV.

Laryngeal cancers can arise from above the true vocal folds (supraglottic region), below the true vocal folds (subglottic region) or from the true vocal folds (glottic region). The latter represents greater than 75% of all laryngeal cancers.

For patients with glottic laryngeal cancer, dysphonia (hoarseness) is the most common presenting symptom. Any hoarseness that persists longer than 2 weeks, especially in a patient with associated risk factors of tobacco or alcohol use, should undergo laryngeal examination. Patients with hoarseness, however, are more likely to have a non-malignant cause for their symptoms than to have laryngeal cancer.

Laryngeal cancers arising from the subglottis or supraglottis usually present at a later stage than do glottic cancers, as hoarseness does not develop until late in the disease process. Oftentimes, the presenting symptom can be life-threatening stridor from an obstructive mass. Emergent awake tracheotomy is sometimes required to secure a stable patent airway in these cases. Other symptoms can include globus sensation (“lump in throat”) and dysphagia. Evaluation for preexisting swallowing dysfunction is emerging as an essential part of the diagnostic workup for laryngeal cancers. Because of the emphasis on organ-preservation strategies, identification of patients likely to end up with a nonfunctioning larynx may alter treatment planning. Currently this is an area of active investigation.

Unlike oral cavity and oropharyngeal cancer (T-staged by tumor size), cancers of the larynx are T-staged by anatomic spread of disease (Table 15–11). One important factor is determination of vocal cord fixation. This can be reliably determined with greater than 90% accuracy based on in-office flexible fiberoptic evaluation combined with high-resolution CT imaging of the larynx. Laryngeal cancer N-staging follows the convention for other head and neck subsites (except nasopharynx).

Therapy for early (T1-T2) glottic cancer has traditionally been radiation therapy, especially for early, diffuse disease involving both true vocal folds and the anterior commissure. In these cases, surgical resection would result in significant disruption of the normal vocal fold architecture and function. This should be balanced with the knowledge that radiation therapy is essentially a one-time treatment modality, which carries its own spectrum of side effects and sequelae.

The goal of organ preservation (ie, preserving a functional ability to phonate and protect the airway during deglutition) should be kept in mind when planning treatment options. In the now famous “fireman’s study,” McNeil et al found that many people would accept a 20% decrease in survival, rather than lose their larynx. Surgical organ preservation strategies include endoscopic microsurgical excision, supracricoid laryngectomy, and vertical partial laryngectomy. Endoscopic microsurgical excision can allow maximal preservation of vocal function in selected T1 glottic cancers, while maintaining a sound oncologic outcome. In this approach, dissection is meticulously performed just deep to the most involved layer of the true vocal fold (epithelium, superficial lamina propria, deep lamina propria or vocal ligament, vocalis muscle). Partial laryngectomies

Table 15–11. T stage for cancers of the larynx.

Supraglottis	
T1	Tumor limited to one subsite of the supraglottis. Normal vocal cord mobility.
T2	Tumor invades mucosa of more than one subsite of the supraglottis, glottis, or adjacent structure (tongue base, vallecula, medial wall of pyriform). Normal vocal cord mobility.
T3	Tumor limited to the larynx but presence of vocal cord fixation, and/or invades postcricoid, preepiglottic tissues, paraglottic space, <i>inner cortex only</i> invasion of thyroid cartilage.
T4	
T4a	Tumor invades through thyroid cartilage and/or extends to other tissues beyond the larynx (eg, trachea, deep extrinsic tongue muscles, strap muscles, thyroid, esophagus).
T4b	Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures.
Glottis	
T1	
T1a	Tumor limited to unilateral true vocal cord with normal mobility (may involve anterior or posterior commissure).
T1b	Tumor limited to bilateral true vocal cords with normal mobility (may involve anterior or posterior commissure).
T2	Tumor extends to supraglottis and/or subglottis and/or impaired vocal cord mobility.
T3	Tumor limited to larynx with vocal cord fixation and/or invades paraglottic space, and/or minor thyroid cartilage invasion (<i>inner cortex only</i>).
T4	
T4a	Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (trachea, soft tissues of the neck including deep extrinsic tongue muscles, strap muscles, thyroid, esophagus).
T4b	Tumor invades prevertebral space, encases carotid artery or invades mediastinal structures.
Subglottis	
T1	Tumor limited to subglottis.
T2	Tumor extends to true vocal cord(s) with normal or impaired mobility (but no fixation).
T3	Tumor limited to larynx, with vocal cord fixation.
T4	
T4a	Tumor invades cricoid or thyroid cartilage and/or invades tissues beyond larynx (trachea, soft tissues of the neck including deep extrinsic tongue muscles, strap muscles, thyroid, esophagus).
T4b	Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures.

(vertical partial and supracricoid) can yield satisfactory voice and swallowing function, but require extensive patient cooperation in the postoperative period. Supracricoid laryngectomy involves removal of the supraglottis, false and true vocal cords, and thyroid cartilage. The hyoid bone, cricoid cartilage, and at least one arytenoid are preserved. The movement of the remaining arytenoid against the tongue base allows phonation and (eventual) preservation of swallowing function. Postoperatively, aspiration is to be expected and patients with poor preoperative pulmonary function should not be offered this option. Total laryngectomy is the treatment of choice for salvage of organ-preservation failures, as well as the primary treatment for most advanced glottic (T3 and T4) cancers.

Outcomes for patients with laryngeal cancer can be excellent. For early stage I glottic carcinoma (tumor limited to the true vocal folds), 5-year overall survival rates of 90% can be expected. Overall, laryngeal cancer carries a 5-year survival for stage I-II disease of 79%. With invasion of adjacent structures characteristic of stage III-IVb disease, 5-year survival decreases to 55%, and with distant metastases (stage IVc) the 5-year survival is 35%.

► Cancers of the Hypopharynx

The hypopharynx is a continuation of the oropharynx, and extends superiorly from the level of the hyoid bone to the level of the inferior aspect of the cricoid cartilage. It consists of the pyriform sinuses (the most common subsite for hypopharyngeal cancer), the posterior pharyngeal wall and postcricoid regions. The hypopharynx is lined with stratified squamous epithelium and is invested with an abundant lymphatic drainage network. Patients with hypopharyngeal cancer typically present with advanced stage disease, stage III or worse. There are several contributing factors, including lack of specific symptoms for small lesions in this region, and a lack of anatomic boundaries to prevent spread of disease. Typical presenting symptoms can include referred otalgia, odynophagia, and dysphagia. Other symptoms can include a neck mass (from nodal metastases), hoarseness (due to laryngeal involvement), and weight loss. Like laryngeal cancer, hypopharyngeal cancer is chiefly related to excessive alcohol and tobacco exposure. There is also some evidence for a possible contribution of GERD to hypopharyngeal cancer. This may explain the increased likelihood for patients with Plummer-Vinson syndrome to develop hypopharyngeal cancer, regardless of tobacco or alcohol exposure. In Plummer-Vinson syndrome, patients develop esophageal webs, and chronic acid exposure above the site of webbing is thought to possibly result in chronic inflammation predisposing to malignancy.

Hypopharyngeal cancer T-staging is somewhat unique, as it is a combination of tumor size (as for oral cavity and oropharyngeal tumors) and anatomic spread (as for laryngeal cancer). The T-staging criteria for hypopharyngeal

Table 15–12. T stage for cancers of the hypopharynx.

T1	Tumor limited to 1 subsite and 2 cm or less in greatest dimension
T2	No fixation of hemilarynx, and tumor – invades more than subsite or an adjacent area (larynx, oropharynx) and/or – more than 2 cm, but not more than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension or fixation of hemilarynx
T4	Tumor invades through adjacent structures (thyroid/cricoid cartilage, hyoid bone, thyroid gland, esophagus, central compartment)
T4a	
T4b	Tumor involves prevertebral fascia, mediastinal structures, and/or encases carotid artery

cancer are summarized in Table 15–12. N-staging and M-staging are the same as for the majority of head and neck sites (except nasopharynx).

Early stage (T1-T2 tumors) hypopharyngeal cancer is often treated with primary radiotherapy. Surgical resection is more likely in these instances to lead to dysphagia and aspiration. Alternatively, laryngeal conservation surgery may be a reasonable option for some of these early-stage cancers. More advanced (T3-T4) tumors can be treated by surgical resection with postoperative radiotherapy, or chemotherapy/radiation therapy. The standard surgical procedure is total laryngectomy with partial pharyngectomy. Tumor extension into the esophagus requires a cervical esophagectomy. The resulting alimentary tract defects require repair by various methods, including microvascular jejunal free flap, gastric pull up, or microvascular myocutaneous flap (most often tubed radial forearm or anterolateral thigh). Organ preservation surgical strategies can achieve laryngeal preservation rates of up to 40% for highly selected cases, but these remain somewhat controversial. As previously described for laryngeal cancer, preoperative evaluation of a patient’s pulmonary function status is critical, as significant postoperative aspiration can be expected. Because of the high incidence of occult nodal metastases, treatment of the neck lymphatics should be included in any therapeutic plan. For clinically evident neck disease, neck dissection is indicated. For patients with a clinically negative neck, optimal management is still being elucidated. Elective neck dissection represents one option for the clinically negative neck. Alternatively, if radiation therapy is planned for treatment of the primary site, the radiation fields can be adjusted to include treatment doses to the neck lymphatics.

Hypopharyngeal cancer carries the worst prognosis of any head and neck subsite. The underlying reasons for this

are still unclear, and several hypotheses have been suggested. A distinctive pathologic feature of hypopharyngeal cancer is the propensity for submucosal spread of disease, often resulting in clinically understaging disease extent. The abundant lymphatic drainage of the hypopharynx may also predispose the patient to early nodal metastases. It has also been suggested that the lack of definitive anatomic boundaries may allow early spread of disease. Given all of these factors, it should not be surprising that 5-year survival for stage I-II hypopharyngeal cancer is 47%, stage III-IVb is 30%, and stage IVc only 16%.

► Salivary Gland Neoplasms

Neoplasms (both benign and malignant) of the salivary glands are relatively uncommon, representing approximately 2% of all head and neck neoplasms. In general, the larger the salivary gland, the higher the overall incidence of neoplasms—but these neoplasms are also less likely to be malignant. Major salivary glands include the parotid, submandibular, and sublingual glands. The minor salivary glands are scattered mainly throughout the mucosa of the lips and oral cavity, and to a lesser extent the entire upper aerodigestive tract. For these smaller glands, the incidence of neoplasms is lower, but if one does occur it is more likely to be malignant. The parotid gland accounts for 80% of all neoplasms, while 15% arise from the submandibular glands and 5% from the sublingual and minor salivary glands. For any given tumor, the incidence of malignancy is 20% for parotid tumors, 60% for submandibular tumors, and 80% for sublingual and minor salivary gland tumors. Unlike squamous cell carcinoma, tobacco and alcohol exposure do not appear to play an etiologic role in salivary gland malignancy. It should be noted that the parotid gland contains lymph nodes that drain the preauricular and temporal skin; any parotid mass should raise suspicion for a skin cancer with intraparotid nodal metastases and a complete examination of the scalp and preauricular skin is indicated.

The most common benign salivary gland tumor is pleomorphic adenoma (also called benign mixed tumor), representing 60% of all salivary gland neoplasms. Patients typically present with a slowly enlarging, painless firm mass (most often in the parotid gland). Facial nerve paralysis is exceedingly rare, even with very large tumors, due to the slow-growing nature of these neoplasms. Malignant transformation of pleomorphic adenoma is rare but does occur; the resultant malignancy is highly aggressive. Treatment for pleomorphic adenoma is complete surgical excision including a surrounding margin of normal tissue. Due to microscopic transcapsular tumor infiltration, simple enucleation is insufficient for these benign neoplasms.

The second most common benign salivary neoplasm is papillary cystadenoma lymphomatosum (also known as Warthin tumor). This benign tumor is responsible for

10% of parotid neoplasms, but is rare outside of the parotid gland. Bilateral tumors are present in up to 10% of patients so careful palpation and/or imaging of both parotid beds is important if this tumor is suspected. Patients typically present with a slowly enlarging parotid mass, which is painless and rubbery upon palpation. Standard treatment is complete surgical excision (such as superficial parotidectomy with facial nerve preservation) although some authors advocate that enucleation of these tumors may be adequate therapy.

The most common salivary gland malignancy is mucoepidermoid carcinoma. Despite the propensity of the smaller salivary gland neoplasms to be malignant, the most common site for mucoepidermoid carcinoma is still the parotid gland. Approximately 45%-70% of mucoepidermoid carcinomas arise from the parotid gland, while 20% occur in minor salivary glands of the palate. Typical symptoms at presentation can be quite similar to those of benign salivary neoplasms, with a painless enlarging mass. Symptoms such as pain or facial paralysis are uncommon, but when present should raise suspicion for a high-grade aggressive lesion. Mucoepidermoid cancers are graded as low grade (mostly mucus cells), intermediate grade, and high grade (characterized by a hypercellular solid tumor). The latter can be difficult to distinguish from squamous cell carcinoma without immunohistochemical staining. Treatment is tailored to both the extent of disease, tumor grade, and location. Localized disease is usually amenable to surgical excision (parotidectomy with facial nerve preservation, submandibular gland excision, or wide local excision for minor salivary gland origin). Advanced disease requires extensive resection, often combined with neck dissection and/or postoperative radiotherapy.

The second most common salivary gland malignancy is adenoid cystic carcinoma. It is most common in the submandibular, sublingual, and minor salivary glands. Of all parotid neoplasms, adenoid cystic carcinoma is more likely to present with pain or paresthesias, although an asymptomatic mass is still the more common presentation. Adenoid cystic carcinoma is characterized by a propensity for perineural spread. Thus, preoperative imaging with gadolinium-enhanced MRI is often helpful in therapeutic planning. Treatment consists of complete surgical resection (sometimes requiring facial nerve sacrifice) and postoperative radiation therapy. There is some evidence that postoperative proton-beam therapy offers improved outcomes compared to traditional radiation therapy, although the former is available at only a few centers in the United States. Adenoid cystic carcinoma rarely spreads to cervical lymphatics, so neck dissection is not routinely advocated. It does, however, have a propensity for distant metastases—especially the lung. The disease is also characterized by frequent local recurrence, up to 40% even after adequate local excision. Because of the relatively slow growing nature of this disease, survival for adenoid cystic carcinoma at 5 years is favorable, approximately 65% for all stages. Due to the propensities for local

Table 15–13. T stage for major salivary gland cancer.

T1	Tumor 2 cm or less in greatest dimension, no extraparenchymal extension
T2	Tumor more than 2 cm, but not more than 4 cm in greatest dimension, no extraparenchymal extension
T3	Tumor more than 4 cm in greatest dimension and/or extraparenchymal extension
T4	
T4a	Tumor invades through adjacent structures (skin, mandible, external auditory canal, and/or facial nerve involvement)
T4b	Tumor invades skull base, pterygoid plates, and/or encases carotid artery

recurrence and distant metastases, however, this statistic decreases to 12%-15% at 15 years.

As mentioned above, malignant degeneration of pleomorphic adenomas can occur although it is uncommon. Some authors have estimated the risk of malignant degeneration at 1.5% for the first 5 years, increasing to 9.5% by 15 years or longer. The resulting malignant tumor is termed “carcinoma ex-pleomorphic adenoma” and is characterized by an aggressive natural history and poor clinical outcome. The most common presentation is sudden rapid growth of a previously stable parotid mass. Histologically, the malignant cells can take the form of any epithelial malignancy except acinic cell. Carcinoma ex-pleomorphic adenoma is characterized by frequent lymph node metastases, and up to 25% of patients will have clinically evident cervical lymphadenopathy on presentation. Treatment includes radical surgical resection, often combined with neck dissection and/or postoperative radiotherapy.

The prognosis of salivary gland malignancies varies according to histologic type, location, extent of disease, and grade. The criteria for T-staging are similar to other head and neck sites with directly measurable tumor size, and are summarized in Table 15–13. Overall, early stage (stage I-II) salivary gland cancers carry an excellent prognosis, greater than 80% at 5 years. Advanced (stage III-IV) salivary gland cancers on the other hand, have overall 5-year survival rates ranging from 23% to 56% depending on type and grade.

MULTIPLE CHOICE QUESTIONS

- You are asked to evaluate a 6-year-old child with nasal pain. She is on the pediatric hematology-oncology service, and is undergoing chemotherapy for acute lymphoblastic leukemia. She has no other pertinent medical history. The pain has been present for 12 hours. On examination, you note no abnormalities in the oral cavity, oropharynx, or external head and neck examination. Her pulse is regular and her respirations are nonlabored. On nasal examination you note a slight dusky to the anterior face of the left middle turbinate. An appropriate response would be
 - Reassure the child and her parents that she is most likely fine, and schedule a follow-up visit for the following day
 - Take her to the operating room immediately for an emergent biopsy
 - Order a contrasted MRI of the nose/face/orbits and a complete blood count (CBC) with differential
 - Start her on nasal decongestant spray (oxymetazoline) twice daily, nasal saline irrigations, and an oral antihistamine once daily
- You are asked to evaluate a patient in the emergency room with rapid onset of lip and tongue swelling. He develops shortness of breath and stridor during your examination. Following an emergent tracheotomy to establish his airway you do a thorough review of his medication history. Which of the following drug class(es) is/are known to be associated with acute angioedema?
 - Angiotensin converting enzyme inhibitors (ACE inhibitors, such as lisinopril)
 - Angiotensin II receptor blockers (ARBs, such as losartan)
 - Recombinant tissue plasminogen activators (r-tPAs, such as alteplase)
 - Anticoagulant direct thrombin inhibitors (such as lepirudin)
 - All of the above

3. A 34-year-old woman is seen in the emergency department with submandibular swelling, fever, and pain. She is unable to open her mouth more than a few millimeters. One hour later she collapses, and she has only minimal air movement with bag-mask ventilation. Attempts at oral intubation are unsuccessful. Fortunately, you are standing nearby and offer to perform an emergency cricothyrotomy. Where is the best place to rapidly create an airway inferior to the vocal cords with a minimum danger of hemorrhage?
- Immediately superior to the cricoid cartilage
 - Immediately superior to the hyoid bone
 - Immediately superior to the jugular notch
 - Immediately superior to the third tracheal ring
 - Immediately superior to the thyroid cartilage
4. A 25-year-old man sees his surgeon for follow up care 1 month after undergoing a parathyroidectomy. The patient has vocal hoarseness, so a transnasal endoscopy is performed. The left vocal fold is found to be immobile and paramedian. Denervation of which of the following muscles is most likely responsible for the vocal fold position noted?
- Left cricothyroid muscle
 - Left lateral cricoarytenoid muscle
 - Left posterior cricoarytenoid muscle
 - Left thyroarytenoid muscle
 - Left vocalis muscle
5. Which of the following patients with squamous cell carcinoma of the head and neck most likely has the worse prognosis?
- 46-year old woman, nonsmoker and occasional drinker with oral tongue cancer measuring 2.5 cm × 1.0 cm. No neck nodes or distant metastases are noted on examination.
 - 84-year old woman, 48 pack-year smoking history and drinks 2-3 liquor drinks per day. Has a hoarse voice for 3 months and is found to have a T2N0M0 laryngeal cancer.
 - 45-year old man, nonsmoker who drinks 1 glass of red wine daily. Has a prominent right level III neck mass. On oral examination has a 2.5 cm right tonsil mass consistent with an oropharyngeal primary.
 - 25-year old man with 12 pack-year tobacco history and chronic severe gastroesophageal reflux. Presents with throat pain and dysphagia (trouble swallowing). On fiberoptic endoscopy is found to have a 3 cm ulcerated hypopharyngeal mass. No palpable neck adenopathy is present.

Thyroid & Parathyroid

Gerard M. Doherty, MD

16

THE THYROID GLAND

EMBRYOLOGY & ANATOMY

The main anlage of the thyroid gland develops as a median endodermal downgrowth from the first and second pharyngeal pouches (Figure 16–1). During its migration caudally, it contacts the ultimobranchial bodies developing from the fourth pharyngeal pouches. When it reaches the position it occupies in the adult, with the isthmus situated just below the cricoid cartilage, the thyroid divides into two lobes. The site from which it originated persists as the foramen cecum at the base of the tongue. The path the gland follows may result in thyroglossal remnants (cysts) or ectopic thyroid tissue (lingual thyroid). A pyramidal lobe is frequently present. Agenesis of one thyroid lobe, almost always the left, may occur.

The normal thyroid weighs 15–25 g and is attached to the trachea by loose connective tissue. It is a highly vascularized organ that derives its blood supply principally from the superior and inferior thyroid arteries. A thyroid ima artery may also be present.

PHYSIOLOGY

The function of the thyroid gland is to synthesize, store, and secrete the hormones thyroxine (T_4) and triiodothyronine (T_3). Iodide is absorbed from the gastrointestinal tract and actively trapped by the acinar cells of the thyroid gland. It is then oxidized and combined with tyrosine in thyroglobulin to form monoiodotyrosine (MIT) and diiodotyrosine (DIT). These are coupled to form the active hormones T_4 and T_3 , which initially are stored in the colloid of the gland. Following hydrolysis of the thyroglobulin, T_4 and T_3 are secreted into the plasma, becoming almost instantaneously bound to plasma proteins. Most T_3 in euthyroid individuals, however, is produced by extrathyroidal conversion of T_4 to T_3 .

The function of the thyroid gland is regulated by a feedback mechanism that involves the hypothalamus and pituitary. Thyrotropin-releasing factor (TRF), a tripeptide amide, is formed in the hypothalamus and stimulates the release of the thyroid-stimulating hormone (TSH) thyrotropin, a glycoprotein, from the pituitary. Thyrotropin binds to TSH receptors on the thyroid plasma membrane, stimulating increased adenyl cyclase activity; this increases cyclic adenosine monophosphate (cAMP) production and thyroid cellular function. Thyrotropin also stimulates the phosphoinositide pathway and—along with cAMP—stimulates thyroid growth.

EVALUATION OF THE THYROID

In a patient with enlargement of the thyroid (goiter), the history (including local and systemic systems and family history) and examination of the gland are most important and are complemented by the selective use of thyroid function tests. The surgeon must develop a systematic method of palpating the gland to determine its size, contour, consistency, nodularity, and fixation and to examine for displacement of the trachea and the presence of palpable cervical lymph nodes. Normal or abnormal structures that are attached to the larynx, such as the thyroid gland, move cephalad with deglutition, whereas adjacent lymph nodes typically do not. The isthmus of the thyroid gland crosses the front of the trachea immediately caudal to the cricoid cartilage.

Thyroid function is assessed by highly sensitive TSH assays that can differentiate among patients with hypothyroidism (increased TSH levels), euthyroidism, and hyperthyroidism (decreased TSH levels). In most cases, therefore, serum T_3 , T_4 , and other variables need not be measured. A free T_4 level is helpful in monitoring patients during treatment for Graves disease because the TSH level may remain suppressed despite the patient's status

A

B

▲ **Figure 16-1.** Thyroid anatomy. *The recurrent laryngeal nerve runs in the tracheoesophageal groove on the left and has a slightly more oblique course on the right before it enters the larynx just posterior to the cricothyroid muscle at the level of the cricoid cartilage.

improving. A serum T_3 level is useful for diagnosing T_3 toxicosis (high T_3 and low TSH), or the euthyroid sick, low T_3 syndrome (low T_3 and normal or slightly increased TSH).

Radioactive iodine (RAI) uptake is useful for differentiating between hyperthyroidism and increased secretion of thyroid hormone (low TSH and increased RAI uptake) on

the one hand and subacute thyroiditis (low TSH and low RAI uptake) on the other. Patients with the latter “leak” thyroid hormone from the gland, which suppresses serum TSH levels and, consequently, iodine uptake by the thyroid. Patients with Graves disease have increased levels of thyroid-stimulating immunoglobulins that increase iodine uptake despite low TSH levels.

DISEASES OF THE THYROID

HYPERTHYROIDISM (THYROTOXICOSIS)

ESSENTIALS OF DIAGNOSIS

- ▶ Nervousness, weight loss with increased appetite, heat intolerance, increased sweating, muscular weakness and fatigue, increased bowel frequency, polyuria, menstrual irregularities, infertility
- ▶ Goiter, tachycardia, atrial fibrillation, warm moist skin, thyroid thrill and bruit, cardiac flow murmur; gynecomastia
- ▶ Eye signs: stare, lid lag, exophthalmos
- ▶ TSH low or absent; TSI, iodine uptake, T_3 and T_4 increased; T_3 suppression test abnormal (failure to suppress radioiodine uptake)

▶ General Considerations

Hyperthyroidism is caused by the increased secretion of thyroid hormone (Graves disease, Plummer disease, iodine-induced [Jodbasedow effect], amiodarone toxicity, TSH-secreting pituitary tumors, human chorionic gonadotropin [hCG]-secreting tumors), or by other disorders that increase thyroid hormone levels without increasing thyroid gland secretion (excess exogenous thyroid hormone intake, subacute thyroiditis, struma ovarii, and, rarely, metastatic thyroid cancers that secrete excess thyroid hormone). The most common causes of hyperthyroidism are diffusely hypersecretory goiter (Graves disease) and nodular toxic goiter (Plummer disease).

In all forms, the symptoms of hyperthyroidism are due to increased levels of thyroid hormone in the blood stream. The clinical manifestations of thyrotoxicosis may be subtle or marked and tend to go through periods of exacerbation and remission. Some patients ultimately develop hypothyroidism spontaneously (~ 15%) or as a result of treatment. Graves disease is an autoimmune disease—often with a familial predisposition—whereas the etiology of Plummer disease is unknown. Most cases of hyperthyroidism are easily diagnosed on the basis of the signs and symptoms; others (eg, mild or apathetic hyperthyroidism—which occurs most commonly in the elderly) may be recognized only with laboratory testing for a suppressed TSH level.

Thyrotoxicosis has been described with a normal T_4 concentration, normal or elevated radioiodine uptake, and normal protein binding but with increased serum T_3 by RIA (T_3 toxicosis). T_4 pseudothyrotoxicosis is occasionally seen in critically ill patients and is characterized by increased

levels of T_4 and decreased levels of T_3 due to failure to convert T_4 to T_3 . Thyrotoxicosis associated with toxic nodular goiter is usually less severe than that associated with Graves disease and is only rarely if ever associated with the extra-thyroidal manifestations of Graves disease such as exophthalmos, pretibial myxedema, thyroid acropathy, or periodic hypocalcemic paralysis.

If left untreated, thyrotoxicosis causes progressive and profound catabolic disturbances and cardiac damage. Death may occur in thyroid storm or because of heart failure or severe cachexia.

▶ Clinical Findings

A. Symptoms and Signs

The clinical findings are those of hyperthyroidism as well as those related to the underlying cause (Table 16–1). Nervousness, increased diaphoresis, heat intolerance, tachycardia, palpitations, fatigue, and weight loss in association with a nodular, multinodular, or diffuse goiter are the classic findings in hyperthyroidism. The patient may have a flushed and staring appearance. The skin is warm, thin, and moist, and the hair is fine.

In Graves disease, there may be exophthalmos, pretibial myxedema, or vitiligo, virtually never seen in single or multinodular toxic goiter. The Achilles reflex time is shortened in hyperthyroidism and prolonged in hypothyroidism. The patient on the verge of thyroid storm has accentuated symptoms and signs of thyrotoxicosis, with hyperpyrexia, tachycardia, cardiac failure, neuromuscular excitation, delirium, or jaundice.

B. Laboratory Findings

Laboratory tests reveal a suppressed TSH and an elevation of T_3 , free T_4 , and radioactive iodine. A history of medications is important, since certain drugs and organic iodinated compounds affect some thyroid function tests, and iodine excess may result in either iodide-induced hypothyroidism or iodine-induced hyperthyroidism (Jodbasedow effect). In mild forms of hyperthyroidism, the usual diagnostic laboratory tests are likely to be only slightly abnormal. In these difficult-to-diagnose cases, two additional tests are helpful: the T_3 suppression test and the thyrotropin-releasing hormone (TRH) test. In the T_3 suppression test, hyperthyroid patients fail to suppress the thyroidal uptake of radioiodine when given exogenous T_3 . In the TRH test, serum TSH levels fail to rise in response to administration of TRH in hyperthyroid patients.

Other findings include a high thyroid-stimulating immunoglobulin (TSI) level, low serum cholesterol, lymphocytosis, and occasionally hypercalcemia, hypercalciuria, or glycosuria.

Table 16–1. Clinical findings in thyrotoxicosis.

Clinical Manifestations	Frequency
Tachycardia	Nearly all
Nervousness	Nearly all
Goiter	Nearly all
Skin changes	Nearly all
Tremor	Nearly all
Increased sweating	Majority
Hypersensitivity to heat	Majority
Palpitations	Majority
Fatigue	Majority
Weight loss	Majority
Bruit over thyroid	Majority
Dyspnea	Majority
Eye signs	Majority
Weakness	Majority
Increased appetite	Majority
Eye complaints	Majority
Leg swelling	Some
Hyperdefecation (without diarrhea)	Some
Diarrhea	Some
Atrial fibrillation	Some
Splenomegaly	Few
Gynecomastia	Few
Anorexia	Few
Liver palms	Few
Constipation	Few
Weight gain	Few

► Differential Diagnosis

Anxiety neurosis, heart disease, anemia, gastrointestinal disease, cirrhosis, tuberculosis, myasthenia and other muscular disorders, menopausal syndrome, pheochromocytoma, primary ophthalmopathy, and thyrotoxicosis factitia may be clinically difficult to differentiate from hyperthyroidism.

Differentiation is especially difficult when the thyrotoxic patient presents with minimal or no thyroid enlargement. Patients may also have painless or spontaneously resolving thyroiditis and are hyperthyroid because of increased release of thyroid hormone from the thyroid gland. This condition, however, is self-limited, and treatment with antithyroid drugs, radioactive iodine, or surgery is rarely necessary.

Anxiety neurosis is perhaps the condition most frequently confused with hyperthyroidism. Anxiety is characterized by persistent fatigue usually unrelieved by rest, clammy palms, a normal sleeping pulse rate, and normal laboratory tests of thyroid function. The fatigue of hyperthyroidism is often relieved by rest, the palms are warm and moist, tachycardia persists during sleep, and thyroid function tests are abnormal.

Organic disease of nonthyroidal origin that may be confused with hyperthyroidism must be differentiated largely on the basis of evidence of specific organ system involvement and normal thyroid function tests.

Other causes of exophthalmos (eg, orbital tumors) or ophthalmoplegia (eg, myasthenia) must be ruled out by ophthalmologic, ultrasonographic, computed tomography (CT) or magnetic resonance imaging (MRI) scans, and neurologic examinations.

► Treatment

Hyperthyroidism may be effectively treated by antithyroid drugs, radioactive iodine, or thyroidectomy. Treatment must be individualized and depends on the patient's age and general state of health, the size of the goiter, the underlying pathologic process, and the patient's ability to obtain follow-up care.

A. Antithyroid Drugs

The principal antithyroid drug used in the United States is methimazole, 30-100 mg orally daily; propylthiouracil (PTU), 300-1000 mg orally daily has become an infrequent choice due to side effects. These agents interfere with organic binding of iodine and prevent coupling of iodotyrosines in the thyroid gland. One advantage over thyroidectomy and radioiodine in the treatment of Graves disease is that drugs inhibit the function of the gland without destroying tissue; therefore, there is a lower incidence of subsequent hypothyroidism. This form of treatment is usually used in preparation for surgery or RAI treatment but may be used as definitive treatment. Reliable patients with small goiters are good candidates for this regimen. A prolonged remission after 18 months of treatment occurs in 30% of patients, some of whom eventually become hypothyroid. Side effects of PTU include rashes and fever (3%-4%), agranulocytosis (0.1%-0.4%), and, rarely, liver failure. Patients must be warned to immediately stop the drug, see a physician, and have a white blood cell count if sore throat or fever develops.

B. Radioiodine

Radioiodine (^{131}I) may be given safely after the patient has been treated with antithyroid medications and has become euthyroid. Radioiodine is indicated for patients who are over 40 years or are poor risks for surgery and for patients with recurrent hyperthyroidism. It is less expensive than operative treatment and is effective. Radioiodine treatment at doses necessary to treat hyperthyroidism does not appear to increase the risk of leukemia or of congenital anomalies. However, an increased incidence of benign thyroid tumors and, rarely, thyroid cancer has been noted to follow treatment of hyperthyroidism with radioiodine. In young patients, the radiation hazard is certainly increased, and the chance of developing hypothyroidism is virtually 100%. After the first year of treatment with radioiodine, the incidence of hypothyroidism increases about 3% per year.

Hyperthyroid children and pregnant women should not be treated with radioiodine.

C. Surgery

1. Indications for Thyroidectomy—The main advantages of thyroidectomy is a more rapid and certain control of the disease than can be achieved with radioiodine treatment. Surgery is often the preferred treatment: (1) in the presence of a very large goiter or a multinodular goiter with relatively low RAI uptake, (2) if there is a suspicious or malignant thyroid nodule, (3) for patients with ophthalmopathy, (4) for the treatment of pregnant patients or children, (5) for the treatment of women who wish to become pregnant within 1 year after treatment, and (6) for patients with amiodarone-induced hyperthyroidism.

2. Preparation for Surgery—The risk of thyroidectomy for toxic goiter is small since the introduction of the combined preoperative use of iodides and antithyroid drugs. Methimazole or another antithyroid drug is administered until the patient becomes euthyroid and is continued until the time of operation. Three drops of potassium iodide solution or Lugol iodine solution are then given for about 10 days before surgery in conjunction with the propylthiouracil as this may decrease the friability and vascularity of the thyroid, thereby technically facilitating thyroidectomy.

An occasional untreated or inadequately treated hyperthyroid patient may require an emergency operation for some unrelated problem such as acute appendicitis and thus require immediate control of the hyperthyroidism. Such a patient should be treated in a manner similar to one in thyroid storm, since thyroid storm or hyperthyroid crises may be precipitated by surgical stress or trauma. Treatment of hyperthyroid patients requiring an emergency operation or those in thyroid storm is as follows: prevent release of preformed thyroid hormone by administration of Lugol

iodine solution or with ipodate sodium; give β -adrenergic blocking agents to antagonize the peripheral manifestations of thyrotoxicosis; and decrease thyroid hormone production and extrathyroidal conversion of T_4 to T_3 by giving propylthiouracil.

The combined use of β -blocking agents and iodide lowers serum thyroid hormone levels. Other important considerations are to treat precipitating causes (eg, infection, drug reactions); to support vital functions by giving oxygen, sedatives, intravenous fluids, and corticosteroids; and to reduce fever. Benzodiazepines may be useful in the patient in whom nervousness is a prominent symptom, and a cooling blanket should be used in patients if needed for temperature control.

3. Subtotal Thyroidectomy—The treatment of hyperthyroidism by subtotal, near-total, or total thyroidectomy eliminates both the hyperthyroidism and the goiter. As a rule, nearly all of the thyroid gland is removed, sparing the parathyroid glands and the recurrent laryngeal nerves. A very complete total thyroidectomy is generally indicated for patients with Graves ophthalmopathy.

The death rate associated with these procedures is extremely low—less than 0.1%. Thyroidectomy thus provides safe and rapid correction of the thyrotoxic state. The frequency of recurrent hyperthyroidism and hypothyroidism depends on the amount of thyroid remaining and on the natural history of the hyperthyroidism. Given an accomplished surgeon and good preoperative preparation, injuries to the recurrent laryngeal nerves and parathyroid glands occur in less than 2% of cases. Adequate exposure and avoidance of injury to the recurrent laryngeal nerves and parathyroid glands are essential.

► Ocular Manifestations of Graves Disease

The pathogenesis of the ocular problems in Graves disease remains unclear. Evidence originally supporting the role of either long-acting thyroid stimulator (LATS) or exophthalmos-producing substance (EPS) has not been authenticated.

The eye complications of Graves disease may begin before there is any evidence of thyroid dysfunction or after the hyperthyroidism has been appropriately treated. Usually, however, the ocular manifestations develop concomitantly with the hyperthyroidism. Relief of the eye problems is often difficult to accomplish until coexisting hyperthyroidism or hypothyroidism is controlled.

The eye changes of Graves disease vary from no signs or symptoms to loss of sight. Mild cases are characterized by upper lid retraction and stare with or without lid lag or proptosis. These cases present only minor cosmetic problems and usually require no treatment unless the eyes are dry. When moderate to severe eye changes occur, there is retro-orbital soft tissue involvement with proptosis, extraocular

muscle involvement, and finally optic nerve involvement. Some cases may have marked chemosis, periorbital edema, conjunctivitis, keratitis, diplopia, ophthalmoplegia, and impaired vision. Ophthalmologic consultation is required.

Treatment of the ocular problems of Graves disease includes maintaining the patient in a euthyroid state without increase in TSH secretion, protecting the eyes from light and dust with dark glasses and eye shields, elevating the head of the bed, using diuretics to decrease periorbital and retrobulbar edema, and giving methylcellulose or guanethidine eye drops. High doses of glucocorticoids are beneficial in certain patients, but their effectiveness is variable and unpredictable. If exophthalmos progresses despite medical treatment, lateral tarsorrhaphy, retrobulbar irradiation, or surgical decompression of the orbit may be necessary. Total thyroidectomy is the treatment of choice when it can be done with a low risk of complications. Graves disease is more likely to worsen after radioiodine treatment than after thyroidectomy. It is important that patients with ophthalmopathy be made aware of the natural history of the disease and also that they be kept euthyroid, since hyperthyroidism and hypothyroidism may produce visual deterioration. Operations to correct diplopia should be deferred until after the ophthalmopathy has stabilized.

EVALUATION OF THYROID NODULES & GOITERS

► Thyroid Nodules

The clinician should determine whether a nodular goiter or thyroid nodule is causing localized or systemic symptoms and whether it is benign or malignant. The differential diagnosis includes benign goiter, intrathyroidal cysts, thyroiditis, benign and malignant tumors, and, rarely, metastatic tumors to the thyroid. The history should specifically emphasize the duration of swelling, recent growth, local symptoms (dysphagia, pain, or voice changes), and systemic symptoms (hyperthyroidism, hypothyroidism, or those from possible tumors metastatic to the thyroid). The patient's age, gender, place of birth, family history, and history of radiation to the neck are most important. Low-dose therapeutic radiation (6.5-2000 cGy) in infancy or childhood is associated with an increased incidence of benign goiter (~ 35%) or thyroid cancer (~ 13%) in later life. A thyroid nodule is more likely to be a cancer in a man than in a woman, and in younger (under 20 years) and older (over 60 years) patients rather than in others. In certain geographic areas, endemic goiter and benign nodules are common. Thyroid cancer is familial in about 25% of patients with medullary thyroid cancer (familial medullary thyroid cancer, multiple endocrine neoplasia [MEN] types 2A and 2B) and in about 7% of patients with papillary or Hürthle cell cancer. Papillary thyroid can-

cer occurs more often in patients with Cowden syndrome, Gardner syndrome, or Carney syndrome.

The clinician must systematically palpate the thyroid to determine whether there is a solitary thyroid nodule or if it is a multinodular gland and whether there are palpable lymph nodes. A solitary hard thyroid nodule is likely to be malignant, whereas most multinodular goiters are benign. Ultrasound evaluation helps document the number of nodules, whether a nodule is suspicious for cancer, and whether there are coexistent suspicious lymph nodes.

In many patients, the possibility of cancer is difficult to exclude without microscopic examination of the gland itself. Percutaneous needle biopsy is the most cost-effective diagnostic test and, along with ultrasound, has replaced radioiodine scanning for the evaluation of nodules. Cytologic results are classified by the Bethesda criteria (Table 16-2). False-positive diagnoses of cancer are rare, but about 20% of biopsy specimens reported as one of the indeterminate categories (follicular lesion of unknown significance or neoplasms) and there are more rare falsely benign results. If the specimen is reported as inadequate, biopsy should be repeated. Needle biopsy is not as helpful in patients with a history of irradiation to the neck because radiation-induced tumors are often multifocal, and a negative biopsy may therefore be unreliable. About 40% of these patients will have thyroid cancer. Radioiodine scanning can be used selectively to determine whether a follicular neoplasm by cytologic examination is functioning (warm or hot) or nonfunctioning (cold). Hot solitary thyroid nodules may cause hyperthyroidism but are rarely malignant, whereas cold solitary thyroid nodules have an incidence of cancer of 15%-20%. Thyroid carcinoma is uncommon (~ 3%) in

Table 16-2. Bethesda classification for thyroid cytology.

Cytology Result	Likelihood of Malignancy	Usual Management
Nondiagnostic	Unknown	Reaspiration
Benign	< 1%	Follow
Follicular lesion of undetermined significance	5%-10%	Consider follow, reaspiration or molecular testing of aspirate
Follicular or Hürthle cell neoplasm	20%-30%	Consider follow, reaspiration or molecular testing of aspirate
Suspicious for malignancy	50%-75%	Generally treat as for malignancy
Malignant	100%	Treat for malignancy

multinodular goiters, but if there is a dominant nodule or one that enlarges, it should be biopsied or removed. Thyroid cancer occurs in nearly 40% of the children with solitary thyroid nodules; therefore, fine-needle biopsy or thyroidectomy is indicated. Ultrasound differentiates solid and cystic lesions and, as mentioned, may detect enlarged lymph nodes. About 15% of cold solitary lesions are cystic. CT or MRI scans are usually not necessary but are helpful when the limits of the tumor cannot be defined, such as in patients with large, invasive, or substernal goiters or tumors.

The principal indications for surgical removal of a nodular goiter are: (1) suspicion of or documented cancer, (2) symptoms of pressure, (3) hyperthyroidism, (4) substernal extension, and (5) cosmetic deformity. Incidentally discovered thyroid nodules by ultrasonography, CT, MRI, or positron emission tomography (PET) scans should be evaluated by ultrasound, then, if indicated, fine-needle aspiration biopsy. Nonoperative treatment is indicated in patients with small or moderately sized multinodular goiters and Hashimoto thyroiditis unless there is a clinically suspicious area, a nodule that is growing, a personal history of radiation exposure or a family history of thyroid carcinoma.

▶ Simple or Nontoxic Goiter (Diffuse & Multinodular Goiter)

Simple goiter may be physiologic, occurring during puberty or pregnancy, or it may occur in patients from endemic (iodine-poor) regions or as a result of prolonged exposure to goitrogenic foods or drugs. As the goiter persists, there is a tendency to form nodules. Goiter may also occur early in life as a consequence of a congenital defect in thyroid hormone production or in patients with Hashimoto thyroiditis. It is generally assumed that nontoxic goiter represents a compensatory response to inadequate thyroid hormone production, although thyroid growth immunoglobulins may also be important. Nontoxic diffuse goiter usually responds favorably to thyroid hormone administration.

Symptoms are usually awareness of a neck mass and dyspnea, dysphagia, or symptoms caused by interference with venous obstruction. In diffuse goiter, the thyroid is symmetrically enlarged and has a smooth surface; however, most patients have multinodular glands by the time they seek medical care. Thyroid function is usually normal, though the sensitive TSH may be suppressed and the radioiodine uptake increased. Surgery is indicated to relieve the pressure symptoms of a large goiter for substernal goiter or to rule out cancer when there are localized areas of hardness or rapid growth. Aspiration biopsy cytology is helpful in these patients.

INFLAMMATORY THYROID DISEASE

The inflammatory diseases of the thyroid are termed acute, subacute, or chronic thyroiditis, which can be either suppurative or nonsuppurative.

Acute suppurative thyroiditis is uncommon and is characterized by the sudden onset of severe neck pain accompanied by dysphagia, fever, and chills. It usually follows an acute upper respiratory tract infection; can be diagnosed by percutaneous aspiration, smear, and culture; and is treated by surgical drainage. The organisms are most often streptococci, staphylococci, pneumococci, or coliforms. It may also be associated with a piriform sinus fistula. A barium swallow is therefore recommended in persistent or recurrent cases.

Subacute thyroiditis, a noninfectious disorder, is characterized by thyroid swelling, head and chest pain, fever, weakness, malaise, palpitations, and weight loss. Some patients with subacute thyroiditis have no pain (silent thyroiditis), in which case the condition must be distinguished from Graves disease. In subacute thyroiditis, the erythrocyte sedimentation rate and serum gamma globulin are almost always elevated, and radioiodine uptake is very low or absent with increased or normal thyroid hormone levels. The illness is usually self-limited, and aspirin and corticosteroids relieve symptoms. Most of these patients eventually become euthyroid.

Hashimoto thyroiditis, the most common form of thyroiditis, is usually characterized by enlargement of the thyroid with or without pain and tenderness. It is much more common in women (~ 15% of US women) and occasionally causes dysphagia or hypothyroidism.

Hashimoto thyroiditis is an autoimmune disease. Serum titers of antimicrosomal and antithyroglobulin antibodies are elevated. Appropriate treatment for most patients consists of giving small doses of thyroid hormone. Operation is indicated for marked pressure symptoms, for suspected malignant tumor, and for cosmetic reasons. If the thyroid is large or asymmetric, or if it contains a discrete nodule, or grows rapidly, percutaneous needle biopsy or thyroidectomy is recommended. Thyroid lymphoma can rarely occur in patients with Hashimoto thyroiditis.

Riedel thyroiditis is a rare condition that presents as a hard woody mass in the thyroid region with marked fibrosis and chronic inflammation in and around the gland. The inflammatory process infiltrates muscles and causes symptoms of tracheal compression. Hypothyroidism is usually present, and hypoparathyroid may develop. Surgical treatment is required to relieve tracheal or esophageal obstruction.

BENIGN TUMORS OF THE THYROID

Benign thyroid tumors are adenomas, involutary nodules, cysts, or localized thyroiditis. Most adenomas are of the follicular type. Adenomas are usually solitary and encapsulated and compress the adjacent thyroid. The major reasons for removal are a suspicion of cancer, functional overactivity producing hyperthyroidism, and cosmetic disfigurement.

MALIGNANT TUMORS OF THE THYROID

ESSENTIALS OF DIAGNOSIS

- ▶ History of irradiation to the neck in some patients
- ▶ Painless or enlarging nodule, dysphagia, or hoarseness
- ▶ Firm or hard, fixed thyroid nodule; ipsilateral cervical lymphadenopathy
- ▶ Normal thyroid function; nodule stippled with microcalcifications and solid (ultrasound), cold (radioiodine scan); positive or suspicious cytology
- ▶ Family history of thyroid cancer

General Considerations

An appreciation of the classification of malignant tumors of the thyroid is important, because thyroid tumors demonstrate a wide range of growth and malignant behavior. At one end of the spectrum is papillary carcinoma, which usually occurs in young adults, grows very slowly, metastasizes through lymphatics, and is compatible with long life even in the presence of metastases (Figure 16-2). At the other extreme is undifferentiated carcinoma, which appears late in life and is nonencapsulated and invasive, forming large infiltrating tumors composed of small or large anaplastic cells. Most patients with anaplastic thyroid carcinoma succumb as a consequence of local recurrence, pulmonary metastasis, or both within 9 months. Between these two extremes are follicular, Hürthle cell, and medullary carcinomas, sarcomas, lymphomas, and metastatic tumors. The prognosis depends on the histologic pattern, the age and gender of the patient, the extent of tumor spread at the time of diagnosis, whether the tumor takes up radioiodine, and other factors. On average, 5% of patients with papillary, 10% of those with follicular, 15% of those with Hürthle cell, and 20% of those with medullary thyroid cancer will die within 10 years from these tumors.

The cause of most cases of thyroid carcinoma is unknown, although persons who received low-dose (6.5-2000 cGy) therapeutic radiation to the thymus, tonsils, scalp, and skin in infancy, childhood, and adolescence have an increased risk of developing thyroid tumors. Children are most susceptible to radiation exposure such as occurred with the

▲ **Figure 16-2.** Survival rates after thyroidectomy for papillary, mixed papillary-follicular, follicular, medullary, and undifferentiated thyroid cancer.

Chernobyl nuclear accident, but adults up to 50 years of age who were exposed to the atomic blast at Hiroshima had an increased incidence of benign and malignant thyroid tumors. The incidence of thyroid cancer increases for at least 30 years after irradiation. *RET/PTC* rearrangements occur in about 80% of radiation associated papillary thyroid cancers.

Types of Thyroid Cancer

A. Papillary Carcinoma

Papillary adenocarcinoma accounts for 85% of cancers of the thyroid gland. The tumor usually appears in early adult life and presents as a solitary nodule. It then spreads via intraglandular lymphatics within the thyroid gland and then to the subcapsular and pericapsular lymph nodes. Fifty percent of children and 20% of adults present with palpable lymph nodes. The tumor may metastasize to lungs or bone. Microscopically, it is composed of papillary projections of columnar epithelium. Psammoma bodies are present in about 60% of cases. Mixed papillary-follicular, follicular variants of papillary carcinoma, and poorly differentiated cancers including tall cell and columnar cell papillary thyroid cancers are sometimes found. The rate of growth may be stimulated by TSH. A *BRAF* mutation is the most

common mutation in papillary thyroid cancer and is associated with lymph node metastases and a higher recurrence rate.

B. Follicular Adenocarcinoma

Follicular adenocarcinoma accounts for approximately 10% of malignant thyroid tumors. It appears later in life than the papillary form and may be rubbery or even soft on palpation. Follicular tumors are encapsulated. Microscopically, follicular carcinoma may be difficult to distinguish from normal thyroid tissue. Capsular (invasion through the capsule) and vascular invasion distinguish follicular carcinoma from follicular adenoma. Follicular thyroid cancers only occasionally (~5%) metastasize to the regional lymph nodes, but they have a greater tendency to spread by the hematogenous route to the lungs, the skeleton, and, rarely, the liver. Metastases from this tumor often demonstrate avidity for RAI after total thyroidectomy. Skeletal metastases may appear years after resection of the primary lesion. Hürthle cell carcinoma is considered a clinical variant of follicular carcinoma. It is more likely to be multifocal and involve lymph nodes than follicular carcinoma. Like follicular carcinoma, it makes thyroglobulin, however it does not usually take up radioiodine. The prognosis is not as good for either follicular or Hürthle cell cancers as with the papillary type (Figure 16–3).

C. Medullary Carcinoma

Medullary carcinoma accounts for approximately 7% of malignant tumors of the thyroid and 15% of thyroid cancer deaths. It contains amyloid and is a solid, hard, nodular

▲ **Figure 16–3.** Subperiosteal resorption of radial side of second phalanges.

tumor that does not take up radioiodine and secretes calcitonin. Medullary carcinomas arise from parafollicular cells of the ultimobranchial bodies or C cells. Familial medullary carcinoma occurs in about 25% of patients. It may be isolated or occur with pheochromocytomas (often bilateral), lichen planus amyloidosis, and hyperparathyroidism (MEN2A, Table 16–3). It may also occur with or without pheochromocytomas (usually bilateral), marfanoid habitus, multiple neuromas, and ganglioneuromatosis (MEN2B). Hirschsprung disease occurs more frequently in patients with familial medullary cancer. All patients with medullary thyroid cancer should be screened for an *RET* point mutation on chromosome 10 because 10% of patients without a positive family history have de novo mutations. For patients detected by family genetic screening, most experts recommend prophylactic total thyroidectomy at an age determined by the risk associated with the specific mutation. Isolated familial medullary thyroid cancer is the least aggressive form, whereas this cancer is most aggressive in MEN2B patients.

D. Undifferentiated Carcinoma

This rapidly growing tumor, also known as anaplastic carcinoma, occurs principally beyond middle life and accounts for 1% of all thyroid cancers. This tumor usually evolves from a papillary or follicular neoplasm. It is a solid, quickly enlarging, hard, irregular mass diffusely involving the gland and often invades the trachea, muscles, and neurovascular structures. The tumor may be painful and somewhat tender, may be fixed on swallowing, and may cause laryngeal or esophageal obstructive symptoms. Microscopically, there are three major types: giant cell, spindle cell, and small cell. Mitoses are frequent. Cervical lymphadenopathy and pulmonary metastases are common. Local recurrence after surgical treatment is the rule. Combination treatment with external radiation therapy, chemotherapy, and surgery offers palliation to some patients but is rarely curative (Figure 16–2).

▶ Treatment

The treatment of differentiated thyroid carcinoma (which does not include anaplastic carcinoma or medullary thyroid cancer) is operative removal. For papillary carcinoma over 1 cm, acceptable operations are near-total or total thyroidectomy. For solitary papillary carcinomas less than 1 cm, thyroid lobectomy is adequate treatment. Subtotal or partial lobectomy is contraindicated because the incidence of tumor recurrence is greater and survival is shorter. Total thyroidectomy is recommended for papillary (> 1.0 cm), follicular, Hürthle cell, and medullary carcinomas if the operation can be done without producing permanent hypoparathyroidism or injury to the recurrent laryngeal nerves. Total thyroidectomy is preferred over other operations because of the high incidence of multifocal tumor within the gland, a clinical recurrence rate of

Table 16–3. Multiple endocrine neoplasia syndromes.

about 7% in the contralateral lobe if it is spared, and the ease of assessment for recurrence by serum thyroglobulin assay and neck ultrasound examinations during follow-up examinations. This also allows one to use adjuvant or therapeutic radioiodine treatment. Preoperative ultrasound is essential in patients with papillary cancer, and all abnormal central and lateral neck lymph nodes should be removed. Whether an ipsilateral prophylactic central neck dissection should be done is controversial.

A functional modified radical neck dissection preserving the jugular vein, sternocleidomastoid muscle, spinal accessory nerve, and sensory nerves is performed if lymph nodes in the lateral neck are clinically involved.

Medullary carcinoma is associated with such a high incidence of nodal involvement that a bilateral central neck node compartment dissection should be done in all patients. Concomitant ipsilateral and contralateral modified radical neck dissection may be indicated selectively for primary tumors more than 1.5 cm in diameter and when the central neck nodes are involved. When serum calcitonin or carcinoembryonic antigen (CEA) levels remain elevated after thyroidectomy, ultrasound or MRI examination of the neck and MRI of the mediastinum should be done. Laparoscopic evaluation of the liver for the common miliary metastases is recommended for patients with markedly elevated calcitonin levels. If there is no metastatic in the liver, then central neck dissection and bilateral functional neck dissections should be done, if not already done, including removal of nodes from the superior mediastinum.

Isolated distant metastatic deposits of differentiated thyroid carcinoma should be removed surgically if possible and treated with ^{131}I after total thyroidectomy or thyroid

ablation with radioactive iodine. All patients with thyroid cancer should be maintained indefinitely on suppressive doses of thyroid hormone (mild suppression for low-risk patients). For follow-up, it is helpful to measure basal and TSH-stimulated serum levels of thyroglobulin (a tumor marker for differentiated thyroid cancer), which are usually increased (> 2 ng/mL) in patients with residual tumor after total thyroidectomy.

For **undifferentiated carcinoma, malignant lymphoma, or sarcoma**, the tumor should be excised as completely as possible and then treated by radiation and chemotherapy. It is common that no operation beyond a diagnostic biopsy is useful for these patients, as they may be locally inoperable with a course dictated by the systemic disease.

THE PARATHYROID GLANDS

EMBRYOLOGY & ANATOMY

Phylogenetically, the parathyroids appear rather late, being first seen in amphibia. They arise from pharyngeal pouches

III and IV and may be arrested as high as the level of the hyoid bone during their descent to the posterior capsule of the thyroid gland. Four parathyroid glands are present in 85% of the population, and 85% are situated on the posterior lateral surface of the thyroid gland. About 15% of people have more than four glands. Occasionally, one or more may be incorporated into the thyroid gland or thymus and hence are intrathyroidal or intrathyric in location. Parathyroid III, which normally assumes the inferior position, may be found in the anterior mediastinum, usually in the thymus. The upper parathyroids (parathyroid IV) usually remain in close association with the upper portion of the lateral thyroid lobes at the level of the cricoid cartilage but may be loosely attached by a long vascular pedicle and migrate caudally in the tracheoesophageal groove into the posterior mediastinum. About 85% of parathyroid glands lie within 1 cm of where the inferior thyroid artery and recurrent laryngeal nerve cross.

The normal parathyroid gland has a distinct yellowish-brown color, is ovoid, tongue-shaped, polypoid, or spherical, and averages $2 \times 3 \times 7$ mm. The total mean weight of four normal parathyroid glands is about 150 mg. These encapsulated glands are usually supplied by a branch of the inferior thyroid artery but may be supplied by the superior thyroid artery. The vessels can be seen entering a hilum-like structure, a feature that differentiates parathyroid glands from fat.

PHYSIOLOGY

Parathyroid hormone (PTH), vitamin D, and calcitonin play vital roles in calcium and phosphorus metabolism in bone, kidney, and gut. Specific radioimmunoassays are available to measure PTH, vitamin D, and calcitonin. Ionized calcium, the physiologically important fraction, can now be accurately measured. Total serum calcium concentration is composed of approximately 48% ionized calcium, 46% protein-bound calcium, and 6% calcium complexed to organic anions. Total serum calcium varies directly with plasma protein concentrations, but calcium ion concentrations are unaffected.

PTH and calcitonin work in concert to modulate fluctuations in plasma levels of ionized calcium. When the ionized calcium level falls, the parathyroid glands secrete more PTH, and the parafollicular cells within the thyroid secrete less calcitonin. The rise in PTH and fall in calcitonin produce increased bone resorption and increased resorption of calcium in the renal tubules. More calcium enters the blood, and ionized calcium levels return to normal.

In the circulation, immunoreactive PTH is heterogeneous, consisting of the intact hormone and several hormonal fragments. The amino terminal (N-terminal) fragment is biologically active, whereas the carboxyl terminal (C-terminal) fragment is biologically inert. Measurement of intact PTH by immunoassay is best for screening for hyperparathyroidism and for selective venous catheterization to

localize the source of PTH production. PTH-related peptide (PTHrP) that is secreted by nonparathyroid malignant tumors does not cross-react with intact PTH assays.

Because PTH levels rise in normal subjects if ionized calcium levels are low, calcium and PTH must be determined from samples drawn simultaneously to diagnose hyperparathyroidism. The combination of increased PTH levels and hypercalcemia without hypocalciuria is almost always diagnostic of hyperparathyroidism.

DISEASES OF THE PARATHYROIDS

PRIMARY HYPERPARATHYROIDISM

ESSENTIALS OF DIAGNOSIS

- ▶ Increased fatigue, weakness, arthralgias, nausea, vomiting, dyspepsia, constipation, polydipsia, polyuria, nocturia, psychiatric disturbances, renal colic, bone pain, and joint pain (“stones, bones, abdominal groans, psychic moans, and fatigue overtones”). Some patients are asymptomatic
- ▶ Nephrolithiasis and nephrocalcinosis, osteopenia, osteoporosis, osteitis fibrosa cystica, peptic ulcer disease, renal dysfunction, gout, pseudogout, chondrocalcinosis, pancreatitis
- ▶ Hypertension, band keratopathy, neck masses
- ▶ Serum calcium, PTH, chloride, usually increased; serum phosphate low or normal; uric acid and alkaline phosphatase sometimes increased; urine calcium increased, normal, or, rarely, decreased; urine phosphate increased; tubular reabsorption of phosphate decreased, osteocalcin and deoxypyridinoline cross-links increased
- ▶ X-rays: subperiosteal resorption of phalanges, demineralization of the skeleton (osteopenia or osteoporosis), bone cysts, and nephrocalcinosis or nephrolithiasis

General Considerations

Primary hyperparathyroidism is due to excess or nonsuppressed PTH secretion from a single parathyroid adenoma (83%), multiple adenomas (6%), hyperplasia (10%), or carcinoma (1%). Once thought to be rare, primary hyperparathyroidism is now found in 0.1%-0.3% of the general population and is the most common cause of hypercalcemia in unselected patients. It is uncommon before puberty; its peak incidence is between the third and fifth decades, and it is two to three times more common in women than in men.

Overproduction of PTH in spite of upper normal or elevated serum levels of calcium results in mobilization of

calcium from bone and inhibition of the renal reabsorption of phosphate, thereby producing hypercalcemia and hypophosphatemia. This causes a wasting of calcium and phosphorus, with osseous mineral loss and osteopenia or osteoporosis. Other associated or related conditions that offer clues to the diagnosis of hyperparathyroidism are nephrolithiasis, nephrocalcinosis, osteitis fibrosa cystica, peptic ulcer, pancreatitis, hypertension, and gout or pseudogout. Hyperparathyroidism also occurs in both MEN1, known as **Wermer syndrome**, and MEN2, known as Sipple syndrome (Table 16–3). The former is characterized by tumors of the parathyroid, pituitary, and pancreas (hyperparathyroidism, pituitary tumors, and functioning or non-functioning islet cell pancreatic tumors) that may cause Zollinger-Ellison syndrome (gastrinoma), hypoglycemia (insulinoma), glucagonoma, somatostatinoma, and pancreatic polypeptide tumors (PPomas). Other tumors in MEN1 syndrome include adrenocortical tumors, carcinoid tumors, multiple lipomas, and cutaneous angiomas. MEN2A consists of hyperparathyroidism (20%) in association with medullary carcinoma of the thyroid (98%), pheochromocytoma (50%), and lichen planus amyloidosis. MEN2B patients have a marfanoid habitus, multiple neuromas, and pheochromocytomas but rarely have hyperparathyroidism. Familial hyperparathyroidism can also occur alone or in the presence of jaw tumor syndrome.

Parathyroid adenomas range in weight from 65 mg to over 35 g, and the size usually parallels the degree of hypercalcemia. Microscopically, these tumors may be of chief cell, water cell, or, rarely, oxyphil cell type.

Primary parathyroid hyperplasia involves all of the parathyroid glands. Microscopically, there are two types: chief cell hyperplasia and water-clear cell (wasserhelle) hyperplasia. Hyperplastic glands vary considerably in size but are usually larger than normal (65 mg).

Parathyroid carcinoma is rare but is more common in patients with profound hypercalcemia and in patients with familial hyperparathyroidism and jaw tumor syndrome. Parathyroid cancers are palpable in half the patients and should be suspected in patients at operation when the parathyroid gland is hard, has a whitish or irregular capsule, or is invasive. Parathyromatosis is a rare condition causing hypercalcemia due to multiple embryologic rests or, more commonly, due to seeding when a parathyroid tumor has ruptured or the tumor capsule has been disrupted.

► Clinical Findings

A. Symptoms and Signs

Historically, the clinical manifestations of hyperparathyroidism have changed. Forty years ago, the diagnosis was based on bone pain and deformity (osteitis fibrosa cystica), and in later years on the renal complications (nephrolithiasis and nephrocalcinosis). At present, over two-thirds of patients

are detected by routine screening, or because of osteopenia or osteoporosis, and some are asymptomatic. Patients with even mild primary hyperparathyroidism are predisposed to cardiovascular events and fractures. After successful surgical treatment, many patients thought to be asymptomatic become aware of improvement in unrecognized preoperative symptoms such as fatigue, mild depression, weakness, constipation, polydipsia and polyuria, and bone and joint pain. Hyperparathyroidism should be suspected in all patients with hypercalcemia and the above symptoms, especially if associated with nephrolithiasis, nephrocalcinosis, hypertension, left ventricular hypertrophy, peptic ulcer, pancreatitis, or gout. Patients with primary hyperparathyroidism appear to have a shortened life expectancy that improves after successful parathyroidectomy. Younger patients and those with less severe hypercalcemia after parathyroidectomy have the best prognosis.

B. Laboratory Findings, Imaging Studies, and Differential Diagnosis (Approach to the Hypercalcemic Patient)

1. Laboratory Findings—Together, hyperparathyroidism and humoral hypercalcemia of malignancy (nonparathyroid cancer) are responsible for about 90% of all cases of hypercalcemia. Hyperparathyroidism is the most common cause of hypercalcemia detected by undirected methods such as routine screening, whereas cancer is the most common cause of hypercalcemia in hospitalized patients. Other causes of hypercalcemia are listed in Table 16–4. In many patients the diagnosis is obvious, while in others it may be difficult. At times, more than one reason for hypercalcemia may exist in the same patient, such as cancer or sarcoidosis plus hyperparathyroidism. A careful history must be obtained documenting: (1) the duration of any symptoms possibly related to hypercalcemia; (2) symptoms related to malignant disease; (3) conditions associated with hyperparathyroidism, such as renal colic, peptic ulcer disease, pancreatitis, hypertension, or gout; and (4) possible excess use of milk products, antacids, baking soda, or vitamins. In patients with a recent cough, wheeze, or hemoptysis, epidermoid carcinoma of the lung should be considered. Hematuria might suggest hypernephroma, bladder tumor, or renal lithiasis. A long history of renal stones or peptic ulcer disease suggests that hyperparathyroidism is likely.

The most important tests for the evaluation of hypercalcemia are, in order of importance, serum calcium, PTH, phosphate, chloride, alkaline phosphatase, creatinine; uric acid and urea nitrogen; urinary calcium; blood hematocrit and pH; serum magnesium; and erythrocyte sedimentation rate (Table 16–5). Measurement of 25-hydroxy and 1,25-hydroxy vitamin D levels, and serum protein electrophoresis are helpful in selected patients when other tests are equivocal.

Table 16–4. Causes of hypercalcemia.

	Approximate Frequency
Cancer Metastatic breast cancer PTH-related peptide secreting (lung, kidney) Multiple myeloma Leukemia Other metastatic cancer	Common
Endocrine Disorders Hyperparathyroidism Hyperthyroidism Addison disease, pheochromocytoma Hypothyroidism, VIPoma	Common
Increased Calcium or Vitamin Intake and Drugs Milk-alkali syndrome Vitamin D and A overdosage Thiazide diuretics, lithium	Uncommon
Granulomatous Diseases Sarcoidosis Tuberculosis	Uncommon
Benign Familial Hypocalciuric Hypercalcemia and Other Disorders Paget disease Immobilization Idiopathic hypercalcemia of infancy Aluminum intoxication Dysproteinemias Rhabdomyolysis	Rare

A high serum calcium and a low serum phosphate suggest hyperparathyroidism, but about half of patients with hyperparathyroidism have normal serum phosphate concentrations. Patients with vitamin D intoxication, sarcoidosis, malignant disease without metastasis, and hyperthyroidism may also be hypophosphatemic, but patients with breast cancer and hypercalcemia are only rarely so. In fact, if hypophosphatemia and hypercalcemia are present in association with breast cancer, concomitant hyperparathyroidism is probable. Measurement of serum PTH has its greatest value in this situation, since the PTH level is low or nil in patients with hypercalcemia due to all causes other than primary hyperparathyroidism or familial hypocalciuric hypercalcemia. In general, serum PTH levels should be measured in all patients with persistent hypercalcemia without an obvious

Table 16–5. Laboratory evaluation of hypercalcemia.

Essential	Selective
Blood Tests	
Calcium	Creatine and BUN
Phosphate	Chloride
PTH (intact or two-site assay)	Uric acid
Alkaline phosphatase	pH Protein electrophoresis or albumin: globulin ratio 25-dihydroxyvitamin D and 1,25-dihydroxyvitamin D
Radiographic or Nuclear Medicine Procedures	
Chest x-ray	Sestamibi scan of neck and ultrasound of neck
Abdominal plain films	
Ultrasound of kidneys	
Bone density (hip, lumbar spine, wrist)	
Urine Tests

¹When urine calcium is < 100 mg/24 h, a diagnosis of benign familial hypocalciuric hypercalcemia must be considered.

cause and in normocalcemic patients who are suspected of having hyperparathyroidism. Determination of intact serum PTH levels is sensitive and is not influenced by tumors that secrete parathyroid-related peptide. Nonparathyroid tumors that secrete pure PTH are extremely rare.

An elevated serum chloride concentration is a useful diagnostic clue found in about 40% of hyperparathyroid patients. PTH acts directly on the proximal renal tubule to decrease the resorption of bicarbonate, which leads to increased resorption of chloride and mild hyperchloremic renal tubular acidosis. An increased serum chloride is not found in other causes of hypercalcemia. Calculation of the serum chloride to phosphate ratio takes advantage of slight increases in serum chloride and slight decreases in serum phosphate concentrations. A ratio above 33 suggests hyperparathyroidism; this was a more clinically useful observation before the availability of rapid and accurate PTH measurement.

A 24-hour urine calcium level is helpful for diagnosing hypercalcemic patients who have low urinary calcium levels resulting from benign familial hypocalciuric hypercalcemia (BFHH) and for patients with marked hypercalciuria (> 400 mg/24 h). Patients with BFHH do not benefit from parathyroidectomy.

Serum protein electrophoretic patterns are helpful for diagnosis of multiple myeloma and sarcoidosis. Hypergammaglobulinemia is rare in hyperparathyroidism but is not uncommon in patients with multiple myeloma and sarcoidosis. Roentgenograms of the skull or site of bone pain in patients with elevated alkaline phosphatase levels will often reveal typical “punched-out” bony lesions, and the diagnosis of myeloma can be firmly established by bone marrow examination. Sarcoidosis can be difficult to diagnose, because it may exist for years with limited clinical findings. A chest x-ray revealing a diffuse fibronodular infiltrate and prominent hilar adenopathy is suggestive, and the demonstration of noncaseating granuloma in lymph nodes is diagnostic.

Serum alkaline phosphate levels are elevated in about 10% of patients with primary hyperparathyroidism and may also be increased in patients with Paget disease and cancer. When the serum alkaline phosphatase level is elevated, serum 5'-nucleotidase, which parallels liver alkaline phosphatase, should be measured to determine if the increase is from bone, which suggests parathyroid disease, or liver.

2. Bone Studies—Bone densitometry and radiographic examination of bone frequently reveals osteopenia (1 standard deviation below normal density) or osteoporosis (2.5 standard deviations below normal), but overt skeletal changes such as subperiosteal resorption or brown tumor are found in less than 10% of patients with hyperparathyroidism. Dual photon bone density studies of the femur, lumbar spine, and radius help document osteopenia that occurs in about 70% of women with hyperparathyroidism. Bone changes of osteitis fibrosa cystica are rare on x-ray unless the serum alkaline phosphatase concentration is increased. Primary and secondary hyperparathyroidism can produce subperiosteal resorption of the phalanges and bone cysts (Figure 16-3). A ground-glass appearance of the skull with loss of definition of the tables and demineralization of the outer aspects of the clavicles are less frequently seen. In patients with markedly elevated serum alkaline phosphatase levels without subperiosteal resorption on x-ray, Paget disease or cancer must be suspected. A 24-hour urine test for deoxypyridinoline cross-link assay or osteocalcin detects increased bone loss.

3. Differential Diagnosis—The differentiation between hyperparathyroidism because of primary parathyroid disease and that due to humoral hypercalcemia of malignancy can now almost always be determined by measuring intact PTH, which is increased in primary hyperparathyroidism but suppressed in humoral hypercalcemia of malignancy.

The most common tumors causing humoral hypercalcemia of malignancy are squamous cell carcinoma of the lung, renal cell carcinoma, and bladder cancer. Less commonly it is due to hepatoma or to cancer of the ovary, stomach, pancreas, parotid gland, or colon. Recent onset of symptoms, increased sedimentation rate, anemia, serum calcium greater than 14 mg/dL, and increased alkaline phosphatase activity without osteitis fibrosa cystica suggest humoral hypercalcemia of malignancy; mild hypercalcemia with a long history of nephrolithiasis or peptic ulcer suggests primary hyperthyroidism. Documented hypercalcemia of 6 months or longer essentially rules out malignancy-associated hypercalcemia.

In milk-alkali syndrome, a history of excessive ingestion of milk products, calcium-containing antacids, and baking soda is often obtained. These patients become normocalcemic after discontinuing these habits. Patients with milk-alkali syndrome usually have renal insufficiency and low urinary calcium concentrations and are usually alkalotic rather than acidotic. Because of the high incidence of ulcer disease in hyperparathyroidism, milk-alkali syndrome may occasionally coexist with that disorder. This is very infrequent now that acid-suppressing medications, such as proton pump inhibitors, are available to manage peptic ulcer disease.

Hyperthyroidism, another cause of hypercalcemia and hypercalciuria, can usually be differentiated because manifestations of thyrotoxicosis rather than hypercalcemia bring the patient to the physician. Occasionally, an elderly patient with apathetic hyperthyroidism may be hypercalcemic. A sensitive TSH test should be evaluated in hypercalcemic patients whose PTH levels are not increased. Treatment of hyperthyroidism with antithyroid medications causes serum calcium to return to normal levels within 8 weeks.

Normal subjects taking **thiazide diuretics** may develop a transient increase in serum calcium levels, usually less than 1 mg/dL. Larger rises in serum calcium induced by thiazides have been reported in patients with primary hyperparathyroidism and idiopathic juvenile osteoporosis. Most patients who have hypercalcemia while taking thiazides have another reason for the increase. The best way to evaluate these patients is to switch them to a nonthiazide antihypertensive agent or diuretic and to measure the PTH level. Thiazide-induced hypercalcemia is not associated with increased serum PTH in patients without hyperparathyroidism.

Benign familial hypocalciuric hypercalcemia is one of the few conditions that causes chronic hypercalcemia and mildly elevated PTH levels. It can be difficult to distinguish from mild primary hyperparathyroidism. The best way to diagnose this disorder is to document a low urinary calcium and a family history of hypercalcemia, especially in children.

Other miscellaneous causes of hypercalcemia are Paget disease, immobilization (especially in Paget disease or in young patients), dysproteinemias, idiopathic hypercalcemia of infancy, aluminum intoxication, and rhabdomyolysis (Table 16–4).

C. Approach to the Normocalcemic Patient With Possible Hyperparathyroidism

Renal failure, hypoalbuminemia, pancreatitis, deficiency of vitamin D or magnesium, and excess phosphate intake may cause serum calcium levels to be normal in hyperparathyroidism. Correction of these disorders results in hypercalcemia if hyperparathyroidism is present. The incidence of normocalcemic hyperparathyroidism in patients with hypercalciuria and recurrent nephrolithiasis (idiopathic hypercalciuria) is not known. Because the serum calcium concentration may fluctuate, it should be measured on more than three separate occasions. Determination of serum ionized calcium is also sometimes revealing, since it may be increased in patients with normal total serum calcium levels.

If a patient has elevated serum levels of ionized calcium and PTH, the diagnosis of normocalcemic hyperparathyroidism has been confirmed. There are three major causes of hypercalciuria and nephrolithiasis: (1) increased absorption of calcium from the gastrointestinal tract (absorptive hypercalciuria), (2) increased renal leakage of calcium (renal hypercalciuria) and (3) primary hyperparathyroidism. Patients with absorptive hypercalcemia absorb too much calcium from the gastrointestinal tract and therefore have low serum PTH levels. Patients with renal hypercalciuria lose calcium from leaky renal tubules and have increased PTH levels. They can be distinguished from patients with normocalcemic hyperparathyroidism by their response to treatment with thiazides. In renal leak hypercalcemia, serum PTH levels become normal because thiazides correct the excessive loss of calcium, whereas in primary hyperparathyroidism increased serum PTH levels persist and the patient often becomes hypercalcemic.

► Natural History of Untreated & Treated Hyperparathyroidism

Patients with untreated hyperparathyroidism have an increased risk of dying prematurely, mainly from cardiovascular and malignant disease. There is decreased respiratory muscular capacity and increased frequency of hypertrophic cardiomyopathy with left ventricular hypertrophy and decreased vascular compliance even in hyperparathyroid patients without hypertension. Hyperparathyroid patients have more hypertension, nephrolithiasis, osteopenia, peptic ulcer disease, gout, renal dysfunction, and pancreatitis. After successful parathyroidectomy, previously hyperpara-

thyroid patients still have an increased risk of premature death, however, younger patients and those with less severe disease return to a normal survival curve sooner than do older patients or those with more severe hyperparathyroidism. Most patients with hyperparathyroidism—even those with normocalcemic hyperparathyroidism—have symptoms and associated conditions. In 80% of patients, these clinical manifestations improve or disappear after parathyroidectomy.

► Treatment

The only curative treatment of primary hyperparathyroidism is parathyroidectomy. There are no convincing data to support a plan of medical observation, and considerable data support a surgical approach. Once associated conditions such as hypertension and renal dysfunction become well established, they seem to progress despite correction of the primary hyperparathyroidism. Thus, it appears to be better to intervene early while it is still possible to correct these problems. In all patients, however, the diagnosis should be established, and short delays to clarify the diagnosis are justified. The criteria for intervention in asymptomatic patients have been revised several times over two decades (Table 16–6), but have always also included the option for correction of the abnormality based on individual patient and physician judgments.

A. Marked Hypercalcemia (Hypercalcemic Crisis)

The initial treatment in patients with marked hypercalcemia and acute symptoms is hydration and correction of hypokalemia and hyponatremia. While the patient is being hydrated, assessment of the underlying problem is essential so that more specific therapy may be started. Milk and alkaline products, estrogens, thiazides, and vitamins A and D should be immediately discontinued. Furosemide is useful to increase calcium excretion in the rehydrated patient. Etidronate, plicamycin, and calcitonin are usually effective for short periods in treating hypercalcemia regardless of cause. Glucocorticoids are very effective in vitamin D intoxication, hyperthyroidism, and sarcoidosis and in many patients with cancer, including those with peptide-secreting tumors, but are less effective when there is extensive bone disease. As mentioned previously, hyperparathyroid patients only occasionally respond to glucocorticoid administration.

In patients with marked hypercalcemia, once the diagnosis of hyperparathyroidism is established, localization studies, cervical exploration, and parathyroidectomy should be performed in a vigorously hydrated patient, since this is the most rapid and effective method of normalizing the serum calcium.

Table 16–6. Indications for parathyroidectomy in asymptomatic primary hyperparathyroidism.

Criterion	1990	2002	2008
Hypercalcemia	Serum calcium > 1.5 mg/dL above normal	Serum calcium > 1 mg/dL above normal	Serum calcium > 1 mg/dL above normal
Hypercalciuria	24 h urine calcium > 400 mg	24 h urine calcium > 400 mg	Not included
Renal insufficiency	Reduced by 30%	Reduced by 30%	GFR < 60 mL/min
Osteoporosis	Z-score < 2	T-score < 2.5	T-score < 2.5 or h/o fragility fracture
Age	< 50 y	< 50 y	< 50 y

B. Localization

Preoperative localization of parathyroid tumors can now be accomplished in about 80%-90% of patients with ultrasonography and sestamibi scans. These studies, however, are helpful in fewer patients with parathyroid hyperplasia (Figure 16–4). Localization studies are essential in patients with persistent or recurrent hyperparathyroidism and can direct a focused exploration in patients with primary hyperparathyroidism. An experienced surgeon can find the tumors in about 95% of patients who have not had previous parathyroid or thyroid surgery without preoperative tests, however preoperative knowledge of the location of the abnormal glands can simplify the operation.

For patients who have had prior neck operations, including thyroid and parathyroid procedures, preoperative localization is especially important. CT scan with specially timed contrast enhancement and selective venous catheterization with PTH immunoassay are often helpful. The surgeon must carefully evaluate these cases prior to exploration to optimize the opportunity for a successful operation. A frequently employed preference is that two concordant studies identify the site of the parathyroid abnormality prior to operating.

C. Operation

Three approaches are now acceptable for patients with sporadic primary hyperparathyroidism. A bilateral neck exploration (exposing all four parathyroid glands) is safe and does not depend upon preoperative tests or intraoperative PTH testing for success. A unilateral approach can be elected when one or more localization tests lateralize a solitary parathyroid tumor. At operation, a normal and abnormal parathyroid should be identified on the side of the localized tumor. A focal operation can be done in similar patients and the operation completed when the intraoperative PTH level decreases according to some planned criteria. When the

sestamibi and ultrasound scans both independently identify the same tumor, a successful operation occurs in approximately 96% of patients. Videoscopic parathyroidectomy is recommended by a minority of surgeons.

In over 80% of cases, the parathyroid tumor is found attached to the posterior capsule of the thyroid gland. The parathyroid glands are usually symmetrically placed, and lower parathyroid glands are situated anterior to the recurrent laryngeal nerve, whereas the upper parathyroid glands lie posterior to the recurrent laryngeal nerve, where it enters the cricothyroid muscle. Parathyroid tumors may also lie cephalad to the superior pole of the thyroid gland, along the great vessels of the neck in the tracheoesophageal area, in thymic tissue, in the substance of the thyroid gland itself, or in the mediastinum. Care must be taken to avoid bleeding and not to traumatize the parathyroid gland or tumors, since color is useful in distinguishing them from surrounding thyroid, thymus, lymph node, and fat. Furthermore, rupture of the parathyroid gland may result in parathyromatosis (seeding of parathyroid tissue) and possible recurrent hyperparathyroidism. Two helpful maneuvers for localizing parathyroid tumors at operation are following the course of a branch of the inferior thyroid artery and looking for the fat that is usually associated with the parathyroid glands. One should attempt to identify four parathyroid glands when a bilateral approach is elected, though there may be more than four or fewer than four.

In a focused parathyroidectomy, if a probable parathyroid adenoma is found, it is removed and the diagnosis of adenoma confirmed by a decrease in PTH of greater than 50% from baseline and into the normal range. If the intraoperative PTH does not fall appropriately, then further exploration to identify additional abnormal parathyroid tissue should be undertaken during the same anesthetic. If normal glands are identified, they should be carefully documented. If two adenomas are found, both are removed, and both normal glands can be biopsied for confirmation but should not be removed.

▲ **Figure 16-4.** Parathyroid adenomas. **A:** Sestamibi scan of right lower parathyroid adenoma. **B:** Longitudinal ultrasound scan of left lower parathyroid adenoma. **C:** Transverse ultrasound scan of left lower parathyroid adenoma.

The presence of a completely normal parathyroid gland at operation indicates that the tumor removed is adenomatous rather than hyperplastic, since in hyperplasia all the parathyroid glands are involved. However, the variation in the appearance of normal parathyroid glands, and the subtlety of hyperplastic glands can make this distinction complex.

When all parathyroid glands are hyperplastic, the most normal gland should be partially resected, leaving a 50 mg remnant, and confirmed to be well-vascularized prior to removal of the remaining glands. The upper thymus and perithymic tract should be removed in patients with hyperplasia, because a fifth parathyroid gland is present in 15% of cases.

If exploration fails to reveal a parathyroid tumor, a missing lower gland is often in the thymus (anterior mediastinum), whereas a missing upper gland is usually paroesophageal (or in the posterior mediastinum). One should therefore perform a careful and thorough exploration of the areas in which parathyroid tissue is likely to reside.

The recurrence rate of hyperparathyroidism after the removal of a single adenoma in patients with sporadic hyperparathyroidism is 2% or less. In patients with multiple endocrine neoplasia and familial hyperparathyroidism, recurrent hyperparathyroidism is expected as long as they have residual parathyroid tissue. Thus, the plan for management of these patients over their lifetime should be to limit both the complications from hyperparathyroidism, and the number and complexity of operations required to manage it.

D. Postoperative Care

Following removal of a parathyroid adenoma or hyperplastic glands, the serum calcium concentration falls to normal or below normal in 24-48 hours. Patients with severe skeletal depletion ("hungry bones"), long-standing hyperparathyroidism, vitamin D deficiency, or high preoperative serum calcium levels may develop profound hypocalcemia with paresthesias, carpopedal spasm, or even seizures. If the symptoms are mild and serum calcium falls slowly, oral supplementation with calcium is all that is required. When marked symptoms develop, it can be necessary to administer intravenous calcium gluconate. If the response is not rapid, the serum magnesium concentration should be determined and replenished. Treatment with calcitriol, 0.5 micrograms twice daily is sometimes required. (See section on Hypoparathyroidism.)

E. Reoperation

Treatment of persistent or recurrent hyperparathyroidism requires careful evaluation and planning. First the diagnosis must be reestablished, and the rationale for correcting the hyperparathyroidism must be specifically confirmed. If operation is planned, then preoperative localization is mandatory. Most surgeons perform noninvasive

localization tests (ultrasound, sestamibi scan, CT scan) initially. If the localization is not clear, then invasive testing follows (selective venous catheterization with PTH measurement, rarely angiography). Most patients have a parathyroid tumor that can be removed through a cervical incision, making mediastinal exploration unnecessary. The success rate for patients requiring reoperation is about 90%, and the complication rate is higher depending upon the nature of the prior operation(s) and the location of the abnormal gland. The success rate is lower in patients with negative or equivocal localization tests and in patients with parathyromatosis and parathyroid cancer.

Bilezikian JP et al: Guidelines for the management of asymptomatic primary hyperparathyroidism: summary statement from the third international workshop. *J Clin Endocrinol Metab.* 2009;94:335.

SECONDARY & TERTIARY HYPERPARATHYROIDISM

In secondary hyperparathyroidism, there is an increase in PTH secretion in response to low plasma concentrations of ionized calcium, usually due to renal disease or vitamin D deficiency, and malabsorption. This results in chief cell hyperplasia. When secondary hyperparathyroidism occurs as a complication of renal disease, the serum phosphorus level is usually high, whereas in malabsorption, osteomalacia, or rickets it is frequently low or normal. Secondary hyperparathyroidism with renal osteodystrophy is a frequent complication of hemodialysis and peritoneal dialysis. Factors that play a role in renal osteodystrophy are: (1) phosphate retention secondary to a decrease in the number of nephrons; (2) failure of the diseased or absent kidneys to hydroxylate 25-dihydroxyvitamin D to the biologically active metabolite 1,25-dihydroxyvitamin D, with decreased intestinal absorption of calcium; (3) resistance of the bone to the action of PTH; and (4) increased serum calcitonin concentrations. The resulting skeletal changes are identical with those of primary hyperparathyroidism but are often more severe.

Most patients with secondary hyperparathyroidism are treated medically. Maintaining relatively normal serum concentrations of calcium and phosphorus during hemodialysis and treatment with calcitriol (orally or intravenously) have decreased the incidence of bone disease.

Indications for operation in patients with secondary hyperparathyroidism include: (1) a calcium \times phosphate product > 70 , (2) severe bone disease and pain, (3) pruritus, (4) extensive soft tissue calcification with tumoral calcinosis, and (5) calciphylaxis. Most patients with secondary hyperparathyroidism requiring parathyroidectomy have very high

serum PTH levels. In the patient with secondary hyperparathyroidism in whom subtotal parathyroidectomy or total parathyroidectomy with autotransplantation is indicated, all but about 50 mg of the most normal parathyroid gland should be removed, or 15 (1-mm) slices of parathyroid tissue should be transplanted into individual muscle pockets in the forearm.

Following parathyroidectomy patients usually respond with dramatic relief of bone and joint pain and pruritus. Profound hypocalcemia frequently results following subtotal or total parathyroidectomy with autotransplantation for renal osteodystrophy, both because of “hungry bones” and because of decreased PTH secretion. Hypocalcemia due to hungry bones can be anticipated in patients with markedly elevated alkaline phosphatase levels and hand films documenting subperiosteal resorption.

Occasionally, a patient with secondary hyperparathyroidism develops relatively autonomous hyperplastic parathyroid glands. In most patients after successful renal transplantation, the serum calcium concentration returns to normal, and the hyperplastic parathyroid glands regress. In some patients, however, profound hypercalcemia develops (tertiary hyperparathyroidism). In general, surgical therapy for so-called tertiary hyperparathyroidism should be delayed until all medical approaches, including treatment with vitamin D, calcium supplementation, and phosphate binders, have been exhausted; if the condition persists beyond 1 year posttransplant, or if the hypercalcemia is severe, then operation for tertiary disease should be considered.

- ▶ Surgical neck scar. Positive Chvostek and Trousseau signs
- ▶ Brittle and atrophied nails, defective teeth, cataracts
- ▶ Hypocalcemia and hyperphosphatemia, low or absent urinary calcium, low or absent circulating parathyroid hormone
- ▶ Calcification of basal ganglia, cartilage, and arteries as seen on x-ray

▶ General Considerations

Hypoparathyroidism, although uncommon, occurs most often as a complication of thyroidectomy, especially when performed for carcinoma or recurrent goiter. Idiopathic hypoparathyroidism, an autoimmune process associated with autoimmune adrenocortical insufficiency, is also unusual, and hypoparathyroidism after ¹³¹I therapy for Graves disease is rare. Neonatal tetany may be associated with maternal hyperparathyroidism. Hypothyroidism as well as hypoparathyroidism may occur in patients with Riedel struma.

▶ Clinical Findings

A. Symptoms and Signs

The manifestations of acute hypoparathyroidism are due to hypocalcemia. Low serum calcium levels precipitate tetany. Latent tetany may be indicated by mild or moderate paresthesias with a positive Chvostek or Trousseau sign. The initial manifestations are paresthesias, circumoral numbness, muscle cramps, irritability, carpopedal spasm, convulsions, opisthotonos, and marked anxiety. Chronically, dry skin, brittleness of the nails, and spotty alopecia including loss of the eyebrows are common. Since primary hypoparathyroidism is rare, a history of thyroidectomy is almost always present. Generally speaking, the sooner the clinical manifestations appear postoperatively, the more serious the prognosis. After many years, some patients become adapted to a low serum calcium concentration, so that tetany is no longer evident.

B. Laboratory Findings

Hypocalcemia and hyperphosphatemia are demonstrable. The urine phosphate is low or absent, tubular resorption of phosphate is high, and the urine calcium is low.

C. Imaging Studies

In chronic hypoparathyroidism, x-rays may show calcification of the basal ganglia, arteries, and external ear.

HYPOPARATHYROIDISM

ESSENTIALS OF DIAGNOSIS

- ▶ Paresthesias, muscle cramps, carpopedal spasm, laryngeal stridor, convulsions, malaise, muscle and abdominal cramps, tetany, urinary frequency, lethargy, anxiety, psychoneurosis, depression, and psychosis

► Differential Diagnosis

A good history is most important in the differential diagnosis of hypocalcemic tetany. Occasionally, tetany occurs with alkalosis and hyperventilation. Symptomatic hypocalcemia occurring after thyroid or parathyroid surgery is due to parathyroid removal or injury, or is secondary to hungry bones. Other major causes of hypocalcemic tetany are intestinal malabsorption and renal insufficiency. These conditions may also be suggested by a history of diarrhea, pancreatitis, steatorrhea, or renal disease. Laboratory abnormalities include decreased concentrations of serum proteins, cholesterol, and carotene and increased concentrations of stool fat in malabsorption and an increased blood urea nitrogen and creatinine in renal failure.

Serum PTH concentrations are low in hypocalcemia secondary to idiopathic or iatrogenic hypoparathyroidism. In hypocalcemia secondary to malabsorption and renal failure, serum PTH concentrations are elevated and the serum alkaline phosphatase concentration is normal or increased.

► Treatment

The aim of treatment is to raise the serum calcium concentration, to bring the patient out of tetany, and to lower the serum phosphate level so as to prevent metastatic calcification. Most postoperative hypocalcemia is transient; if it persists longer than 2-3 weeks or if treatment with calcitriol (1,25-dihydroxyvitamin D) is required, the hypoparathyroidism may be permanent.

A. Acute Hypoparathyroid Tetany

Acute hypoparathyroid tetany requires emergency treatment. Make certain an adequate airway exists. Reassure the anxious patient to avoid hyperventilation and resulting alkalosis, which exacerbates the hypocalcemia. Calcium gluconate IV, 10-20 mL of 10% solution administered slowly resolves the tetany. Fifty milliliters of 10% calcium gluconate may then be added to 500 mL of 5% dextrose solution and administered by intravenous drip at a rate of 1 mL/kg/h. Adjust the rate of infusion so that hourly determinations of serum calcium are normal.

To make the transition to oral supplements to support the serum calcium level, calcitriol (1,25-dihydroxyvitamin D), 0.25-0.5 µg twice daily, is very helpful and takes effect within 48-72 hours. This enables the GI tract to absorb increased amounts of calcium. Calcitriol has a rapid onset of action compared to other vitamin D preparations. Oral calcium supplements of up to 6 g/d can then generally resolve the hypocalcemia even in patients with permanent, severe hypoparathyroidism. Hypomagnesemia is present in some cases of tetany not responding to calcium treatment. In such cases, magnesium (as magnesium sulfate) should

be given in a dosage of 4-8 g/d intramuscularly or 2-4 g/d intravenously.

B. Chronic Hypoparathyroidism

Once tetany has responded to intravenous calcium, change to oral calcium (citrate, gluconate, lactate, or carbonate) three times daily or as necessary. The management of the hypoparathyroid patient is difficult, because the difference between the controlling and intoxicating dose of vitamin D may be quite small. Episodes of hypercalcemia in treated patients are often unpredictable and may occur in the absence of symptoms. Vitamin D intoxication may develop after months or years of good control on a given therapeutic regimen. Dihydroxycholesterol is useful in the exceptional case to supplement treatment with calcium and 1,25-dihydroxyvitamin D, when the usual measures fail to control the hypocalcemia. Frequent serum calcium determinations are necessary to regulate the proper dosage of vitamin D and to avoid vitamin D intoxication. The dose of vitamin D required to correct hypocalcemia may vary from 25,000 to 200,000 IU/d. Phosphorus should also be limited in the diet; in most patients, simple elimination of dairy products is sufficient. In some patients, aluminum hydroxide gel may be necessary to bind phosphorus in the gut to increase fecal losses.

Exogenous PTH analogs may be helpful in the long-term management of bone disease in patients with hypoparathyroidism. The optimal strategies are under development.

Sikjaer T et al: PTH (1-84) replacement therapy in hypoparathyroidism: a randomized controlled trial on pharmacokinetic and dynamic effects following 6 months of treatment. *J Bone Miner Res.* 2013 Oct;28(10):2232-2243.

MULTIPLE CHOICE QUESTIONS

- The best test to assess the thyroid function status of a patient who does not have known pituitary disease is
 - Free T₄
 - T₃
 - T₄
 - TSH
 - T₄/T₃ ratio
- Indications for surgery to correct hyperthyroidism include
 - Pregnancy
 - Age over 50 years
 - Large goiter with low radioiodine uptake
 - Both A and C
 - None of the above

3. Follicular thyroid cancer
 - A. Is separated from papillary thyroid cancer because it develops from the follicular cells of the thyroid
 - B. Is less likely to spread to lymph nodes than is papillary thyroid cancer
 - C. Is commonly inoperable because of local invasion and encompassment of surrounding structures
 - D. Commonly makes thyroid hormone producing hyperthyroidism
 - E. Is best treated with radioiodine therapy, followed by thyroidectomy

4. The differential diagnosis of hypercalcemia includes
 - A. Vitamin A toxicity
 - B. Vigorous exercise
 - C. Hypothyroidism
 - D. Myasthenia gravis
 - E. None of the above

5. Patient characteristics that would meet current indications for surgery to correct asymptomatic hyperparathyroidism include
 - A. Renal insufficiency with a glomerular filtration rate of 72 mL/min
 - B. Age of 57 years
 - C. Positive localization tests with concordant ultrasound and sestamibi scans
 - D. Osteoporosis with a T-score of -2.8
 - E. A serum calcium level of 10.8 mg/dL with an upper limit of normal of 10.3 mg/dL

BENIGN BREAST DISORDERS

FIBROCYSTIC CONDITION

ESSENTIALS OF DIAGNOSIS

- ▶ Painful, often multiple, usually bilateral masses in the breast
- ▶ Rapid fluctuation in the size of the masses is common
- ▶ Frequently, pain occurs or worsens and size increases during premenstrual phase of cycle
- ▶ Most common age is 30-50 years. Rare in postmenopausal women not receiving hormonal replacement

▶ General Considerations

Fibrocystic condition is the most frequent lesion of the breast. Although commonly referred to as “fibrocystic disease,” it does not, in fact, represent a pathologic or anatomic disorder. It is common in women 30-50 years of age but rare in postmenopausal women who are not taking hormonal replacement. Estrogen is considered a causative factor. There may be an increased risk in women who drink alcohol, especially women between 18 and 22 years of age. Fibrocystic condition encompasses a wide variety of benign histologic changes in the breast epithelium, some of which are found so commonly in normal breasts that they are probably variants of normal but have nonetheless been termed a “condition” or “disease.”

The microscopic findings of fibrocystic condition include cysts (gross and microscopic), papillomatosis, adenosis, fibrosis, and ductal epithelial hyperplasia. Although fibrocystic condition has generally been considered to increase the risk of subsequent breast cancer, only the variants with a

component of epithelial proliferation (especially with atypia) or increased breast density on mammogram represent true risk factors.

▶ Clinical Findings

A. Symptoms and Signs

Fibrocystic condition may produce an asymptomatic mass in the breast that is discovered by accident, but pain or tenderness often calls attention to it. Discomfort often occurs or worsens during the premenstrual phase of the cycle, at which time the cysts tend to enlarge. Fluctuations in size and rapid appearance or disappearance of a breast mass are common with this condition as are multiple or bilateral masses and serous nipple discharge. Patients will give a history of a transient lump in the breast or cyclic breast pain.

B. Diagnostic Tests

Mammography and ultrasonography should be used to evaluate a mass in a patient with fibrocystic condition. Ultrasonography alone may be used in women under 30 years of age. Because a mass due to fibrocystic condition is difficult to distinguish from carcinoma on the basis of clinical findings, suspicious lesions should be biopsied. Fine-needle aspiration (FNA) cytology may be used, but if a suspicious mass that is nonmalignant on cytologic examination does not resolve over several months, it should be excised or biopsied by core needle. Surgery should be conservative, since the primary objective is to exclude cancer. Occasionally, FNA cytology will suffice. Simple mastectomy or extensive removal of breast tissue is rarely, if ever, indicated for fibrocystic condition.

▶ Differential Diagnosis

Pain, fluctuation in size, and multiplicity of lesions are the features most helpful in differentiating fibrocystic condition

from carcinoma. If a dominant mass is present, the diagnosis of cancer should be assumed until disproven by biopsy. Mammography may be helpful, but the breast tissue in these young women is usually too radiodense to permit a worthwhile study. Sonography is useful in differentiating a cystic mass from a solid mass, especially in women with dense breasts. Final diagnosis, however, depends on analysis of the excisional biopsy specimen or needle biopsy.

► Treatment

When the diagnosis of fibrocystic condition has been established by previous biopsy or is likely because the history is classic, aspiration of a discrete mass suggestive of a cyst is indicated to alleviate pain and, more importantly, to confirm the cystic nature of the mass. The patient is reexamined at intervals thereafter. If no fluid is obtained by aspiration, if fluid is bloody, if a mass persists after aspiration, or if at any time during follow-up a persistent or recurrent mass is noted, biopsy should be performed.

Breast pain associated with generalized fibrocystic condition is best treated by avoiding trauma and by wearing a good supportive brassiere during the night and day. Hormone therapy is not advisable, because it does not cure the condition and has undesirable side effects. Danazol (100-200 mg orally twice daily), a synthetic androgen, is the only treatment approved by the US Food and Drug Administration (FDA) for patients with severe pain. This treatment suppresses pituitary gonadotropins, but androgenic effects (acne, edema, hirsutism) usually make this treatment intolerable; in practice, it is rarely used. Similarly, tamoxifen reduces some symptoms of fibrocystic condition, but because of its side effects, it is not useful for young women unless it is given to reduce the risk of cancer. Postmenopausal women receiving hormone replacement therapy may stop or change doses of hormones to reduce pain. Oil of evening primrose (OEP), a natural form of gamma-linolenic acid, has been shown to decrease pain in 44%-58% of users. The dosage of gamma-linolenic acid is six capsules of 500 mg orally twice daily. Studies have also demonstrated a low-fat diet or decreasing dietary fat intake may reduce the painful symptoms associated with fibrocystic condition. Further research is being done to determine the effects of topical treatments such as topical nonsteroidal anti-inflammatory drugs as well as topical hormonal drugs such as topical tamoxifen.

The role of caffeine consumption in the development and treatment of fibrocystic condition is controversial. Some studies suggest that eliminating caffeine from the diet is associated with improvement while other studies refute the benefit entirely. Many patients are aware of these studies and report relief of symptoms after giving up coffee, tea, and chocolate. Similarly, many women find vitamin E (400 international units daily) helpful; however, these observations remain anecdotal.

► Prognosis

Exacerbations of pain, tenderness, and cyst formation may occur at any time until menopause, when symptoms usually subside, except in patients receiving hormonal replacement. The patient should be advised to examine her own breasts regularly just after menstruation and to inform her practitioner if a mass appears. The risk of breast cancer developing in women with fibrocystic condition with a proliferative or atypical component in the epithelium or papillomatosis is higher than that of the general population. These women should be monitored carefully with physical examinations and imaging studies.

FIBROADENOMA OF THE BREAST

This common benign neoplasm occurs most frequently in young women, usually within 20 years after puberty. It is somewhat more frequent and tends to occur at an earlier age in black women. Multiple tumors are found in 10%-15% of patients.

The typical **fibroadenoma** is a round or ovoid, rubbery, discrete, relatively movable, nontender mass 1-5 cm in diameter. It is usually discovered accidentally. Clinical diagnosis in young patients is generally not difficult. In women over 30 years, fibrocystic condition of the breast and carcinoma of the breast must be considered. Cysts can be identified by aspiration or ultrasonography. Fibroadenoma does not normally occur after menopause but may occasionally develop after administration of hormones.

No treatment is usually necessary if the diagnosis can be made by needle biopsy or cytologic examination. Excision with pathologic examination of the specimen is performed if the diagnosis is uncertain. Cryoablation, or freezing of the fibroadenoma, appears to be a safe procedure if the lesion is consistent with fibroadenoma on histology prior to ablation. Cryoablation is not appropriate for all fibroadenomas because some are too large to freeze or the diagnosis may not be certain. There is no obvious advantage to cryoablation of a histologically proven fibroadenoma except that some patients may feel relief that a mass is gone. However, at times a mass of scar or fat necrosis replaces the mass of the fibroadenoma. Reassurance seems preferable. It is usually not possible to distinguish a large fibroadenoma from a phyllodes tumor on the basis of needle biopsy results or imaging alone.

Phyllodes tumor is a fibroadenoma-like tumor with cellular stroma that grows rapidly. It may reach a large size and, if inadequately excised, will recur locally. The lesion can be benign or malignant. If benign, phyllodes tumor is treated by local excision with a margin of surrounding breast tissue. The treatment of malignant phyllodes tumor is more controversial, but complete removal of the tumor with a rim of normal tissue avoids recurrence. Because these tumors may be large, simple mastectomy is sometimes necessary. Lymph node dissection is not performed, since the sarcomatous portion of the tumor metastasizes to the lungs and not the lymph nodes.

NIPPLE DISCHARGE

In order of decreasing frequency, the following are the most common causes of nipple discharge in the nonlactating breast: duct ectasia, intraductal papilloma, and carcinoma. The important characteristics of the discharge and some other factors to be evaluated by history and physical examination are listed in Table 17-1.

Spontaneous, unilateral, serous or serosanguineous discharge from a single duct is usually caused by an intraductal papilloma or, rarely, by an intraductal cancer. A mass may not be palpable. The involved duct may be identified by pressure at different sites around the nipple at the margin of the areola. Bloody discharge is suggestive of cancer but is more often caused by a benign papilloma in the duct. Cytologic examination may identify malignant cells, but negative findings do not rule out cancer, which is more likely in women over age 50 years. In any case, the involved bloody duct—and a mass if present—should be excised. A ductogram (a mammogram of a duct after radiopaque dye has been injected) is of limited value since excision of the suspicious ductal system is indicated regardless of findings. Ductoscopy, evaluation of the ductal system with a small scope inserted through the nipple, has been attempted but is not effective management.

In premenopausal women, spontaneous multiple duct discharge, unilateral or bilateral, most noticeable just before menstruation, is often due to fibrocystic condition. Discharge may be green or brownish. Papillomatosis and ductal ectasia are usually detected only by biopsy. If a mass is present, it should be removed.

Table 17-1. Characteristics of nipple discharge in the nonpregnant, nonlactating woman.

Finding	Significance
Serous	Most likely benign FCC, ie, duct ectasia
Bloody	More likely neoplastic—papilloma, carcinoma
Associated mass	More likely neoplastic
Unilateral	Either neoplastic or non-neoplastic
Bilateral	Most likely non-neoplastic
Single duct	More likely neoplastic
Multiple ducts	More likely FCC
Milky	Endocrine disorders, medications
Spontaneous	Either neoplastic or non-neoplastic
Produced by pressure at single site	Either neoplastic or non-neoplastic
Persistent	Either neoplastic or non-neoplastic
Intermittent	Either neoplastic or non-neoplastic
Related to menses	More likely FCC
Premenopausal	More likely FCC
Taking hormones	More likely FCC

FCC, fibrocystic condition.

A milky discharge from multiple ducts in the nonlactating breast may occur from hyperprolactinemia. Serum prolactin levels should be obtained to search for a pituitary tumor. Thyroid-stimulating hormone (TSH) helps exclude causative hypothyroidism. Numerous antipsychotic drugs and other drugs may also cause a milky discharge that ceases on discontinuance of the medication.

Oral contraceptive agents or estrogen replacement therapy may cause clear, serous, or milky discharge from a single duct, but multiple duct discharge is more common. In the premenopausal woman, the discharge is more evident just before menstruation and disappears on stopping the medication. If it does not stop, is from a single duct, and is copious, exploration should be performed since this may be a sign of cancer.

A purulent discharge may originate in a subareolar abscess and require removal of the abscess and the related lactiferous sinus.

When localization is not possible, no mass is palpable, and the discharge is nonbloody, the patient should be

reexamined every 3 or 4 months for a year, and a mammogram and an ultrasound should be performed. Although most discharge is from a benign process, patients may find it annoying or disconcerting. To eliminate the discharge, proximal duct excision can be performed both for treatment and diagnosis.

FAT NECROSIS

Fat necrosis is a rare lesion of the breast but is of clinical importance because it produces a mass (often accompanied by skin or nipple retraction) that is usually indistinguishable from carcinoma even with imaging studies. Trauma is presumed to be the cause, though only about 50% of patients give a history of injury. Ecchymosis is occasionally present. If untreated, the mass effect gradually disappears. The safest course is to obtain a biopsy. Needle biopsy is often adequate, but frequently the entire mass must be excised, primarily to exclude carcinoma. Fat necrosis is common after segmental resection, radiation therapy, or flap reconstruction after mastectomy.

BREAST ABSCESS

During nursing, an area of redness, tenderness, and induration may develop in the breast. The organism most commonly found in these abscesses is *Staphylococcus aureus*.

Infection in the nonlactating breast is rare. A subareolar abscess may develop in young or middle-aged women who are not lactating (Figure 17-1). These infections tend to recur after incision and drainage unless the area is explored during a quiescent interval, with excision of the involved lactiferous duct or ducts at the base of the nipple. In the nonlactating breast, inflammatory carcinoma must always be considered. Thus, incision and biopsy of any indurated tissue with a small piece of erythematous skin is indicated when suspected abscess or cellulitis in the nonlactating breast does not resolve promptly with antibiotics. Often needle or catheter drainage is adequate to treat an abscess, but surgical incision and drainage may be necessary.

DISORDERS OF THE AUGMENTED BREAST

At least 4 million American women have had breast implants. Breast augmentation is performed by placing implants under the pectoralis muscle or, less desirably, in the subcutaneous tissue of the breast. Most implants are made of an outer silicone shell filled with a silicone gel, saline, or some combination of the two. Capsule contraction or scarring around the implant develops in about 15%-25% of patients, leading to a firmness and distortion of the breast that can be painful. Some require removal of the implant and surrounding capsule.

Implant rupture may occur in as many as 5%-10% of women, and bleeding of gel through the capsule is noted even more commonly. Although silicone gel may be an immunologic stimulant, there is no increase in autoimmune disorders in patients with such implants. The FDA has advised symptomatic women with ruptured silicone implants to discuss possible surgical removal with their clinicians. However, women who are asymptomatic and have no evidence of rupture of a silicone gel prosthesis should probably not undergo removal of the implant. Women with symptoms of autoimmune illnesses often undergo removal, but no benefit has been shown.

Studies have failed to show any association between implants and an increased incidence of breast cancer.

However, breast cancer may develop in a patient with an augmentation prosthesis, as it does in women without them. Detection in patients with implants is more difficult because mammography is less able to detect early lesions. Mammography is better if the implant is subpectoral rather than subcutaneous. The prosthesis should be placed retropectorally after mastectomy to facilitate detection of a local recurrence of cancer, which is usually cutaneous or subcutaneous and is easily detected by palpation. Recently there has been an association of lymphoma of the breast with silicone implants.

If a cancer develops in a patient with implants, it should be treated in the same manner as in women without implants. Such women should be offered the option of mastectomy or breast-conserving therapy, which may require removal or replacement of the implant. Radiotherapy of the augmented breast often results in marked capsular contraction. Adjuvant treatments should be given for the same indications as for women who have no implants.

CARCINOMA OF THE FEMALE BREAST

ESSENTIALS OF DIAGNOSIS

- ▶ Risk factors include delayed childbearing, positive family history of breast cancer or genetic mutations (*BRCA1*, *BRCA2*), and personal history of breast cancer or some types of proliferative conditions.
- ▶ **Early findings:** Single, nontender, firm to hard mass with ill-defined margins; mammographic abnormalities and no palpable mass.
- ▶ **Later findings:** Skin or nipple retraction; axillary lymphadenopathy; breast enlargement, erythema, edema, pain; fixation of mass to skin or chest wall.

Incidence & Risk Factors

Breast cancer will develop in one of eight American women. Next to skin cancer, breast cancer is the most common cancer in women; it is second only to lung cancer as a

cause of death. In 2012, there were approximately 229,060 new cases and 39,920 deaths from breast cancer in women in the United States. An additional 63,300 cases of breast carcinoma in situ were detected, principally by screening mammography. Worldwide, breast cancer is diagnosed in approximately 1.38 million women, and about 458,000 die of breast cancer each year, with the highest rates of diagnosis in Western and Northern Europe, Australia, New Zealand, and North America and lowest rates in Sub-Saharan Africa and Asia. These regional differences in incidence are likely due to the variable availability of screening mammography as well as differences in reproductive and hormonal factors. In Western countries, incidence rates decreased with a reduced use of postmenopausal hormone therapy and mortality declined with increased use of screening and improved treatments. In contrast, incidence and mortality from breast cancer in many African and Asian countries has increased as reproductive factors have changed (such as delayed child-bearing) and as the incidence of obesity has risen.

The most significant risk factor for the development of breast cancer is age. A woman's risk of breast cancer rises rapidly until her early 60s, peaks in her 70s, and then declines. A significant family history of breast or ovarian cancer may also indicate a high risk of developing breast cancer. Germline mutations in the *BRCA* family of tumor suppressor genes accounts for approximately 5%-10% of breast cancer diagnoses and tend to cluster in certain ethnic groups, including women of Ashkenazi Jewish descent. Women with a mutation in the *BRCA1* gene, located on chromosome 17, have an estimated 85% chance of developing breast cancer in their lifetime. Other genes associated with an increased risk of breast and other cancers include *BRCA2* (associated with a gene on chromosome 13); ataxia-telangiectasia mutation; and mutation of the tumor suppressor gene *p53*. If a woman has a compelling family history (such as breast cancer diagnosed in two first-degree relatives, especially if diagnosed younger than age 50; ovarian cancer; male breast cancer; or a first-degree relative with bilateral breast cancer), genetic testing may be appropriate. In general, it is best for a woman who has a strong family history to meet with a genetics counselor to undergo a risk assessment and decide whether genetic testing is indicated.

Even when genetic testing fails to reveal a predisposing genetic mutation, women with a strong family history of breast cancer are at higher risk for development of breast cancer. Compared with a woman with no affected family members, a woman who has one first-degree relative (mother, daughter, or sister) with breast cancer has double the risk of developing breast cancer and a woman with two first-degree relatives with breast cancer has triple the risk of developing breast cancer. The risk is further increased for a woman whose affected family member was premenopausal at the time of diagnosis or had bilateral breast cancer. Lifestyle and reproductive factors also contribute to risk of

breast cancer. Nulliparous women and women whose first full-term pregnancy occurred after the age of 30 have an elevated risk. Late menarche and artificial menopause are associated with a lower incidence, whereas early menarche (under the age of 12) and late natural menopause (after the age of 55) are associated with an increase in risk. Combined oral contraceptive pills may increase the risk of breast cancer. Several studies show that concomitant administration of progesterone and estrogen to postmenopausal women may markedly increase the incidence of breast cancer, compared with the use of estrogen alone or with no hormone replacement treatment. The Women's Health Initiative prospective randomized study of hormone replacement therapy stopped treatment with estrogen and progesterone early because of an increased risk of breast cancer compared with untreated women or women treated with estrogen alone. Alcohol consumption, high dietary intake of fat, and lack of exercise may also increase the risk of breast cancer. Fibrocystic breast condition, when accompanied by proliferative changes, papillomatosis, or atypical epithelial hyperplasia, and increased breast density on mammogram are also associated with an increased incidence. A woman who had cancer in one breast is at increased risk for cancer developing in the other breast. In these women, a contralateral cancer develops at the rate of 1% or 2% per year. Women with cancer of the uterine corpus have a risk of breast cancer significantly higher than that of the general population, and women with breast cancer have a comparably increased risk of endometrial cancer. Socioeconomic and racial factors have also been associated with breast cancer risk. Breast cancer tends to be diagnosed more frequently in women of higher socioeconomic status and is more frequent in white women than in black women.

Women at greater than average risk for developing breast cancer (Table 17–2) should be identified by their practitioners and monitored carefully. Risk assessment models have been developed and several have been validated (most extensively the Gail 2 model) to evaluate a woman's risk of developing cancer. Those with an exceptional family history should be counseled about the option of genetic testing. Some of these high-risk women may consider prophylactic mastectomy, oophorectomy, or tamoxifen, an FDA-approved preventive agent. The Prevention and Observation of Surgical Endpoints (PROSE) consortium monitored women with deleterious *BRCA1/2* mutations from 1974 to 2008 and reported that 15% of women with a known *BRCA* mutation underwent bilateral prophylactic mastectomy, and none of them developed breast cancer during the 3 years of follow-up. In contrast, subsequent breast cancer developed in 98 (7%) of the 1372 women who did not have surgery. Moreover, women who underwent prophylactic salpingo-oophorectomy had a lower risk of ovarian cancer, all-cause mortality, as well as breast cancer- and ovarian cancer-specific mortality.

Table 17–2. Factors associated with increased risk of breast cancer.

Race	White
Age	Older
Family history	Breast cancer in parent, sibling, or child especially bilateral or premenopausal)
Genetics	<i>BRCA1</i> or <i>BRCA2</i> mutation
Previous medical history	Endometrial cancer Proliferative forms of fibrocystic disease Cancer in other breast
Menstrual history	Early menarche (under age 12) Late menopause (after age 50)
Reproductive history	Nulliparous or late first pregnancy

Women with genetic mutations in whom breast cancer develops may be treated in the same way as women who do not have mutations (ie, lumpectomy), though there is an increased risk of ipsilateral and contralateral recurrence after lumpectomy for these women. One study showed that of patients with a diagnosis of breast cancer who were found to be carriers of a *BRCA* mutation, approximately 50% chose to undergo bilateral mastectomy.

► Prevention

The National Surgical Adjuvant Breast Project (NSABP) conducted the first Breast Cancer Prevention Trial (BCPT) P-1, which evaluated tamoxifen, a selective estrogen receptor modulator (SERM), as a preventive agent in women with no personal history of breast cancer but at high risk for developing the disease. Women who received tamoxifen for 5 years had about a 50% reduction in noninvasive and invasive cancers compared with women taking placebo. However, women over age 50 who received the drug had an increased incidence of endometrial cancer and deep venous thrombosis.

The SERM raloxifene, effective in preventing osteoporosis, is also effective in preventing breast cancer. The NSABP Study of Tamoxifen and Raloxifene (STAR) P-2 trial compared raloxifene with tamoxifen for the prevention of breast cancer in a high-risk population. With a median follow-up of 81 months, raloxifene was associated with a higher risk of invasive breast cancer but had an equivalent risk for non-invasive disease compared with tamoxifen. Uterine cancer, cataracts, and thromboembolic events were significantly lower in the raloxifene-treated patients than in tamoxifen-treated patients. While SERMs have been shown to be effective at reducing the risk of breast cancer, the uptake of this intervention by women has been relatively low, possibly due to the perceived risks and side effects of therapy.

A cost-effectiveness study based on a meta-analysis of four randomized prevention trials showed that tamoxifen saves costs and improves life expectancy when higher risk (Gail 5-year risk at least 1.66%) women under the age of 55 years were treated.

Similar to SERMs, aromatase inhibitors (AI) such as exemestane have shown great success in preventing breast cancer with a lower risk of uterine cancer and thromboembolic events, although bone loss is a significant side effect of this treatment. In an international phase III clinical trial, 4560 postmenopausal women at high risk for breast cancer were randomly assigned to receive exemestane or placebo for 5 years. "High risk" was defined as at least one of the following: at least 60 years of age, Gail 5-year risk score > 1.66%; prior atypical ductal or lobular hyperplasia or lobular carcinoma in situ (LCIS); or ductal carcinoma in situ (DCIS) with mastectomy. With a median follow up of 35 months, there was a 65% relative risk reduction in the annual risk of invasive breast cancer (0.19% vs 0.55%; hazard ratio, 0.35; 95% CI, 0.18, 0.70; $P = 0.002$) for patients who received exemestane. While exemestane use was associated with a higher rate of adverse events (88% vs 85%; $P = 0.003$), there were no significant differences between the groups in terms of skeletal fractures or cardiovascular events, though longer follow up is needed to accurately assess these outcomes. Based on these data, exemestane is a reasonable risk-reducing option for postmenopausal women at higher risk for breast cancer.

► Early Detection of Breast Cancer

A. Screening Programs

A number of large screening programs, consisting of physical and mammographic examination of asymptomatic women, have been conducted over the years. On average, these programs identify 10 cancers per 1000 women over the age of 50 and 2 cancers per 1000 women under the age of 50. Screening detects cancer before it has spread to the lymph nodes in about 80% of the women evaluated. This increases the chance of survival to about 85% at 5 years.

About one-third of the abnormalities detected on screening mammograms will be found to be malignant when biopsy is performed. The probability of cancer on a screening mammogram is directly related to the Breast Imaging Reporting and Data System (BIRADS) assessment, and workup should be performed based on this classification. Women 20-40 years of age should have a breast examination as part of routine medical care every 2-3 years. Women over age 40 years should have annual breast examinations. The sensitivity of mammography varies from approximately 60%-90%. This sensitivity depends on several factors, including patient's age (breast density) and tumor size, location, and mammographic appearance. In young women with dense breasts, mammography is less sensitive than in older women with fatty breasts, in whom mammography can detect at least 90% of malignancies. Smaller tumors, particularly those without calcifications, are more difficult to detect, especially in dense breasts. The lack of sensitivity and the low incidence of breast cancer in young women have led to questions concerning the value of mammography for screening in women 40-50 years of age. The specificity of mammography in women under 50 years varies from about 30%-40% for nonpalpable mammographic abnormalities to 85%-90% for clinically evident malignancies. In 2009, the US Preventive Services Task Force recommended against routine screening mammography in this age range, and also recommended mammography be performed every 2 years for women between the ages of 50 and 74. The change in recommendation for screening women age 40-50 were particularly controversial in light of several meta-analyses that included women in this age group and showed a 15%-20% reduction in the relative risk of death from breast cancer with screening mammography. To add to the controversy, an analysis of the Surveillance, Epidemiology and End Results (SEER) database from 1976 to 2008 suggests that screening mammography has led to substantial increases in the number of breast cancer cases diagnosed but has only had a minor impact on the rate of women presenting with advanced disease. These data should all be taken into consideration when advising a patient regarding the utility of screening mammography. The American Cancer Society continues to recommend yearly mammography for women beginning at the age of 40, continuing as long as good health lasts.

B. Clinical Breast Examination and Self-Examination

Breast self-examination (BSE) has not been shown to improve survival. Because of the lack of strong evidence demonstrating value, the American Cancer Society no longer recommends monthly BSE. The recommendation is that patients be made aware of the potential benefits, limitations, and harms (increased biopsies or false-positive results) associated with BSE. Women who choose to perform BSE should be advised regarding the proper technique. Premenopausal women should perform the examination 7-8 days after the start of the menstrual period. First, breasts should be inspected before a mirror with the hands at the sides, overhead, and pressed firmly on the hips to contract the pectoralis muscles causing masses, asymmetry of breasts, and slight dimpling of the skin to become apparent. Next, in a supine position, each breast should be carefully palpated with the fingers of the opposite hand. Some women discover small breast lumps more readily when their skin is moist while bathing or showering. While BSE is not a recommended practice, patients should recognize and report any breast changes to their clinicians as it remains an important facet of proactive care. A small number of studies have reported a reduction in breast cancer mortality with screening clinical breast examination (CBE). While the evidence is only fair, in contrast to BSE, the ACS recommends CBE every 3 years in women ages 20-39 and annually starting at the age of 40.

C. Imaging

Mammography is the most reliable means of detecting breast cancer before a mass can be palpated. Most slowly growing cancers can be identified by mammography at least 2 years before reaching a size detectable by palpation. Film screen mammography delivers < 0.4 cGy to the mid-breast per view. Although full-field digital mammography provides an easier method to maintain and review mammograms, it has not been proven that it provides better images or increases detection rates more than film mammography. In subset analysis of a large study, digital mammography seemed slightly superior in women with dense breasts. Computer-assisted detection has not shown any increase in detection of cancers.

Calcifications are the most easily recognized mammographic abnormality. The most common findings associated with carcinoma of the breast are clustered pleomorphic microcalcifications. Such calcifications are usually at least five to eight in number, aggregated in one part of the breast and differing from each other in size and shape, often including branched or V- or Y-shaped configurations. There may be an associated mammographic mass density or, at times, only a mass density with no calcifications. Such a density usually has irregular or ill-defined borders and may lead to architectural distortion within the breast but may be subtle and difficult to detect.

Indications for mammography are as follows: (1) to screen at regular intervals asymptomatic women at high risk for developing breast cancer (see above); (2) to evaluate each breast when a diagnosis of potentially curable breast cancer has been made, and at regular intervals thereafter; (3) to evaluate a questionable or ill-defined breast mass or other suspicious change in the breast; (4) to search for an occult breast cancer in a woman with metastatic disease in axillary nodes or elsewhere from an unknown primary; (5) to screen women prior to cosmetic operations or prior to biopsy of a mass, to examine for an unsuspected cancer; (6) to monitor those women with breast cancer who have been treated with breast-conserving surgery and radiation; and (7) to monitor the contralateral breast in those women with breast cancer treated with mastectomy.

Patients with a dominant or suspicious mass must undergo biopsy despite mammographic findings. The mammogram should be obtained prior to biopsy so that other suspicious areas can be noted and the contralateral breast can be evaluated. Mammography is never a substitute for biopsy because it may not reveal clinical cancer, especially in a very dense breast, as may be seen in young women with fibrocystic changes, and may not reveal medullary cancers.

Communication and documentation among the patient, the referring practitioner, and the interpreting physician are critical for high-quality screening and diagnostic mammography. The patient should be told about *how* she will receive timely results of her mammogram; that mammography does not “rule out” cancer; and that she may receive a correlative examination such as ultrasound at the mammography facility if referred for a suspicious lesion. She should also be aware of the technique and need for breast compression and that this may be uncomfortable. The mammography facility should be informed in writing by the clinician of abnormal physical examination findings. The Agency for Health Care Policy and Research (AHCPR) Clinical Practice Guidelines strongly recommend that all mammography reports be communicated in writing to the patient and referring practitioner.

Magnetic resonance imaging (MRI) and ultrasound may be useful screening modalities in women who are at high risk for breast cancer but not for the general population. The sensitivity of MRI is much higher than mammography; however, the specificity is significantly lower and this results in multiple unnecessary biopsies. The increased sensitivity despite decreased specificity may be considered a reasonable trade-off for those at increased risk for developing breast cancer but not for normal-risk population. In 2009, the National Comprehensive Cancer Network (NCCN) guidelines recommended MRI in addition to screening mammography for high-risk women, including those with *BRCA1/2* mutations, those who have a lifetime risk of breast cancer of $> 20\%$, and those with a personal history of LCIS. Women who received radiation therapy to the chest in their teens

or twenties are also known to be at high risk for developing breast cancer and screening MRI may be considered in addition to mammography. MRI is useful in women with breast implants to determine the character of a lesion present in the breast and to search for implant rupture and at times is helpful in patients with prior lumpectomy and radiation.

► Clinical Findings Associated With Early Detection of Breast Cancer

A. Symptoms and Signs

The presenting complaint in about 70% of patients with breast cancer is a lump (usually painless) in the breast. About 90% of these breast masses are discovered by the patient. Less frequent symptoms are breast pain; nipple discharge; erosion, retraction, enlargement, or itching of the nipple; and redness, generalized hardness, enlargement, or shrinking of the breast. Rarely, an axillary mass or swelling of the arm may be the first symptom. Back or bone pain, jaundice, or weight loss may be the result of systemic metastases, but these symptoms are rarely seen on initial presentation.

The relative frequency of carcinoma in various anatomic sites in the breast is shown in Figure 17-2.

Inspection of the breast is the first step in physical examination and should be carried out with the patient sitting, arms at her sides, and then overhead. Abnormal variations in breast size and contour, minimal nipple retraction, and slight edema, redness or retraction of the skin can be identified (Figure 17-3). Asymmetry of the breasts and retraction or dimpling of the skin can often be accentuated by having

▲ **FIGURE 17-2.** Frequency of breast carcinoma at various anatomic sites.

the patient raise her arms overhead or press her hands on her hips to contract the pectoralis muscles. Axillary and supraclavicular areas should be thoroughly palpated for enlarged nodes with the patient sitting (Figure 17-4). Palpation of the breast for masses or other changes should be performed with the patient both seated and supine with the arm abducted

▲ **Figure 17-3.** Peau d'orange sign (resemblance to the skin of an orange due to lymphedema) in advanced breast cancer. (Copyright Richard P. Usatine, MD; from Usatine RP, Smith MA, Mayeaux EJ Jr, Chumley H. *The Color Atlas of Family Medicine*. 2nd ed. New York, NY: McGraw-Hill; 2013)

▲ **Figure 17-4.** Palpation of axillary region for enlarged lymph nodes.

(Figure 17-5). Palpation with a rotary motion of the examiner's fingers as well as a horizontal stripping motion has been recommended.

Breast cancer usually consists of a nontender, firm or hard mass with poorly delineated margins (caused by local infiltration). Very small (1-2 mm) erosions of the nipple epithelium may be the only manifestation of Paget disease of the breast. Watery, serous, or bloody discharge from the nipple is an occasional early sign but is more often associated with benign disease.

A small lesion, less than 1 cm in diameter, may be difficult or impossible for the examiner to feel but may be discovered by the patient. She should always be asked to demonstrate the location of the mass; if the practitioner fails

▲ **Figure 17-5.** Palpation of breasts. Palpation is performed with the patient supine and arm abducted.

to confirm the patient's suspicions and imaging studies are normal, the examination should be repeated in 2-3 months, preferably 1-2 weeks after the onset of menses. During the premenstrual phase of the cycle, increased innocuous nodularity may suggest neoplasm or may obscure an underlying lesion. If there is any question regarding the nature of an abnormality under these circumstances, the patient should be asked to return after her menses. Ultrasound is often valuable and mammography essential when an area is felt by the patient to be abnormal but the physician feels no mass. MRI may be considered, but the lack of specificity should be discussed by the clinician and the patient. MRI should not be used to rule out cancer because MRI has a false-negative rate of about 3%-5%. Although lower than mammography, this false-negative rate cannot permit safe elimination of the possibility of cancer. False negatives are more likely seen in infiltrating lobular carcinomas and DCIS.

Metastases tend to involve regional lymph nodes, which may be palpable. One or two movable, nontender, not particularly firm axillary lymph nodes 5 mm or less in diameter are frequently present and are generally of no significance. Firm or hard nodes larger than 1 cm are typical of metastases. Axillary nodes that are matted or fixed to skin or deep structures indicate advanced disease (at least stage III). On the other hand, if the examiner thinks that the axillary nodes are involved, that impression will be borne out by histologic section in about 85% of cases. The incidence of positive axillary nodes increases with the size of the primary tumor. Noninvasive cancers (*in situ*) do not metastasize. Metastases are present in about 30% of patients with clinically negative nodes.

In most cases, no nodes are palpable in the supraclavicular fossa. Firm or hard nodes of any size in this location or just beneath the clavicle should be biopsied. Ipsilateral supraclavicular or infraclavicular nodes containing cancer indicate that the tumor is in an advanced stage (stage III or IV). Edema of the ipsilateral arm, commonly caused by metastatic infiltration of regional lymphatics, is also a sign of advanced cancer.

B. Laboratory Findings

Liver or bone metastases may be associated with elevation of serum alkaline phosphatase. Hypercalcemia is an occasional important finding in advanced cancer of the breast. Carcinoembryonic antigen (CEA) and CA 15-3 or CA 27-29 may be used as markers for recurrent breast cancer but are not helpful in diagnosing early lesions. Investigational breast cancer markers through proteomics and hormone assays may prove to be helpful in early detection or evaluation of prognosis.

C. Imaging for Metastases

For patients with suspicious symptoms or signs (bone pain, abdominal symptoms, elevated liver enzymes) or

locally advanced disease (clinically abnormal lymph nodes or large primary tumors), staging scans are indicated prior to surgery or systemic therapy. Chest imaging with CT or radiographs may be done to evaluate for pulmonary metastases. Abdominal imaging with CT or ultrasound may be obtained to evaluate for liver metastases. Bone scans using ^{99m}Tc -labeled phosphates or phosphonates are more sensitive than skeletal radiographs in detecting metastatic breast cancer. Bone scanning has not proved to be of clinical value as a routine preoperative test in the absence of symptoms, physical findings, or abnormal alkaline phosphatase or calcium levels. The frequency of abnormal findings on bone scan parallels the status of the axillary lymph nodes on pathologic examination. Positron emission tomography (PET) scanning alone or combined with CT (PET-CT) is effective for detecting soft tissue or visceral metastases in patients with symptoms or signs of metastatic disease.

D. Diagnostic Tests

1. Biopsy—The diagnosis of breast cancer depends ultimately on examination of tissue or cells removed by biopsy. Treatment should never be undertaken without an unequivocal histologic or cytologic diagnosis of cancer. The safest course is biopsy examination of all suspicious lesions found on physical examination or mammography, or both. About 60% of lesions clinically thought to be cancer prove on biopsy to be benign, while about 30% of clinically benign lesions are found to be malignant. These findings demonstrate the fallibility of clinical judgment and the necessity for biopsy.

All breast masses require a histologic diagnosis with one probable exception, a nonsuspicious, presumably fibrocystic mass, in a premenopausal woman. Rather, these masses can be observed through one or two menstrual cycles. However, if the mass is not cystic and does not completely resolve during this time, it must be biopsied. Figures 17–6 and 17–7 present algorithms for management of breast masses in premenopausal and postmenopausal patients.

The simplest biopsy method is needle biopsy, either by aspiration of tumor cells (FNA cytology) or by obtaining a small core of tissue with a hollow needle (core biopsy).

FNA cytology is a useful technique whereby cells are aspirated with a small needle and examined cytologically. This technique can be performed easily with virtually no morbidity and is much less expensive than excisional or open biopsy. The main disadvantages are that it requires a pathologist skilled in the cytologic diagnosis of breast cancer and it is subject to sampling problems, particularly because deep lesions may be missed. Furthermore, noninvasive cancers usually cannot be distinguished from invasive cancers and immunohistochemical tests to determine expression of hormone receptors and the amplification of the HER2

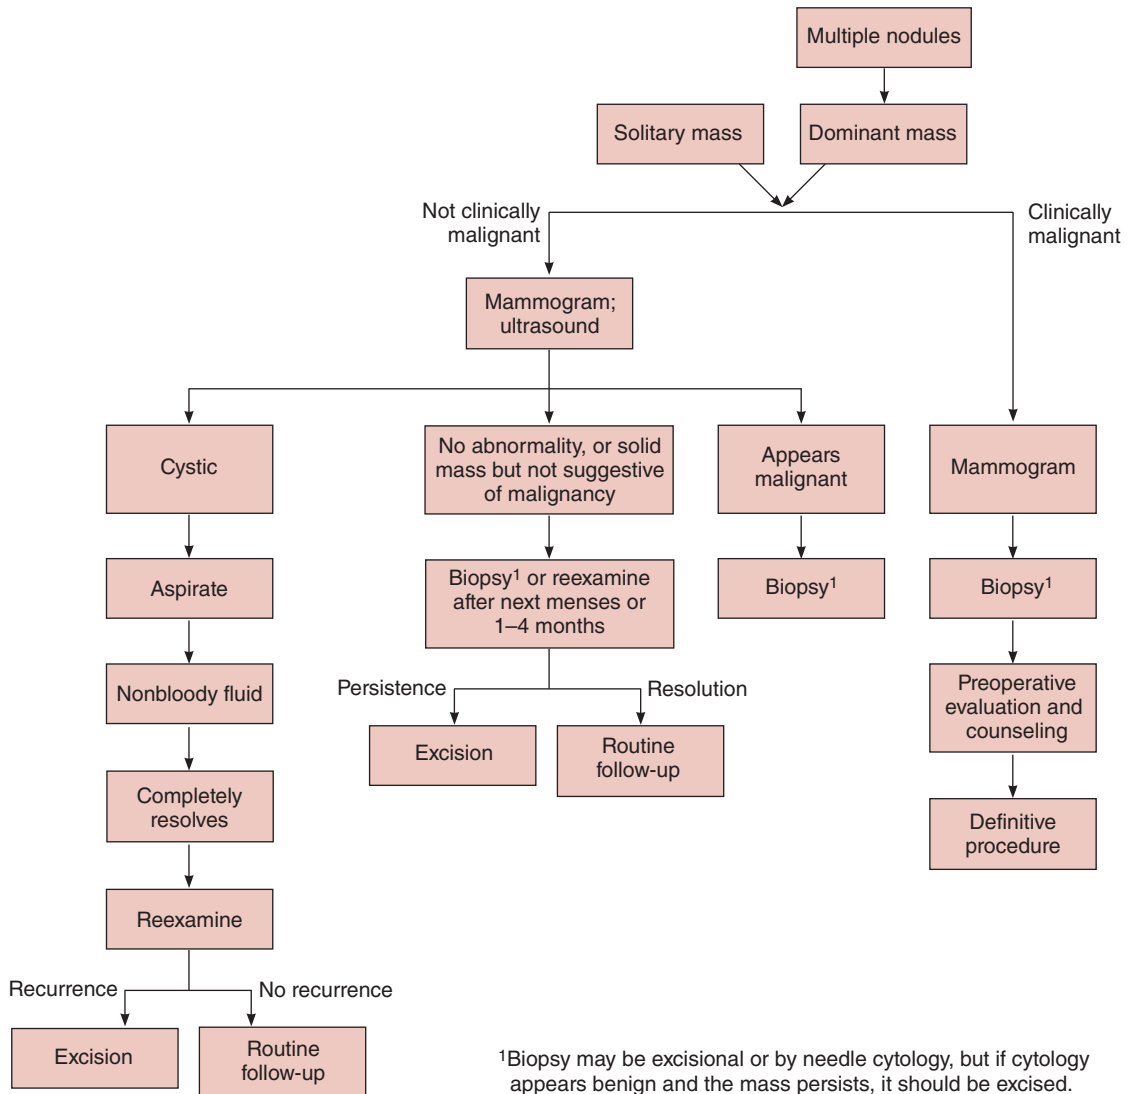

oncogene cannot be reliably performed on FNA biopsies. The incidence of false-positive diagnoses is extremely low, perhaps 1%-2%. The false-negative rate is as high as 10%. Most experienced clinicians would not leave a suspicious dominant mass in the breast even when FNA cytology is negative unless the clinical diagnosis, breast imaging studies, and cytologic studies were all in agreement, such as a fibrocystic lesion or fibroadenoma.

Large-needle (core needle) biopsy removes a core of tissue with a large cutting needle and is the diagnostic procedure of choice for both palpable and image-detected abnormalities. Hand-held biopsy devices make large-core needle biopsy of a palpable mass easy and cost effective in the office with local anesthesia. As in the case of any needle biopsy, the main problem is sampling error due to improper positioning of the needle, giving rise to a false-negative test result. This is extremely unusual with image-guided biopsies. Core biopsy has the advantage that tumor markers, such as estrogen receptor (ER), progesterone receptor (PR), and HER2 overexpression can be performed on cores of tissue.

Open biopsy under local anesthesia as a separate procedure prior to deciding upon definitive treatment is becoming less common with the increasing use of core needle biopsy. Needle biopsy, when positive, offers a more rapid approach with less expense and morbidity, but when nondiagnostic it must be followed by open biopsy. It generally consists of an excisional biopsy, which is done through an incision with the intent to remove the entire abnormality, not simply a sample. Additional evaluation for metastatic disease and therapeutic options can be discussed with the patient after the histologic or cytologic diagnosis of cancer has been established. As an alternative in highly suspicious circumstances, the diagnosis may be made on frozen section of tissue obtained by open biopsy under general anesthesia. If the frozen section is positive, the surgeon can proceed immediately with the definitive operation. This one-step method is rarely used today except when a cytologic study has suggested cancer but is not diagnostic and there is a high clinical suspicion of malignancy in a patient well prepared for the diagnosis of cancer and its treatment options.

In general, the two-step approach—outpatient biopsy followed by definitive operation at a later date—is preferred in the diagnosis and treatment of breast cancer, because patients can be given time to adjust to the diagnosis of cancer, can consider alternative forms of therapy, and can seek a second opinion if they wish. There is no adverse effect from the few week delay of the two-step procedure.

2. Ultrasonography—Ultrasonography is performed primarily to differentiate cystic from solid lesions but may show signs suggestive of carcinoma. Ultrasonography may show

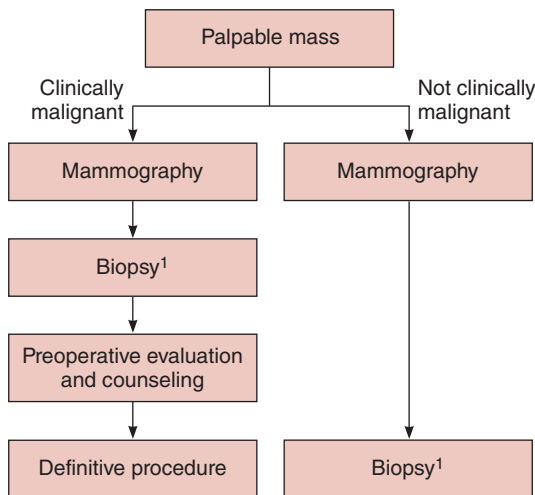

▲ **Figure 17-6.** Evaluation of breast masses in premenopausal women. (Adapted, with permission, from Chang S, Haigh PI, Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. *Practical Gynecologic Oncology*, 4th ed. LWW, 2004.)

an irregular mass within a cyst in the rare case of intracystic carcinoma. If a tumor is palpable and feels like a cyst, an 18-gauge needle can be used to aspirate the fluid and make the diagnosis of cyst. If a cyst is aspirated and the fluid is nonbloody, it does not have to be examined cytologically. If the mass does not recur, no further diagnostic test is necessary. Nonpalpable mammographic densities that appear benign should be investigated with ultrasound to determine

whether the lesion is cystic or solid. These may even be needle biopsied with ultrasound guidance.

3. Mammography—When a suspicious abnormality is identified by mammography alone and cannot be palpated by the clinician, the lesion should be biopsied under mammographic guidance. In the **computerized stereotactic guided core needle** technique, a biopsy needle is inserted

¹Biopsy may be excisional or by needle cytology, but if cytology appears benign and the mass persists, it should be excised.

▲ **Figure 17-7.** Evaluation of breast masses in postmenopausal women. (Adapted, with permission, from Chang S, Haigh PI, Giuliano AE. Breast disease. In: Berek JS, Hacker NF, eds. *Practical Gynecologic Oncology*, 4th ed. LWW, 2004.)

into the lesion with mammographic guidance, and a core of tissue for histologic examination can then be examined. Vacuum assistance increases the amount of tissue obtained and improves diagnosis.

Mammographic localization biopsy is performed by obtaining a mammogram in two perpendicular views and placing a needle or hook-wire near the abnormality so that the surgeon can use the metal needle or wire as a guide during operation to locate the lesion. After mammography confirms the position of the needle in relation to the lesion, an incision is made and the subcutaneous tissue is dissected until the needle is identified. Often, the abnormality cannot even be palpated through the incision—as is the case with microcalcifications—and thus it is essential to obtain a mammogram of the specimen to document that the lesion was excised. At that time, a second marker needle can further localize the lesion for the pathologist. Stereotactic core needle biopsies have proved equivalent to mammographic localization biopsies. Core biopsy is preferable to mammographic localization for accessible lesions since an operation can be avoided. A metal clip should be placed after any image-guided core biopsy to facilitate finding the site of the lesion if subsequent treatment is necessary.

4. Other imaging modalities—Other modalities of breast imaging have been investigated for diagnostic purposes. Automated breast ultrasonography is useful in distinguishing cystic from solid lesions but should be used only as a supplement to physical examination and mammography. Ductography may be useful to define the site of a lesion causing a bloody discharge, but since biopsy is almost always indicated, ductography may be omitted and the blood-filled nipple system excised. Ductoscopy has shown some promise in identifying intraductal lesions, especially in the case of pathologic nipple discharge, but in practice, this technique is rarely used. MRI is highly sensitive but not specific and should not be used for screening except in highly selective cases. For example, MRI is useful in differentiating scar from recurrence postlumpectomy and may be valuable to screen high-risk women (eg, women with *BRCA* mutations). It may also be of value to examine for multicentricity when there is a known primary cancer; to examine the contralateral breast in women with cancer; to examine the extent of cancer, especially lobular carcinomas; or to determine the response to neoadjuvant chemotherapy. Moreover, MRI-detected suspicious findings that are not seen on mammogram or ultrasound may be biopsied under MRI guidance. PET scanning does not appear useful in evaluating the breast itself but is useful to examine for distant metastases.

5. Cytology—Cytologic examination of nipple discharge or cyst fluid may be helpful on rare occasions. As a rule, mammography (or ductography) and breast biopsy are required when nipple discharge or cyst fluid is bloody or cytologically questionable. Ductal lavage, a technique that washes individual duct systems with saline and loosens epithelial cells for cytologic evaluation, is being evaluated as a risk assessment tool but appears to be of little value.

► Differential Diagnosis

The lesions to be considered most often in the differential diagnosis of breast cancer are the following, in descending order of frequency: fibrocystic condition of the breast, fibroadenoma, intraductal papilloma, lipoma, and fat necrosis.

► Staging

The American Joint Committee on Cancer and the International Union Against Cancer have agreed on a TNM (tumor, regional lymph nodes, distant metastases) staging system for breast cancer. Using the TNM staging system enhances communication between researchers and clinicians. Table 17-3 outlines the TNM classification.

Table 17–3. TNM staging for breast cancer.

Primary Tumor (T)	
Definitions for classifying the primary tumor (T) are the same for clinical and for pathologic classification. If the measurement is made by physical examination, the examiner will use the major headings (T1, T2, or T3). If other measurements, such as mammographic or pathologic measurements, are used, the subsets of T1 can be used. Tumors should be measured to the nearest 0.1 cm increment.	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Tis (DCIS)	Ductal carcinoma in situ
Tis (LCIS)	Lobular carcinoma in situ
Tis (Paget)	Paget disease of the nipple with no tumor
<i>Note:</i> Paget disease associated with a tumor is classified according to the size of the tumor.	
T1	Tumor 2 cm or less in greatest dimension
T1mic	Microinvasion 0.1 cm or less in greatest dimension
T1a	Tumor more than 0.1 cm but not more than 0.5 cm in greatest dimension
T1b	Tumor more than 0.5 cm but not more than 1 cm in greatest dimension
T1c	Tumor more than 1 cm but not more than 2 cm in greatest dimension
T2	Tumor more than 2 cm but not more than 5 cm in greatest dimension
T3	Tumor more than 5 cm in greatest dimension
T4	Tumor of any size with direct extension to: (a) chest wall; or (b) skin, only as described below
T4a	Extension to chest wall, not including pectoralis muscle
T4b	Edema (including peau d'orange [Figure 17–3]) or ulceration of the skin of the breast, or satellite skin nodules confined to the same breast
T4c	Both T4a and T4b
T4d	Inflammatory carcinoma
Regional Lymph Nodes (N)	
<i>Clinical</i>	
NX	Regional lymph nodes cannot be assessed (eg, previously removed)
N0	No regional lymph node metastasis
N1	Metastasis in movable ipsilateral axillary lymph node(s)
N2	Metastases in ipsilateral axillary lymph nodes fixed or matted, or in clinically apparent ¹ ipsilateral internal mammary nodes in the <i>absence</i> of clinically evident axillary lymph node metastasis
N2a	Metastasis in ipsilateral axillary lymph nodes fixed to one another (matted) or to other structures
N2b	Metastasis only in clinically apparent ¹ ipsilateral internal mammary nodes and in the <i>absence</i> of clinically evident axillary lymph node metastasis
N3	Metastasis in ipsilateral infraclavicular lymph node(s) with or without axillary lymph node involvement, or in clinically apparent ¹ ipsilateral internal mammary lymph node(s) and in the <i>presence</i> of clinically evident axillary lymph node metastasis; or metastasis in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastasis in ipsilateral infraclavicular lymph node(s)
N3b	Metastasis in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastasis in ipsilateral supraclavicular lymph node(s)
<i>Regional Lymph Nodes (pN)²</i>	
Pnx	Regional lymph nodes cannot be assessed (eg, previously removed, or not removed for pathologic study)
pN0	No regional lymph node metastasis histologically, no additional examination for isolated tumor cells

(continued)

Table 17–3. TNM staging for breast cancer. (Continued)

Note: Isolated tumor cells (ITC) are defined as single tumor cells or small cell clusters not > 0.2 mm, usually detected only by immunohistochemical (IHC) or molecular methods but which may be verified on hematoxylin and eosin stains. ITCs do not usually show evidence of malignant activity, eg, proliferation or stromal reaction.

pN0(i ⁻)	No regional lymph node metastasis histologically, negative IHC
pN0(i ⁺)	No regional lymph node metastasis histologically, positive IHC, no IHC cluster > 0.2 mm
pN0(mol ⁻)	No regional lymph node metastasis histologically, negative molecular findings (RT-PCR) ³
pN0(mol ⁺)	No regional lymph node metastasis histologically, positive molecular findings (RT-PCR) ³
pN1	Metastasis in one to three axillary lymph nodes, and/or in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent ⁴
pN1mi	Micrometastasis (> 0.2 mm, none > 2.0 mm)
pN1a	Metastasis in one to three axillary lymph nodes
pN1b	Metastasis in internal mammary nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent ⁴
pN1c	Metastasis in one to three axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent. ⁴ (If associated with greater than three positive axillary lymph nodes, the internal mammary nodes are classified as pN3b to reflect increased tumor burden)
pN2	Metastasis in four to nine axillary lymph nodes, or in clinically apparent ¹ internal mammary lymph nodes in the absence of axillary lymph node metastasis
pN2a	Metastasis in four to nine axillary lymph nodes (at least one tumor deposit > 2.0 mm)
pN2b	Metastasis in clinically apparent ¹ internal mammary lymph nodes in the absence of axillary lymph node metastasis
pN3	Metastasis in 10 or more axillary lymph nodes, or in infraclavicular lymph nodes, or in clinically apparent ¹ ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes; or in more than three axillary lymph nodes with clinically negative microscopic metastasis in internal mammary lymph nodes; or in ipsilateral supraclavicular lymph nodes
pN3a	Metastasis in 10 or more axillary lymph nodes (at least one tumor deposit > 2.0 mm), or metastasis to the infraclavicular lymph nodes
pN3b	Metastasis in clinically apparent ¹ ipsilateral internal mammary lymph nodes in the presence of one or more positive axillary lymph nodes; or in more than three axillary lymph nodes and in internal mammary lymph nodes with microscopic disease detected by sentinel lymph node dissection but not clinically apparent ⁴
pN3c	Metastasis in ipsilateral supraclavicular lymph nodes

Distant Metastasis (M)

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Stage Grouping

Stage 0	Tis	N0	M0
Stage 1	T1 ⁵	N0	M0
Stage IIA	T0	N1	M0
	T1 ⁵	N1	M0

Table 17-3. TNM staging for breast cancer. (Continued)

Stage IIIB	T4	N0	M0
	T4	N1	M0
	T4	N2	M0
Stage IIIC	Any T	N3	M0
Stage IV	Any T	Any N	M1

Note: Stage designation may be changed if postsurgical imaging studies reveal the presence of distant metastases, provided that the studies are carried out within 4 months of diagnosis in the absence of disease progression and provided that the patient has not received neoadjuvant therapy.

¹Clinically apparent is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination or grossly visible pathologically.

²Classification is based on axillary lymph node dissection with or without sentinel lymph node dissection. Classification based solely on sentinel lymph node dissection without subsequent axillary lymph node dissection is designated (sn) for "sentinel node," eg, pN0(i+)(sn).

³RT-PCR, reverse transcriptase/polymerase chain reaction.

⁴Not clinically apparent is defined as not detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination.

⁵T1 includes T1mic.

► Pathologic Types

Numerous pathologic subtypes of breast cancer can be identified histologically (Table 17-4).

Except for the *in situ* cancers, the histologic subtypes have only a slight bearing on prognosis when outcomes are compared after accurate staging. The noninvasive cancers by definition are confined by the basement membrane of the ducts and lack the ability to spread. Histologic parameters for invasive cancers, including lymphovascular invasion and tumor grade, have been shown to be of prognostic value. Immunohistochemical analysis for expression of hormone receptors and for overexpression of HER2 in the primary tumor offers prognostic and therapeutic information.

SPECIAL CLINICAL FORMS OF BREAST CANCER

► Paget Carcinoma

Paget carcinoma is not common (about 1% of all breast cancers). Over 85% of cases are associated with an underlying invasive or noninvasive cancer, usually a well-differentiated infiltrating ductal carcinoma or a DCIS. The ducts of the nipple epithelium are infiltrated, but gross nipple changes are often minimal, and a tumor mass may not be palpable.

Because the nipple changes appear innocuous, the diagnosis is frequently missed. The first symptom is often itching or burning of the nipple, with superficial erosion or ulceration. These are often diagnosed and treated as dermatitis or bacterial infection, leading to delay or failure in detection. The diagnosis is established by biopsy of the area of erosion. When the lesion consists of nipple changes only, the incidence of axillary metastases is less than 5%, and the

prognosis is excellent. When a breast mass is also present, the incidence of axillary metastases rises, with an associated marked decrease in prospects for cure by surgical or other treatment.

Table 17-4. Histologic types of breast cancer.

Type	Frequency of Occurrence (%)
Infiltrating ductal (not otherwise specified)	80-90
Medullary	5-8
Colloid (mucinous)	2-4
Tubular	1-2
Papillary	1-2
Invasive lobular	6-8
Noninvasive	4-6
Intraductal	2-3
Lobular in situ	2-3
Rare cancers	< 1
Juvenile (secretory)	
Adenoid cystic	
Epidermoid	
Sudoriferous	

► Inflammatory Carcinoma

This is the most malignant form of breast cancer and constitutes less than 3% of all cases. The clinical findings consist of a rapidly growing, sometimes painful mass that enlarges the breast. The overlying skin becomes erythematous, edematous, and warm. Often there is no distinct mass, since the tumor infiltrates the involved breast diffusely. The inflammatory changes, often mistaken for an infection, are caused by carcinomatous invasion of the subdermal lymphatics, with resulting edema and hyperemia. If the clinician suspects infection but the lesion does not respond rapidly (1-2 weeks) to antibiotics, biopsy should be performed. The diagnosis should be made when the redness involves more than one-third of the skin over the breast and biopsy shows infiltrating carcinoma with invasion of the subdermal lymphatics. Metastases tend to occur early and widely, and for this reason inflammatory carcinoma is rarely curable. Radiation, hormone therapy, and chemotherapy are the measures most likely to be of value rather than operation. Mastectomy is indicated when chemotherapy and radiation have resulted in clinical remission with no evidence of distant metastases. In these cases, residual disease in the breast may be eradicated.

► Breast Cancer Occurring During Pregnancy or Lactation

Breast cancer complicates approximately 1 in 3000 pregnancies. The diagnosis is frequently delayed, because physiologic changes in the breast may obscure the lesion and screening mammography is not done in young or pregnant women. When the cancer is confined to the breast, the 5-year survival rate is about 70%. In 60%-70% of patients, axillary metastases are already present, conferring a 5-year survival rate of 30%-40%. A retrospective analysis of women who were younger than 36 years when breast cancer was diagnosed showed that while women with pregnancy-associated breast cancer were more frequently diagnosed with later stage breast cancer, they had similar rates of locoregional recurrence, distant metastases, and overall survival as women with nonpregnancy-associated breast cancer. It is thus important for primary care and reproductive specialists to aggressively workup any breast abnormality discovered in a pregnant woman. Pregnancy (or lactation) is not a contraindication to operation or treatment, and therapy should be based on the stage of the disease as in the nonpregnant (or nonlactating) woman. Overall survival rates have improved, since cancers are now diagnosed in pregnant women earlier than in the past and treatment has improved. Breast-conserving surgery may be performed and chemotherapy given even during the pregnancy.

► Bilateral Breast Cancer

Bilateral breast cancer occurs in less than 5% of cases, but there is as high as a 20%-25% incidence of later occurrence

of cancer in the second breast. Bilaterality occurs more often in familial breast cancer, in women under age 50 years, and when the tumor in the primary breast is lobular. The incidence of second breast cancers increases directly with the length of time the patient is alive after her first cancer—about 1%-2% per year.

In patients with breast cancer, mammography should be performed before primary treatment and at regular intervals thereafter, to search for occult cancer in the opposite breast or conserved ipsilateral breast. MRI may be useful in this high-risk group.

► Noninvasive Cancer

Noninvasive cancer can occur within the ducts (DCIS) or lobules (LCIS). DCIS tends to be unilateral and most often progresses to invasive cancer if untreated. In approximately 40%-60% of women who have DCIS treated with biopsy alone, invasive cancer develops within the same breast. LCIS, although thought to be a premalignant lesion or a risk factor for breast cancer, in fact may behave like DCIS. In a 2004 analysis of multiple NSABP studies, invasive lobular breast cancer not only developed in patients with LCIS but it developed in the same breast and indexed location as the original LCIS. Although more research needs to be done in this area, the invasive potential of LCIS is being reconsidered. Higher grade and pleomorphic LCIS may behave more like DCIS, and may be associated with invasive carcinoma. For this reason, some surgeons are now recommending that pleomorphic LCIS be surgically removed with clear margins.

The treatment of intraductal lesions is controversial. DCIS can be treated by wide excision with or without radiation therapy or with total mastectomy. Conservative management is advised in patients with small lesions amenable to lumpectomy. Although research is defining the malignant potential of LCIS, it can be managed with observation. Patients unwilling to accept the increased risk of breast cancer may be offered surgical excision of the area in question or bilateral total mastectomy. Currently, the accepted standard of care offers the alternative of chemoprevention, which is effective in preventing invasive breast cancer in both LCIS and DCIS that has been completely excised. Axillary metastases from *in situ* cancers should not occur unless there is an occult invasive cancer. Sentinel node biopsy may be indicated in large DCIS treated with mastectomy.

BIOMARKERS & GENE EXPRESSION PROFILING

Determining the ER, PR, and HER2 status of the tumor at the time of diagnosis of early breast cancer and, if possible, at the time of recurrence is critical, both to gauge a patient's prognosis and to determine the best treatment regimen. In addition to ER status and PR status, the rate at which tumor divides (assessed by an immunohistochemical stain for Ki-67) and the grade and differentiation of the cells are also important prognostic factors. These markers may be obtained on core biopsy or surgical specimens. Patients whose tumors are hormone receptor-positive tend to have a more indolent disease course than those whose tumors are receptor-negative. Moreover, treatment with an antihormonal agent is an essential component of therapy for hormone-receptor positive breast cancer at any stage. While up to 60% of patients with metastatic breast cancer will respond to hormonal manipulation if their tumors are ER-positive, less than 5% of patients with metastatic, ER-negative tumors will respond.

Another key element in determining treatment and prognosis is the amount of the HER2 oncogene present in the cancer. HER2 overexpression is measured by an immunohistochemical assay that is scored using a numerical system: 0 and 1+ are considered negative for overexpression, 2+ is borderline/indeterminate, and 3+ is overexpression. In the case of 2+ expression, fluorescence in situ hybridization (FISH) is recommended to more accurately assess HER2 amplification. According to the College of American Pathologists, a FISH score of less than 1.8 is negative for amplification, 1.8-2.2 is indeterminate, and greater than 2.2 is amplified. The presence of HER2 amplification and overexpression is of prognostic significance and predicts the response to trastuzumab.

Individually these biomarkers are predictive and thus provide insight to guide appropriate therapy. Moreover, when combined they provide useful information regarding risk of recurrence and prognosis. In general, tumors that lack expression of HER2, ER, and PR ("triple negative") have a higher risk of recurrence and metastases and are associated with a worse survival compared with other types. Neither endocrine therapy nor HER2-targeted agents are useful for this type of breast cancer, leaving chemotherapy as the only treatment option. In contrast, patients with early stage, hormone receptor-positive breast cancer may not benefit

from the addition of chemotherapy to hormonal treatments. Several molecular tests have been developed to assess risk of recurrence and to predict which patients are most likely to benefit from chemotherapy. Oncotype DX (Genomic Health) evaluates the expression of 21 genes relating to ER, PR, HER2, and proliferation in a tumor specimen and categorizes a patient's risk of recurrence (recurrence score) as high, intermediate, or low risk. In addition to providing prognostic information, the test also has predictive value since studies have shown that patients in the high-risk category are most likely to respond to chemotherapy. This test is primarily indicated for ER-positive, node-negative tumors but at least one study has shown that it may also have value in node-positive tumors. Centralized testing for ER, PR, HER2, and Ki67 by standard immunohistochemical techniques is able to provide as much prognostic information as Oncotype DX. Mammprint (Agendia) is another assay that is available for evaluating prognosis. This 70-gene signature is FDA-approved and may be performed on fresh frozen tumor tissue taken at the time of a patient's surgery. This test classifies patients into good and poor prognostic groups to predict clinical outcome and may be used on patients with hormone receptor positive or negative breast cancer. Several other assays are in development to better stratify patients based on risk assessment.

► Treatment: Curative

Clearly, not all breast cancer is systemic at the time of diagnosis. For this reason, a pessimistic attitude concerning the

management of breast cancer is unwarranted. Most patients with early breast cancer can be cured. Treatment with a curative intent is advised for clinical stage I, II, and III disease (see Tables 17–3 and 39–4). Patients with locally advanced (T3, T4) and even inflammatory tumors may be cured with multimodality therapy, but in most, palliation is all that can be expected. Treatment with palliative intent is appropriate for all patients with stage IV disease and for patients with unresectable local cancers.

A. Choice and Timing of Primary Therapy

The extent of disease and its biologic aggressiveness are the principal determinants of the outcome of primary therapy. Clinical and pathologic staging help in assessing extent of disease (Table 17–3), but each is to some extent imprecise. Other factors such as tumor grade, hormone receptor assays, and HER2 oncogene amplification are of prognostic value and are key to determining systemic therapy, but are not important in determining the type of local therapy.

Controversy has surrounded the choice of primary therapy of stages I, II, and III breast carcinoma. Currently, the standard of care for stage I, stage II, and most stage III cancer is surgical resection followed by adjuvant radiation or systemic therapy, or both, when indicated. Neoadjuvant therapy is becoming more popular since large tumors may be shrunk by chemotherapy prior to surgery, making some patients who require mastectomy candidates for lumpectomy. It is important for patients to understand all of the surgical options, including reconstructive options, prior to having surgery. Patients with large primary tumors, inflammatory cancer, or palpably enlarged lymph nodes should have staging scans performed to rule out distant metastatic disease prior to definitive surgery. In general, adjuvant systemic therapy is started when the breast has adequately healed, usually within 4–8 weeks after surgery. While no prospective studies have defined the appropriate timing of adjuvant chemotherapy, one retrospective population-based study has suggested that chemotherapy should be initiated within 12 weeks of surgery to avoid a compromise in relapse-free and overall survival.

B. Surgical Resection

1. Breast-conserving therapy—Multiple, large, randomized studies including the Milan and NSABP trials show that disease-free and overall survival rates are similar for patients with stage I and stage II breast cancer treated with partial mastectomy (breast-conserving lumpectomy) plus axillary dissection followed by radiation therapy and for those treated by modified radical mastectomy (total mastectomy plus axillary dissection).

Tumor size is a major consideration in determining the feasibility of breast conservation. The lumpectomy trial of the

NSABP randomized patients with tumors as large as 4 cm. To achieve an acceptable cosmetic result, the patient must have a breast of sufficient size to enable excision of a 4-cm tumor without considerable deformity. Therefore, large tumor size is only a relative contraindication. Subareolar tumors, also difficult to excise without deformity, are not contraindications to breast conservation. Clinically detectable multifocality is a relative contraindication to breast-conserving surgery, as is fixation to the chest wall or skin or involvement of the nipple or overlying skin. The patient—not the surgeon—should be the judge of what is cosmetically acceptable. Given the relatively high risk of poor outcome after radiation, concomitant scleroderma is a contraindication to breast-conserving surgery. A history of prior therapeutic radiation to the ipsilateral breast or chest wall (or both) is also a contraindication for breast conservation.

Axillary dissection is primarily used to properly stage cancer and plan radiation and systemic therapy. Intraoperative lymphatic mapping and sentinel node biopsy identify lymph nodes most likely to harbor metastases if present (Figure 17–8). Sentinel node biopsy is a reasonable alternative to axillary dissection in selected patients with invasive cancer. If sentinel node biopsy reveals no evidence of axillary metastases, it is highly likely that the remaining lymph nodes are free of disease and axillary dissection may be omitted. An important study from the American College of Surgeons Oncology group randomized women with sentinel node metastases to undergo completion of axillary dissection or to receive no further axillary treatment after lumpectomy; no difference in survival was found, showing that axillary dissection for selected node-positive women is not necessary. These results challenge standard treatment regimens.

▲ **Figure 17–8.** Sentinel node. (Used with permission from Giuliano AE.)

Breast-conserving surgery with radiation is the preferred form of treatment for patients with **early-stage breast cancer**. Despite the numerous randomized trials showing no survival benefit of mastectomy over breast-conserving partial mastectomy and irradiation, breast-conserving surgery still appears to be underutilized.

2. Mastectomy—Modified radical mastectomy is the standard therapy for most patients with early-stage breast cancer. This operation removes the entire breast, overlying skin, nipple, and areolar complex as well as the underlying pectoralis fascia with the axillary lymph nodes in continuity. The major advantage of modified radical mastectomy is that radiation therapy may not be necessary, although radiation may be used when lymph nodes are involved with cancer or when the primary tumor is large (≥ 5 cm). The disadvantage of mastectomy is the cosmetic and psychological impact associated with breast loss. Radical mastectomy, which removes the underlying pectoralis muscle, should be performed rarely, if at all. Axillary node dissection is not indicated for noninfiltrating cancers because nodal metastases are rarely present. Skin-sparing and nipple-sparing mastectomy is currently gaining favor but is not appropriate for all patients. Breast-conserving surgery and radiation should be offered whenever possible, since most patients would prefer to save the breast. Breast reconstruction, immediate or delayed, should be discussed with patients who choose or require mastectomy. Patients should have an interview with a reconstructive plastic surgeon to discuss options prior to making a decision regarding reconstruction. Time is well spent preoperatively in educating the patient and family about these matters.

C. Radiotherapy

Radiotherapy after partial mastectomy consists of 5-7 weeks of five daily fractions to a total dose of 5000-6000 cGy. Most radiation oncologists use a boost dose to the cancer location. Early results of studies examining the utility and recurrence rates after intraoperative radiation or dose dense radiation in which the time course of radiation is shortened show promising results similar to standard techniques. Accelerated partial breast irradiation, in which only the portion of the breast from which the tumor was resected is irradiated for 1-2 weeks, appears effective in achieving local control. The American Society of Breast Surgeons Registry Trial reported that in 1440 patients treated with brachytherapy, the 3-year actuarial rate of ipsilateral breast cancer recurrence was 2.15% and no unexpected adverse events were seen. Long-term follow-up will be necessary as will results from ongoing randomized clinical trials comparing brachytherapy to standard external beam radiation.

Current studies suggest that radiotherapy after mastectomy may improve recurrence rates and survival in

patients with tumors 5 cm or more or positive lymph nodes. Researchers are also examining the utility of axillary irradiation as an alternative to axillary dissection in the clinically node-negative patient with sentinel node micrometastases. A Canadian trial (MA20) of postoperative nodal irradiation after lumpectomy and axillary dissection shows improved survival with nodal irradiation.

D. Adjuvant Systemic Therapy

The goal of systemic therapy, including hormone modulating drugs (endocrine therapy), cytotoxic chemotherapy, and the HER2-targeted agent trastuzumab, is to kill cancer cells that have escaped the breast and axillary lymph nodes as micrometastases before they become macrometastases (ie, stage IV cancer). Systemic therapy improves survival and is advocated for most patients with curable breast cancer. In practice, most medical oncologists are currently using adjuvant chemotherapy for patients with either node-positive or higher-risk (eg, hormone receptor-negative or HER2-positive) node-negative breast cancer and using endocrine therapy for all hormone receptor-positive invasive breast cancer unless contraindicated. Prognostic factors other than nodal status that are used to determine the patient's risks of recurrence are tumor size, ER and PR status, nuclear grade, histologic type, proliferative rate, oncogene expression (Table 17-5), and patient's age and menopausal status. In general, systemic chemotherapy decreases the chance of recurrence by about 30% and hormonal modulation

Table 17-5. Prognostic factors in node-negative breast cancer.

Prognostic Factors	Increased Recurrence	Decreased Recurrence
Size	T3, T2	T1, T0
Hormone receptors	Negative	Positive
DNA flow cytometry	Aneuploid	Diploid
Histologic grade	High	Low
Tumor labeling index	< 3%	> 3%
S phase fraction	> 5%	< 5%
Lymphatic or vascular invasion	Present	Absent
Cathepsin D	High	Low
HER-2/neu oncogene	High	Low
Epidermal growth factor receptor	High	Low

decreases the risk of recurrence by 40%-50% (for hormone receptor-positive cancer). Systemic chemotherapy is usually given sequentially, rather than concurrently with radiation. In terms of sequencing, typically chemotherapy is given before radiation and endocrine therapy is started concurrent with or after radiation therapy.

The long-term advantage of systemic therapy has been well established. All patients with invasive hormone receptor-positive tumors should consider the use of hormone-modulating therapy. Most patients with HER2-positive tumors should receive trastuzumab-containing chemotherapy regimens. In general, adjuvant systemic chemotherapy should not be given to women who have small node-negative breast cancers with favorable histologic findings and tumor markers. The ability to predict more accurately which patients with HER2-negative, hormone receptor-positive, lymph node-negative tumors should receive chemotherapy is improving with the advent of prognostic tools, such as Oncotype DX and mammaprint. These tests are undergoing prospective evaluation in two clinical trials (TAILORx and MINDACT).

1. Chemotherapy—The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) meta-analysis involving over 28,000 women enrolled in 60 trials of adjuvant polychemotherapy versus no chemotherapy demonstrated a significant beneficial impact of chemotherapy on clinical outcome in early breast cancer. This study showed that adjuvant chemotherapy reduces the risk of recurrence and breast cancer-specific mortality in all women but also showed that women under the age of 50 derive the greatest benefit. On the basis of the superiority of anthracycline-containing regimens in metastatic breast cancer, both doxorubicin and epirubicin have been studied extensively in the adjuvant setting. Studies comparing Adriamycin (doxorubicin) and cyclophosphamide (AC) or epirubicin and cyclophosphamide (EC) to cyclophosphamide-methotrexate-5-fluorouracil (CMF) have shown that treatments with anthracycline-containing regimens are at least as effective, and perhaps more effective, than treatment with CMF. The EBCTCG analysis including over 14,000 patients enrolled in trials comparing anthracycline-based regimens to CMF, showed a small but statistically significant improved disease-free and overall survival with the use of anthracycline-based regimens. It should be noted, however, that most of these studies included a mixed population of HER2-positive and HER2-negative breast cancer patients and were performed before the development of trastuzumab. Retrospective analyses of a number of these studies suggest that anthracyclines may be primarily effective in tumors with HER2 overexpression or alteration in the expression of topoisomerase IIa (the target of anthracyclines and close to the HER2 gene). Given this, for HER2-negative,

node-negative breast cancer, four cycles of AC or six cycles of CMF are probably equally effective.

When taxanes (T = paclitaxel and docetaxel) emerged in the 1990s, multiple trials were conducted to evaluate their use in combination with anthracycline-based regimens. The majority of these trials showed an improvement in disease-free survival and at least one showed an improvement in overall survival with the taxane-based regimen. A meta-analysis of taxane versus nontaxane anthracycline-based regimen trials showed an improvement in disease-free and overall survival for the taxane-based regimens.

Several regimens have been reported including AC followed by paclitaxel or docetaxel (AC-T), TAC (docetaxel concurrent with AC), 5-fluorouracil (F)EC-docetaxel, and FEC-paclitaxel. Results from CALGB 9741 showed that compared with a standard dose regimen, administration of "dose-dense" AC-P chemotherapy (that is, in an accelerated fashion, in which the frequency of administration is increased without changing total dose or duration) with granulocyte colony stimulating factor (G-CSF) support led to improved both disease-free (82% vs 75% at 4 years) and overall survival (92% vs 90%). Exploratory subset analysis suggested that patients with hormone receptor-negative tumors derived the most benefit from the dose-dense approach.

The US Oncology trial 9735 compared four cycles of AC with four cycles of taxotere (docetaxel) and cyclophosphamide (TC). With a median of 7 years follow-up, this study showed a statistically significantly improved disease-free survival and overall survival in the patients who received TC. Until this, no trial had compared a non-anthracycline taxane-based regimen to an anthracycline-based regimen.

An important ongoing study (US Oncology 06090) is prospectively evaluating whether anthracyclines add any incremental benefit to a taxane-based regimen by comparing six cycles of TAC to six cycles of TC in HER2-negative breast cancer patients. A third arm was added to evaluate the benefit of adding bevacizumab, a monoclonal antibody directed against vascular endothelial growth factor (VEGF), to TC. While awaiting the results of this trial, oncologists are faced with choosing from among the above treatment regimens for HER2-negative breast cancer. It is interesting to note a sharp decline in the use of anthracyclines has been observed since 2006. Given the benefits described above, taxanes are now used for most patients receiving chemotherapy for early breast cancer.

The overall duration of adjuvant chemotherapy still remains uncertain. However, based on the meta-analysis performed in the Oxford Overview (EBCTCG), the current recommendation is for 3-6 months of the commonly used regimens. Although it is clear that dose intensity to a specific threshold is essential, there is little, if any, evidence

to support the long-term survival benefit of high-dose chemotherapy with stem cell support.

Chemotherapy side effects are now generally well controlled. Nausea and vomiting are abated with drugs that directly affect the central nervous system, such as ondansetron and granisetron. Infertility and premature ovarian failure are common side effects of chemotherapy, especially in women over the age of 40, and should be discussed with patients prior to starting treatment. The risk of life-threatening neutropenia associated with chemotherapy can be reduced by use of growth factors such as pegfilgrastim and filgrastim (G-CSF), which stimulate proliferation and differentiation of hematopoietic cells. Long-term toxicities from chemotherapy, including cardiomyopathy (anthracyclines), peripheral neuropathy (taxanes), and leukemia/myelodysplasia (anthracyclines and alkylating agents), remain a small but significant risk.

2. Targeted Therapy—

- A. **HER2 overexpression** Approximately 20% of breast cancers are characterized by amplification of the HER2 oncogene leading to overexpression of the HER2 oncoprotein. The poor prognosis associated with HER2 overexpression has been drastically improved with the development of HER2-targeted therapy. Trastuzumab (Herceptin [H]), a monoclonal antibody that binds to HER2, has proved effective in combination with chemotherapy in patients with HER2 overexpressing metastatic and early breast cancer. In the adjuvant setting, the first and most commonly studied chemotherapy backbone used with trastuzumab is AC-T. Subsequently, the BCIRG006 study showed similar efficacy for AC-TH and a nonanthracycline-containing regimen, TCH (docetaxel, carboplatin, trastuzumab). Both were significantly better than AC-T in terms of disease-free and overall survival and TCH had a lower risk of cardiac toxicity. Both AC-TH and TCH are FDA-approved for nonmetastatic, HER2-positive breast cancer. In these regimens, trastuzumab is given with chemotherapy and then continues beyond the course of chemotherapy to complete a full year. The reporting of two trials in 2012 (the Herceptin Adjuvant [HERA] evaluating 1 vs 2 years of trastuzumab and the Protocol for Herceptin as Adjuvant therapy with Reduced Exposure [PHARE] study evaluating 6 vs 12 months of trastuzumab) have thus far confirmed that 1 year of trastuzumab should remain the standard of care. At least one study (N9831) suggests that concurrent, rather than sequential, delivery of trastuzumab with chemotherapy may be more beneficial. Another question being addressed in trials is whether to

treat small (> 1 cm), node-negative tumors with trastuzumab plus chemotherapy. Retrospective studies have shown that even small (stage T1a,b) HER2-positive tumors have a worse prognosis compared with same-sized HER2-negative tumors. The NSABP B43 study is also ongoing to evaluate whether the addition of trastuzumab to radiation therapy is warranted for DCIS.

Cardiomyopathy develops in a small but significant percent (1%-4%) of patients who receive trastuzumab-based regimens. For this reason, anthracyclines and trastuzumab are rarely given concurrently and cardiac function is monitored periodically throughout therapy.

- B. **Endocrine Therapy** Adjuvant hormone modulation therapy is highly effective in decreasing recurrence and mortality by 25% in women with hormone receptor-positive tumors regardless of menopausal status. The traditional regimen has been 5 years of the estrogen-receptor antagonist/agonist tamoxifen until the 2012 reporting of the Adjuvant Tamoxifen Longer Against Shorter (ATLAS) trial in which 5 versus 10 years of adjuvant tamoxifen were compared. In this study, women who received 10 years of tamoxifen had a significantly improved disease free as well as overall survival, particularly after year 10. Though these results are impressive and potentially practice changing, the clinical application of long-term tamoxifen use must be discussed with patients individually, taking into consideration risks of tamoxifen such as secondary uterine cancers, venous thromboembolic events as well as side effects that impact quality of life. Ovarian ablation in premenopausal patients with ER-positive tumors may produce a benefit similar to that of adjuvant systemic chemotherapy. Whether the use of ovarian ablation plus tamoxifen (or an AI) is more effective than either measure alone is still unclear. In the Stockholm subset of the Zoladex in Premenopausal Patients (ZIPP) study, 927 premenopausal women were randomly assigned to goserelin, tamoxifen, the combination of both, or to no endocrine therapy for 2 years. With a median follow-up of 12.3 years, this substudy showed that goserelin and tamoxifen each significantly reduce the risk of recurrence of hormone receptor-positive breast cancer compared to control (goserelin 32%, [$P = 0.005$] and tamoxifen 27% [$P = 0.018$]), yet the combination of goserelin and tamoxifen was not superior to either treatment alone. This issue is still not settled and is being addressed in ongoing clinical trials (Suppression of Ovarian Function Trial [SOFT] and Tamoxifen and Exemestane Trial [TEXT]) that have not yet

reported. AIs, including anastrozole, letrozole, and exemestane, reduce estrogen production and are also effective in the adjuvant setting for postmenopausal women. Approximately seven large randomized trials enrolling more than 24,000 patients have compared the use of AIs with tamoxifen or placebo as adjuvant therapy. All of these studies have shown small but statistically significant improvements in disease-free survival (absolute benefits of 2%-6%) with the use of AIs. In addition, AIs have been shown to reduce the risk of contralateral breast cancers and to have fewer associated serious side effects (such as endometrial cancers and thromboembolic events) than tamoxifen. However, they are associated with accelerated bone loss and an increased risk of fractures as well as a musculoskeletal syndrome characterized by arthralgias or myalgias (or both) in up to 50% of patients. The American Society of Clinical Oncology and the NCCN have recommended that postmenopausal women with hormone receptor-positive breast cancer be offered an AI either initially or after tamoxifen therapy. HER2 status should not affect the use or choice of hormone therapy.

3. Bisphosphonates—Two randomized studies (ZO-FAST and ABCSG-12) have evaluated the use of an adjuvant intravenous bisphosphonate (zoledronic acid) in addition to standard local and systemic therapy. The results showed a 32%-40% relative reduction in the risk of cancer recurrence for hormone receptor-positive nonmetastatic breast cancer. In fact, at the San Antonio Breast Cancer Symposium in 2011, with a median follow-up of 76 months, the ABCSG-12 study reported improved overall survival for patients treated with zoledronic acid. Conflicting results have been reported from the AZURE study. In this randomized study that enrolled premenopausal and postmenopausal patients, there was no disease-free or overall survival benefits associated with the addition of zoledronic acid to endocrine therapy for the overall study population. However, a prespecified subset analysis in patients who were postmenopausal for at least 5 years did demonstrate a significant disease-free and overall survival benefit with the addition of the bisphosphonate. Side effects associated with intravenous bisphosphonate therapy include bone pain, fever, osteonecrosis of the jaw (rare), and renal failure. Currently, the adjuvant use of bisphosphonates and other bone stabilizing drugs, such as inhibitors of receptor activator of nuclear factor kappa B ligand (RANK-B), remains investigational.

4. Adjuvant therapy in older women—Data relating to the optimal use of adjuvant systemic treatment for women

over the age of 65 are limited. Results from the EBCTCG overview indicates that while adjuvant chemotherapy yields a smaller benefit for older women compared with younger women, it still improves clinical outcomes. Moreover, individual studies do show that older women with higher risk disease derive benefits from chemotherapy. One study compared the use of oral chemotherapy (capecitabine) to standard chemotherapy in older women and concluded that standard chemotherapy is preferred. Another study (USO TC vs AC) showed that women over the age of 65 derive similar benefits from the taxane-based regimen as women who are younger. The benefits of endocrine therapy for hormone receptor-positive disease appear to be independent of age. In general, decisions relating to the use of systemic therapy should take into account a patient's comorbidities and physiological age, more so than chronologic age.

E. Neoadjuvant Therapy

The use of chemotherapy or endocrine therapy prior to resection of the primary tumor (neoadjuvant) is gaining popularity. This enables the assessment of *in vivo* chemosensitivity. Patients with hormone receptor-negative or HER2 positive breast cancer (or both) are more likely to have a pathologic complete response to neoadjuvant chemotherapy than those with hormone receptor-positive breast cancer. A complete pathologic response at the time of surgery is associated with improvement in survival. Neoadjuvant chemotherapy also increases the chance of breast conservation by shrinking the primary tumor in women who would otherwise need mastectomy for local control. Survival after neoadjuvant chemotherapy is similar to that seen with postoperative adjuvant chemotherapy. Neoadjuvant AI therapy has been evaluated in a phase II study involving 115 postmenopausal patients with hormone receptor-positive breast cancer. The overall response rate was 62% in this study, and 38% of patients initially ineligible for breast conservation were able to have lumpectomy. There is considerable concern as to the timing of sentinel lymph node biopsy (SLNB), since the chemotherapy may affect any cancer present in the lymph nodes. Several studies have shown that sentinel node biopsy can be done after neoadjuvant therapy. However, a large multicenter study, ACOSOG 1071, demonstrated a false-negative rate of 10.7%, well above the false-negative rate outside the neoadjuvant setting (< 1%-5%). Many physicians recommend performing SLNB before administering the chemotherapy in order to avoid a false-negative result and to aid in planning subsequent radiation therapy. Others prefer to perform SLNB after neoadjuvant therapy to avoid a second operation and assess postchemotherapy nodal status. If a complete dissection is necessary, this can be performed at the time of the definitive breast surgery.

Important questions remaining to be answered are the timing and duration of adjuvant and neoadjuvant chemotherapy, which chemotherapeutic agents should be applied for which subgroups of patients, the use of combinations of hormonal therapy and chemotherapy as well as possibly targeted therapy, and the value of prognostic factors other than hormone receptors in predicting response to therapy.

► Treatment: Palliative

Palliative treatments are those to manage symptoms, improve quality of life, and even prolong survival, without the expectation of achieving cure. Only 10% of patients have *de novo* metastatic breast cancer at the time of diagnosis. However, in most patients who have a breast cancer recurrence after initial local and adjuvant therapy, the recurrence presents as metastatic rather than local (in breast) disease. Breast cancer most commonly metastasizes to the liver, lungs, and bone, causing symptoms such as fatigue, change in appetite, abdominal pain, respiratory symptoms, or bone pain. Triple negative (ER-, PR-, HER2-negative) and HER2-positive tumors have a higher rate of brain metastases than hormone-receptor positive, HER2-negative tumors. Headaches, imbalance, vision changes, vertigo, and other neurologic symptoms may be signs of brain metastases.

A. Radiotherapy and Bisphosphonates

Palliative radiotherapy may be advised for primary treatment of locally advanced cancers with distant metastases to control ulceration, pain, and other manifestations in the breast and regional nodes. Irradiation of the breast and chest wall and the axillary, internal mammary, and supraclavicular nodes should be undertaken in an attempt to cure locally advanced and inoperable lesions when there is no evidence of distant metastases. A small number of patients in this group are cured in spite of extensive breast and regional node involvement.

Palliative irradiation is of value also in the treatment of certain bone or soft-tissue metastases to control pain or avoid fracture. Radiotherapy is especially useful in the treatment of isolated bony metastases, chest wall recurrences, brain metastases, and acute spinal cord compression.

In addition to radiotherapy, bisphosphonate therapy has shown excellent results in delaying and reducing skeletal events in women with bony metastases. Zoledronic acid is an FDA-approved intravenous bisphosphonate given monthly for bone metastases from breast cancer. Denosumab, a fully human monoclonal antibody that targets RANK-ligand, was approved by the FDA in 2010 for the treatment of advanced breast cancer causing bone metastases, based on data showing that it reduced the time to first skeletal-related event (eg, pathologic fracture) compared to zoledronic acid.

Caution should be exercised when combining radiation therapy with chemotherapy because toxicity of either or both may be augmented by their concurrent administration. In general, only one type of therapy should be given at a time unless it is necessary to irradiate a destructive lesion of weight-bearing bone while the patient is receiving another regimen. The regimen should be changed only if the disease is clearly progressing. This is especially difficult to determine for patients with destructive bone metastases, since changes in the status of these lesions are difficult to determine radiographically.

B. Targeted Therapy

1. Endocrine Therapy for Metastatic Disease—Targeted therapy refers to agents that are directed specifically against a protein or molecule expressed uniquely on tumor cells or in the tumor microenvironment. The first targeted therapy was the use of antiestrogen therapy in hormone receptor-positive breast cancer. The administration of hormones (eg, estrogens, androgens, progestins; Table 17-6); ablation of the ovaries, adrenals, or pituitary; administration of drugs that block hormone receptors (such as tamoxifen) or drugs that block the synthesis of hormones (such as AIs) have all been shown to be effective in hormone receptor-positive metastatic breast cancer. Palliative treatment of metastatic cancer should be based on the ER status of the primary tumor or the metastases. Because only 5%-10% of women with ER-negative tumors respond, they should not receive endocrine therapy except in unusual circumstances, for example, in an older patient who cannot tolerate chemotherapy. The rate of response is nearly equal in premenopausal and postmenopausal women with ER-positive tumors. A favorable response to hormonal manipulation occurs in about one-third of patients with metastatic breast cancer. Of those whose tumors contain ER, the response is about 60% and perhaps as high as 80% for patients whose tumors contain PR as well. The choice of endocrine therapy depends on the menopausal status of the patient. Women within 1 year of their last menstrual period are arbitrarily considered to be premenopausal and should receive tamoxifen therapy or rarely ovarian ablation, whereas women whose menses ceased more than a year before are postmenopausal and may receive tamoxifen or an AI. Women with ER-positive tumors who do not respond to first-line endocrine therapy or experience progression should be given a different form of hormonal manipulation. Because the quality of life during endocrine manipulation is usually superior to that during cytotoxic chemotherapy, it is best to try endocrine manipulation whenever possible. However, when receptor status is unknown, disease is progressing rapidly or involves visceral organs, chemotherapy should be used as first-line treatment.

Table 17–6. Agents commonly used for hormonal management of metastatic breast cancer.

Drug	Action	Dose, Route, Frequency	Major Side Effects
Tamoxifen citrate (Nolvadex)	SERM	20 mg orally daily	Hot flushes, uterine bleeding, thrombophlebitis, rash
Fulvestrant (Faslodex)	Steroidal estrogen receptor antagonist	500 mg intramuscularly day 1, 15, 29 and then monthly	Gastrointestinal upset, headache, back pain, hot flushes, pharyngitis
Toremifene citrate (Fareston)	SERM	40 mg orally daily	Hot flushes, sweating, nausea, vaginal discharge, dry eyes, dizziness
Diethylstilbestrol (DES)	Estrogen	5 mg orally three times daily	Fluid retention, uterine bleeding, thrombophlebitis, nausea
Goserelin (Zoladex)	Synthetic luteinizing hormone releasing analogue	3.6 mg subcutaneously monthly	Arthralgias, blood pressure changes, hot flushes, headaches, vaginal dryness
Megestrol acetate (Megace)	Progestin	40 mg orally four times daily	Fluid retention
Letrozole (Femara)	AI	2.5 mg orally daily	Hot flushes, arthralgia/arthritis, myalgia, bone loss
Anastrozole (Arimidex)	AI	1 mg orally daily	Hot flushes, skin rashes, nausea and vomiting, bone loss
Exemestane (Aromasin)	AI	25 mg orally daily	Hot flushes, increased arthralgia/arthritis, myalgia, bone loss

AI, aromatase inhibitor; SERM, selective estrogen receptor modulator.

A. The Premenopausal Patient

- (i). *Primary Hormonal Therapy* The potent SERM tamoxifen is by far the most common and preferred method of hormonal manipulation in the premenopausal patient, in large part because it can be given with less morbidity and fewer side effects than cytotoxic chemotherapy and does not require oophorectomy. Tamoxifen is given orally in a dose of 20 mg daily. The average remission associated with tamoxifen lasts about 12 months.

There is no significant difference in survival or response between tamoxifen therapy and bilateral oophorectomy. Bilateral oophorectomy is less desirable than tamoxifen in premenopausal women because tamoxifen is so well tolerated. However, oophorectomy can be achieved rapidly and safely either by surgery, by irradiation of the ovaries if the patient is a poor surgical candidate, or by chemical ovarian ablation using a gonadotropin-releasing hormone (GnRH) analog. Oophorectomy presumably works by eliminating estrogens, progestins, and androgens, which stimulate growth of the tumor. AIs should not be used in a patient with functioning ovaries since they do not block ovarian production of estrogen.

(ii). *Secondary or Tertiary Hormonal Therapy*

Patients who do not respond to tamoxifen or ovarian ablation may be treated with chemotherapy or may try a second endocrine regimen, such as GnRH analog plus AI. Whether to opt for chemotherapy or another endocrine measure depends largely on the sites of metastatic disease (visceral being more serious than bone-only, thus sometimes warranting the use of chemotherapy), the disease burden, the rate of growth of disease, and patient preference. Patients who take chemotherapy and then later have progressive disease may subsequently respond to another form of endocrine treatment (Table 17–6). The optimal choice for secondary endocrine manipulation has not been clearly defined for the premenopausal patient.

Patients who improve after oophorectomy but subsequently relapse should receive tamoxifen or an AI; if one fails, the other may be tried. Megestrol acetate, a progesterone agent, may also be considered. Adrenalectomy or hypophysectomy, procedures rarely done today, induced regression in 30%-50% of patients who previously responded to oophorectomy. Pharmacologic hormonal manipulation has replaced these invasive procedures.

B. The Postmenopausal Patient

(i). *Primary Hormonal Therapy* For postmenopausal women with metastatic breast cancer amenable to endocrine manipulation, tamoxifen or an AI is the initial therapy of choice. The side effect profile of AIs differs from tamoxifen and may be more effective. The main side effects of tamoxifen are nausea, skin rash, and hot flashes. Rarely, tamoxifen induces hypercalcemia in patients with bony metastases. Tamoxifen also increases the risk of venous thromboembolic events and uterine hyperplasia and cancer. The main side effects of AIs include hot flashes, vaginal dryness, and joint stiffness; however, osteoporosis and bone fractures are significantly higher than with tamoxifen. Phase II data from the randomized Fulvestrant fIRSt-line Study comparing endocrine Treatments (FIRST) suggest that the pure estrogen antagonist, fulvestrant may be even more effective than front-line anastrozole in terms of time to progression. The combination of fulvestrant plus anastrozole may also be more effective than anastrozole alone, though two studies evaluating this question have yielded conflicting results.

(ii). *Secondary or Tertiary Hormonal Therapy* AIs are also used for the treatment of advanced breast cancer in postmenopausal women after tamoxifen treatment. In the event that the patient responds to AI but then has progression of disease, fulvestrant, has shown efficacy with about 20%-30% of women benefiting from use. Postmenopausal women who respond initially to a SERM or AI but later manifest progressive disease may be crossed over to another hormonal therapy. Until recently, patients who experienced disease progression on or after treatment with a SERM or AI were routinely offered chemotherapy. This standard practice changed in 2012 with the approval of everolimus (Afinitor), an oral inhibitor of the mammalian target of rapamycin (MTOR)—a protein whose activation has been associated with the development of endocrine resistance. A phase III, placebo-controlled trial (BOLERO-2) evaluated exemestane with or without everolimus in 724 patients with AI-resistant, hormone receptor-positive metastatic breast cancer, and at interim analysis found that patients treated with everolimus had a significantly improved progression free survival (10.6 months vs 4.1 months; HR, 0.36; 95% CI, 0.27-0.47; $P <$

0.001). Androgens (such as testosterone) have many toxicities and should be used infrequently. As in premenopausal patients, neither hypophysectomy nor adrenalectomy should be performed. High-dose estrogen therapy has also paradoxically been shown to induce responses in advanced breast cancer. A study that evaluated the use of low-dose (6 mg) versus high-dose (30 mg) estradiol daily orally for postmenopausal women with metastatic AI-resistant breast cancer showed that the two doses yielded similar clinical benefit rates (29% and 28%, respectively) and, as expected, the higher dose was associated with more adverse events than the low dose.

(iii). *Newer Agents in Development* Although endocrine therapy can lead to disease control for months to years in some patients, *de novo* and acquired resistance to hormonal manipulation remains an enormous barrier to the effective treatment of these patients. Thus, molecularly targeted agents are still needed to circumvent signaling pathways that lead to drug resistance. A randomized phase II study evaluating letrozole with or without an oral cyclin-D kinase (cdk) 4/6 inhibitor for the first-line treatment of postmenopausal women with hormone receptor-positive advanced breast cancer was reported at the San Antonio Breast Cancer Symposium in December 2012. A striking and highly significant 18.6 months improvement in progression free survival was observed with the cdk4/6-inhibitor (26.1 months with cdk 4/6 inhibitor vs 7.5 months in control arm). Phase III evaluation of this promising molecule is being planned.

2. HER2 targeted agents—For patients with HER2 over-expressing or amplified tumors, trastuzumab plus chemotherapy has been shown to significantly improve clinical outcomes including survival compared to chemotherapy alone. Trastuzumab plus chemotherapy was therefore the standard first-line treatment for HER2-positive metastatic breast cancer until 2012 when pertuzumab was granted FDA approval. Pertuzumab is a monoclonal antibody that targets the extracellular domain of HER2 at a different epitope than targeted by trastuzumab and inhibits receptor dimerization. A phase III placebo-controlled randomized study (CLEOPATRA) showed that patients treated with the combination of pertuzumab, trastuzumab, and docetaxel had a significantly longer progression free survival (18.5 months vs 12.4 months; HR, 0.62; 95% CI, 0.51-0.75; $P <$ 0.001) compared with those treated with docetaxel and trastuzumab. Longer follow up revealed a

significant overall survival benefit associated with pertuzumab as well.

A. Trastuzumab-Pretreated Disease

Lapatinib is an oral targeted drug that works by inhibiting the intracellular tyrosine kinases of the epidermal growth factor and HER2 receptors. This drug is FDA-approved for the treatment of trastuzumab-resistant HER2-positive metastatic breast cancer in combination with capecitabine, thus, a completely oral regimen. The combination of trastuzumab plus lapatinib has been shown to be more effective than lapatinib alone for trastuzumab-resistant metastatic breast cancer. Moreover, several trials have shown a significant clinical benefit for continuing HER2-targeted agents beyond progression. T-DM1 (trastuzumab emtansine) is a novel antibody drug conjugate in which trastuzumab is stably linked to a derivative of maytansine, enabling targeted delivery of the cytotoxic chemotherapy to HER2-overexpressing cells. The phase III trial (EMILIA) that evaluated T-DM1 in patients with HER2-positive, trastuzumab-pretreated advanced disease showed that T-DM1 is associated with improved progression free and overall survival compared to lapatinib plus capecitabine (EMILIA). Regulatory approval of T-DM1 is expected in 2013. Evaluation of T-DM1 in combination with pertuzumab for the first-line treatment of advanced breast cancer is ongoing in the phase III MARIANNE study and trials evaluating the use of these agents in early breast cancer are being planned. Several other drugs targeting the HER2 pathway are in development including everolimus, afatinib, neratinib, and HER2-targeted vaccines.

3. Targeting angiogenesis—Bevacizumab is a monoclonal antibody directed against VEGF. This growth factor stimulates endothelial proliferation and neoangiogenesis in cancer. A phase III randomized trial (E2100) in women with metastatic breast cancer showed increased response rate and progression-free survival rate with the combination of bevacizumab and paclitaxel as first-line treatment compared with paclitaxel alone; however, there was no significant overall survival benefit. This led to the accelerated FDA approval of bevacizumab in early 2008. Since that time, two additional prospective randomized clinical trials (AVADO and RIBBON-1) have reported that the addition of bevacizumab to standard chemotherapy improves disease-free survival and objective response rates compared with single-agent chemotherapy alone. A benefit in overall survival has not been demonstrated. Side effects from bevacizumab include hypertension, bleeding, and thromboembolic events.

While initial results were promising, the lack of both survival benefit and data to identify those tumor types most likely to benefit from bevacizumab resulted in the FDA revoking its approval of bevacizumab for metastatic breast cancer in 2011.

4. Targeting “triple-negative” breast cancer—Until very recently, breast cancers lacking expression of the hormone receptors ER and PR, and HER2 have only been amenable to therapy with cytotoxic chemotherapy. This type of “triple-negative” breast cancer, while heterogeneous, generally behaves aggressively and is associated with a poor prognosis. Newer classes of targeted agents are being evaluated specifically for triple-negative breast cancer. Some triple-negative breast cancers may be characterized by an inability to repair double-strand DNA breaks (due to mutation or epigenetic silencing of the *BRCA* gene). **Poly-ADP ribose-polymerase (PARP) inhibitors** are a class of agents that prevent the repair of single strand DNA breaks and are showing promise in *BRCA*-mutated and triple-negative breast cancer. One relatively small randomized phase II clinical trial evaluating gemcitabine plus carboplatin with or without an agent that inhibits PARP (BSI-201) for triple-negative metastatic breast cancer showed improved clinical outcomes, including improved overall survival for PARP inhibitor-treated patients. However, the phase III randomized study of this agent failed to meet its endpoints, possibly relating to its relative weak inhibition of PARP. Research in this area is rapidly expanding with multiple clinical trials of other PARP inhibitors and other molecularly targeted agents ongoing.

► Palliative Chemotherapy

Cytotoxic drugs should be considered for the treatment of metastatic breast cancer: (1) if visceral metastases are present (especially brain, liver, or lymphangitic pulmonary); (2) if hormonal treatment is unsuccessful or the disease has progressed after an initial response to hormonal manipulation; or (3) if the tumor is ER-negative or HER2-positive. Prior adjuvant chemotherapy does not seem to alter response rates in patients who relapse. A number of chemotherapy drugs (including vinorelbine, paclitaxel, docetaxel, gemcitabine, ixabepilone, carboplatin, cisplatin, capecitabine, albumin-bound paclitaxel, eribulin, and liposomal doxorubicin) may be used as single agents with first-line objective response rates ranging from 30% to 50%.

Combination chemotherapy yields statistically significantly higher response rates and progression-free survival rates, but has not been conclusively shown to improve overall survival rates compared with sequential single-agent therapy. Combinations that have been tested in phase III studies and have proven efficacy compared with single-agent therapy include capecitabine/docetaxel, gem-

citabine/paclitaxel, and capecitabine/ixabepilone. Various other combinations of drugs have been tested in phase II studies, and a number of clinical trials are ongoing to identify effective combinations. For patients whose tumors have progressed after several lines of therapy and who are considering additional therapy, clinical trial participation with experimental drugs in phase I, II, or III testing should be encouraged.

In the past, high-dose chemotherapy and autologous bone marrow or stem cell transplantation aroused widespread interest for the treatment of metastatic breast cancer. However, multiple clinical trials failed to show any improvement in survival with high-dose chemotherapy with stem cell transplant over conventional chemotherapy and the procedure is now rarely, if ever, performed for stage IV breast cancer.

► Prognosis

Stage of breast cancer is the most reliable indicator of prognosis (Table 17–7). Axillary lymph node status is the best-analyzed prognostic factor and correlates with survival at all tumor sizes. When cancer is localized to the breast with no evidence of regional spread after pathologic examination, the clinical cure rate with most accepted methods of therapy ranges from 75% to greater than 90%. In fact, patients with small mammographically detected biologically favorable tumors and no evidence of axillary spread have a 5-year survival rate greater than 95%. When the axillary lymph nodes are involved with tumor, the survival rate drops to 50%-70% at 5 years and probably around 25%-40% at 10 years. Increasingly, the use of biologic markers, such as ER, PR, grade, and HER2, is helping to identify high-risk tumor types as well as direct treatment used (see Biomarkers & Gene Expression Profiling). Tumors with marked aneuploidy have a poor prognosis (Table 17–5). Gene analysis

Table 17–7. Approximate survival (%) of patients with breast cancer by TNM stage.

TNM Stage	5 Years	10 Years
0	95	90
I	85	70
IIA	70	50
IIB	60	40
IIIA	55	30
IIIB	30	20
IV	5-10	2
All	65	30

studies, such as Oncotype Dx, can predict disease-free survival for some subsets of patients.

The mortality rate of breast cancer patients exceeds that of age-matched normal controls for nearly 20 years. Thereafter, the mortality rates are equal, though deaths that occur among breast cancer patients are often directly the result of tumor. Five-year statistics do not accurately reflect the final outcome of therapy.

In general, breast cancer appears to be somewhat more malignant in younger than in older women, and this may be related to the fact that fewer younger women have ER-positive tumors. Adjuvant systemic chemotherapy, in general, improves survival by about 30% and adjuvant hormonal therapy by about 25%.

For those patients whose disease progresses despite treatment, studies suggest supportive group therapy may improve survival. As they approach the end of life, such patients will require meticulous palliative care (see Chapter 5).

Wishart GC et al: PREDICT: a new UK prognostic model that predicts survival following surgery for invasive breast cancer. *Breast Cancer Res.* 2010;12(1):R1. [PMID: 20053270]

► Follow-up Care

After primary therapy, patients with breast cancer should be monitored long-term in order to detect recurrences and to observe the opposite breast for a second primary carcinoma. Local and distant recurrences occur most frequently within the first 2-5 years. During the first 2 years, most patients should be examined every 6 months (with mammogram every 6 months on the affected breast), then annually there-

after. Since these women are at an increased risk for local or contralateral breast tumor, MRI is being used by many breast surgeons to monitor patients with prior malignancies. Most insurance companies will reimburse for this. Special attention is paid to the contralateral breast because a new primary breast malignancy will develop in 20%-25% of patients. In some cases, metastases are dormant for long periods and may appear 10-15 years or longer after removal of the primary tumor. Although studies have failed to show an adverse effect of hormonal replacement in disease-free patients, it is rarely used after breast cancer treatment, particularly if the tumor was hormone receptor positive. Even pregnancy has not been associated with shortened survival of patients rendered disease free—yet many oncologists are reluctant to advise a young patient with breast cancer that it is safe to become pregnant, and most will not support prescribing hormone replacement for the postmenopausal breast cancer patient. The use of estrogen replacement for conditions such as osteoporosis, vaginal dryness, and hot flushes may be considered for a woman with a history of breast cancer after discussion of the benefits and risks; however, it is not routinely recommended, especially given the availability of nonhormonal agents for these conditions (such as bisphosphonates and denosumab for osteoporosis). Vaginal estrogen is frequently used to treat vaginal atrophy with no obvious ill effects.

A. Local Recurrence

The incidence of local recurrence correlates with tumor size, the presence and number of involved axillary nodes, the histologic type of tumor, the presence of skin edema or skin and fascia fixation with the primary tumor, and the type of definitive surgery and local irradiation. Local recurrence on the chest wall after total mastectomy and axillary dissection develops in as many as 8% of patients. When the axillary nodes are not involved, the local recurrence rate is less than 5%, but the rate is as high as 25% when they are heavily involved. A similar difference in local recurrence rate was noted between small and large tumors. Factors such as multifocal cancer, in situ tumors, positive resection margins, chemotherapy, and radiotherapy have an effect on local recurrence in patients treated with breast-conserving surgery. Adjuvant systemic therapy greatly decreases the rate of local recurrence.

Chest wall recurrences usually appear within the first several years but may occur as late as 15 or more years after mastectomy. All suspicious nodules and skin lesions should be biopsied. Local excision or localized radiotherapy may be feasible if an isolated nodule is present. If lesions are multiple or accompanied by evidence of regional involvement in the internal mammary or supraclavicular nodes, the disease is best managed by radiation treatment of the entire chest wall

including the parasternal, supraclavicular, and axillary areas and usually by systemic therapy.

Local recurrence after mastectomy usually signals the presence of widespread disease and is an indication for studies to search for evidence of metastases. Distant metastases will develop within a few years in most patients with locally recurrent tumor after mastectomy. When there is no evidence of metastases beyond the chest wall and regional nodes, irradiation for cure after complete local excision should be attempted. After partial mastectomy, local recurrence does not have as serious a prognostic significance as after mastectomy. However, those patients in whom a recurrence develops have a worse prognosis than those who do not. It is speculated that the ability of a cancer to recur locally after radiotherapy is a sign of aggressiveness and resistance to therapy. Completion of the mastectomy should be done for local recurrence after partial mastectomy; some of these patients will survive for prolonged periods, especially if the breast recurrence is DCIS or occurs more than 5 years after initial treatment. Systemic chemotherapy or hormonal treatment should be used for women in whom disseminated disease develops or those in whom local recurrence occurs.

B. Breast Cancer Survivorship Issues

Given that most women with nonmetastatic breast cancer will be cured, a significant number of women face survivorship issues stemming from either the diagnosis or the treatment of the breast cancer. These challenges include psychological struggles, upper extremity lymphedema, cognitive decline (also called “chemo brain”), weight management problems, cardiovascular issues, bone loss, postmenopausal side effects, and fatigue. One randomized study reported that survivors who received psychological intervention from the time of diagnosis had a lower risk of recurrence and breast cancer–related mortality. A randomized study in older, overweight cancer survivors showed that diet and exercise reduced the rate of self-reported functional decline compared with no intervention. Cognitive dysfunction is a commonly reported symptom experienced by women who have undergone systemic treatment for early breast cancer. Studies are ongoing to understand the pathophysiology leading to this syndrome. An interesting study reported that 200 mg of modafinil daily improved speed and quality of memory as well as attention for breast cancer survivors dealing with cognitive dysfunction. This promising study requires validation in a larger clinical trial.

1. Edema of the arm—Significant edema of the arm occurs in about 10%-30% of patients after axillary dissection with or without mastectomy. It occurs more commonly if radiotherapy has been given or if there was postoperative infection. Partial mastectomy with radiation to the axillary lymph nodes is followed by chronic edema of the arm in 10%-20%

of patients. Sentinel lymph node dissection has proved to be a more accurate form of axillary staging without the side effects of edema or infection. Judicious use of radiotherapy, with treatment fields carefully planned to spare the axilla as much as possible, can greatly diminish the incidence of edema, which will occur in only 5% of patients if no radiotherapy is given to the axilla after a partial mastectomy and lymph node dissection.

Late or secondary edema of the arm may develop years after treatment, as a result of axillary recurrence or infection in the hand or arm, with obliteration of lymphatic channels. When edema develops, a careful examination of the axilla for recurrence or infection is performed. Infection in the arm or hand on the dissected side should be treated with antibiotics, rest, and elevation. If there is no sign of recurrence or infection, the swollen extremity should be treated with rest and elevation. A mild diuretic may be helpful. If there is no improvement, a compressor pump or manual compression decreases the swelling, and the patient is then fitted with an elastic glove or sleeve. Most patients are not bothered enough by mild edema to wear an uncomfortable glove or sleeve and will treat themselves with elevation or manual compression alone. Benzopyrones have been reported to decrease lymphedema but are not approved for this use in the United States. Rarely, edema may be severe enough to interfere with use of the limb. Traditionally, patients were advised to avoid weight lifting with the ipsilateral arm to prevent a worsening in lymphedema. However, a prospective randomized study has shown that twice weekly progressive weight lifting improves lymphedema symptoms and exacerbations and improves extremity strength.

2. Breast reconstruction—Breast reconstruction is usually feasible after total or modified radical mastectomy. Reconstruction should be discussed with patients prior to mastectomy, because it offers an important psychological focal point for recovery. Reconstruction is not an obstacle to the diagnosis of recurrent cancer. The most common breast reconstruction has been implantation of a silicone gel or saline prosthesis in the subpectoral plane between the pectoralis minor and pectoralis major muscles. Alternatively, autologous tissue can be used for reconstruction.

Autologous tissue flaps are aesthetically superior to implant reconstruction in most patients. They also have the advantage of not feeling like a foreign body to the patient. The most popular autologous technique currently is the transrectus abdominis muscle flap (TRAM flap), which is done by rotating the rectus abdominis muscle with attached fat and skin cephalad to make a breast mound. The free TRAM flap is done by completely removing a small portion of the rectus with overlying fat and skin and using microvascular surgical techniques to reconstruct the

vascular supply on the chest wall. A latissimus dorsi flap can be swung from the back but offers less fullness than the TRAM flap and is therefore less acceptable cosmetically. An implant often is used to increase the fullness with a latissimus dorsi flap. Reconstruction may be performed immediately (at the time of initial mastectomy) or may be delayed until later, usually when the patient has completed adjuvant therapy. When considering reconstructive options, concomitant illnesses should be considered, since the ability of an autologous flap to survive depends on medical comorbidities. In addition, the need for radiotherapy may affect the choice of reconstruction as radiation may increase fibrosis around an implant or decrease the volume of a flap.

3. Risks of pregnancy—Data are insufficient to determine whether interruption of pregnancy improves the prognosis of patients who are identified to have potentially curable breast cancer and who receive definitive treatment during pregnancy. Theoretically, the high levels of estrogen produced by the placenta as the pregnancy progresses could be detrimental to the patient with occult metastases of hormone-sensitive breast cancer. However, retrospective studies have not shown a worse prognosis for women with gestational breast cancer. The decision whether or not to terminate the pregnancy must be made on an individual basis, taking into account the clinical stage of the cancer, the overall prognosis for the patient, the gestational age of the fetus, the potential for premature ovarian failure in the future with systemic therapy, and the patient's wishes. Women with early-stage gestational breast cancer who choose to continue their pregnancy should undergo surgery to remove the tumor and systemic therapy if indicated. Retrospective reviews of patients treated with anthracycline-containing regimens for gestational cancers (including leukemia and lymphomas) have established the relative safety of these regimens during pregnancy for both the patient and the fetus. Taxane-based and trastuzumab-based regimens have not been evaluated extensively, however. Radiation therapy should be delayed until the pregnant patient has delivered.

Equally important is the advice regarding future pregnancy (or abortion in case of pregnancy) to be given to women of child-bearing age who have had definitive treatment for breast cancer. To date, no adverse effect of pregnancy on survival of women who have had breast cancer has been demonstrated. When counseling patients, oncologists must take into consideration the patients' overall prognosis, age, comorbidities, and life goals.

In patients with inoperable or metastatic cancer (stage IV disease), induced abortion is usually advisable because of the possible adverse effects of hormonal treatment, radio-

therapy, or chemotherapy upon the fetus in addition to the expectant mother's poor prognosis.

CARCINOMA OF THE MALE BREAST

ESSENTIALS OF DIAGNOSIS

- ▶ A painless lump beneath the areola in a man usually over 50 years of age
- ▶ Nipple discharge, retraction, or ulceration may be present
- ▶ Generally poorer prognosis than in women

General Considerations

Breast cancer in men is a rare disease; the incidence is only about 1% of that in women. The average age at occurrence is about 70 years and there may be an increased incidence of breast cancer in men with prostate cancer. As in women, hormonal influences are probably related to the development of male breast cancer. There is a high incidence of both breast cancer and gynecomastia in Bantu men, theoretically owing to failure of estrogen inactivation by a liver damaged by associated liver disease. It is important to note that first-degree

relatives of men with breast cancer are considered to be at high risk. This risk should be taken into account when discussing options with the patient and family. In addition, *BRCA2* mutations are common in men with breast cancer. Men with breast cancer, especially with a history of prostate cancer, should receive genetic counseling. The prognosis, even in stage I cases, is worse in men than in women. Blood-borne metastases are commonly present when the male patient appears for initial treatment. These metastases may be latent and may not become manifest for many years.

► Clinical Findings

A painless lump, occasionally associated with nipple discharge, retraction, erosion, or ulceration, is the primary complaint. Examination usually shows a hard, ill-defined, nontender mass beneath the nipple or areola. Gynecomastia not uncommonly precedes or accompanies breast cancer in men. Nipple discharge is an uncommon presentation for breast cancer in men but is an ominous finding associated with carcinoma in nearly 75% of cases.

Breast cancer staging is the same in men as in women. Gynecomastia and metastatic cancer from another site (eg, prostate) must be considered in the differential diagnosis. Benign tumors are rare, and biopsy should be performed on all males with a defined breast mass.

► Treatment

Treatment consists of modified radical mastectomy in operable patients, who should be chosen by the same criteria as women with the disease. Breast conserving therapy is rarely performed. Irradiation is the first step in treating localized metastases in the skin, lymph nodes, or skeleton that are causing symptoms. Examination of the cancer for hormone receptor proteins and HER2 overexpression is of value in determining adjuvant therapy. Men commonly have ER-positive tumors and rarely have overexpression of HER2. Adjuvant systemic therapy and radiation is used for the same indications as in breast cancer in women.

Because breast cancer in men is frequently a disseminated disease, endocrine therapy is of considerable importance in its management. Tamoxifen is the main drug for management of advanced breast cancer in men. Tamoxifen (20 mg orally daily) should be the initial treatment. There is little experience with AIs though they should be effective. Castration in advanced breast cancer is a successful measure and more beneficial than the same procedure in women but is rarely used. Objective evidence of regression may be seen in 60%-70% of men with hormonal therapy for metastatic disease—approximately twice the proportion in women. The average duration of tumor growth remission is about 30 months, and life is prolonged. Bone is the most frequent site of metastases from

breast cancer in men (as in women), and hormonal therapy relieves bone pain in most patients so treated. The longer the interval between mastectomy and recurrence, the longer the remission following treatment is likely. As in women, there is correlation between ERs of the tumor and the likelihood of remission following hormonal therapy.

AIs should replace adrenalectomy in men as they have in women. Corticosteroid therapy alone has been considered to be efficacious but probably has no value when compared with major endocrine ablation. Either tamoxifen or AIs may be primary or secondary hormonal manipulation.

Estrogen therapy—5 mg of diethylstilbestrol three times daily orally—may be effective hormonal manipulation after others have been successful and failed, just as in women. Androgen therapy may exacerbate bone pain. Chemotherapy should be administered for the same indications and using the same dosage schedules as for women with metastatic disease or for adjuvant treatment.

► Prognosis

Men with breast cancer seem to have a worse prognosis than women with breast cancer because breast cancer is diagnosed in men at a later stage. However, a large population based, international study reported that after adjustment for prognostic features (age, stage, treatment), men had a significantly improved relative survival from breast cancer compared to women. For node-positive disease, 5-year survival is approximately 69%, and for node-negative disease, it is 88%. A practice-patterns database study reported that based on NCCN guidelines, only 59% of patients received the recommended chemotherapy, 82% received the recommended hormonal therapy, and 71% received the recommended postmastectomy radiation, indicating a relatively low adherence to NCCN guidelines for men.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

MULTIPLE CHOICE QUESTIONS

1. Fibrocystic condition of the breast is
 - A. Communicable disease
 - B. Common in postmenopausal women
 - C. Caused at least in part by estrogen stimulation of breast tissue
 - D. Carries a threefold increased risk of breast cancer
 - E. Does not actually include any cysts on histology
2. Risk factors for breast cancer include
 - A. Early childbearing
 - B. Iodine deficiency
 - C. *BRCA1* mutation only in families of Ashkenazi Jewish descent
 - D. A personal history of breast cancer
 - E. None of the above
3. Breast cancer screening in asymptomatic women
 - A. Identifies about 2 cancers per 1000 women over age 50 years
 - B. Identifies cancer without node involvement in about 80% of detected cases
 - C. Includes a history, physical examination, bilateral mammogram, and ultrasound for women between ages 40 and 50 years
 - D. Is followed by a 5-year survival of 95% for women diagnosed through screening
 - E. Should include all women yearly after the age of 30 years
4. The clinical findings at breast cancer presentation most commonly include
 - A. A painless mass identified by the patient
 - B. A new mass discovered during a clinician physical examination (60% of cases)
 - C. Nipple discharge (60% of cases)
 - D. An axillary mass due to metastatic lymph nodes (40% of cases)
 - E. None of the above
5. Axillary lymph node metastases from breast cancer
 - A. Are not important for predicting patient survival in women with breast cancer
 - B. Are generally palpable if present
 - C. Can be reliably detected by sestamibi scintigraphy
 - D. Can be reliably detected by sentinel lymph node biopsy in women with clinically uninvolved axillary lymph nodes
 - E. Are frequently present in residual lymph nodes when sentinel lymph node biopsy shows no evidence of disease

Thoracic Wall, Pleura, Mediastinum, & Lung

ANATOMY & PHYSIOLOGY

ANATOMY OF THE CHEST WALL & PLEURA

The physiology of respiration and the anatomy of the chest wall are tightly linked. The chest wall is an airtight, expandable, cone-shaped cage. Normal ventilation occurs when expansion of the rib cage and simultaneous diaphragmatic excursion create negative intrathoracic pressure, allowing inward flow of air.

The function of the chest wall is made possible by its segmentally arranged anatomy. The ventral wall of the bony thorax extends from the suprasternal notch to the xiphoid, approximately 18 cm in the adult. It is formed by the manubrium, sternum, and xiphoid process. The remainder of the anterior wall and the lateral walls are formed by 12 ribs. The first seven pairs of ribs articulate directly with the sternum, the next three pairs connect to the lower border of the preceding rib, and the last two terminate in the wall of the abdomen. The sides of the chest wall consist of the upper 10 ribs, which slope obliquely downward from their posterior attachments. The posterior chest wall is formed by the twelve thoracic vertebrae, their transverse processes, and the 12 ribs (Figure 18-1). The upper ventral portion of the thoracic cage is covered by the clavicle and the subclavian vessels. Laterally, it is covered by the shoulder girdle and axillary nerves and vessels; dorsally, it is covered in part by the scapula.

The superior aperture of the thorax (also called either the thoracic inlet or the thoracic outlet) is a downwardly slanted 5- to 10-cm kidney-shaped opening bounded by the first costal cartilages and ribs laterally, the manubrium anteriorly, and the body of the first thoracic vertebra posteriorly. The inferior aperture of the thorax is bounded by the twelfth vertebra and ribs posteriorly and the cartilages of the seventh to tenth ribs and the xiphisternal joint anteriorly. It

is much wider than the superior aperture and is occupied by the diaphragm.

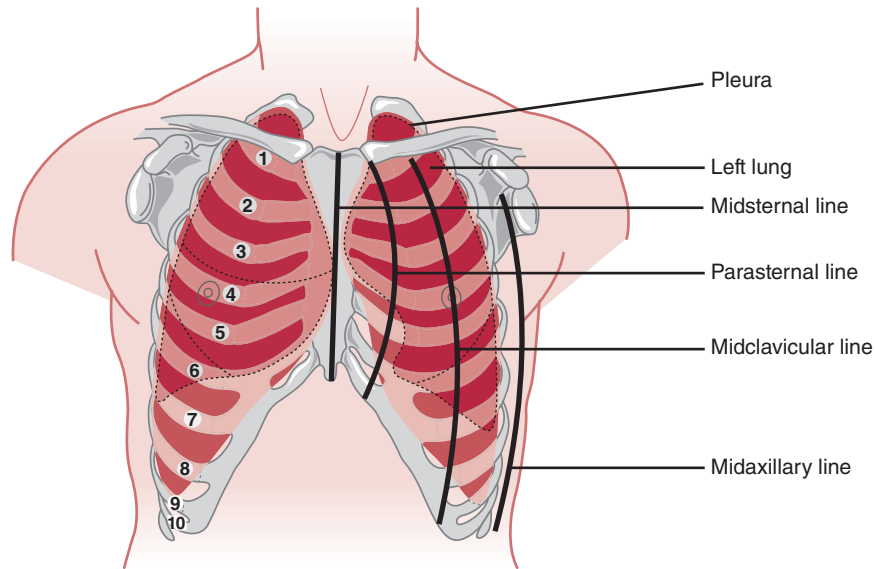

The blood supply and innervation of the chest wall are via the intercostal vessels and nerves (Figures 18-2 and 18-3). The upper thorax also receives vessels and nerves from the cervical and axillary regions. The underside of the sternum's blood supply derives from the internal thoracic artery branches, which anastomose with the intercostal vessels along the lateral aspect of the chest wall.

The entirety of the thoracic cavity is lined by a pleural membrane. The parietal pleura is the innermost lining of the chest wall and is divided into four parts: the cervical pleura (cupola or cupula), costal pleura, mediastinal pleura, and diaphragmatic pleura. The visceral pleura is a mesodermal layer investing the lungs and is continuous with the parietal pleura, joining it at the hilum of the lung. The potential pleural space is a capillary gap that normally contains only a few drops of serous fluid. However, this space may be enlarged when fluid (hydrothorax), blood (hemothorax), pus (pyothorax or empyema), lymphatic fluid (chylothorax), or air (pneumothorax) fills this potential cavity.

PHYSIOLOGY OF THE CHEST WALL & PLEURA

► Mechanics of Respiration

Ventilation is the process of moving gas through the conducting airways, to and from the alveoli, and occurs when elevation of the rib cage and descent of the diaphragm cause an increase in thoracic volume and generate negative intrathoracic pressure. In infants, the ribs have not yet assumed their oblique contour and ventilation depends on diaphragmatic breathing. Furthermore, accessory muscles of respiration contribute to the conformational change in the thoracic cage during periods of intense exercise or respiratory distress (Figure 18-4).

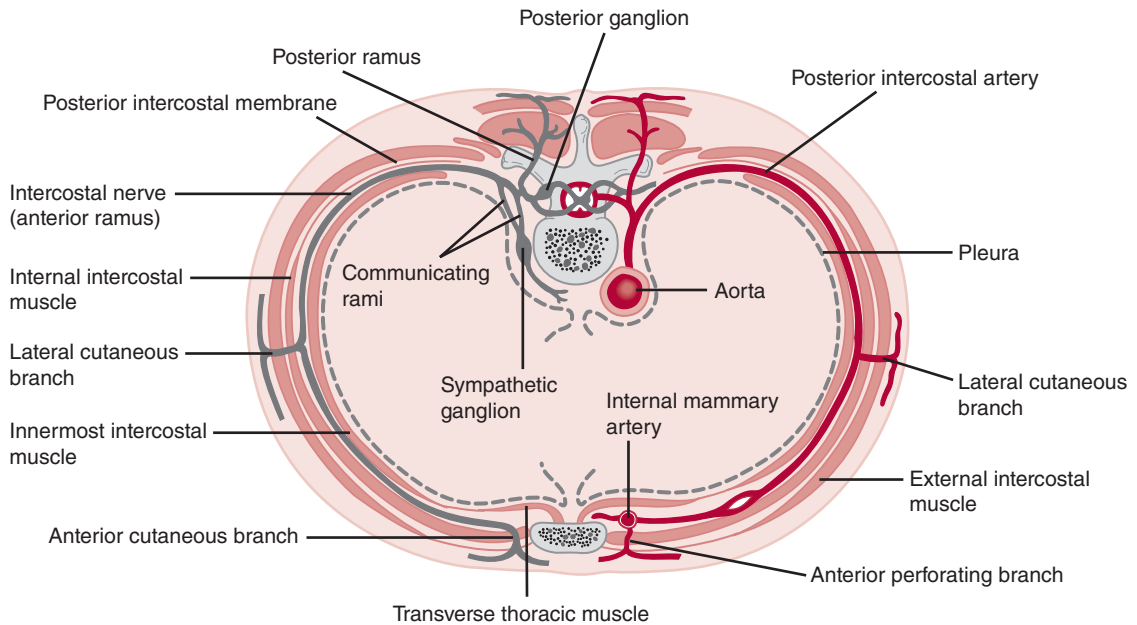

▲ **Figure 18-1.** The thorax, showing rib cage, pleura, and lung fields.

Expiration is mainly passive, resulting from elastic recoil of the lungs. An exception to this is deep breathing, when the abdominal musculature contracts, pulling the rib cage downward and simultaneously elevating the diaphragm by compressing the abdominal viscera against it.

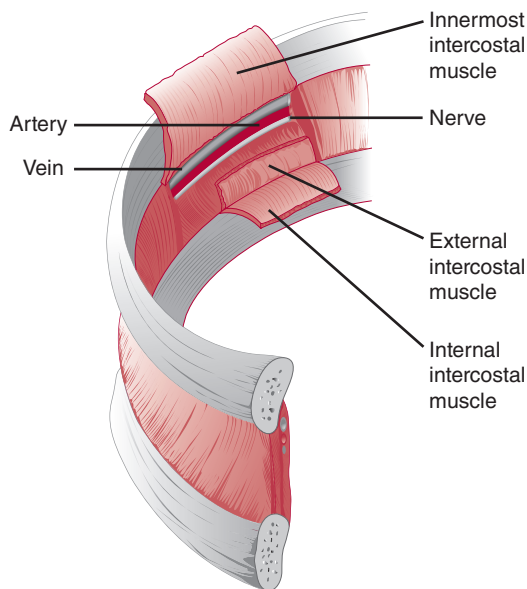

► Physiology of the Pleural Space

A. Pressure

The pleural cavity pressure is normally negative, owing to the opposing forces of elastic recoil of the lung and active

▲ **Figure 18-2.** Transverse section of thorax.

▲ **Figure 18-3.** Intercostal muscles, vessels, and nerves.

expansion of the space by the chest wall. During quiet respiration, it varies from -15 cm H_2O with inspiration to 2 cm H_2O during expiration. Larger pressure changes (eg, -60 cm H_2O during forced inspiration to $+30$ cm H_2O during vigorous expiration) may occur with deep breathing. Because of gravity, pleural pressure at the apex is more negative when the body is upright and changes about 0.2 cm H_2O per centimeter of vertical height.

B. Fluid Formation and Reabsorption

The formation (transudation) and reabsorption of fluid within the pleural space depends on hydrostatic, colloid, and tissue pressures (the Starling equation) in addition to permeability of the pleural membrane. In health, fluid is formed by the parietal pleura and absorbed by the visceral pleura (Figure 18-5). Since systemic capillary hydrostatic pressure is 30 cm H_2O , and intrapleural negative pressure averages -5 cm H_2O there is a net *hydrostatic* pressure of 35 cm H_2O . Additionally, the colloid osmotic pressure of the systemic capillaries is 34 cm H_2O and an opposing 8 cm H_2O of pleural space osmotic pressure. Thus, a net 26 cm H_2O osmotic pressure draws fluid back into systemic capillaries. Since systemic hydrostatic pressure (35 cm H_2O) exceeds osmotic capillary pressure (26 cm H_2O) by 9 cm H_2O , there is a 9 cm H_2O net drive of fluid into the pleural space by systemic capillaries in the chest wall. Similar calculations for the visceral pleura involving the low-pressure pulmonary circulation will show that there is a resulting net drive of 10 cm H_2O that attracts pleural fluid into pulmonary

capillaries. Thus, there is normally a balance favoring neither loss nor gain of fluid in this space.

In health, pleural fluid is low in protein (<100 mg/dL). When it increases in disease to about 1 g/dL, the net colloid osmotic pressure of the visceral pleural capillaries is equaled and pleural fluid reabsorption becomes dependent on lymphatic drainage. Thus, abnormal amounts of pleural fluid may accumulate: (1) when hydrostatic pressure is increased, such as in heart failure; (2) when capillary permeability is increased, as in inflammatory or neoplastic disease; or (3) when colloid osmotic pressure is decreased.

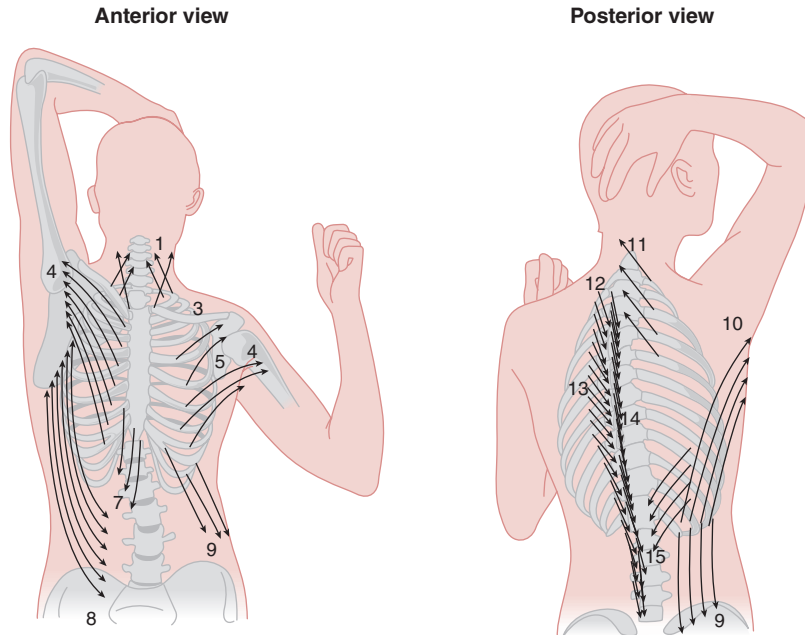

ANATOMY OF THE MEDIASTINUM

The mediastinum is the compartment between the pleural cavities. It extends anteriorly from the suprasternal notch to the xiphoid process and posteriorly from the first to the eleventh thoracic vertebrae. Superiorly, fascial planes in the neck are in direct communication; inferiorly, the mediastinum is limited by the diaphragm. Apertures through the inferior extent of the mediastinum are traversed by the aorta, inferior vena cava, esophagus, and vagus nerve.

The mediastinum may be divided into a number of compartments in several ways. Classically, it may be divided into the superior, anterior, middle, and posterior compartments. The superior compartment extends above a line drawn from the fourth thoracic vertebrae to the sternonubrial junction (Angle of Louis.) In the three-compartment Burkell classification (Figure 18-6), the anterior mediastinum contains the thymus gland, the lymph nodes, the ascending aorta and transverse aorta, the great vessels, and areolar tissue. The middle mediastinum contains the heart, the pericardium, the trachea, the hila of the lungs, the phrenic nerves, lymph nodes, and areolar tissue. The posterior mediastinum contains the sympathetic chains, the vagus nerves, the esophagus, the thoracic duct, lymph nodes, and the descending aorta.

Congenital abnormalities within the mediastinum are numerous. A defect in the anterior mediastinal pleura with communication of the right and left hemithorax is rare. This retrosternal part of the anterior mediastinum is normally thin, and overexpansion of one pleural space may cause “mediastinal herniation” or a bulge of mediastinal pleura toward the opposite side.

Displacements of the mediastinum occur from masses or from accumulations of air, fluid, blood, or chyle interfering with vital functions. Tracheal compression, vena caval obstruction, and esophageal obstructions cause clinical symptoms. The mediastinum can also be displaced laterally when pathologic processes of one hemithorax cause mediastinal shift. Fibrosis and lung volume loss can shift the mediastinum toward the affected side. Open pneumothorax and massive hemothorax shift the mediastinum away from the affected side. Open pneumothorax produces

alternating paradoxical mediastinal shifts with respiration and will adversely affect ventilation. Acute mediastinal displacement may produce hypoxia or reduced venous return and cause dysrhythmias, hypotension, or cardiac arrest.

ANATOMY OF THE LUNG

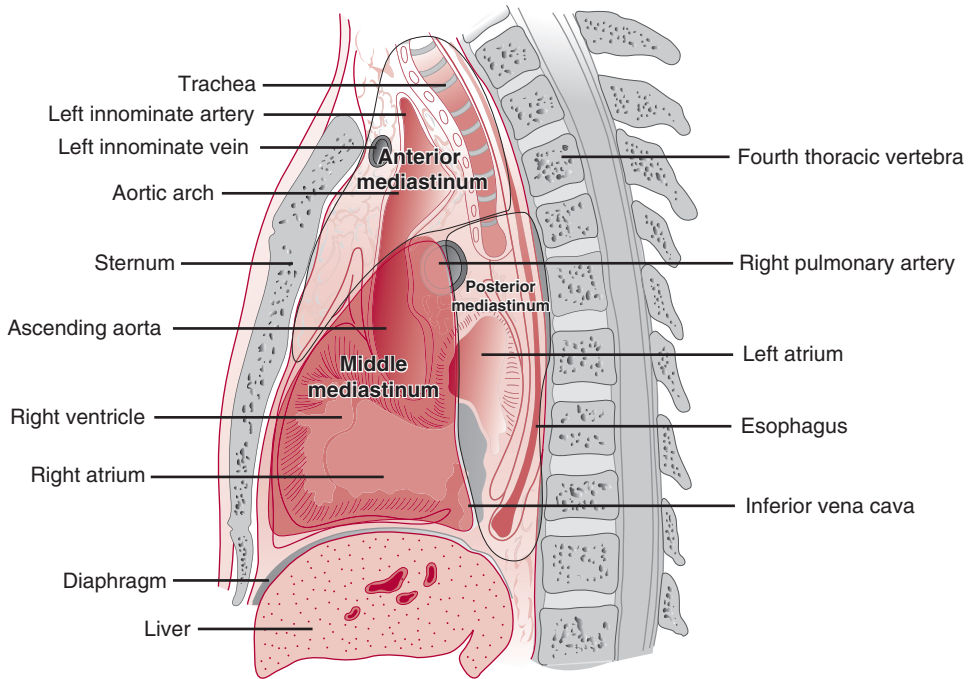

The fundamental unit of lung anatomy is a bronchopulmonary segment (Figure 18-7). The right lung has three lobes: upper, middle, and lower. The left lung consists of two lobes: upper and lower. On the left, the lingular segments of the upper lobe are the homolog of the right middle lobe. Two fissures of varying completeness separate the lobes on the right side. The major, or oblique, fissure divides the upper and middle lobes from the lower lobe. The minor, or horizontal, fissure separates the middle from the upper lobe. On the left side, the single oblique fissure separates the upper and lower lobes. The parenchymal anatomy can be seen by studying the sequential division of the bronchopulmonary tree. The trachea and main stem bronchi and

their branches contain a posterior membranous area and are prevented from collapsing by horseshoe-shaped anterior segments of cartilage in their walls. The cartilaginous reinforcement of the airway gradually becomes less complete as the branches become smaller, and reinforcement ceases with bronchi of 1-2 mm. The bronchopulmonary segmental anatomy is designated by numbers (Boyden) or by name (Jackson and Huber). There are typically 18 bronchopulmonary segments (right upper 3, right middle 2, right lower 5, left upper 4, left lower 4) as shown in Figure 18-7. The segmental bronchial anatomy is most constant with the pulmonary vascular structures showing more variability.

The lungs have a dual blood supply: the pulmonary and the bronchial arterial systems. The pulmonary arteries transmit deoxygenated blood from the right ventricle for oxygenation. They closely accompany the bronchi. The bronchial arteries usually arise directly from the aorta or nearby intercostal arteries and are variable in number. They transmit oxygenated blood to the bronchial wall up to the level of the terminal bronchioles. The pulmonary veins

▲ **Figure 18–5.** Movement of fluid across the pleural space, showing production and absorption of pleural fluid.

▲ **Figure 18-7.** Segmental anatomy of the lungs.

travel in the interlobar septa and do not correspond to the distribution of the bronchi or the pulmonary arteries.

THE LYMPHATIC SYSTEM

The lymphatics travel in intersegmental septa centrally as well as to the parenchymal surface to form subpleural networks. Drainage continues toward the hilum in channels that follow the bronchi and pulmonary arteries. The lymphatics eventually enter lymph nodes in the major fissures of the lungs, the hilum, and the paratracheal regions.

The direction of lymphatic drainage—irrespective of the primary site—is cephalad and ipsilateral, but contralateral flow may occur from any lobe. The usual sequence of lymphatic spread of pulmonary cancer is first to the regional parabronchial nodes and then to the ipsilateral paratracheal, subcarinal, scalene, or inferior deep cervical nodes. The lymphatics from the left lower lobe may be almost equally distributed to the left and right. From the left upper lobe, distribution is often to the anterior mediastinal group (A-P window and para-aortic lymph nodes).

DIAGNOSTIC STUDIES**► Skin Tests**

Skin tests are used in the diagnosis of tuberculosis, histoplasmosis, and coccidioidomycosis. Tuberculin testing is usually done with purified protein derivative (PPD) injected intradermally. Intermediate-strength PPD should be used in patients who seem likely to have active disease. Induration of 10 mm or more at the injection site after 48-72 hours is positive and indicates either active or arrested disease. Because false-negative reactions are rare, a negative test fairly reliably rules out tuberculosis. Mumps antigen is usually placed on the opposite forearm to test for anergy. Skin tests for histoplasmosis and coccidioidomycosis are performed in a similar way, but skin tests for fungal infections are unreliable and serologic tests should be performed instead.

► Endoscopy**A. Laryngoscopy**

Indirect laryngoscopy is used to assess vocal cord mobility in patients suspected of having lung carcinoma when there has been a voice change. It should also be performed to search for an otherwise occult source for malignant cells in sputum or metastases in cervical lymph nodes.

B. Bronchoscopy

Roentgenographic evidence of bronchial obstruction, unresolved pneumonia, foreign body, suspected carcinoma, hemoptysis, aspiration pneumonia, and lung abscess are only a few of the indications for bronchoscopy. Depending on the indication, either flexible or rigid bronchoscopy may be performed. Rigid bronchoscopy must be done under general anesthesia and is most often used for clearing major airways of bulky obstructing lesions such as tumors, foreign bodies, or blood clots. Tumor ablation may be done via multiple techniques, including the use of Nd:YAG laser.

Flexible bronchoscopy is a highly effective diagnostic and therapeutic tool. It can be performed under local and intravenous sedation. Washings are usually obtained for bacterial or fungal culture and cytologic examination. Visible lesions are biopsied directly and brush biopsies are obtained from specific bronchopulmonary segments. Occasionally, transcarinal needle biopsy of a subcarinal node is obtained.

Bronchoscopically, 30%-50% of lung tumors are visible. Brushing, random biopsies, and sputum cytology may still yield a positive diagnosis of cancer or tuberculosis in the absence of a visible lesion. The yield is influenced by size, location, and histologic cell type of the lesion.

Additional techniques available during bronchoscopy include the use of endo-bronchial ultrasound (EBUS) and electromagnetic navigational bronchoscopy. EBUS enables visualization of masses and lymph nodes from the central

airways, and facilitates fine needle aspiration of these lesions. Navigational bronchoscopy integrates use of a virtual bronchoscopy obtained from cross-sectional imaging (usually CT scan) and a tracking system based on three dimensional feedback from electromagnetic signals to allow access to lesions deep within the lung parenchyma.

► Mediastinoscopy

Cervical mediastinoscopy remains a mainstay of evaluation of the mediastinum despite advances in imaging. Properly performed mediastinoscopy samples nodes from at least three stations, including ipsilateral and contralateral paratracheal levels 2 and 4 and subcarinal level 7. Cervical mediastinoscopy is performed through a 3- to 4-cm incision one fingerbreadth above the sternal notch. Dissection proceeds beneath the pretracheal fascia, allowing safe access to mediastinal nodes and avoiding major vascular structures. After palpation, the mediastinoscope can be inserted and nodes biopsied under direct vision. Unclear structures are aspirated prior to attempted biopsy.

Enlarged lymph nodes in the aorticopulmonary window are technically inaccessible by means of standard cervical mediastinoscopy. Extended cervical mediastinoscopy provides access to these aorticopulmonary window nodes. It is performed through the same neck incision as standard mediastinoscopy except the dissection is carried laterally beside the left carotid artery toward and then over the aorta into the aorticopulmonary space. Because of the surrounding structures, this procedure carries significant risks and in patients with dilated or calcific aortas or previous cardiac operations, is contraindicated.

In experienced hands, the complications of mediastinoscopy are minimal (< 1%-2%). Major bleeding complications requiring sternotomy or thoracotomy for repair are infrequent (1%-2%). Other possible complications include pneumothorax, recurrent nerve injury, infection, and esophageal injury.

Mediastinoscopy is almost invariably accurate in the diagnosis of sarcoidosis. It is also useful to diagnose tuberculosis, histoplasmosis, Castleman silicosis, metastatic carcinoma, lymphoma, and carcinoma of the esophagus. It should not be used in the investigation of primary mediastinal tumors, which should be approached by an incision permitting definitive excision.

► Chamberlain Procedure

Anterior mediastinotomy (the Chamberlain procedure) is used to sample nodes and biopsy tissue in the anterior mediastinum, most commonly in the aortopulmonary window. A small (3-4 cm) incision is made over the second or third interspace on the appropriate side of the lesion. Alternatively, the procedure can be performed with videoscopic guidance (video-assisted thoracoscopic surgery [VATS]). The mediastinum is approached through the interspace directly or after

excising the costochondral cartilage using either the mediastinoscope or an open technique. Careful attention is paid to preserving the mammary vessels encountered in the dissection. The mediastinum is approached extrapleurally unless lesions specifically within the thorax—effusions, tumors invading the hilum or chest wall—need to be investigated. Furthermore, if additional access is required to facilitate the dissection or to treat a complication, the incision can be converted to a larger anterior thoracotomy.

Complications resulting from anterior mediastinotomy include bleeding, recurrent nerve injury, and infection. Major morbidity is less than 1%-2%.

Scalene lymph node biopsy has been largely replaced by mediastinoscopy although remains important particularly for evaluation of suspicious suprascervical lymphadenopathy.

► Video-Assisted Thoracoscopic Surgery

VATS plays an important role in the diagnosis and staging of thoracic malignancies as well as in the resection of isolated peripheral pulmonary nodules and bullous lung disease. Furthermore, it has been an advance in lung biopsy and pleurodesis procedures. Although some oncologic concerns persist, thoracoscopic procedures are the standard of care for many resections, although they have not entirely supplanted open resection. As instruments and techniques have evolved, complications from VATS procedures (persistent air leaks, hemorrhage, tumor seeding, etc) have decreased. Overall, major complication rates of 1%-2% are reported. Faster patient recovery, shorter hospital stays, decreased pain are major advantages of VATS, although long-term differences between videoscopic and formal thoracotomy using muscle-sparing incisions are yet to be demonstrated.

► Pleural Biopsy

Biopsies of the pleura can be performed either using percutaneous needle techniques, VATS, or open surgical approaches. It is indicated when the cause of a pleural effusion cannot be determined by analysis of the fluid or when tuberculosis is suspected. A definitive diagnosis can be obtained in 60%-80% of cases of tuberculosis or cancer. The principal complication is pneumothorax. Five percent to 10% of biopsy specimens are inadequate for diagnosis. Biopsy of the pleura can be performed via videoscopic or open technique with minimal morbidity, providing the pathologist with a specimen superior to that of needle biopsy.

Yasufuku K et al: A prospective controlled trial of endobronchial ultrasound-guided transbronchial needle aspiration compared with mediastinoscopy for mediastinal lymph node staging of lung cancer. *J Thorac Cardiovasc Surg* 2011;142(6):1393.

► Lung Biopsy

A. Needle Biopsy

The most common indication for the use of transthoracic needle biopsy of the lung is the evaluation of a solitary pulmonary nodule. It may also be used to confirm the presence of metastatic disease. Lung biopsy may also be indicated in diffuse parenchymal disease and in some patients with localized lesions. Most commonly, lung biopsies are now performed under CT guidance. Complications following percutaneous needle biopsy include pneumothorax (5%-30%), hemothorax, hemoptysis, and air embolism. Pulmonary hypertension or cysts and bullae are contraindications. Several deaths have been reported. There is about a 60% chance of obtaining useful information. Additionally, there is controversy concerning the risks of spreading the tumor by needle biopsy in localized disease.

B. Surgical Biopsy

Thoracoscopy is the standard approach for open lung biopsy in patients who can tolerate single lung ventilation. Techniques for port placement vary, but all allow introduction of a stapler and operating thoracoscope. In addition to allowing smaller incisions, thoracoscopy allows for the visualization of multiple segments and taking multiple biopsies in diffuse diseases. For open biopsies a limited intercostal or anterior parasternal incision is used to remove a 3- to 4-cm wedge of lung tissue in diffuse parenchymal lung disease. The site of incision is selected for accessibility and potential diagnostic value. The incision is generally made at the fifth interspace on the right at the anterior axillary line to allow for access to all three lobes for biopsy. The middle lobe and lingula are selected in specific cases when pathology exists only in these areas, as they generally yield results of the poorest quality. Open lung biopsy is associated with a lower death rate, fewer complications, and greater diagnostic yield than needle biopsy. It is especially useful in critically ill, immunosuppressed patients for differentiation of infectious infiltrative lesions from neoplastic infiltrative lesions. Peripheral lesions are totally excised by wedge or segmental resection, and deeply placed lesions are removed by lobectomy in suitable candidates.

► Sputum Analysis

Sputum cytology can be valuable for detecting lung cancer. Specimens are obtained by deep coughing or by abrasion with a brush, or bronchial washings are obtained by either bronchoscopic or percutaneous transtracheal washing techniques. Specimens should be collected in the morning and delivered to the laboratory promptly. Centrifugation or filtration can be used to concentrate the cellular elements.

In primary lung cancer, sputum cytology is positive in 30%-60% of cases. Repeated sputum examination improves

the diagnostic return. Examination of the first bronchoscopic washing material yields a diagnosis in 60% of cases. Postbronchoscopy sputum analysis should always be made at 6-12 and 24 hours, as findings may be positive at these times when previous tests were negative. Cytologic analysis using immunohistochemistry to molecular markers (cytokeratins, hnRNP, etc) has improved accuracy and sensitivity and the ability to detect premalignant lesions.

► Computed Tomography Scan

Computed tomography (CT) is a cornerstone of evaluation of chest pathology. CT scanning is critical in the staging of carcinoma, and has value in defining the extent of metastatic disease.

► Magnetic Resonance Imaging

Although the major value of magnetic resonance imaging (MRI) in the thorax has been in cardiovascular imaging, it can also show invasion of lung cancer into the chest wall, vertebrae, and spinal cord as well as mediastinal structures. MRI has a particular niche in the evaluation of superior sulcus (Pancoast) tumors to establish involvement of the brachial plexus, subclavian vessel, or bony chest wall.

► Positron Emission Tomography

Positron emission tomography (PET) is an important tool in staging and workup of the cancer patient. PET scanners are widely available. PET scanning may identify unsuspected regional or distant disease in up to 20%-30% of patients with lung cancer or esophageal cancer compared with conventional imaging methods (CT, bone scan). PET scanning is more accurate than CT scan in detection of cancer spread to mediastinal lymph nodes. Because of the high negative predictive value of PET scanning, a negative PET scan in the mediastinum permits direct progression to thoracotomy. The presence of a positive PET scan in the mediastinum mandates either mediastinoscopy or, more recently, endoscopic evaluation of mediastinal lymph nodes because of false-positive PET scan results.

The combined PET/CT is highly accurate (> 90%), but by itself it has a 10%-20% false-positive rate in the mediastinum. Therefore, interpretations of PET results must be accepted with caution and must be confirmed by surgical staging when inconsistent with the overall clinical picture.

DISEASES OF THE CHEST WALL

LUNG HERNIA

A lung hernia results from a defect in the chest wall may be congenital or acquired as the result of trauma or a surgical operation. Most lung hernias are thoracic in location, but

cervical (defects of Sibson fascia) or diaphragmatic herniation may occur occasionally. Lung hernias may present as a tender subcutaneous mass that enlarges with cough or Valsalva. Other than this mass, they are usually asymptomatic. Once diagnosed, these hernias should be repaired, with repair of the skeletal defect and prosthetic mesh reinforcement. This may be done open or with VATS techniques.

CHEST WALL INFECTIONS

Infections of the chest wall or pleural spaces may pose complex challenges in medical management. Infections that appear to involve only the skin and soft tissues may actually represent outward extensions of deeper infection of the ribs, cartilage, sternum, or even the pleural space (empyema necessitatis). Inadequate drainage of superficial infection can lead to inward extension into the pleural space, causing empyema.

Subpectoral abscess is caused by suppurative adenitis of the axillary lymph nodes, rib or pleural infection, or posterior extension of a breast abscess. It may also occur as a complication of chest wall surgery (eg, mastectomy, pacemaker placement). Symptoms include erythema, induration of the pectoral region, and obliteration of the normal infraclavicular depression and may progress to systemic sepsis. Shoulder movement is painful. Organisms most commonly involved include hemolytic streptococci and *Staphylococcus aureus*. Treatment involves incisional drainage along the lateral border of the pectoralis major muscle and administration of systemic antibiotics.

Subscapular abscess may arise from osteomyelitis of the scapula but most commonly follows thoracic operations such as thoracotomy or thoracoplasty. Winging of the scapula or paravertebral induration of the trapezius muscle is usually present. A pleural communication is suggested if a cough impulse is present or if the size of the mass varies with position or direct pressure. The diagnosis is established by needle aspiration. Open drainage is indicated for pyogenic infections not involving the pleural space. Tubercular lesions should be treated by chemotherapy and needle aspiration, if possible.

► Osteomyelitis of the Ribs

In the past, osteomyelitis of the ribs was often caused by typhoid fever and tuberculosis. Except in children, hematogenous osteomyelitis is a rare problem today. Thoracotomy incisions may result in osteomyelitis.

► Sternal Osteomyelitis

Infection of the sternum most commonly follows median sternotomy incisions, particularly in diabetics. It presents as a postoperative wound infection or mediastinitis with drainage, fever, leukocytosis, and instability of the sternal closure.

Treatment consists of control of systemic sepsis with appropriate antibiotics, open drainage, resection of the involved sternum, and reconstruction of the defect with pectoralis muscle, serratus muscle, or omental coverage. Occasionally, sternal osteomyelitis will be due to tuberculosis.

► Infection of the Costal Cartilages & Xiphoid

Costal cartilage infections are relatively unresponsive to antibiotic therapy. Once devascularized, perichondral tissue necroses and acts as a foreign body to perpetuate the infection and favor sinus tract formation. The most common cause is direct extension of other surgical infections (eg, wound infection, subphrenic abscess). Surgical division of costal cartilages, as in a thoracoabdominal incision, may predispose to cartilage infection postoperatively if local sepsis develops. A wide variety of organisms have been implicated.

Erythema and induration with fluctuance and often spontaneous drainage can occur. The course can be fulminant or may be indolent over months or years, with periodic exacerbations. Associated osteomyelitis of the sternum, ribs, or clavicle may occur.

The treatment of choice includes resection of the involved cartilage and adjacent involved bony structures. Recurrence is due to underestimation of the extent of disease and inadequate resection.

► Reconstruction of the Chest Wall

Chest wall reconstruction may be necessary following trauma, surgical resection, or infection resulting in destruction of chest wall structures. Rigid reconstruction of the chest wall is generally recommended for defects greater than 5 cm, although posterior resections covered by the scapula will not necessarily need rigid mesh reconstruction. Advances in the use of musculocutaneous flaps and the supportive use of methyl methacrylate and Marlex mesh to produce solidity below these muscular flaps have facilitated repairs. In massive chest wall defects, vascularization of the area is essential and can be accomplished by use of omental flaps as well as pectoralis, latissimus dorsi, and rectus flaps. Microsurgical techniques for repair of such defects have greatly expanded the ability of plastic surgeons to deal with extensive resectional and infective processes.

Mahabir RC, Butler CE: Stabilization of the chest wall: autologous and alloplastic reconstructions. *Semin Plast Surg* 2011; 25: 34-42.

TIETZE SYNDROME (COSTOCHONDRITIS)

Tietze syndrome is a painful, nonsuppurative inflammation of the costochondral cartilages and is of unknown cause. Recent evidence suggests that costochondritis may represent a manifestation of seronegative rheumatic disease. Local

swelling and tenderness are the only symptoms; they usually disappear without therapy. The syndrome may recur.

Several reports have suggested the use of bone scintigraphy and chest CT for diagnosis of infected costochondritis. Bone scanning was effective in localizing and identifying inflamed costochondral junctions. Treatment is symptomatic and may include analgesics (NSAIDs) and local or systemic corticosteroids. When symptoms persist longer than 3 weeks and tumefaction suggests neoplasm, excision of the involved cartilage may be indicated and is usually curative.

Stochendahl MJ, Christensen HW: Chest pain in focal musculoskeletal disorders. *Medical Clin North Am* 2010;94(2):259-273.

MONDOR DISEASE (THROMBOPHLEBITIS OF THE THORACOEPIGASTRIC VEIN)

Mondor disease consists of localized thrombophlebitis of the anterolateral chest wall. It is more prominent in women than in men and occasionally follows mastectomy. There are few symptoms other than the presence of a localized tender, cordlike structure in the subcutaneous tissues of the abdomen, thorax, or axilla. The disease is self-limited and does not pose a risk of thromboembolism. The possibility of an infective origin or stasis of the interrupted venous return due to neoplasm must be ruled out.

CHEST WALL TUMORS

Chest wall tumors may be simulated by enlarged costal cartilages, chest wall infection, fractures, rickets, scurvy, hyperparathyroidism, and other conditions. Most commonly, chest wall lesions present as a mass with localized or referred pain; less than 25% are asymptomatic. Approximately 60% of all chest wall masses prove to be malignant. Lesions arise from one of the three components of the chest wall, including soft tissues (eg, muscle, nerve, fascia), bone, and cartilage.

The majority of tumors arise from either bone or cartilage. Rib involvement is more common than sternal presentation. Chest CT offers the most information for diagnosis and staging. Chest wall sarcomas are associated with pulmonary metastasis. Simple chest x-rays may initially identify a mass, especially if it is calcified. Bone scans should be obtained in all cases.

Initial diagnosis is obtained by limited incisional biopsy (transverse) if the mass is large (> 4 cm). Smaller lesions are excised en bloc, ensuring negative margins, with full knowledge that a malignancy is present in many cases. Classic teaching has been to perform en bloc wide local excisions with immediate reconstruction for all lesions at initial presentations. Progress with adjuvant multimodality therapy, however, for tumors such as rhabdomyosarcomas

and Ewing sarcoma supports the use of initial limited biopsy for tissue diagnosis to guide treatment planning.

► Specific Neoplasms

A. Benign Soft Tissue Tumors

1. Lipomas—Lipomas are the most common benign tumors of the chest wall. Occasionally, they are very large and lobulated, and they may have dumbbell-shaped extensions that indent the endothoracic fascia beneath the sternum through an intercostal space. They may communicate with a large mediastinal or supraclavicular component.

2. Neurogenic tumors—These may arise from intercostal or superficial nerves. Solitary neurofibromas are most common, followed by neurolemmomas.

3. Cavernous hemangiomas—Hemangiomas of the thoracic wall are usually painful and occur in children. Tumors may be isolated or may involve other tissues (eg, lung), as in Rendu-Osler-Weber syndrome.

4. Lymphangiomas—This rare lesion is seen most often in children. It may have poorly defined borders that make complete excision difficult.

B. Malignant Soft Tissue Tumors

Roughly 50% of all chest wall masses are sarcomas, yet overall they represent only a small percentage (5%) of all malignant soft tissue sarcomas. Survival is determined by the histologic grade, the completeness of resection, and the presence and development of metastases (synchronous or metachronous). Low-grade tumors have 5-year and 10-year survivals approaching 90% and 82%, respectively. With high-grade lesions, however, 5-year survival rates are only 30%-50%. The development of metastasis greatly reduces the chances of survival.

Treatment is directed at a complete resection with emphasis on achieving negative margins (1-2 cm). En bloc resection techniques include raising skin flaps and reconstruction with soft tissue flaps, Marlex mesh, and methyl methacrylate to correct chest wall deformity and prevent paradoxical chest movement.

There are many histologic subtypes of soft tissue sarcoma. Typically, low-grade sarcomas include desmoids or liposarcomas with low-grade features. Next most frequently seen are malignant fibrosarcoma, rhabdomyosarcoma, and malignant fibrous histiocytoma, which are usually high-grade lesions.

Individual histologic subtype is *not* by itself a significant prognostic variable, but histologic grade *is* significant. Metastases—either synchronous or metachronous—are most commonly to the lungs (75%) and should be resected if negative margins can be achieved and adequate lung func-

tion preserved. Therapy for low-grade lesions should consist of a complete resection. Incompletely resected lesions should be treated with external beam radiation therapy. High-grade lesions should be resected and patients enrolled in clinical trials evaluating the efficacy of systemic adjuvant chemotherapy. Postoperative radiotherapy is often helpful in the setting of close margins or tumor spillage.

1. Fibrosarcomas—Fibrosarcoma is the most common primary soft tissue cancer of the chest wall. It occurs most frequently in young adults. Treatment is neoadjuvant chemotherapy followed by resection. A subtype of these tumors includes neurofibrosarcomas, which involve the thoracic wall almost twice as often as other parts of the body. Also referred to as malignant peripheral nerve sheath tumors or malignant schwannomas, they often occur in patients with neurofibromatosis and usually originate from intercostal nerves.

2. Malignant fibrous histiocytoma/high-grade pleomorphic sarcoma—Malignant fibrous histiocytoma has a bimodal distribution, with peaks between 20 and 30 years of age and between 50 and 60. Although they are the most common soft tissue sarcoma of adults, they rarely rise from the chest wall. Treatment is neoadjuvant chemotherapy followed by resection, followed by additional adjuvant chemotherapy.

3. Rhabdomyosarcoma—Rhabdomyosarcoma is an uncommon tumor in adults but is the second most common chest wall tumor in children. Treatment is neoadjuvant chemoradiation, surgical resection, then ongoing chemotherapy and radiation. These tumors are aggressive and often unresectable.

4. Liposarcomas—These tumors account for approximately one-third of all primary cancers of the chest wall. They occur more often in men.

C. Benign Skeletal Tumors

1. Chondromas, osteochondromas, and myxochondromas—The combined frequency of these three cartilaginous tumors is about 30%-45% of all benign skeletal tumors. Cartilaginous tumors are usually single and occur with equal frequency in males and females between childhood and the fourth decade. The tumors are usually painless and tend to occur anteriorly along the costal margin or in the parasternal area. Wide local excision is curative.

2. Fibrous dysplasia—Fibrous dysplasia (bone cyst, osteofibroma, fibrous osteoma, and fibrosis ossificans) accounts for a third or more of benign skeletal tumors of the chest wall. This cystic bone tumor can occur in any portion of the skeletal system, but approximately half involve the ribs. The differential diagnosis includes cystic bone lesions

associated with hyperparathyroidism. The tumor is usually single and may be related to previous trauma. Some patients experience swelling, tenderness, or vague discomfort, but the lesion is usually silent and is detected on routine chest x-ray. Treatment consists of local excision.

3. Eosinophilic granuloma—Eosinophilic granuloma may occur in the clavicle, the scapula, or (rarely) the sternum. Coexisting infiltrates of the lung are often present. This condition often represents a more benign form of Langerhans cell histiocytosis or Hand-Schüller-Christian disease. Fever, malaise, leukocytosis, eosinophilia, or bone pain may be present. Rib involvement presents as a swelling with cortical bone destruction and periosteal new growth. The clinical picture can resemble osteomyelitis or Ewing sarcoma. When the disease is localized, excision will result in cure.

4. Hemangioma—Cavernous hemangioma of the ribs presents as a painful mass in infancy or childhood. The tumor appears on chest x-ray either as multiple radiolucent areas or as a single trabeculated cyst.

4. Miscellaneous—Fibromas, lipomas, osteomas, and aneurysmal bone cysts are all relatively rare lesions of the chest wall. The diagnosis is established after excisional biopsy.

D. Malignant Skeletal Tumors

1. Chondrosarcomas—Chondrosarcomas are the most common primary malignant tumor of the chest wall (20%-40%). They most commonly develop from the costochondral junctions of the first four ribs but can involve the sternum. About 15%-20% of all skeletal chondrosarcomas occur in the ribs or sternum. Most appear in patients 20-40 years of age. Local involvement of pleura, adjacent ribs, muscle, diaphragm, or other soft tissue may develop. Pain is uncommon and most patients complain only of the mass. Chest x-ray shows destroyed cortical bone, usually with diffuse mottled calcification, and the border of the tumor is indistinct. Successful treatment necessitates wide local excision and en bloc resection to achieve negative margins. Incomplete excision carries a significantly worse prognosis. Overall survival, as in all soft tissue sarcomas, is heavily dependent on the histologic grade. Completely resected low-grade chondrosarcoma has a 60%-80% 5-year survival rate. Patients with high-grade lesions who subsequently develop distant metastasis have only 20%-30% 5-year survival.

Although a complete resection can often be curative, local recurrence portends future metastatic disease and poor survival. Therefore, even in the setting of large tumors (> 15-20 cm), resection should be considered even if it necessitates removal of more than eight ribs. With epidural pain control and immediate reconstruction techniques, most patients will do well. Despite large chest wall resections, most patients can be immediately extubated and will not suffer drastic changes in pulmonary function or chest wall dynamics.

2. Ewing sarcoma (hemangioendothelioma, endothelioma)—Ewing sarcoma is a small, round cell-type tumor which most commonly occurs in a single rib. It accounts for 10%-15% of all primary chest wall tumors. Presentation as a primary chest lesion is not common (< 15%). Typically, Ewing sarcoma presents as a large, warm, painful soft tissue mass usually associated with pleural effusion. Systemic symptoms such as fever, malaise, and weight loss are common. Radiologic studies demonstrate the classic “onion skin” appearance caused by widening and sclerosis of the cortex as multiple layers of new bone are produced.

Diagnosis can usually be made by fine-needle aspirate or incisional biopsy. Histologically, these tumors are unique and consist of broad sheets of small polyhedral cells with pale cytoplasm and small hyperchromatic nuclei. They stain periodic acid-Schiff-positive.

Ewing sarcoma is commonly a disease of childhood and adolescence. The most important prognostic indicator for survival is development of distant metastases. Current therapy consists of neoadjuvant chemotherapy (including cyclophosphamide, dactinomycin, doxorubicin, and vincristine) surgical resection if the tumor is well demarcated and can be completely resected. Radiotherapy may be indicated as postoperative adjuvant treatment, or in the case of tumors that are not completely resectable. Overall, 5-year survivals range from 15% to 60%. Long-term survivals (10 years) are achievable in patients who do not develop metastases.

3. Osteogenic sarcoma (osteosarcoma)—Osteosarcoma occurs in the second and third decades, and 60% of cases occur in men. It is more aggressive than chondrosarcoma. X-ray findings consist of bone destruction and recalcification at right angles to the bony cortex, which gives the characteristic “sunburst” appearance. Osteogenic sarcoma most commonly presents as an extremity lesion, with only a small percentage of cases being chest wall primaries. Overall, less than 5% of all osteogenic sarcomas arise in the chest wall. Osteogenic sarcoma occurs in the second to fourth decades of life, half-again more commonly in men than in women. It is associated with environmental triggers, as well as with mutations in the retinoblastoma gene (RB1, 500-1000x risk) and Li-Fraumeni syndrome (p53, 15x risk). Typically, they are more aggressive tumors with a propensity for early metastasis to lung and bone.

Osteogenic sarcoma differs from chondrosarcoma in that it is usually sensitive to chemotherapy. They are treated with neoadjuvant chemotherapy followed by surgical resection. Even with neoadjuvant treatment, however overall 5-year survival after complete resection and postoperative chemotherapy may only be 15%.

4. Myeloma (solitary plasmacytoma)—Solitary plasmacytomas of the chest wall are comparatively rare lesions. They

constitute 5%-20% of all chest wall tumors. Radiologically, they present as classic “punched-out” lytic lesions without evidence of new bone formation. They are more common in men than in women and typically present in the fifth to seventh decades of life. Over 75% of the time, solitary chest wall plasmacytomas are associated with diffuse multiple myeloma. Survival is based on the development of systemic disease. Local control and relief of pain are achieved with radiation therapy (usually 3000-4600 cGy). Once systemic disease is diagnosed, treatment consists of chemotherapy. Overall, 5-year and 10-year survivals for solitary plasmacytomas of the chest wall are 35%-40% and 15%-20%, respectively. Typical median survivals after treatment with radiation therapy and chemotherapy average 56 months.

E. Metastatic Chest Wall Tumors

Metastases to bones of the thorax are often multiple and are usually from tumors of the kidney, thyroid, lung, breast, prostate, stomach, uterus, or colon. Renal cell and thyroid malignancies have a high propensity for metastasizing to the sternum. Occasionally, they present as a pulsatile mass due to the excessive vascularity of the metastasis. An aneurysm of the ascending thoracic aorta, while rare, must be considered in the differential diagnosis and ruled out prior to attempts at excisional biopsy. Involvement by direct extension occurs in carcinoma of the breast and lung. Primary lung cancer with direct extension to chest wall without nodal involvement (T3 N0) carries a reasonable 5-year survival (40%-50%) when treated with radical en bloc resection. Lung metastasis with direct chest wall extension should be treated with radical en bloc resection of the chest wall and underlying lung.

DISEASES OF THE PLEURA

Diseases of the pleura may be benign or malignant and may represent primary pleural processes, localized extrapleural diseases, or systemic illnesses. The most common pleural problem is the presence of air (pneumothorax) within the pleural space. Pleural effusions—accumulations of fluid—result from benign sterile fluid, malignant fluid, pus, chyle, or blood. Primary pleural tumors are uncommon, but involvement of the pleura with metastatic cancer is common.

The most common symptoms of pleural disease are pain and dyspnea. The pain is sharp, and it is characteristically worsened by respiratory movements, often inhibiting inspiration. Pleural pain is mediated through somatic intercostal

nerves of the chest wall (cervical and costal pleura) and through the phrenic nerve (diaphragmatic and mediastinal pleura), causing chest wall or back pain and pain referred to the shoulder, respectively. The visceral pleura contains only sympathetic and parasympathetic nerve fibers and therefore is insensate; however, extension of visceral processes to involve the parietal pleura can produce typical pleuritic chest pain.

PLEURAL EFFUSION

Pleural effusion is the presence of fluid within the pleural space. More specific terminology may be used when the nature of the fluid is known. Hydrothorax is a collection of serous (most often transudative but also exudative) fluid, while pus in the pleural cavity is referred to as a pyothorax or empyema. Additional terms are used for blood (hemothorax) and chyle (chylothorax). Abnormal pleural fluid accumulates as a result of one or more of the following mechanisms: (1) increase in the pulmonary vascular hydrostatic pressure (congestive heart failure, mitral stenosis); (2) decrease in the vascular colloid oncotic pressure (hypoproteinemia); (3) increase in the capillary permeability due to inflammation (eg, pneumonia, pancreatitis, sepsis); (4) decrease in the intrapleural pressure (atelectasis); (5) decrease in the lymphatic drainage (carcinomatosis); (6) transdiaphragmatic movement of abdominal fluid through lymphatics or physical defects (ascites, pancreatic pseudocyst rupture); and (7) rupture of a vascular or lymphatic structure (traumatic injury).

Decreased respiratory excursion, diminished breath sounds, dullness to percussion, a pleural friction rub, and local tenderness are signs that indicate the presence of pleural effusion. With long-standing and advanced disease, contraction of the hemithorax with narrowed intercostal spaces and localized bulging, swelling, or redness may occur. Chest radiographs demonstrate varying degrees of opacification of the ipsilateral hemithorax. Accumulation of 300-500 mL fluid causes blunting of the costophrenic angle on x-ray. If the entire hemithorax is opacified, 2000-2500 mL may be present. The mediastinum may be shifted to the contralateral side in the presence of a large effusion, or it may remain in the midline—particularly if proximal bronchial obstruction results in lobar or total lung atelectasis, if the mediastinum is fixed from fibrosis or tumor infiltration, if the ipsilateral lung is infiltrated with tumor, or if malignant mesothelioma is present. CT scanning may be required to evaluate complex, loculated, or recurrent pleural fluid collections. Interventional radiology services are useful for loculated pleural effusions that may be managed by percutaneous drain placement under CT guidance.

Generally, serous effusions are separated into two broad categories—transudates and exudates—based on the physical and cellular characteristics of the pleural fluid. Identification of the specific type of effusion aids in determination of the cause and most often depends on examination of at least

20 mL of fluid obtained by thoracentesis. Basic tests should include total protein, lactate dehydrogenase (LDH), total and differential cell counts, glucose, pH, cytology, and Gram stain with culture. Furthermore, simultaneous serum total protein, LDH, and glucose should be measured. Effusions with total protein content less than 3 g/dL (or a fluid-serum

ratio lower than 0.5), an LDH level less than 200 units/dL (or a fluid-serum ratio < 0.6), and a specific gravity below 1.016 represent transudates, while all other effusions are classified as exudates. The results of these basic tests frequently allow the underlying pathologic process to be elucidated (Table 18–1).

Table 18–1. Differential diagnosis of pleural effusions.¹

	Tuberculosis	Cancer	Congestive Heart Failure	Pneumonia and Other Nontuberculous Infections	Rheumatoid Arthritis and Collagen Disease	Pulmonary Embolism
Clinical context	Younger patient with history of exposure to tuberculosis.	Older patient in poor general health.	Presence of congestive heart failure.	Presence of respiratory infection.	History of joint involvement; subcutaneous nodules.	Postoperative immobilized, or venous disease.
Gross appearance	Usually serous; often sanguineous.	Often sanguineous.	Serous.	Serous.	Turbid or yellow-green.	Often sanguineous.
Microscopic examination	May be positive for acid-fast bacilli; cholesterol crystals.	Cytology positive in 50%.	—	May be positive for bacilli.	—	—
Cell count	Few have > 10,000 erythrocytes; most have > 1000 leukocytes, mostly lymphocytes.	Two-thirds bloody; 40% > 1000 leukocytes, mostly lymphocytes.	Few have > 10,000 erythrocytes or > 1000 leukocytes.	Polymorphonuclears predominate.	Lymphocytes predominate.	Erythrocytes predominate.
Culture	May have positive pleural effusion; few have positive sputum or gastric washings.	—	—	May be positive.	—	—
Specific gravity	Most > 1.016.	Most > 1.016.	Most > 1.016.	> 1.016.	> 1.016.	> 1.016.
Protein	90% 3 g/dL or more.	90% 3 g/dL or more.	75% > 3 g/dL.	3 g/dL or more.	3 g/dL or more.	3 g/dL or more.
Sugar	60% < 60 mg/dL.	Rarely < 60 mg/dL.	—	Occasionally < 60 mg/dL.	5–17 g/dL (rheumatoid arthritis).	—
Other	No mesothelial cells on cytology. Tuberculin test usually positive. Pleural biopsy positive.	If hemorrhagic fluid, 65% will be due to tumor; tends to recur after removal.	Right-sided in 55%–70%.	Associated with infiltrate on x-ray.	Rapid clotting time; LE cell or rheumatoid factor may be present.	Source of emboli may be noted.

Other exudates: $\text{sppr} > 1.016$

Fungal infection: Exposure in endemic area. Source fluid. Microscopy and culture may be positive for fungi. Protein 3 g/dL or more. Skin and serologic tests may be helpful.

Trauma: Serosanguineous fluid. Protein 3 g/dL or more.

Chylothorax: History of injury or cancer. Chylous fluid with no protein but with fat droplets.

1. Hydrothorax

► Malignancy

More than 25% of all pleural effusions are secondary to cancer, and 35% of patients with lung cancer, 23% of patients with breast cancer, and 10% of patients with lymphoma develop malignant pleural effusions during the course of their disease. Approximately 10% of malignant effusions are secondary to primary pleural tumors, mostly mesothelioma. The mechanism is primarily through lymphatic obstruction in either the peripheral lung or central lymph node channels of the mediastinum. Malignant pleural effusions can be serous, serosanguineous, or bloody and are diagnosed primarily by demonstrating malignant cells in the fluid. Cytologic confirmation is successful 50%, 65%, and 70% of the time after one, two, or three thoracenteses, respectively. Closed pleural biopsy alone is successful in only 50% of cases, but coupled with thoracentesis it can increase the diagnostic yield to 80%. Thoracoscopy with direct pleural biopsy, however, is successful in 97% of patients and should be considered in any patient with a suspicious effusion after two negative thoracenteses.

Treatment of malignant effusions is strictly palliative: Most patients die within 3-6 months of developing a malignant pleural effusion, so prompt diagnosis and therapy are essential. The goals of treatment are lung reexpansion and pleural symphysis. This is most readily accomplished with placement of a chest tube (2028F) and closed-tube drainage for 24-48 hours. Generally, no more than 1 L is allowed to drain initially. Subsequently, 200-500 mL is allowed to drain every 1-2 hours until the effusion is fully drained. This controlled draining avoids the rare complication of reexpansion pulmonary edema. Once full lung expansion is obtained pleurodesis should be performed with an appropriate agent before loculations have formed. Different chemical, radioactive, and infectious agents have been used in the past with varying success rates, but most commonly used are talc (87%-100% insufflation; 83%-100% slurry), or doxycycline. Finally, mechanical pleurectomy without chemical instillation can control pleural effusions in over 99% of patients, but this requires an operative procedure. Talc is inexpensive, highly effective, and easily administered either as a powder insufflated into the open chest or as a slurry instilled through a chest tube.

Complications following pleurodesis include pneumothorax, loculated hydrothorax, fever, infection (empyema), acute respiratory distress syndrome (particularly following bilateral simultaneous pleurodesis, which for this reason alone are contraindicated), and recurrence. Problems are uncommon, and most patients can have their chest tubes removed within 48-72 hours following talc pleurodesis.

► Cardiovascular Disease

Pleural effusions are common findings in patients with moderate to severe congestive heart failure. Heart failure

may be secondary to ischemia, valvular heart disease, viral myocarditis, congenital heart disease, and other less common lesions. The effusion may be bilateral or unilateral. When unilateral, the right hemithorax is most often affected. Fluid frequently involves the interlobar fissures (most commonly the minor fissure on the right) and can form localized collections simulating mass lesions known as "pseudotumors." Other cardiovascular causes of pleural effusions include constrictive pericarditis and pulmonary venous obstruction.

► Renal Disease

Hydronephrosis, nephrotic syndrome, and acute glomerulonephritis are on occasion associated with pleural effusions. Rupture of the collecting system into the pleural space can also produce a hydrothorax. In this latter case, the pleural fluid creatinine will be elevated (fluid-serum creatinine ratio significantly > 1.0).

► Pancreatitis

Moderate to severe pancreatitis is associated with a pleural effusion that characteristically occurs on the left and contains fluid with an amylase concentration substantially higher than that in the serum. Rarely pseudocysts of the capsule of the pancreas may communicate with the pleural space, resulting in high-volume pleural effusions.

► Cirrhosis

Approximately 5% of patients with cirrhosis and ascites will develop a pleural effusion. In contrast to pancreatitis, nearly all of these effusions occur on the right side.

► Thromboembolism

Pulmonary thromboemboli are sometimes accompanied by a pleural effusion. These effusions are typically serosanguineous and small, but they may be frankly bloody and massive. Characteristic x-ray findings are almost always present in the lung. Since the fluid is usually reabsorbed in a short period of time, drainage is seldom necessary.

2. Thoracic Empyema

Pyothorax (empyema thoracis) is the accumulation of pus within the pleural cavity. The pus is usually thick, creamy, and malodorous. If empyema occurs in the setting of underlying suppurative lung disease (ie, pneumonia, lung abscess, or bronchiectasis), it is referred to as a parapneumonic empyema (60% of cases). Other causes of thoracic empyema are surgery (20%), trauma (10%), esophageal rupture, other chest wall or mediastinal infections, bronchopleural fistula, extension of a subphrenic or hepatic abscess, instrumentation of the pleural space (thoracentesis, chest tube placement,

etc), and, rarely, hematogenous seeding from a distant site of infection.

Empyemas are divided into three phases based on their natural history: acute exudative, fibrinopurulent, and chronic organizing. The *acute exudative phase* is characterized by the outpouring of sterile pleural fluid (incited by pleural inflammation), with a low viscosity, white blood cell count, and LDH concentration as well as normal glucose level and normal pH. The pleura remains mobile during this phase. The *fibrinopurulent phase* develops at approximately 2-7 days, marked by an increase in the turbidity, white blood cell count, and LDH levels in the fluid. Glucose levels and pH of the fluid decrease and fibrin is deposited on pleural surfaces, limiting the empyema but also fixing (trapping) the lung. The chronic organizing phase begins 7-28 days after the onset of the disease and is characterized by a pleural fluid glucose level less than 40 mg/dL and a pH less than 7.0. The pleural exudate becomes thick, and the pleural fibrin deposits thicken and begin to organize, further immobilizing the lung. In patients with inadequately treated chronic empyema, erosion through the chest wall (empyema necessitatis), chondritis, osteomyelitis of the ribs or vertebral bodies, pericarditis, and mediastinal abscesses may occur.

The bacteriology of thoracic empyema has evolved over the years. Prior to the discovery of penicillin in the 1940s, most empyemas were caused by pneumococci and streptococci. With modern antibiotics and improved anaerobic culture techniques, however, the most common isolates from adult empyemas are now anaerobic bacteria, particularly bacteroides species as well as fusobacterium and *Peptococcus* species.

Staphylococcus is the most common organism causing empyema (92% in children under 2 years), and staphylococcal empyema is one of the most common complications of staphylococcal pneumonias in both adults and children (Table 18-2). Gram-negative bacteria also continue to be significant pathogens, particularly in parapneumonic empyemas. *Escherichia coli* and pseudomonas species account for 66% of aerobic gram-negative empyemas, and

other organisms include *Klebsiella pneumoniae*, *Proteus* species, *Enterobacter aerogenes*, and *Salmonella*. Rarely, fungi (*Aspergillus*, *Coccidioides immitis*, *Blastomyces*, and *Histoplasma capsulatum*) and parasites such as *Entamoeba histolytica* can cause empyemas. In a review, empyemas were found to contain anaerobic bacteria in only 35% of cases, aerobic bacteria in only 24%, and a combination in 41%. In addition, the average number of bacterial species isolated was 3.2 per patient.

Aspiration of oropharyngeal flora may represent a source of polymicrobial infection. Although patients may rarely be completely asymptomatic, most patients with thoracic empyemas present with varying symptoms depending on the underlying disease process, the extent of the pleural involvement, and the immunologic state of the patient. Patients typically complain of fever, pleuritic chest pain or a sense of chest heaviness, dyspnea, hemoptysis, and a cough usually productive of purulent sputum. Signs of thoracic empyema include anemia, tachycardia, tachypnea, diminished breath sounds with dullness to percussion on the involved side, clubbing of fingertips, and occasionally pulmonary osteoarthropathy.

Although the medical history and physical examination often suggest the presence of thoracic empyema, the plain chest radiograph is the most important noninvasive diagnostic test. Empyemas may be associated with an underlying pneumonia, lung abscess, or pleural effusion and appear as posterolateral D-shaped densities on x-ray. In large empyemas, the mediastinum may be shifted away from the affected side. Bronchoscopy should be performed on all patients to exclude the presence of endobronchial obstruction. CT scanning provides critical anatomic detail regarding loculations and can assist in differentiation of empyema from lung abscess.

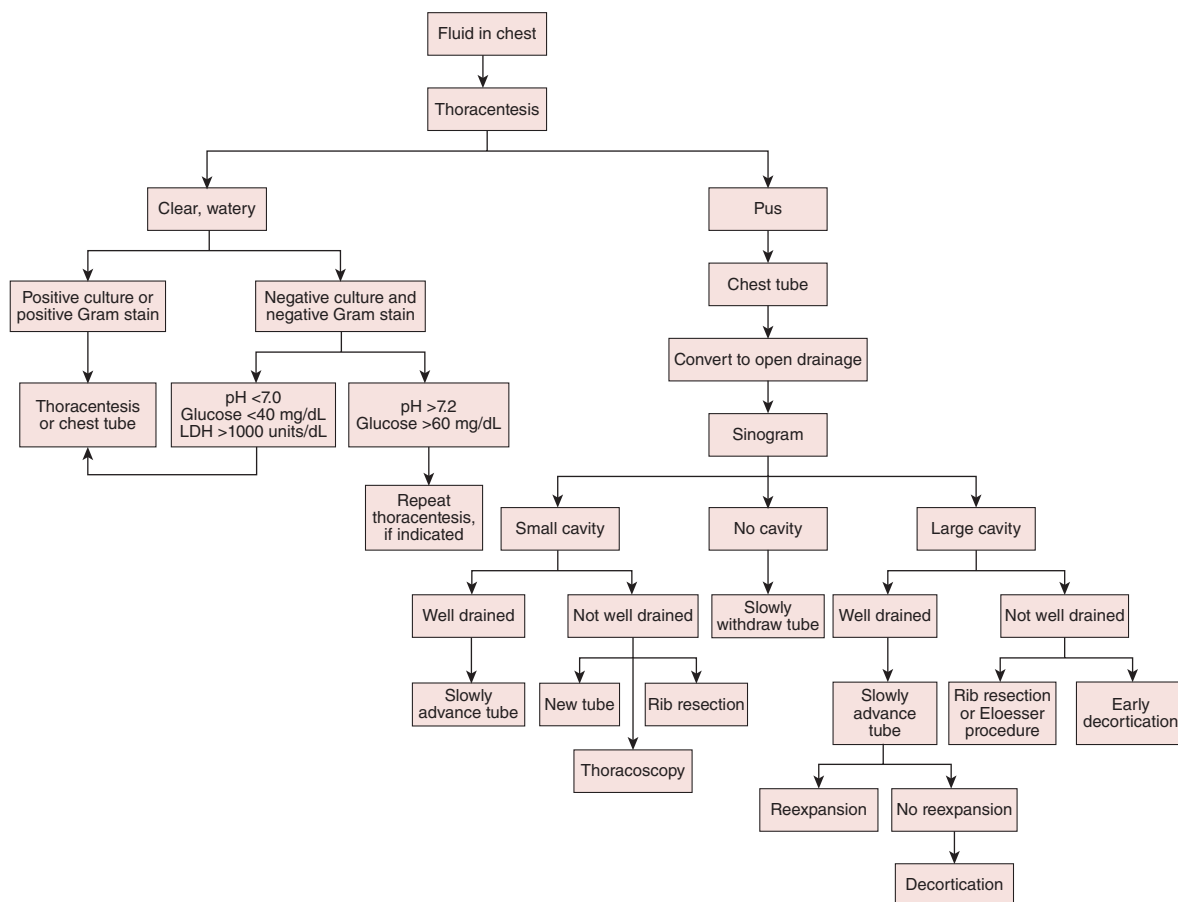

Thoracentesis is the procedure of choice for the diagnosis of thoracic empyema. Aspiration of pus establishes the diagnosis, permitting identification of the offending organisms. In early empyemas—particularly those partially treated with antibiotics—the pleural fluid may not be frankly purulent. In these cases, a pleural fluid pH less than 7.0, glucose less than 40 mg/dL, and an LDH level greater than 1000 units/L strongly suggest an evolving empyema even if Gram stain and cultures fail to identify organisms.

Goals for the treatment of thoracic empyemas include: (1) control of the infection; (2) removal of the purulent material with obliteration and sterilization of the pleural space and reexpansion of the lung; and (3) elimination of the underlying disease process.

Options for treatment include repeated thoracentesis, closed tube thoracostomy, rib resection and open drainage, decortication and empyemectomy, thoracoplasty, and muscle flap closure. Adjunctive maneuvers reported to aid in the disruption and drainage of loculated empyemas include instillation of fibrinolytic enzymes (such as tPA) and video-

Table 18-2. Incidence of various complications of staphylococcal pneumonia in adults and children (in %).

	Adults	Children
Abscess	25	50
Empyema	15	15
Pneumatocele	1	35
Effusion	30	55

▲ **Figure 18–8.** Management of empyema. (Modified and reproduced with permission from Shields TW. *General Thoracic Surgery*, 3rd ed. Williams & Wilkins, Baltimore, 1989.)

assisted thoracoscopic debridement. A rational approach to empyema management is outlined in Figure 18–8. Initially, an intercostal catheter of adequate size is carefully inserted into the most dependent portion of the empyema cavity. If after 24–72 hours sepsis persists—or if there is any question as to the adequacy of drainage—a CT scan should be obtained. If, on the other hand, complete drainage and reexpansion of the lung are achieved, no further drainage procedures are necessary.

Patients with residual spaces that are inadequately drained, patients with continued sepsis, and patients thought to require prolonged tube drainage are candidates for open drainage procedures. These can usually be safely performed 10–14 days after closed-tube drainage, since the pleurae fuse by that time and the risk of pneumothorax and lung collapse is eliminated. Options for an open drainage include simple rib resection and open flap drainage

(Eloesser procedure). Simple rib resection involves the removal of short segments (3–6 cm) of one, two, or three ribs at the most dependent portion of the empyema cavity (at or anterior to the posterior axillary line). A tube can be placed through this opening and effective drainage established. A second approach involves the creation of a U-shaped flap of chest wall that is sewn to the parietal pleura after resection of short segments (3–6 cm) of one, two, or three ribs. This creates an epithelialized tract for long-term tubeless drainage of empyema cavities. This type of an open drainage allows the empyema cavity to drain reliably and to be easily debrided, irrigated, and cleaned. Ultimately, through lung reexpansion, wound contraction, and granulation, the cavity often completely disappears.

Another option is early decortication and empyemectomy. This is especially useful for good-risk patients with early loculated empyemas and inadequate tube drainage

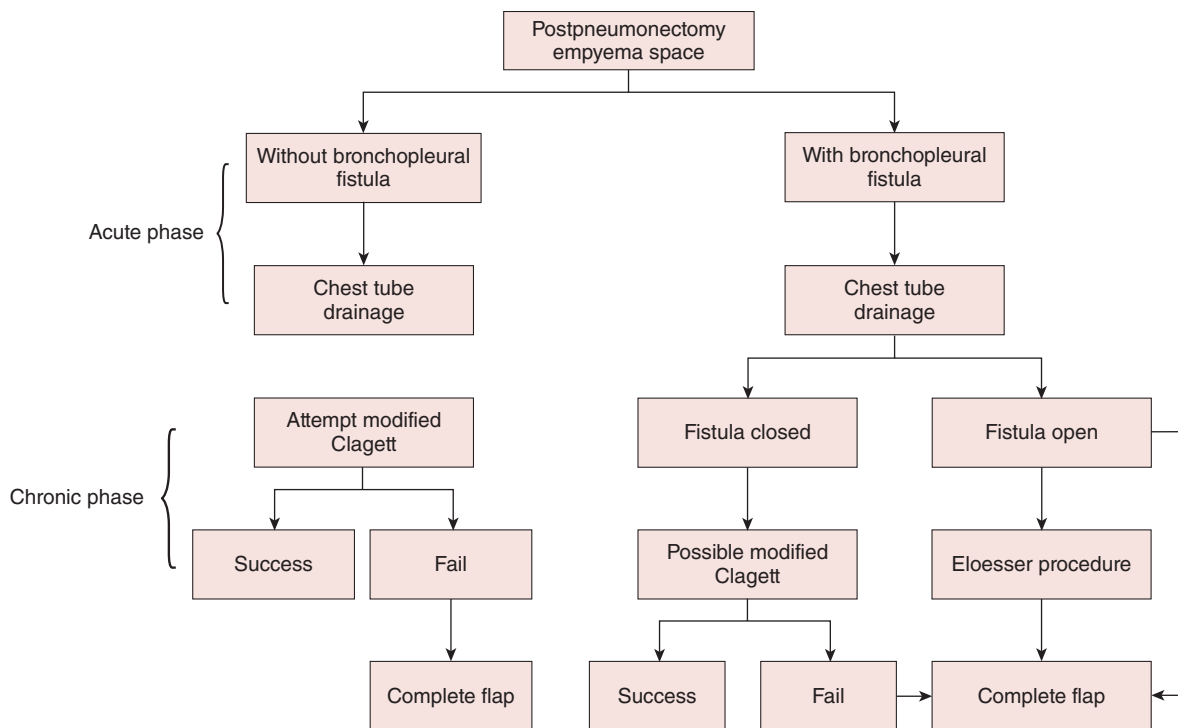

▲ **Figure 18-9.** Postlobectomy empyema. (Modified and reproduced with permission from Shields TW. *General Thoracic Surgery*, 3rd ed. Williams & Wilkins, Baltimore, 1989.)

or lung expansion. Furthermore, if performed early in the course of the process, resection of both parietal and visceral pleural peels (decortication) can be performed as a thoracoscopic procedure. More advanced or chronic disease involves a thoracotomy with decortication with resection of the intact empyema itself (empyemectomy), if possible. The best results with this approach are obtained when the underlying lung is entirely normal and reexpands fully. Posttraumatic empyema, in particular, has been amenable to this treatment.

Empyemas that occur following pulmonary resection may be difficult to manage. If residual lung is present (resections less than pneumonectomy), the general principles outlined above still apply, although a complicating bronchopleural fistula is often present (Figure 18-9). Simple tube drainage is instituted initially followed by open drainage if necessary. Empyemas following pneumonectomy, however, pose a special problem because there is no longer any lung to obliterate the infected space. In addition, postpneumonectomy empyemas frequently are associated with bronchopleural fistulas. In these patients, specific surgical procedures designed to obliterate residual intrathoracic spaces and in many cases close remaining bronchopleural fistulas may be required (Figure 18-10). In the absence of a bronchopleural fistula, sterilization and closure of a postpneumonectomy space (without obliteration) may be attempted using an irrigation catheter inserted into the apex of the chest cavity.

An antibiotic solution specific for the organisms present is then infused into the chest. The solution is allowed to drain through a dependent tube or opening created by simple rib resection. After 2-8 weeks, the catheters are removed and the cavity is closed. The success rate with this technique is quite variable and is reported to be 20%-88%. For patients who fail this approach and for those patients with bronchopleural fistulas, the main goal of therapy is to obliterate the residual space and close any bronchopleural fistulas. This is most readily accomplished by the transposition of muscle with or without omentum into the empyema cavity. Multiple muscles may be required, including pectoralis major, latissimus dorsi, serratus anterior, intercostal muscle, and rectus abdominis (Figure 18-11). Use of these muscles is highly successful in closing any remaining bronchopleural fistulas and in completely obliterating the remaining intrathoracic space. The success of muscle flap closure of empyema spaces has made thoracoplasty (once a common procedure for reducing empyema spaces) a rare operation.

Antibiotics are an important adjunct in the treatment of empyemas, but it must be emphasized that drainage is the primary treatment modality. Although antibiotic therapy is always instituted early in the course of therapy when signs of systemic infection generally are present, they need not be continued once effective drainage is established. In fact, overuse of antibiotics may lead to the generation of resistant bacteria and therefore compromise the success of

▲ **Figure 18–10.** Postpneumonectomy empyema. (Modified and reproduced with permission from Shields TW. *General Thoracic Surgery*, 3rd ed. Williams & Wilkins, Baltimore, 1989.)

any subsequent procedures designed to obliterate residual intrathoracic space.

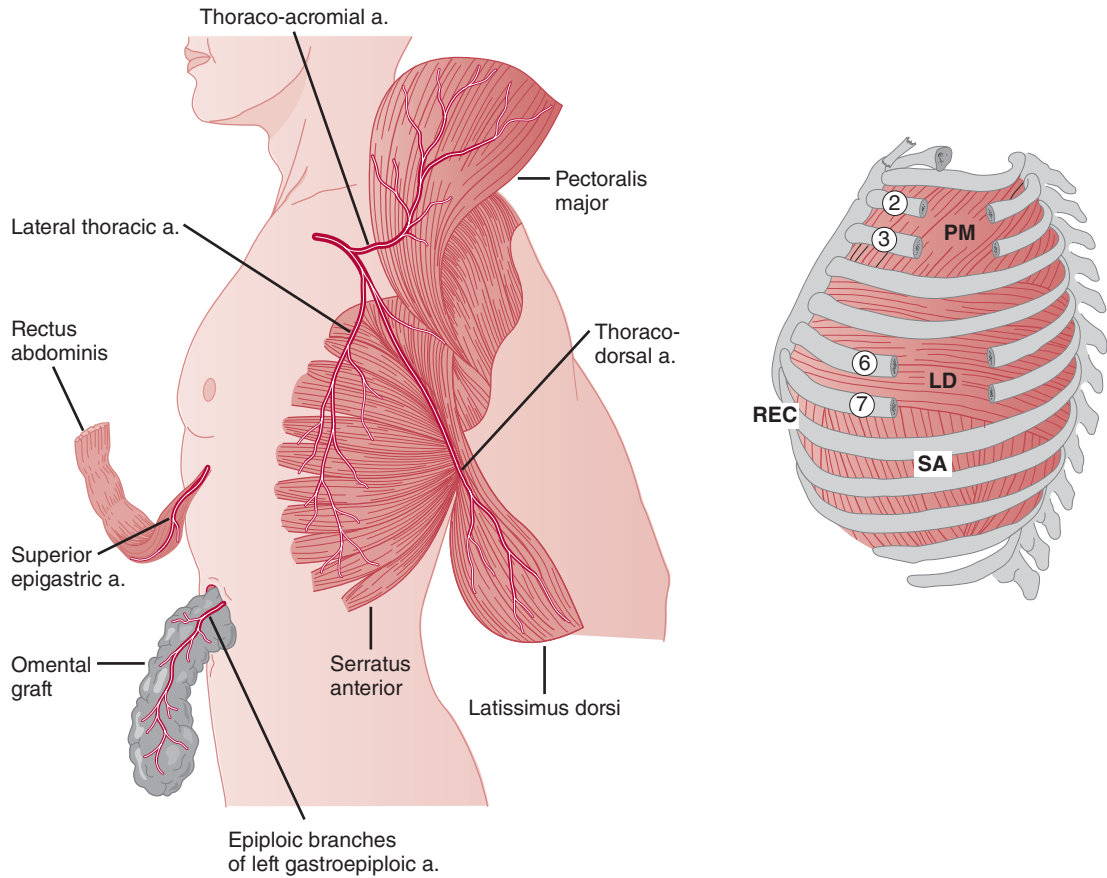

Krassas A et al: Current indications and results for thoracoplasty and intrathoracic muscle transposition. *Eur J Cardiothorac Surg* 2010;37(5):1215.

3. Hemothorax

Blood in the pleural space usually occurs secondary to trauma, surgery, diagnostic or therapeutic procedures, neoplasms, pulmonary infarction, and infections (tuberculosis). Most hemothoraces can be treated effectively with large-bore (32-36F) closed chest tube drainage, particularly since small amounts of blood (occupying less than one-third of the hemithorax) are readily reabsorbed by the body. However, if significant blood clot has formed (occupying more than one-third of the hemithorax) or if secondary infection occurs, further measures must be taken to avoid the development of an empyema or fibrothorax with pulmonary compromise. Many hemothoraces requiring more than simple tube drainage can be managed with VATS procedures. Rarely, open thoracotomy may be required for complete decortication and evacuation.

4. Chylothorax

Accumulation of chyle within the pleural space is most often due to surgical procedures, particularly cardiothoracic and esophageal operations. Trauma, malignancy, central venous catheterization, congenital lymphatic malformations, thoracic aortic aneurysms, filariasis, and cirrhosis may also rarely cause chylothorax. Penetrating thoracic trauma can lacerate the thoracic duct at any level, but blunt thoracic trauma usually causes a shearing of the duct at the right crus of the diaphragm. This may also occur with violent coughing or hyperextension of the spine. The initial treatment of chylothorax is similar to that of a malignant pleural effusion. Closed chest tube drainage is instituted; the lung is fully reexpanded; and a low-fat diet is started. In some cases, intravenous hyperalimentation (either peripheral or central) may greatly improve the patient's condition. Some evidence supports the use of somatostatin to decrease the output from chylous effusions. The irritating nature of chyle promotes pleurodesis, and in half of patients the leak will stop spontaneously. The instillation of sclerosing agents (see section on pleural effusion, above) has also been advocated to increase the chances of success. If chyle continues to drain for more than 7 days or if significant drainage

▲ **Figure 18-11.** Extrathoracic muscle flap closure of a postpneumonectomy empyema cavity.

continues for even a shorter period of time, serious consideration should be given to operation since patients quickly become malnourished from the large associated protein losses. Video-assisted thoracoscopic techniques are usually ideal, making open thoracotomy rarely necessary. The standard approach is via the right chest, where the thoracic duct may be identified as it emerges from beneath the diaphragm between the aorta and the azygos vein. Ligation of the tissues in this area is usually all that is needed.

PNEUMOTHORAX

Air in the pleural space (pneumothorax) can occur as a result of a breach in either the parietal (trauma, esophageal perforation, surgery, etc) or visceral pleura (bullae, fine-needle aspirations, etc). Rarely, infections of the pleural space with gas-forming organisms may produce a pneumothorax. Since a chest radiograph is only a two-dimensional representation of a three-dimensional space, a relatively small separation of

the pleural surfaces (eg, 1 cm) on a chest x-ray can translate into a relatively large pneumothorax. A large amount of intrapleural air that causes a shift of the mediastinum toward the contralateral lung is referred to as a tension pneumothorax. A pneumothorax associated with an open chest wound may be termed an open pneumothorax or sometimes a “sucking chest wound.” *Tension and open pneumothoraces are surgical emergencies because both ventilation and venous return of blood to the heart are compromised.* Intrapleural air may mix with blood, as frequently occurs after trauma (hemopneumothorax) or esophageal perforation (pyopneumothorax).

Pneumothoraces usually are classified as either spontaneous or acquired (those caused by a specific event such as trauma, invasive procedures, etc). Spontaneous pneumothoraces sometimes are divided into “primary” and “secondary” categories; however, all spontaneous pneumothoraces are secondary to some underlying pathologic process, and such a division is therefore strictly artificial. Most commonly,

spontaneous pneumothoraces are caused by rupture of small subpleural blebs due to increased transpulmonary pressure most pronounced at the apex of the lung (apex of the upper lobe and superior segment of the lower lobe). Coughing, rapid falls in atmospheric pressure (> 10 millibars/24 h), rapid decompression (scuba divers), and high altitudes (jet pilots) all are associated with increased transpulmonary pressures and spontaneous pneumothorax. In addition, normal transpulmonary pressures can cause rupture of blebs in patients with connective tissue disorders such as Marfan syndrome. Other causes of spontaneous pneumothorax include apical bullae (patients with chronic obstructive pulmonary disease [COPD]), *Pneumocystis* pneumonia (patients with AIDS), metastatic cancer (particularly sarcomas), lymphangiomyomatosis, eosinophilic granuloma, rupture of the esophagus or of a lung abscess, cystic fibrosis, and menstruation (catamenial pneumothorax). Classically, however, spontaneous pneumothoraces occur in asthenic males (male-to-female ratio 6:1) between the ages of 16 and 24, often with a history of smoking. The true incidence is unknown, since up to 20% of patients remain asymptomatic and do not seek medical attention.

Patients with pneumothoraces complain of pleuritic chest pain and dyspnea. If severe underlying cardiopulmonary disease exists or if a tension pneumothorax develops, symptoms become much more dramatic and include diaphoresis, cyanosis, weakness, and symptoms of hypotension and cardiovascular collapse. Physical examination reveals tachypnea, tachycardia, deviation of the trachea away from the involved side (tension pneumothorax), decreased breath sounds, hyperresonance, and diminished vocal fremitus on the involved side. Arterial blood gases may demonstrate hypoxia and occasionally hypocapnia from hyperventilation, and the EKG may show axis deviations, nonspecific ST segment changes, and T wave inversion. The standard test for the diagnosis of pneumothoraces is the posteroanterior (PA) and lateral chest radiograph. Exhalation accentuates the contrast between the collapsed lung and the intrapleural air as well as the magnitude of the collapse. Rarely, a CT scan may be necessary to differentiate a pneumothorax from a large bulla in patients with severe emphysema. In 5%-10% of patients, a small pleural effusion may be present and can be hemorrhagic.

The treatment of spontaneous pneumothoraces varies depending on the patient's symptoms and condition, the degree of collapse, the cause, and the estimate of the chance of recurrence. Small (< 20%-25%), stable, asymptomatic pneumothoraces in otherwise healthy patients can be followed (often on an outpatient basis) with the expectation of complete resolution within several weeks, since air is normally reabsorbed at a rate of 1%-1.25% per day. Larger asymptomatic pneumothoraces taking longer than 2-3 weeks to resolve place the patient at risk for developing trapped lung as a result of deposition of fibrin on the visceral pleura. These patients—as well as patients with symptoms, increas-

ing pneumothoraces, or pneumothoraces associated with pleural effusions—should have them evacuated. In highly selected patients, this can be accomplished with simple aspiration as long as the immediate and 2-hour delayed chest radiographs document reexpansion. It should be emphasized, however, that some small breaks in the visceral pleural seal once the lung collapses and can reopen with reexpansion. The chance of recurrence is 20%-50% with this method, and follow-up x-ray is therefore mandatory after 24 hours.

Most patients with significant pneumothoraces (> 30%) require placement of a closed-chest catheter (8-20F) for acceptable reexpansion. This catheter then can be placed either to underwater suction drainage or to a Heimlich (one-way) valve. If a Heimlich valve maintains full expansion, the patient may be treated as an outpatient; however, if a Heimlich valve fails to reexpand the lung fully or if the patient's condition is not optimal, admission to hospital and underwater chest tube suction drainage is required. Unless some contraindication exists, chest tubes should be placed in the midaxillary line at the level of the fifth intercostal space (nipple line). In women, the breast tissue should be retracted medially and avoided in the dissection to the chest wall. Placement with the use of blunt clamp dissection avoids the dangers of trocar insertion and should almost always be used. Following resolution of any air leakage, the tube may be taken off suction (water seal) and removed if the lung remains fully inflated. In patients with classic spontaneous pneumothoraces, the chance of recurrence increases with each episode. Following a single episode, the risk of a recurrent pneumothorax is 40%-50%. After two episodes, the risk increases to 50%-75%, and with three previous episodes, the risk is in excess of 80%. Currently, most first-time patients are treated initially with simple chest tube drainage; however, with subsequent recurrences, additional therapy generally is indicated. Furthermore, with the development of VATS, some feel that a more aggressive approach should be taken even for first-time pneumothoraces.

Patients with air leaks lasting longer than 7 days, patients who do not fully reexpand their lungs, patients in high-risk occupations (scuba divers, airline pilots, etc), patients with large bullae or poor pulmonary function, and patients with bilateral or recurrent pneumothoraces are candidates for additional medical (pleurodesis) or surgical intervention. Furthermore, patients who frequently travel to places distant from medical care are offered early surgical intervention. Previously, tetracycline pleurodesis was used to decrease the incidence of recurrent pneumothoraces. The use of this substance, however, was associated with significant pain and controversy. It is currently no longer available. The use of talc slurry or powder in this setting is also controversial due to the potential for long-term fibrothorax and restrictive lung disease but has been shown to reduce the recurrence rate to as low as 2%. Many other chemical agents have been used in the past, including mechlorethamine, doxycycline,

iodoform, guaiacol, urea, and hypertonic glucose, with varying success rates. Since pleurodesis can make subsequent surgical procedures more difficult, the use of this treatment continues to generate controversy.

Medically fit patients who are candidates for pleurodesis are also candidates for operation. The procedures used to prevent recurrent pneumothoraces include: (1) axillary thoracotomy with apical bullectomy, mechanical pleurodesis, and partial pleurectomy; and (2) complete parietal pleurectomy. Both procedures can be performed with either open or VATS techniques. Complete parietal pleurectomy generally is avoided, since some patients may require future thoracic surgical procedures that are extremely difficult in the face of total parietal pleurectomy. Apical bullectomy, mechanical pleurodesis, and partial apical pleurectomy have been shown to reduce the recurrence rate to near zero. In addition, this procedure is easily accomplished either with VATS techniques or through a small transaxillary thoracotomy, both of which are well tolerated.

Several special situations exist that require particular expertise in treatment decisions. Patients with cystic fibrosis and severe COPD may be candidates for lung transplantation, and both pleurodesis and operation may make subsequent transplantation more dangerous. Therefore, consultation with a transplant surgeon is advisable prior to considering these therapies. AIDS patients with *Pneumocystis* pneumonia and pneumothorax are extremely difficult to manage, having a high rate of persistent bronchopleural fistula, treatment failure, and death. For optimal management, the pulmonary surgeon should have extensive experience in the management of chest catheters.

PRIMARY PLEURAL TUMORS

Primary pleural tumors are uncommon neoplasms of two main types: diffuse malignant pleural mesotheliomas and localized fibrous tumors of the pleura (previously referred to as localized mesotheliomas). Although diffuse malignant pleural mesothelioma is the most common primary pleural tumor, involvement of the pleura with metastatic disease is more frequent and represents the most likely cause of any newly diagnosed pleural malignancy.

1. Localized Fibrous Tumors of the Pleura

Localized fibrous tumors of the pleura arise from subpleural fibroblasts that produce an array of lesions varying from peripheral pulmonary nodules to sessile subpleural masses to the more typical large pedunculated neoplasms. The visceral pleura is involved more often than the parietal pleural, and both benign (70%) and malignant (30%) variations exist. Histologically, benign tumors can exhibit three patterns—fibrous, cellular, and mixed—while malignant ones also have three distinct appearances: tubulopapillary, fibrous, and dimorphic. These tumors behave more like sarcomas

of the pleura than diffuse malignant mesotheliomas. Most localized fibrous tumors of the pleura are asymptomatic, discovered only incidentally on chest radiography. Extremely large tumors, however, may produce symptoms of bronchial compression with dyspnea, cough, and chest heaviness—and, rarely, symptoms of hypoglycemia from the production of an insulin-like peptide (4% of patients). On physical examination, signs of clubbing and hypertrophic pulmonary osteoarthropathy (20%-35%) may be present. Chest radiography most often demonstrates a well-circumscribed mass that may move with changes in position if the tumor is pedunculated. A pleural effusion is present in 15% of cases and can be bloody, though this does not indicate unresectability. Fine-needle aspiration cytology may be suggestive; however, the diagnosis generally can be established with certainty only at surgery.

The treatment of these lesions is a complete resection. Although lobectomy is usually not required for lesions involving the visceral pleura, wedge resection of the pulmonary parenchyma in the area of the tumor is recommended. For neoplasms arising from the parietal pleura, chest wall resection is prudent. Following complete surgical excision, no further therapy is indicated and the prognosis is good, with some patients surviving for over 10 years without recurrence; however, if the resection is incomplete, radiation therapy should be contemplated because the prognosis is poor, with a median survival of only 7 months.

2. Diffuse Malignant Pleural Mesothelioma

Diffuse malignant pleural mesothelioma is the most common primary tumor of the pleura. Since 1960, the disorder has been strongly linked to the use of asbestos. Thick serpentine asbestos fibers (chrysotile) generally are deposited in the proximal airways and are easily cleared with less risk of the development of tumors; however, thin needle-like amphibole fibers (crocidolite, amosite, actinolite, anthophyllite, and tremolite) and the soil silicate zeolite, found in the Anatolia region of Turkey, usually lodge in the terminal airways and migrate to the pleura, thereby increasing the risk of diffuse malignant pleural mesothelioma to more than 300 times that of the general population. The increased incidence of mesothelioma in shipbuilders exposed to asbestos-laden insulation from World War II-era ships further implicates asbestosis in the pathophysiology of the disease. The latency period after exposure ranges from 15 to 50 years. Recent research suggests that the generation of free radicals (including nitric oxide), depression of the immune system (both cellular and humoral), induction of cytokines (tumor necrosis factor [TNF]- α , interleukin [IL]-1 α , IL-1 β , and IL-6), and the production of genetic defects, such as abnormalities of chromosomes 1, 3, 4, 6, 7, 9, 11, 17 (p53), and 22 (involves *c-sis*, which encodes for one chain of platelet-derived growth factor) all may play a role in the mechanism of asbestos-related disease.

Histologically, diffuse malignant pleural mesotheliomas are divided into four categories: (1) epithelial or tubopapillary (35%-40%), which are associated with pleural effusions and a slightly better prognosis; (2) fibrosarcomatous or mesenchymal (20%), which are often “dry” mesotheliomas; (3) mixed (35%-40%); and (4) undifferentiated (5%-10%). The right hemithorax (60%) is affected more often than the left (35%) and 5% are bilateral.

Most patients with diffuse malignant pleural mesotheliomas complain of dyspnea on exertion and chest wall discomfort, but other symptoms, such as cough, fever (paraneoplastic), malaise, weight loss, and dysphagia, also occur. Complaints of severe chest wall pain, abdominal distention, pericardial tamponade, and superior vena cava syndrome suggest advanced disease. Although most patients develop distant metastases at some time during the course of their disease, these lesions rarely become symptomatic. Chest radiographs are distinctly abnormal, showing pleural thickening, effusion (75%), and narrowing of intercostal spaces. CT often suggests the diagnosis because of diffuse irregular pleural thickening. The diagnosis generally requires substantial tissue samples and is not generally obtainable from fine-needle aspiration cytology. Tissue can be easily acquired with VATS techniques.

Immunohistochemical stains for carcinoembryonic antigen, LeuM1, B72.3, and BerEP4 are usually negative, while those for vimentin and keratin are generally positive. Calretinin stain, which is specific for cells of mesothelial origin, has recently become available. This immunohistochemical marker can with near certainty determine whether an epithelial malignant tumor is either metastatic to pleura, for example, an adenocarcinoma (calretinin-negative) or a primary malignant mesothelioma (calretinin-positive). This stain has become an important clinical tool and should be performed on all suspected cases of diffuse malignant pleural mesothelioma. Electron microscopy may also be helpful in distinguishing this disorder from metastatic adenocarcinoma, with which it is often confused. Pathologic staging of diffuse malignant pleural mesothelioma, like its treatment (see below), has been controversial. The original Butchart staging system and a more recently promulgated tumor, node, metastases (TNM) staging system are set forth in the Table 18-3; however, neither is widely accepted or utilized.

The treatment of diffuse malignant pleural mesothelioma also remains variable. Owing to the low incidence of this disease, its natural history has not been carefully defined with regard to various prognostic factors, and few randomized trials have been conducted to compare treatment strategies. The reported median survival for all patients ranges from 7 months to 16 months. Recent randomized prospective trials have demonstrated benefit of platinum-based chemotherapy in combination with the antifolates pemetrexed or raltitrexed. Vogelzang and co-workers randomized 448 patients with unresectable pleural mesothelioma to receive cisplatin

Table 18-3. Staging systems for malignant mesothelioma.

BUTCHART STAGING SYSTEM

Stage I: Tumor is confined within the “capsule” of the parietal to pleura, ie, involving the ipsilateral pleura, lung, diaphragm, and external surface of the pericardium within the pleural reflection only.

Stage II: Tumor invades the chest wall or mediastinum (esophagus, trachea, or great vessels). Alternatively, lymph nodes within the chest are involved with metastatic disease.

Stage III: Tumor penetrates the diaphragmatic muscle to involve the peritoneum or retroperitoneum, the pericardium to involve the internal surface or heart, and the mediastinum to involve the contralateral pleura. Alternatively, lymph nodes outside the chest are involved with metastatic disease.

Stage IV: Distant hematogenous metastatic.

TNM STAGING SYSTEM

Tumor stage

TX: The primary tumor cannot be assessed.

T0: No evidence of primary tumor exists.

T1: The primary tumor is limited to the ipsilateral parietal or visceral pleura.

T2: Tumor invades any of the following: ipsilateral lung, endothoracic fascia, diaphragm, pericardium.

T3: Tumor invades any of the following: ipsilateral chest wall muscles, ribs, mediastinal organs or tissues.

T4: Tumor extends to any of the following: contralateral pleura or lung by direct extension, peritoneum or intra-abdominal organs by direct extension, cervical tissues.

Lymph node stage

NX: Regional lymph nodes cannot be assessed.

N0: No regional lymph node metastases are present.

N1: Metastases are present in ipsilateral bronchopulmonary or hilar lymph nodes.

N2: Metastases are present in ipsilateral mediastinal lymph nodes.

N3: Metastases are present in contralateral mediastinal, internal mammary, supraclavicular, or scalene lymph nodes.

Metastatic stage

MX: The presence of distant metastases cannot be assessed.

M0: No distant metastases exist.

M1: Distant metastases are present.

STAGE GROUPINGS

Stage I: T1-2, N0, M0

Stage II: T1-2, N1, M0

Stage III: T3, N0-1, M0; T1-3, N2, M0

Stage IV: T4, any N, M0; any T, N3, M0; any T, any N, M1

versus cisplatin in combination with pemetrexed. Patients treated with pemetrexed in addition to cisplatin demonstrated improved median survival (12.1 vs 9.3 months) and progression-free survival. The improved survival came at a cost of increased bone marrow-related toxicity (neutropenia and leukopenia). van Meerbeek and co-workers demonstrated similar findings in a randomized sample of patients comparing cisplatin and combination cisplatin and raltitrexed. Mean survival in the cohort receiving combination cisplatin and

raltitrexed was 11.2 months versus 8.8 months in patients receiving cisplatin alone. Newer chemotherapeutic agents under active investigation include ranpirnase, intrapleural IL-2, and vascular endothelial-derived growth factor antagonists (bevacizumab).

Surgery alone has also been used in attempts to improve survival, and two major approaches have been utilized: radical pleuropneumectomy or parietal pleurectomy with decortication. The initial experience with radical pleuropneumectomy demonstrated only a higher associated morbidity but not better long-term survival when compared to less radical pleurectomy and decortication. When combined with postoperative chest wall irradiation, the latter procedure results in a median survival of up to 25 months. Other approaches have combined preoperative chemotherapy (MD Anderson), intraoperative and postoperative chemotherapy (Lung Cancer Study Group, Cleveland Clinic), photodynamic therapy (NCI), and immunotherapy with TNF- α as well as interferon (IFN)- α and IFN- Γ (NCI, SWOG) with limited success. Currently, the use of intraoperative radiation therapy (UCSF, MSKCC) and gene therapy are also being investigated. Although the general impression is that multimodality therapy is superior to any one therapy alone, the exact combination of treatment options for this disease is yet to be defined. It is clear, however, that new therapies are needed.

DISEASES OF THE MEDIASTINUM

MEDIASTINITIS

Mediastinitis may be acute or chronic. There are four sources of mediastinal infection: direct contamination, hematogenous or lymphatic spread, extension of infection from the neck or retroperitoneum, and extension from the lung or pleura. The most common direct contamination is esophageal perforation. Acute mediastinitis may follow esophageal, cardiac, and other mediastinal operations. Rarely, the mediastinum is directly infected by suppurative conditions involving the ribs or vertebrae. Most direct mediastinal infections are caused by pyogenic organisms. Most mediastinal infections that invade via the hematogenous and lymphatic routes are granulomatous. Contiguous involvement of the mediastinum along fascial planes from cervical infection is frequent; this

occurs less commonly from the retroperitoneum because of the influence of the diaphragm. Empyema often loculates to form a paramediastinal abscess, but extension to form a true mediastinal abscess is uncommon. Extension of mediastinal infections to involve the pleura is common.

1. Acute Mediastinitis

Esophageal perforation, the source of 90% of acute mediastinal infections, can be caused by vomiting (Boerhaave syndrome), iatrogenic trauma (endoscopy, dilation, operation), external trauma (penetrating or blunt), cuffed endotracheal tubes, ingestion of corrosives, carcinoma, or other esophageal disease. Mediastinal infection secondary to cervical disease may follow oral surgery; cellulitis; external trauma involving the pharynx, esophagus, or trachea; and cervical operative procedures such as tracheostomy, mediastinoscopy, and thyroidectomy.

► Clinical Findings

Emetogenic esophageal perforation (Boerhaave syndrome) is usually associated with a history of vomiting but in some cases is insidious in onset. Severe boring pain located in the substernal, left or right chest, or epigastric regions is the chief complaint in over 90% of cases. One-third of patients have radiation to the back, and in some cases pain in the back may predominate. Low thoracic mediastinitis can sometimes be confused with acute abdominal diseases or pericarditis. Acute mediastinitis is often associated with chills, fever, or shock. If pleural extension develops, breathing may aggravate the pain or cause radiation to the shoulder. Swallowing increases the pain, and dysphagia may be present. The patient is febrile, and tachycardia is noted. About 60% of patients have subcutaneous emphysema or pneumomediastinum. A pericardial crunching sound with systole (Hamman sign) is often a late sign. Fifty percent of patients with esophageal perforation have pleural effusion or hydropneumothorax. Pneumomediastinum or pneumothorax following esophageal endoscopy is sine qua non of esophageal perforation. Neck tenderness and crepitation are more often found in cervical perforations.

The diagnosis may be confirmed by contrast x-ray examination of the esophagus, preferably using thin barium. If no esophageal leak is evident then the study is completed using standard concentration barium. The use of water-soluble media is to be avoided to prevent consequences of water-soluble contrast aspiration in this population that is at increased risk for respiratory complication. Endoscopic visualization of the perforation is not recommended as an initial diagnostic maneuver as this may inadvertently extend the perforation. Chest CT scan with oral and intravenous contrast is helpful in determining the level of the perforation and the degree of mediastinal soilage as well as possible underlying esophageal or pulmonary pathology. The

patient, however, must be clinically stable to be subjected to the rigors of these tests. For more critically ill patients, simple oral administration (or administration through a proximally placed nasogastric tube) of contrast and a simultaneous portable chest x-ray in an intensive care setting can often confirm the diagnosis. Myocardial infarction is sometimes mistakenly diagnosed in patients with esophageal perforation when a predisposing cause of pneumomediastinum is not apparent.

► Treatment

Surgical management of intrathoracic esophageal perforation depends on the underlying cause (iatrogenic, tumor, stricture, etc) and the amount of elapsed time from leak to diagnosis. All intrathoracic leaks should be surgically explored. Initial management includes immediate drainage of associated pleural contamination by large-bore chest tubes and decompression of the occasional pneumothorax. Broad-spectrum antibiotics, including antifungal therapy, are initiated and vigorous fluid hydration administered.

Typically, a right thoracotomy offers the most access to the intrathoracic esophagus and should be used through the sixth interspace. Even distal left-sided perforations can be managed from the right side. A left thoracotomy, however, is useful when a perforated esophagus from a distal esophageal stricture is encountered.

Treatment of an immediately recognized (< 24 h) iatrogenic esophageal perforation in an otherwise normal esophagus includes primary two-layer closure with careful attention to complete mucosal closure by interrupted absorbable sutures or surgical staplers. Esophageal muscle is then closed over the mucosal injury and buttressed with either a flap of parietal pleura, diaphragm, or intercostal muscle. Copious irrigation and wide drainage is performed. Occasionally, closure over a T-tube drain has been successful.

Esophageal perforations more than 48 hours old are widely drained and the esophagus either defunctionalized or resected. This depends on the degree of mediastinal soiling discovered upon exploration, the extent of sepsis, and the patient's performance status. When perforation occurs secondary to esophageal cancer or manipulation for severe reflux stricture, achalasia, or an otherwise abnormal esophagus, different surgical options exist. If the perforation is recognized immediately and the patient is not floridly septic, esophageal resection is preferred. Reconstruction (usually using a gastric conduit) can be done at the same setting but only if the patient is stable and the degree of contamination minimal. Otherwise, reconstruction is performed at a later date when the patient has fully recovered from the septic event. Esophageal stent placement and adequate drainage of the mediastinal and pleural spaces also can be considered.

The mortality associated with esophageal perforation remains high (30%-60%) despite advances in critical care, nutritional support, and operative management. The specific

surgical approach—repair, resection, or endoscopic—must be tailored to the individual circumstances (mechanism of perforation, underlying pathology, time to diagnosis, and patient performance status) in order to achieve optimal results.

2. Chronic Mediastinitis

Chronic mediastinitis usually involves specific granulomatous processes with associated mediastinal fibrosis and chronic abscesses. Histoplasmosis, tuberculosis, actinomycosis, nocardiosis, blastomycosis, and syphilis have been incriminated. Amebic abscesses and parasitic disease such as echinococcal cysts are rare causes. The infectious process is usually due to histoplasmosis or tuberculosis and involves the mediastinal lymph nodes. Esophageal obstructions may occur. Adjacent mediastinal structures may become secondarily infected. Granulomatous mediastinitis and fibrosing mediastinitis are different manifestations of the same disease. Mediastinal fibrosis is a term used synonymously with idiopathic, fibrous, collagenous, or sclerosing mediastinitis. Eighty or more cases of mediastinal fibrosis have been reported, but the cause has been determined in only 16%, and of these over 90% were due to histoplasmosis. In only 25% of 103 cases of granulomatous mediastinitis has the cause been identified. Histoplasmosis was the most common known cause (60%) and tuberculosis the second-most common (25%).

About 85% of patients with mediastinal fibrosis have symptoms from entrapment of mediastinal structures as follows: superior vena caval obstruction in 82%; tracheo-bronchial obstruction, 9%; pulmonary vein obstruction, 6%; pulmonary artery occlusion, 6%; and esophageal obstruction, 3%. Rarely, inferior vena caval obstruction or involvement of the thoracic duct, atrium, recurrent laryngeal nerve, or stellate ganglion is found. Multiple structures may be simultaneously involved.

Seventy-five percent of patients with granulomatous mediastinitis have no symptoms, and disease is discovered by chest x-ray, which shows a mediastinal mass. The mass is in the right paratracheal region in 75% of cases. In the 25% of patients with symptoms, about half have superior vena caval obstruction and one-third have esophageal obstruction. Occasional patients have bronchial obstruction, broncho-esophageal fistula, or pulmonary venous obstruction.

A mediastinal tuberculous or fungal abscess occasionally dissects long distances to present on the chest wall paravertebrally or parasternally. Secondary rib or costal cartilage infections with multiple draining sinus tracts occur.

► Clinical Findings

A. Symptoms and Signs

Granulomatous and fibrosing mediastinitis affects women two to three times more commonly than men. Women aged 20-30 years are most typically affected, though

the disorder may present in the fourth to fifth decades. Esophageal involvement results in dysphagia or hematemesis. Tracheobronchial involvement may cause severe cough, hemoptysis, dyspnea, wheezing, and episodes of obstructive pneumonitis. Pulmonary vein obstruction—the most common serious manifestation—produces congestive heart failure resembling advanced mitral stenosis and is usually fatal. Although not diagnostic, the respective skin tests in cases due to histoplasmosis or tuberculosis are strongly positive.

B. Imaging Studies

X-ray findings demonstrate a right paratracheal or anterior mediastinal mass. There may be spotty or subcapsular calcifications. Classically, histoplasmosis presents with hilar node calcification or so-called popcorn granuloma appearance. Calcification can also occur in thymoma or teratoma located in the anterior mediastinum. Chest CT (with intravenous and oral contrast) is most effective in defining the extent of mediastinal fibrosis and impingement on vital structures.

► Treatment

Specific antimicrobial therapy is indicated when an infecting organism is identified. Patients with symptomatic mediastinal masses and fibrosis can require resection for relief of obstruction.

► Prognosis

The prognosis following surgical excision of granulomatous mediastinal masses is good. Operative procedures do not appear to activate fibrosing mediastinitis, but success in treatment has been unpredictable. Most patients with fibrosing mediastinitis—whether treated or not—survive but have persistent symptoms.

SUPERIOR VENA CAVAL SYNDROME

Superior vena caval obstruction produces a distinctive clinical syndrome. Malignant tumors are the cause in 80%-90% of cases; lung cancer accounts for about 90%. The incidence of superior vena caval syndrome in lung cancer patients is 3%-5%. The male-to-female ratio is about 5:1. Other primary mediastinal tumors that may cause superior vena caval obstruction include thymoma, Hodgkin disease, and lymphosarcoma. Metastatic tumors from the breast or

thyroid or from melanoma also occasionally cause superior vena caval obstruction. Benign tumors are an unusual cause, but substernal goiter, any large benign mediastinal masses, and atrial myxoma have been implicated. Thrombotic conditions, either idiopathic or associated with polycythemia, mediastinal infection, or indwelling catheters, are unusual causes. The association of superior vena caval obstruction with chronic mediastinitis is discussed in the preceding section. Trauma may produce acute venous obstruction (eg, traumatic asphyxia, mediastinal hematoma).

The clinical manifestations depend on the abruptness of onset, the location of the obstruction, the completeness of occlusion, and the availability of collateral pathways.

Venous pressure measured in the arms or head varies from 200 to 500 mm H₂O, and severity of symptoms is correlated with the pressure. Fatal cerebral edema can occur within minutes of an acute complete obstruction, whereas a slowly evolving one permits development of collaterals and may be only mildly symptomatic. Symptoms are milder when the azygos vein is patent. Azygous blood flow—normally about 11% of the total venous return—can increase to 35% of the venous return from the head, neck, and upper extremities. Thus, the most severe cases occur when occlusion is complete and the azygos vein is involved. The thrombus may propagate proximally to occlude the innominate and axillary veins.

► Clinical Findings

Symptoms include puffiness of the face, arms, and shoulders and a blue or purple discoloration of the skin. Central nervous system symptoms include headache, nausea, dizziness, vomiting, distortion of vision, drowsiness, stupor, and convulsions. Respiratory symptoms include cough, hoarseness, and dyspnea, often due to edema of the vocal cords or trachea. Nasal congestion is often an early presenting symptom. These symptoms are made worse when the patient lies flat or bends over. In long-standing cases, esophageal varices may develop and produce gastrointestinal bleeding. The veins of the neck and upper extremities are visibly distended, and in long-standing cases there are marked collateral venous channels over the anterior chest and abdomen. Chronic pleural effusions may develop as a result of impaired lymphatic drainage. Onset of symptoms in fibrosing mediastinitis may be insidious, consisting initially of early morning edema of the face and hands. Occasionally, symptoms and findings are localized to one side when the level of obstruction is above the vena cava and only the innominate vein is blocked. In this situation, symptoms are mild because communicating veins in the neck usually decompress the affected side.

The diagnosis can be confirmed by measuring upper extremity venous pressure; in patients with severe symptoms, a pressure of 350 mm H₂O or more is usual. Of patients with malignant vena caval obstruction studied by

venography, 35% have thrombosis involving the innominate or axillary veins, 15% have complete caval obstruction without thrombosis, and 50% have partial superior vena caval obstruction. If patency of the azygos vein is in question, interosseous azygography may be useful. Chest x-ray may show a right upper lobe lung lesion or right paratracheal mass. Aortography is occasionally required to exclude aortic aneurysm. CT or MRI scan with contrast enhancement provides sufficient anatomic detail, supplanting the need for arteriography or venography as a diagnostic modality for this syndrome. The differential diagnosis may include angioneurotic edema, congestive heart failure, constrictive pericarditis, and fibrosing mediastinitis. Effort thrombosis of the axillary vein and innominate vein obstruction from elongation and buckling of the innominate artery can be considered in unilateral cases.

► Complications

In patients with partial superior vena caval obstruction, thrombosis may suddenly change mild symptoms to marked venous distention, cyanotic swelling, vocal cord edema, and impaired cerebration. Bleeding from esophageal varices is rare except in severe long-standing cases.

► Treatment

Superior vena caval obstruction caused by cancer should be treated with diuretics, restriction, avoidance of upper extremity intravenous lines, head elevation, and prompt radiation therapy. Cases of superior vena cava obstruction due to tumor begin to subside by 7-10 days of treatment. Because of the possibility of thrombosis in malignant cases, the use of fibrinolytic agents has been suggested. Caution must be advised in using anticoagulants, however, because many patients have advanced disease and may harbor occult cerebral metastases. Therefore, before starting therapy, patients should undergo CT or MRI brain scanning to prevent the occurrence of intracerebral hemorrhage. Recently, the use of intravascular expansile stents has been pioneered. Limited early experience suggests that the lumen can be reopened and that good venous drainage and decompression can be achieved by minimally invasive interventional radiologic techniques. Long-term results have not been reported, and disadvantages include the need for anticoagulation to prevent recurrent thrombosis. Chemotherapy is sometimes used alone or with radiotherapy. Most cases of malignant superior vena caval obstruction are not remediable by operation. Tissue diagnosis is important for diagnosis and for guiding therapy. Invasive procedures, however, must be tailored to the individual patient and the severity of the caval obstruction. Patients with new, severe, or rapidly progressive symptoms should receive immediate palliative radiation therapy. Patients with subacute presentations can better tolerate the time required to make the diagnosis.

Fine-needle aspiration, bronchoscopy, cervical mediastinoscopy, and anterior mediastinotomy—and even, occasionally, thoracotomy—offer possible approaches for obtaining tissue. Caution must be advised, however, in the setting of acute fulminant superior vena caval obstruction because any invasive procedure will carry a significantly higher morbidity due to bleeding from venous obstruction. In this case, attempts at invasive techniques for tissue diagnosis should be avoided. Most frequently, the disease process has been previously histologically confirmed because superior vena caval obstruction presents typically as a complication of locally advanced disease. In benign incomplete superior vena caval obstruction, surgical excision of the compressing mass can provide an excellent result. In total obstruction, such as occurs in fibrosing mediastinitis, most patients will gradually improve without treatment. There are numerous surgical procedures designed to bypass caval obstruction, replace the superior vena cava, or recanalize the vena caval lumen. These procedures have been dramatically effective in some cases, but only recently have they been sufficiently successful to warrant consideration.

► Prognosis

Radiotherapy is most effective when superior vena caval obstruction is incomplete. Mean survival of patients with malignant caval obstruction from lung cancer is 6-8 months. The death rate from causes related to vena caval obstruction itself is only 1%-2%.

MEDIASTINAL MASS LESIONS

Lesions within the mediastinum include a variety of masses, both malignant and benign, that arise from the diverse organs and tissues which occupy the central thorax. Overall, the incidence of all mediastinal masses is low, especially compared with the frequency of lesions arising within the lung (bronchogenic cancer, etc). Mediastinal malignancies constitute less than 20% of all thoracic tumors.

Mediastinal masses arise from specific structures that reside in relatively constant anatomic arrangement. The mediastinum itself is defined laterally by the mediastinal pleura of each lung; superiorly and inferiorly by the thoracic inlet and diaphragm, respectively; anteriorly by the sternum; and posteriorly by the vertebral bodies. For purposes of definition, the mediastinum is divided loosely into three main compartments: anterior (or anterosuperior), middle, and posterior. The anterior mediastinum contains the thymus, fat, and lymph nodes while the middle mediastinum contains the heart, pericardium, ascending and transverse aorta, brachiocephalic veins, trachea, bronchi, and lymph nodes. The posterior mediastinum consists of the descending thoracic aorta, esophagus, azygous vein, autonomic ganglia and nerves, lymph nodes, and fat. This has important implications for diagnosing suspected masses. The

likelihood of malignancy is influenced primarily by three main factors: anatomic location, age, and the presence or absence of symptoms. Although two-thirds of mediastinal tumors are benign, masses in the anterior compartment are more likely to be malignant. Age is an important predictor as well with many lymphomas and germ cell tumors presenting between the second and fourth decade of life. Symptomatic patients are more likely to have a malignancy. Although classically in adults the majority of mediastinal masses tend to be benign (cysts, neurogenic tumors, etc), recent series have demonstrated a shift toward malignant processes being more prevalent.

An anterior mediastinal mass can indicate the following: thymoma (the most common), thymic hyperplasia, thymolipoma, thymic cyst, thymic carcinoid, thymic carcinoma, germ cell tumor (teratoma, seminoma, and non-seminomatous germ cell tumor), lymphoma, parathyroid adenoma, substernal thyroid, and lymphangioma. A middle mediastinal mass can include lymphoma, pericardial cyst, bronchogenic cyst, aneurysm, and lymphadenopathy. A posterior mediastinal mass can include neurogenic tumor, enteric cyst, bronchogenic cyst, meningocele, diaphragmatic or hiatus hernia, and paravertebral abscess. The most common mediastinal masses in children are neurogenic tumors (50%-60%). In young children (< 4 years of age), they are invariably malignant (neuroblastomas). In the adults, a neurogenic tumor is the most common mediastinal mass. This arises in the posterior compartment (typically from a peripheral nerve sheath) and is usually benign, occasionally calcified, and well circumscribed.

An extensive workup of a mediastinal lesion is usually not required for diagnosis since surgery is usually required both to establish the diagnosis and provide effective treatment. Standard PA and especially lateral chest films will often provide much useful information; however, contrast CT scanning has become the diagnostic test of choice. MRI, while helpful for assessing vascular or spinal cord extension, has not proved to be more effective than dynamic CT scanning.

Fluoroscopy may show pulsation or variation of shape or location with change of position and respiration. Tomography may reveal calcification or air-fluid levels. Barium swallow is used to evaluate intrinsic esophageal lesions or esophageal displacement by extrinsic masses. Contrast studies of the intestinal tract may reveal the stomach, colon, or small bowel in a hernia. Myelography can be of crucial importance in neurogenic tumors to explain symptoms or to plan operative management. CT angiography can identify aneurysms or displacement. Pulmonary arteriography may be useful to distinguish mediastinal and pulmonary tumors.

Scintigraphy scanning is important in evaluating possible substernal goiter in anterior mediastinal lesions, since goiters can generally be removed by the standard cervi-

cal approach. Skin tests and serologic studies may be used in suspected granulomatous disease. Bone marrow examination, hormone assays, and serum tumor markers (α -fetoprotein [AFP], β -human chorionic gonadotropin [β -HCG], and LDH) are important adjuncts to evaluate a suspected germ cell tumor.

Bronchoscopy and esophagoscopy are occasionally useful to identify primary lung lesions or lesions of the esophagus. Mediastinoscopy and mediastinal biopsy must be used cautiously in mediastinal tumors that are potentially curable. Excisional biopsy is imperative in lesions (eg, thymomas) that are histologically difficult to evaluate since a curable but locally invasive malignancy might be dispersed. Mediastinoscopy is useful for the diagnosis of sarcoidosis, Castleman disease, or disseminated lymphoma.

► Clinical Findings

Symptoms are more frequent among patients with malignant rather than benign lesions. About one-third of patients have no symptoms. Those patients who become symptomatic can present with cough (60%), chest pain (30%), fevers/chills (20%), or dyspnea (16%). Hemoptysis and, rarely, expectoration of cyst contents may occur. Weight loss and dysphagia are found each in about 10% of patients. Myasthenia gravis (MG) (15%-20% with thymoma), fever, and superior vena caval obstruction are each found in about 5% of patients.

Symptoms can be categorized into two groups: localizing symptoms and systemic symptoms. Localizing symptoms are secondary to tumor invasion and include respiratory compromise, dysphagia, paralysis of the limbs, diaphragm, and vocal cords, Horner syndrome, and superior vena cava syndrome. These findings are concerning for a malignant process. Malignant tumors, especially lymphomas, may produce chylothorax. Systemic symptoms are typically due to the release of excess hormones, antibodies, or cytokines. Thymoma has been associated with myasthenia, hypogammaglobulinemia, Whipple disease, red blood cell aplasia, and Cushing disease. Hypoglycemia is a rare complication of mesothelioma, teratoma, and fibroma. Hypertension and diarrhea occur with pheochromocytoma and ganglioneuroma. Neurogenic tumors may produce specific neurologic findings from cord pressure or may be associated with hypertrophic osteoarthropathy and peptic ulcer disease.

A. Neurogenic Tumors

Neurogenic tumors are derived from tissue of the neural crest, including cells of the peripheral, autonomic, and paraganglionic nervous systems. Neurogenic tumors almost always occur in the posterior mediastinum—often the superior portion—arising from intercostal or sympathetic nerves. Rarely, the vagus or phrenic nerve is involved. Seventy to eighty percent of all neurogenic tumors are benign. The most common tumor (40%-65%) arises from the nerve

sheath (schwannoma and neurofibroma) and is usually benign. Malignant tumors occur more frequently in children. Most malignant tumors (neuroblastoma, etc) arise from the nerve cells. Neurogenic tumors may be multiple or dumbbell in type, with widening of the intervertebral foramen. In these cases, MRI is necessary to determine if the mass extends within the spinal canal. Dumbbell tumors have been removed in the past by a two-stage approach, though a single-stage approach is now more widespread. ^{123}I metaiodobenzylguanidine scintigraphy can be applicable particularly for patients with middle metastinal tumor suspected to be a pheochromocytoma.

B. Mediastinal Cystic Lesions

Cysts of the mediastinum may arise from the pericardium, bronchi, esophagus, or thymus. Pericardial cysts are also called “springwater” or mesothelial cysts. Seventy-five percent are located near the cardiophrenic angles and 75% of these are on the right side. Ten percent are actually diverticula of the pericardial sac that communicate with the pericardial space. Bronchogenic cysts arise close to the main stem bronchus or trachea, often just below the carina. Histologically, these contain elements found in bronchi, such as cartilage, and are lined by respiratory epithelium. Enterogenous cysts are known by several names, including esophageal cyst, enteric cyst, or duplication of the alimentary tract. They arise along the surface of the esophagus and may be embedded within its wall. They may be lined by squamous epithelium similar to the esophagus or gastric mucosa. Enterogenous cysts are occasionally associated with congenital abnormalities of the vertebrae. About 10% of cysts in the mediastinum are nonspecific, without a recognizable lining.

C. Germ Cell Tumors

Germ cell tumors are common mass lesions found in young adults and represent 15% of anterior mediastinal mass lesions. Malignant germ cell tumors are more common in men (>90%). Historically, they are both solid and cystic, and the more differentiated tumors can contain hair or teeth. Microscopically, ectodermal, endodermal, and mesodermal elements are present. These tumors occasionally rupture into the pleural space, lung, pericardium, or vascular structures. Most germ cell tumors of the mediastinum are metastatic and present with concomitant retroperitoneal disease.

Primary mediastinal extragonadal germ cell malignancies are rare, representing less than 5% of all mediastinal germ cell cancers and less than 5% of all primary mediastinal tumors. As pluripotent cells, germ cell tumors (GCTs) can give rise to several histologically distinct malignancies, including seminoma (40%), embryonal carcinomas and non-gestational choriocarcinomas (20%), and yolk sac tumors (20%). Teratomas (20%) can have both benign and malignant components. Almost all such tumors (> 90%) produce

tumor markers, including β -HCG and AFP. LDH—a non-specific tumor marker—is produced by most bulky mediastinal germ cell tumors and is often an effective indicator of tumor burden.

Much progress in treating these tumors has been made with multi-modality therapy (surgery, radiation therapy, and chemotherapy). Currently, over 50% 5-year survival is achievable for nonseminomatous GCT, and over 90% 5-year survival is typical for seminomatous mediastinal GCT. Patients should be screened and followed with AFP, β -HCG, and LDH markers. Resection should be offered after combination chemotherapy has been administered and only after all elevated tumor markers have normalized.

Residual mediastinal masses following chemotherapy and normalization of tumor markers should be resected. At surgery, approximately 40% will be mature teratomas (with the potential for malignant degeneration), 40% necrotic tumors, and 20% residual tumors (requiring postoperative salvage chemotherapy). Rarely is palliative debulking surgery indicated if tumor markers remain elevated after several cycles of chemotherapy. Instead, alternative chemotherapy or investigational therapy should be offered.

D. Lymphoma

Lymphoma is usually associated with disseminated disease metastatic to the mediastinum. It is typically identified in the anterior compartment but can present anywhere through the mediastinum. This is the second-most common mass in the anterior mediastinum. Occasionally, lymphosarcoma, Hodgkin disease, or reticulum cell sarcoma arises as a primary mediastinal lesion.

► Treatment

Treatment is tailored to the specific disease process causing the mediastinal mass. In almost all cases, tissue diagnosis is imperative for guiding appropriate therapy. Minimally invasive techniques (fine-needle aspiration or core-needle biopsy) or mediastinoscopy and mediastinotomy are appropriate for diagnosis of a mediastinal mass that is secondary to metastatic disease (eg, lymphomas and germ cell tumors). Mediastinal masses that represent primary malignancies (thymoma, neurogenic tumors, etc) are treated usually with initial resection. Percutaneous biopsy of primary malignancies should be reserved for patients with locally advanced disease, considered either unresectable or suitable for pre-operative systemic therapy and/or radiation therapy prior to attempted resection.

Surgical approaches include median sternotomy (anterior masses), posterolateral thoracotomy (posterior and middle mediastinal masses) as well as VATS or bilateral anterior thoracotomy (all mediastinal compartments). Adjuvant chemotherapy is important for malignant germ cell lesions, malignant neurogenic tumors, and bulky or

advanced thymomas. Postoperative radiation therapy decreases local recurrence in higher stage thymoma and in other incompletely resected lesions. Radiation and chemotherapy constitutes the principal therapy for primary mediastinal lymphoma.

Complete resection is the treatment of choice for all neurogenic tumors. A standard posterolateral thoracotomy offers optimal exposure; however, more limited incisions, including thoracoscopy, can be effective for resection of clinically benign small (< 6 cm) lesions. Dumbbell lesions involving the spinal canal warrant a neurosurgical consultation. For lesions that cannot be completely excised, postoperative radiation may decrease local recurrence and symptoms. Incompletely excised or especially large or infiltrative neuroblastomas should receive combination radiation and chemotherapy in conjunction with surgery.

► Prognosis

Overall, the outlook for patients with mediastinal masses has improved, with advances in combined chemotherapy and multimodality therapy. Surgical morbidity and mortality remain low (1%-4%). Patients with benign mediastinal lesions do significantly better (> 95% cure rates) than those who have malignant mediastinal masses (< 50% overall survival).

TUMORS OF THE THYMUS & MYASTHENIA GRAVIS

The thymic gland is the site of a variety of neoplasms that include thymoma, lymphoma, (eg, Hodgkin disease), granuloma, and other less common tumors. Cell types of the thymus include epithelial cells, myoid cells, thymic lymphocytes, and B lymphocytes. Tumors of the thymus can arise from any of these cell types with thymic epithelial tumors (thymoma, thymic carcinoma, and neuroendocrine tumor) being the most common. Lymphoid or hematopoietic neoplasms and mesenchymal tumors occur less frequently. Thymoma is a primary neoplasm of the thymus gland arising from thymic epithelial cells without cytologic or histologic signs of malignancy. A well-differentiated thymic carcinoma has some cytologic features of atypia, and thymic cancer cells are cytologically malignant. Thymoma is the most common tumor of the anterior mediastinum composing approximately 50% of all tumors of the anterior mediastinum and 15%-20% of all mediastinal tumors.

Thymoma may be classified according to predominant cell type into lymphocytic (25%), epithelial (25%), and lymphoepithelial (50%) varieties. Spindle cell tumor, which is sometimes associated with red cell aplasia, is considered

among the epithelial tumors. The histologic subtypes have not been associated with prognostic significance. The World Health Organization (WHO) consensus guidelines provide a histologic classification system for thymoma and thymic carcinoma based on both morphology and lymphocyte-to-epithelial cell ratio. The WHO classification system classifies thymoma and thymic carcinoma in categories ranging from type A (bland spindle cells and limited lymphocytes) to type C (grossly atypical cells that are indicative of thymic carcinoma). The identification of a single pathologic subtype is difficult however, since there is considerable histologic heterogeneity. The Masaoka staging system, originally described in 1981 and revised in 1994, is the most frequently used staging method of thymoma and thymic carcinoma. This staging system classifies thymoma into four stages based on the presence of invasion and anatomic extent of involvement observed both clinically and histopathologically. The Masaoka staging system has been shown to be a significant independent factor for survival, with 5-year survival rates by stage approaching 98%-100% for stage I and II diseases, 88% in stage III disease, and 70% for patients with stage IVa and 52% for IVb, respectively. The WHO classification system as well as the Masaoka staging system is set forth in Table 18-4.

MG is a neuromuscular disorder characterized by weakness and fatigability of voluntary muscles owing to decreased numbers of acetylcholine receptors at neuromuscular junctions. Because of the high incidence of thymic abnormalities, improvement after thymectomy, association with other autoimmune disorders, and presence in the serum of 90% of patients of an antibody against acetylcholine receptors, MG is thought to be of autoimmune etiology. About 30% of patients with thymoma have MG, and about 15% of patients with myasthenia develop a thymoma. Thymic carcinoma, which carries a worse prognosis than other thymomas, is

Table 18-4. Staging system for malignant thymoma.

STAGE	DESCRIPTION
I	Macroscopically, completely encapsulated; microscopically, no capsular invasion.
Ila	Macroscopic invasion into surrounding fatty tissues or mediastinal pleura (without microscopic invasion).
Ilb	Microscopic evidence of capsular invasion or microscopic invasion of surrounding fatty tissues or mediastinal pleura.
III	Macroscopic invasion into a neighboring organ (pericardium, great vessels, or lung).
IVa	Pleural or pericardial dissemination.
IVb	Lymphatic or hematogenous distant metastases.

rarely associated with MG. About 85% of patients with MG have thymic abnormalities consisting of germinal center formation in 70% and thymoma in 15%. MG can occur in association with tumors of any cell type but is more common with the lymphocytic variety. The mean age of patients with thymoma-associated MG is between 44 and 49 years of age without significant differences between males and females. Patients with thymoma-associated MG tend to be younger than those with non-MG thymoma.

► Clinical Findings

Fifty percent of thymomas are first identified in an asymptomatic patient on a chest x-ray obtained for another purpose. Symptomatic patients may present with chest pain, dysphagia, myasthenic symptoms, dyspnea, or superior vena caval syndrome. Paraneoplastic symptoms are fairly common in the setting of thymoma and account for approximately 60% of all presentations of thymoma.

CT with intravenous contrast of the chest provides information on the size, density, and relationship of the tumor to the surrounding intrathoracic organs and vessels. It may also reveal any pleural metastases. MRI is occasionally helpful to assess vascular invasion.

The diagnosis of MG can be made from the patient's history of easy fatigability and associated decremental response in muscular contraction to repeated stimulation of the motor nerve or from improvement in these abnormalities in response to edrophonium (Tensilon), a short-acting anticholinesterase drug.

Level of clinical suspicion for thymoma may dictate the need for biopsy prior to resection. In patients with a high likelihood of thymoma, excision without biopsy may be both diagnostic and therapeutic. CT-guided core needle biopsy is a useful and less invasive technique for determining histology of an anterior mediastinal mass, but should be considered only if there is evidence for local invasion such that a greater extent of resection might be necessary. Definitive diagnosis of thymoma is based on histologic study of a tissue sample usually after excisional biopsy or a complete resection has been performed. Small, well-encapsulated anterior mediastinal masses should not be biopsied, as the procedure penetrates the tumor capsule and can lead to tumor seeding and recurrence, thus jeopardizing the opportunity for cure of an early-stage thymoma.

► Treatment

The surgical approaches to thymectomy are varied and reflect the balance between complete, curative resection and the magnitude and morbidity of a procedure. All approaches enable a complete resection of the capsular thymus with the extent of peri-thymic mediastinal and cervical tissue resection distinguishing each of the procedures. The goal of the operation is total thymectomy. Transsternal thymectomy

with en bloc resection of the anterior mediastinal fat tissue from phrenic to phrenic laterally and the diaphragm to the thyroid gland is considered the standard, classical operative approach. Alternative approaches include transcervical thymectomy and minimally invasive approaches such as VATS thymectomy and robotic-assisted thymectomy. The latter approaches, while useful for thymectomy for benign conditions (myasthenia, etc), arguably have a limited role in the surgical treatment of malignant thymoma.

Despite a paucity of randomized controlled trials, summary treatment guidelines for each stage of the disease have been established by consensus in the literature. Multidisciplinary discussion is encouraged to assure appropriate therapy is recommended and provided. For disease stages I and II (see Table 18-4), complete resection alone is the standard of care. Radiotherapy may be considered for patients at risk for recurrence. Risk factors for recurrence include invasion through the capsule, close surgical margins, WHO grade B type, and a tumor adherent to the pericardium. Patients presenting with resectable or potentially resectable stage III disease should be evaluated for multimodality therapy. Surgical resection can be considered either initially or following neoadjuvant therapy if complete resection is not initially feasible. Neoadjuvant or induction chemotherapy may decrease the volume of the tumor, thereby facilitating complete resection. If resection is not appropriate then chemotherapy, either concurrent or sequential, with radiotherapy can be considered. For patients with stage IVA disease, operation can be considered only if pleural or pericardial metastases are resectable.

Anticholinesterase drugs (eg, neostigmine bromide) are given as initial treatment to patients with MG. Corticosteroids may be given in selected cases, but a high incidence of side effects makes them unsuitable for more liberal use. Early thymectomy is now recommended for all patients with symptomatic MG whether or not a thymoma is suspected. The course of the disease is usually improved, and subsequent development of a malignant thymoma is eliminated. Thymectomy can be postponed in the occasional patient with mild disease well controlled by anticholinesterase therapy.

Following thymectomy, about 75% of patients with MG are improved and 30% achieve complete remission. Younger patients benefit more from thymectomy than do those over the age of 40 years, but a positive effect also accrues to the latter group. Recently, minimally invasive approaches to thymectomy for myasthenia patients has resulted in reduced length of stay, decreased blood loss, and decreased pain in comparison with more traditional partial sternal splitting procedures.

► Prognosis

The rates of complication and death with thymectomy are low except in the setting of locally advanced disease.

Respiratory care of patients with MG in the immediate postoperative period now presents little difficulty because of the availability of anticholinesterase drugs. Recent evidence including a retrospective review by Okereke et al suggests that neither MG nor paraneoplastic syndromes are associated with a poor prognosis and there are no differences in survival between those with and without MG.

The Masaoka staging system has been widely accepted as the best predictor of survival in thymoma patients. Although in general the WHO histologic classification of thymoma has been considered reproducible, issues have been raised regarding interobserver variability which may impact its prognostic ability. Completeness of resection has been shown to be an important independent predictor of survival.

Overall survival rates are extremely good for early-stage thymomas, and 10-year survival rates are excellent. Stage I lesions approach 100% 10-year survival rates. Stage II tumors with resection and postoperative radiation therapy have approximately 75% 10-year survival rates. Patients with locally advanced stage III thymoma, however, have long-term survival rates of less than 25%. Outcomes with multimodality therapy (neoadjuvant chemotherapy, surgery followed by chemotherapy and radiation therapy) are improving, as marked by significant tumor responses and enhanced resectability rates. Long-term disease specific survival can be expected not only after surgery for early-stage thymoma but also after surgery for advanced disease, including select patients with pleural metastases. However, patients who undergo surgery for stage IVa disease have reduced disease-free survival.

THYMIC CARCINOMA

This tumor is a rare variant (< 15%) of thymic lesions and is histologically and biologically quite different from invasive or malignant thymoma. A large number of histologic types of thymic carcinoma have been described and range from low-grade, well-differentiated neoplasms to high-grade, poorly differentiated malignancies. The most common type of thymic carcinoma in Western patients is poorly differentiated, nonkeratinizing squamous cell carcinoma. Thymic carcinomas tend to be very invasive and difficult to resect completely. Unfortunately, even in the setting of a complete resection, recurrence is common both locally and at distant sites. Still, when at all possible, an aggressive combined-modality approach (induction chemotherapy, resection, and postoperative chemoradiotherapy) should be employed. Typically, these are young men (< age 50 years) with an otherwise excellent performance status. While a good response to induction therapy and a complete resection will provide a significant disease-free interval, long-term survival is still unlikely. Better systemic agents and a molecular understanding of this cancer holds hope for significant improvements in cure rates.

DISEASES OF THE LUNGS

CONGENITAL CYSTIC ANOMALIES OF THE LUNG

Congenital lesions of the lung include primarily tracheobronchial atresia, bronchogenic cysts, pulmonary dysplasia, pulmonary sequestration, congenital cystic adenomatoid malformations (CCAM), and congenital lobar emphysema (CLE). Although many of these lesions present early in life with dramatic symptoms and physical findings, most remain occult until late childhood and even into adult life. These uncommon lesions arise from aberrations in normal aerodigestive tract development, which begins during the fourth week of fetal life when the lung bud forms at the caudal end of a groove in the primordial pharynx. An initial phase of sequential airway branching occurs until as many as 20-25 generations are reached by the sixteenth week of fetal life. These branches are divided into three zones: a proximal conductive zone (branches 1-16), an intermediate transitional zone (branches 17-19), and a distal respiratory zone (branches 20-25). A second canalicular phase is then entered as capillaries develop in the distal air passages. Finally, the alveolar phase begins at approximately 26 weeks of fetal life as prototype alveolar air sacs appear complete with both type I and type II pneumocytes. The number and size of alveoli continue to increase until the total alveolar surface reaches the adult size of nearly 100 m².

A. Tracheobronchial Atresia

Atresia of the tracheobronchial tree can occur at any level and may involve an isolated segment or multiple diffuse areas of the airway. Tracheal atresia is associated with polyhydramnios, prematurity, esophageal atresia, and tracheoesophageal fistula. Typically, neonates present with intractable cyanosis and despite a normal-appearing larynx are unable to be intubated. Emergency tracheostomy can be life-sustaining in babies with isolated subglottic atresia; in other infants with more diffuse disease, mask ventilation can achieve some palliation through anomalous esophagobronchial connections. Diffuse airway involvement, however, is invariably fatal.

Isolated bronchial atresia results in a bronchus that ends in a blind pouch. A mucocele develops distal to the

obstruction and, as a result of compression of neighboring normal bronchial structures, causes emphysematous changes in the surrounding lung. Since children frequently develop wheezing, stridor, and pulmonary infections in the involved segments, resection is almost always indicated. Like bronchial atresia, true congenital bronchial stenosis is rare, although right main stem bronchial stenosis occurs not infrequently from iatrogenic airway trauma in chronically ventilated patients.

Related anomalies of the tracheobronchial tree include anomalous tracheal or esophageal bronchi and tracheal diverticula. These rare lesions often present with symptoms of bronchial obstruction and in many cases require resection of involved lung tissue due to chronic infection and the development of bronchiectasis (see section on Bronchiectasis). Similar to pulmonary sequestration, these lesions can have a dominant systemic arterial blood supply that must be kept in mind if operation is contemplated.

B. Bronchogenic Cysts

Bronchogenic cysts are the most common cystic lesions of the mediastinum and arise from abnormal budding of the foregut during development. The cyst wall consists of fibroelastic tissue, smooth muscle, and cartilage, whereas the cyst itself is lined with respiratory tract epithelia. It may also contain mucus-producing cuboidal cells, which contribute to enlargement of the cyst with mucus. They may occur anywhere along the tracheobronchial tree but occur most commonly in the vicinity of the right pulmonary hilum and subcarinal region. Less frequently, they present in the neck, lower lobes of the lung, pleura, pericardium, or below the diaphragm. When large, cysts can compress surrounding vital structures, including the aerodigestive tract causing dysphagia, pneumothorax, cough, or hemoptysis or become infected. The diagnosis is confirmed by CT as a spherical fluid- or mucus-filled nonenhancing mass. An air-fluid level may be present thus suggesting communication with the airway. Cysts within the pulmonary parenchyma more commonly communicate with a bronchus, as opposed to those in the mediastinum. In general, mediastinal bronchogenic cysts present with airway compression and parenchymal cysts are manifested by pulmonary infection. Some cysts have been noted to enlarge rapidly and rupture into the pleural space, causing tension pneumothorax. Rare cases of malignant transformation have been reported. All bronchogenic cysts—regardless of location—are best treated with either simple or segmental resection by VATS or thoracotomy. Rarely, lobectomy is required.

Masters IB: Congenital airway lesions and lung disease. *Pediatr Clin North Am* 2009;56(1):227.

C. Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia (BPD) is a form of chronic lung disease that occurs in infants, usually in preterm infants receiving respiratory support with mechanical ventilation or prolonged oxygen supplementation. With the introduction of positive pressure ventilation in newborn infants Northway et al originally described a pattern of lung injury characterized by airway injury, inflammation, and parenchymal fibrosis in preterm infants who had received mechanical ventilation. Since the introduction and implementation of antenatal corticosteroids and postnatal surfactant replacement BPD now more commonly affects those of extremely low birth weight and born less than 26 weeks of gestation. BPD nowadays is fundamentally viewed as the result of abnormal reparative processes in response to injury and inflammation occurring in an immature lung of a genetically susceptible infant. The pathogenesis of BPD begins with a very immature lung complicated by iatrogenic damage from therapy with oxygen and volume ventilation with superimposed infection and inflammation as well as pulmonary edema complicated by poor nutrition. Treatment is supportive combining new approaches to ventilation (nasal CPAP and inhaled nitric oxide) with vitamin A. The American Thoracic Society has recently published a position paper on the care of the child with chronic lung disease of infancy and childhood that addresses many of these issues.

D. Pulmonary Aplasia and Agenesis

Pulmonary hypoplasia is a relatively common abnormality of lung development and is defined pathologically as an abnormally low radial alveolus count and low ratio of lung weight to body weight. Pulmonary hypoplasia is termed primary pulmonary hypoplasia when no inciting cause is identified and is likely caused by abnormalities of the transcription factors that regulate early lung morphogenesis. These neonates present with tachypnea and hypoxemia resistant to administration of supplemental oxygen due to abnormal thickening of the pulmonary arteriolar wall. Persistent fetal circulation, hypoxemia, hypercapnia, and acidosis lead to early death in over 75% of patients. Secondary pulmonary hypoplasia is associated with a restriction of lung growth or the absence of fetal breathing. Any reduction of the chest cavity by a mass, effusion, or external compression can impact lung growth. The most common of these abnormalities is congenital diaphragmatic hernia (see Chapter 43). Other conditions associated with secondary pulmonary hypoplasia include those that produce oligohydramnios and direct chest compression (eg, bilateral renal agenesis [Potter syndrome], renal dysplasia, and amniotic fluid leaks); those with abnormal bone development and small rigid chest walls (eg, achondroplasia, chondrodystrophia fetalis calcificans, osteogenesis imperfecta, and spondyloepiphyseal dysplasia); those with decreased fetal respiratory movements

(eg, phrenic nerve agenesis, abdominal masses or ascites with elevation of the diaphragm, arthrogryposis multiplex congenita, camptodactyly, and congenial myotonic dystrophy); those with intrathoracic mass lesions (eg, CCAM, cystic hygroma, esophageal duplication cysts); and those with pulmonary vascular abnormalities (eg, scimitar syndrome, pulmonary artery agenesis).

Unilateral pulmonary agenesis occurs when one lung and the associated vascular structures fail to develop. Neonates with pulmonary agenesis may present with tachypnea and cyanosis, particularly if associated cardiac anomalies exist (50% of cases). Some patients, however, remain asymptomatic until childhood, when they complain of dyspnea and wheezing suggestive of asthma. Physical examination in these patients reveals marked tracheal deviation toward the side of the agenesis, and chest x-ray, barium esophagography, and chest CT may be required to exclude other diagnostic possibilities such as total lung atelectasis from foreign body aspiration, total lung sequestration, and esophageal bronchus.

E. Pulmonary Sequestration

Pulmonary sequestration describes a mass of lung parenchyma that arises through abnormal budding of the caudal embryonic foregut and consequently has *no bronchial communication* with the otherwise normal tracheobronchial tree. Sequestration may occur either within normal lung tissue, termed intralobar sequestration, or as separate masses with their own visceral pleura, referred to as extralobar sequestration. The majority (85%) of sequestrations are of the intralobar type. Intralobar sequestrations receive their blood supply from the thoracic or abdominal aorta and splenic artery and their venous drainage from the pulmonary veins. In some cases this may be associated with anomalous venous drainage of the normal lung. Intralobar sequestrations are most commonly found on the left side in the lower lobe. Extralobar sequestrations are less common and receive their blood supply from the thoracic or abdominal aorta and the venous drainage via the systemic veins such as the hemiazygos or azygos veins or inferior vena cava. Both are associated with foregut communications but more commonly in extralobar sequestrations.

Intralobar sequestrations are usually diagnosed later in childhood or adolescence with multiple episodes of pneumonia. Common symptoms include a chronic or recurrent cough. Extralobar sequestrations usually present in infancy with respiratory distress and chronic cough or manifest as gastrointestinal symptoms if a communication with the gastrointestinal tract exists. In rare instances, patients may present with hemoptysis or congestive heart failure from large left-to-right shunts through the sequestration. The diagnosis is usually suspected on chest x-ray and confirmed with a CT scan of the chest delineating the arterial and venous

drainage. Angiography can be used to confirm the diagnosis and elucidate aberrant vascular anatomy. Treatment consists of segmental resection or, if necessary, lobectomy via thoracotomy or video-assisted procedure. Great care must be taken to identify the nature of both the arterial blood supply and the venous drainage to avoid exsanguinating hemorrhage from division of an unrecognized systemic artery or venous infarction of the normal lung from ligation of the common draining vein. Following successful resection, the prognosis is favorable.

F. Congenital Cystic Adenomatoid Malformation

CCAM is the second most common cause of newborn respiratory distress, secondary to structural problems. CCAM is a discrete, space-occupying intrapulmonary mass that contain variable-sized cysts. These lesions do not function in normal gas exchange yet airspaces within these masses communicate with the tracheobronchial tree. Histologically, CCAM is distinguished from other lesions and normal lung by polypoid projections of the mucosa, an increase in smooth muscle and elastic tissue within cyst walls, an absence of cartilage, the presence of mucus-secreting cells, and the absence of inflammation. The classification system described by Stocker organizes these lesions on pathologic appearance and clinical outcome. Class I consists of large cysts greater than 2 cm; class II consists of small cysts less than 2 cm; class III consists of solid lesions without cysts. Children will present either at birth or in early childhood with recurrent respiratory infections. The growth of CCAMs usually plateaus between 25 and 28 weeks, at which time the fetus appears to grow around the lesion. The vast majority of small- to moderate-sized CCAMs remain asymptomatic during fetal life. Approximately 15% of CCAMs will shrink significantly before birth. However, large lesions represent 5%-10% of CCAMs and may produce significant mass effect, which can lead to pulmonary hypoplasia, impaired fetal swallowing and polyhydramnios, and impaired venous return and heart failure. Fetal hydrops can result and appears to depend on the size and rate of growth of the mass, and result from compression of the superior vena cava and impaired venous return. As therapeutic fetal interventions have become feasible, the ability to predict which infants will progress to hydrops has become critical. High-resolution fetal MRI can calculate a cyst volume ratio which is useful in predicting progression to hydrops. Fetal interventions including a short course of maternal betamethasone for microcystic CCAM and minimally invasive *in utero* thoracoamniotic shunting for macrocystic CCAM have been shown to be successful. If fetal development is uncomplicated, early delivery is not encouraged. At birth, the infants are stratified based on symptoms. Critically ill infants require immediate resection of the involved lobe. An asymptomatic neonate should be initially evaluated with chest radiography. While surgery can

be delayed in those patients with small lesions, any patient with known CCAM should undergo elective resection due to possible future complications including pneumonia and malignant transformation.

G. Congenital Lobar Emphysema

CLE is the cause of half of the episodes of newborn respiratory distress due to structural abnormalities and is defined as an overdistended lobe resulting from the obstruction of a lobar bronchus. Obstruction can arise from abnormal cartilage development or an ischemic event during bronchial development. CLE also can develop as the result of meconium aspiration, lobar torsion, or an extrinsic cause such as obstructing lymph nodes. The left upper lobe is most commonly involved, and with the right middle lobe next in prevalence. In addition, neonates who require prolonged mechanical ventilation (eg, those with hyaline membrane disease) can develop lobar emphysema from a combination of suction catheter trauma and barotrauma. The right lower lobe is most frequently affected in such patients. Most infants present within the first 6 months of life with respiratory distress. In some patients, severe respiratory distress may occur in the neonatal period, requiring emergency evaluation and treatment. Almost all infants present with tracheal and mediastinal deviation away from the affected side, hyperresonance and decreased breath sounds on the affected side, and a chest radiograph demonstrating hyperlucency in the area of the affected lobe with compression of adjacent lung. A chest radiograph often is sufficient before proceeding with operation. Occasional patients, particularly older children, may require chest CT scans to exclude other pathology (eg, bronchogenic cysts, anomalous pulmonary vessels, and hilar lymphadenopathy). Bronchoscopy also may be necessary to rule out the presence of a foreign body causing ball-valve airway obstruction. Successful therapy in all patients requires pulmonary resection, which almost uniformly consists of lobectomy. Great care is necessary with airway management at the time of induction of general anesthesia in these patients as positive-pressure ventilation can result in further shifting of the mediastinum resulting in impaired venous return and cardiovascular collapse. If such a situation arises, an emergent thoracotomy should be preformed to allow for the affected lobe to “herniate out” of the incision decompressing mediastinal pressure. Even after lung resection, patients may have bronchomalacia and a tendency toward bronchospasm.

CONGENITAL VASCULAR LESIONS OF THE LUNG

Vascular diseases of the lung include two main processes: arteriovenous malformations and vascular rings. Arteriovenous malformations are uncommon congenital lesions that develop as a result of abnormal capillary formation during the canalicular phase of development. Most

arise from the pulmonary artery, but occasionally a systemic arterial source can be involved similar to that in pulmonary sequestration. Rarely, an arteriovenous malformation can arise from a coronary artery, with the right coronary artery involved 55% of the time. Coronary arteriovenous fistulas drain into the right ventricle (40%), right atrium (25%), pulmonary artery (20%), coronary sinus (7%), superior vena cava (1%), or left-sided heart chambers (7%). Patients are either asymptomatic or develop signs of congestive heart failure. Myocardial infarction is rare. A continuous murmur and signs of reduced left ventricular afterload may be present. Although the diagnosis often can be established with echocardiography and color Doppler imaging, the definitive diagnosis, shunt fraction, and complete preoperative planning require catheterization and angiography. Operation is indicated for symptomatic patients and for those asymptomatic patients with large shunts.

Vascular rings occur from abnormal development of the aortic arches and major branches, with resulting compression of the trachea and esophagus. In normal fetal development, a dual system of six aortic arches regresses in such a way that the left fourth arch becomes the main left-sided aorta, the left sixth arch develops as the ductus arteriosus, and the right fourth arch persists as the right innominate artery and subclavian artery. Most vascular rings, however, are associated with a right-sided aortic arch and are classified as complete vascular rings or incomplete rings (arterial slings). Complete vascular rings include a double aortic arch (67%, the most common complete ring), a right aortic arch with a left subclavian and left ductus arteriosus (30%), a right aortic arch with mirror-image branching and a left ductus arteriosus (rare), and a left aortic arch with an aberrant right subclavian and right ductus arteriosus (very rare). Incomplete rings consist of an aberrant right subclavian artery that originates on the left side and passes posterior to the esophagus (most common incomplete ring) and an anomalous left pulmonary artery arising from the right pulmonary artery and passing between the trachea and the esophagus (pulmonary artery sling).

Most patients present with symptoms of tracheal or esophageal compression. Patients with an anomalous right subclavian artery may present later in life with obstructive symptoms (dysphagia lusoria), while those with complete vascular rings and pulmonary artery slings typically present early in life (within 6 months) with symptoms of respiratory distress (often frank stridor), particularly with neck flexion and poor feeding. The diagnosis is often suggested by characteristic findings on barium esophagogram. Bilateral indentations imply double aortic arch. A posterior indentation suggests an aberrant right subclavian artery, large right-sided indentations suggest complete rings associated with a right aortic arch, and an anterior impression is typical of a pulmonary artery sling. Often, the diagnosis can be confirmed by echocardiography. MRI/MRA often

provides useful anatomic details. Surgical repair of these lesions is indicated once the diagnosis is established and is accomplished by dividing the vascular ring usually through a left thoracotomy. With double aortic arches, the smaller of the two arches is divided distal to the subclavian artery, while other complete rings generally are treated by division of the ligamentum arteriosum. Aberrant right subclavian arteries may be simply divided or, if necessary, divided and transposed to the right side. Pulmonary artery slings require reimplantation of the left pulmonary artery and often resection of the compressed trachea, which often has severe tracheomalacia and stenosis. Rarely, tracheomalacia secondary to vascular ring compression necessitates suspension of the aortic arch from the sternum.

SUPPURATIVE DISEASES OF THE LUNG

1. Lung Abscess

A lung abscess usually begins as a necrotizing pneumonia progressing to liquefactive necrosis of the lung parenchyma. The liquefied necrotic material eventually empties into a draining bronchus, forming a necrotic cavity of pus containing an air-fluid level. With rupture, the infection can extend into the pleural space, producing an empyema. Arbitrarily, abscesses are termed acute if the duration is less than 6 weeks and chronic if more than 6 weeks. Although the incidence of lung abscesses fell dramatically following the introduction of effective antibiotics in the 1940s and 1950s, a recent increase in the number of immunocompromised individuals secondary to organ transplantation, chemotherapy, and AIDS has resulted in a resurgence in the numbers of lung abscesses requiring treatment.

Lung abscesses can be divided into two major categories based on etiology: primary and secondary. Lung abscesses are termed primary when they arise in a previously healthy individual or secondary to an underlying cause. Most commonly a primary abscess occurs as a result of aspiration owing to impaired consciousness or swallowing dysfunction due to neuromuscular or esophageal diseases. Sixty to seventy percent of lung abscesses present in the right lung in the dependent posterior segment of the right-upper lobe and superior segment of the lower lobe. They are most commonly polymicrobial with a predominance of anaerobic organisms including *Peptostreptococcus*, *Bacteroides fragilis*, and *Fusobacterium*. Conditions that predispose to aspiration include anesthesia (both general and monitored), neurologic disorders (cerebrovascular accidents, seizures, diabetic coma, head trauma, etc), drug ingestion (alcohol, narcotics, etc), normal sleep, poor oral hygiene (increases bacterial load), and esophageal disease (gastroesophageal reflux, achalasia, cancer, tracheoesophageal fistula). Secondary causes include bronchial obstruction (tumor, foreign body, hilar lymphadenopathy), necrotizing pneumonia (*S aureus*, *K pneumoniae*),

chronic pneumonia (due to fungi, tubercle bacilli), and opportunistic infection in an immunodeficient host. Over the years the incidence of secondary lung abscess arising in the setting of an immunocompromised state has increased. As a result, virulent aerobic species such as *Klebsiella*, *Pseudomonas*, *Proteus*, *Enterobacter*, and *S aureus* now comprise the majority of these infections as opposed to anaerobic species. Gram-negative lung abscess occurs in elderly and immunocompromised patients with nosocomial pneumonia. Cavitating lesions may arise in the setting of a malignancy or pulmonary infarct. Direct extension of a localized infection such as amebiasis or subphrenic abscess may also progress to a secondary lung abscess. Blood-borne infections can give rise to multiple lung abscesses in the periphery of the lung and are the result of septic emboli from bacteria, endocarditis, septic thrombophlebitis, or subphrenic infection. It should be noted that secondary infections of congenital or acquired cystic lesions, such as bronchogenic cysts, bullae, tuberculous cavities, and hydatid cysts, are not true pulmonary abscesses because they occur in a preformed space.

► Clinical Findings & Diagnosis

Patients with lung abscesses typically reports symptoms of cough, fever, putrid sputum, hemoptysis, dyspnea, pleuritic chest pain, and weight loss. Symptoms are often insidious in onset and associated with malaise and weight loss if chronic. Complications include rupture into a bronchus, with initial hemoptysis followed by the production of foul-smelling, purulent sputum (and the potential for life-threatening pneumonia from aspiration of pus into normal lung); rupture into the pleural space with resulting pyopneumothorax, sepsis, and possibly empyema necessitatis; and, rarely, massive hemoptysis requiring emergent pulmonary resection. On physical examination, signs of lobar consolidation predominate; but clubbing, signs of pleural effusion, cachexia, and rarely a draining chest wound (empyema necessitatis) can be present. Laboratory studies should include a differential white blood cell count and sputum culture. Chest radiography and CT scan of the thorax are usually sufficient to aid diagnosis and differentiate between empyema and abscess. Cavitation is generally apparent on chest radiographs 2 weeks after the onset of symptoms. Radiological resolution lags behind clinical and biochemical improvement, taking up to 3 months to resolve in up to 70%. In cases of suspected bronchial obstruction or in all patients with unexplained lung abscesses, bronchoscopy is indicated. Fine-needle aspiration of the abscess cavity for diagnostic culture has been shown to isolate the offending pathogens in 94% of patients compared with only 11% and 3% from sputum culture and bronchoalveolar lavage, respectively. Early fine-needle aspiration can prompt a change of the antibiotic regimen in 43% of cases and can be life-saving in immunocompromised patients with unusual organisms.

► Treatment

Antibiotic administration has been the mainstay of therapy following general resuscitation measures. First-line treatment should include aerobic and anaerobic coverage for a period of 4-6 weeks. Once the acute sepsis subsides (after up to 2 weeks), therapy can frequently be changed to an oral outpatient regimen and continued until complete resolution of the abscess occurs (3-5 months). Important adjuncts to antibiotic administration include chest physiotherapy, postural drainage, bronchoscopy (may require repeated examinations to maintain bronchial drainage), and health maintenance measures (general nutrition, dental hygiene, etc).

In patients who do not respond to this initial regimen and who do not have surgical indications (see below), early percutaneous drainage has been shown to be a safe and effective procedure (mortality rate, 1.5%; morbidity rate, 10%). Specific proposed indications for percutaneous drainage include: (1) an abscess under tension as evidenced by mediastinal shift, displacement of fissures, or downward displacement of the diaphragm; (2) radiographic verification of contralateral lung contamination; (3) unremitting signs of sepsis after 72 hours of adequate antibiotic therapy; (4) abscess size larger than 4 cm or increasing abscess size; (5) rising fluid level; and (6) persistent ventilatory dependency.

In addition to drainage, intervention permits microbiological analysis of the aspirate. In up to 47% of patients, initial antibiotic regimens require adjustment based on microbial speciation and sensitivity analyses. Tube thoracostomy carries risk of parenchymal injury with resulting chronic air leak and/or bronchopleural fistula (BPF). Operative intervention is rarely indicated in the management of lung abscess but should be considered in patients with failure of clinical or radiological improvement after 4-6 weeks of antibiotic therapy, abscesses larger than 6 cm, massive or life-threatening hemoptysis (4%), empyema or BPF (4%), and bronchial obstruction (particularly if secondary to resectable cancer). Furthermore, acute rupture into the pleural space (pyopneumothorax) is still a surgical emergency. When surgery is indicated, either thoracoscopic or open lobectomy generally is the preferred procedure and can be accomplished with low mortality (0%-2%) and morbidity. A double-lumen tube is mandatory to protect the airway due to the high risk of spillage of abscess into the contralateral lung. Routine buttressing of the bronchial stump with a vascularized pedicle (intercostal muscle or pericardial fat) is recommended to prevent BPF.

► Prognosis

Antibiotics given over 4-6 weeks with percutaneous drainage is effective in 85%-95% of patients. Mortality for lung abscess has decreased from 30% to 40% in the preantibiotic era to 10% in the present era, but remains greater for elderly individuals, immunocompromised patients, or those who

have abscess larger than 6 cm, bronchial obstruction, multiple abscesses, necrotizing pneumonia, or gram-negative pneumonia.

Agasthian T. Results of surgery for bronchiectasis and pulmonary abscesses. *Thorac Surg Clin* 2012;22:333.

2. Bronchiectasis

Bronchiectasis is defined as irreversible dilation of the peripheral airways secondary to damage of the structural components of the bronchial wall (elastin, muscles, and cartilage). Mechanisms of damage include bronchial wall injury, bronchial lumen obstruction, and traction from adjacent fibrosis seen in end-stage lung fibrosis. Cole's "vicious cycle" hypothesizes that initial infection, in a background of genetic susceptibility or impaired mucosal clearance, results in retention of microorganisms in the bronchial tree. Overproduction of thick inflammatory mucus in the setting of persistent microbial colonization of dilated airways, together with impairment of mucociliary clearance mechanisms causes a vicious cycle of repeated and prolonged episodes of chronic inflammation resulting in progressive airway and lung damage.

The clinical syndrome manifests as chronic dilation of bronchi, a paroxysmal cough that produces variable amounts of fetid, mucopurulent sputum, and recurrent pulmonary infections. Aspirated foreign bodies, endobronchial neoplasms, and hilar lymphadenopathy (see section on Middle Lobe Syndrome, later) also can cause retention of secretions, infections, and progressive bronchiectasis. The presence of true established bronchiectasis, however, must be distinguished from pseudobronchiectasis, which is a cylindrical bronchial dilation that is associated with acute bronchopneumonia. When left untreated, true bronchiectasis progresses, while pseudobronchiectasis reverses completely after weeks to months.

Most cases are related to acquired disorders and are caused by two factors: infection and bronchial obstruction. Acquired viral and bacterial infections in infancy and childhood (eg, pertussis, measles, influenza, tuberculosis, bronchopneumonia) were common predisposing conditions that led to bronchiectasis in the past and are still common in developing countries. With the reemergence of tuberculosis postinfectious bronchiectasis is also becoming more prevalent, and is seen 11% of patients. In developed countries, immune deficiency syndromes (hypogammaglobulinemia and leukocyte dysfunction), metabolic defects (cystic fibrosis, alpha-1 antitrypsin deficiency), ultrastructural defects (primary ciliary dyskinesia, Young syndrome, Kartagener syndrome, congenital defects of cartilage), and pulmonary sequestration are more common causes.

Reid categorized bronchiectasis into three main types based on pathologic appearance: (1) tubular or cylindrical,

characterized by smooth dilation of the bronchi; (2) varicose, in which the bronchi are dilated with multiple indentations; and (3) cystic or saccular, in which dilated bronchi terminate in blind ending sacs of pus with no communication with the rest of the lung. Saccular bronchiectasis follows severe infections and cases of bronchial obstruction, while the cylindrical variant is associated with tuberculosis and immune disorders. Varicose consists of alternating areas of cylindrical and saccular types.

Bronchiectasis can be classified also as perfused or nonperfused types according to functional hemodynamic perfusion studies as described by Ashour. The perfused type has cylindrical bronchiectatic changes with intact pulmonary artery flow, whereas the nonperfused type involves cystic bronchiectasis with absent pulmonary artery flow and retrograde filling of the pulmonary artery through the systemic circulation.

Taken together, tubular or cylindric bronchiectasis tends to have better prognosis than cystic/varicose varieties, as the lung areas affected by the former tend to have good function and perfusion. Cystic bronchiectasis tends to indicate a completely destroyed, nonfunctional, and nonperfused lung. Additionally, all parameters of respiratory function are worse in the saccular type as compared with the tubular type. Saccular type bronchiectasis also is associated with higher bacterial loads with virulent strains, such as *Pseudomonas*.

In general, bronchiectasis involves the second-order to fourth-order branches of the segmental bronchi, and its distribution is largely characteristic of the underlying pathology. The left lung tends to be more involved than the right lung in 55%-80% of cases. This may be because the left mainstem bronchus is narrower and longer than the right and subject to greater compression pressures, especially by the aortic arch. The lower lobes are commonly affected owing to gravity-dependent retention of infected secretions. Congenital disorders, for example, are associated with diffuse bilateral bronchiectasis, while tuberculosis and granulomatous diseases are characterized by unilateral or bilateral disease, most commonly limited to the upper lobes and superior segments of the lower lobes. Furthermore, bronchiectasis following pyogenic and viral pneumonias usually involves only the lower lobes, middle lobe, and lingula, and postobstructive bronchiectasis is generally limited to the obstructed segments (see also Middle Lobe Syndrome, later). Common pathogens in patients with bronchiectasis include *H influenzae*, *S aureus*, *K pneumoniae*, *E coli*, and, in the chronic setting, *Pseudomonas* species. Mycobacteria, fungi, and *Legionella* should also be cultured.

► Clinical Findings & Diagnosis

Patients with a history of recurrent febrile episodes often complain of a chronic or intermittent cough that produces variable amounts of foul-smelling sputum (up to 500 mL/d).

Hemoptysis occurs in 41%-66%, but rarely is it massive. Bronchiectasis associated with granulomatous disease may not be associated with a productive cough (so-called dry bronchiectasis). Exacerbations and advanced disease are manifested by increased sputum production, fever, dyspnea, anorexia, fatigue, and weight loss. A history of sinus problems, infertility, or a family history of similar problems suggests the presence of an inherited disorder associated with bronchiectasis. Physical examination may reveal cyanosis, clubbing, pulmonary osteoarthropathy, evidence of malnutrition, and, in advanced disease, signs of cor pulmonale. Although bronchiectasis is suspected, an imaging study is usually required for confirmation. Bronchograms were at one time required, but high-resolution chest CT scans are now the imaging procedure of choice to document bronchial dilation, particularly with saccular disease. Even with the diagnosis of bronchiectasis, however, endobronchial neoplasm or foreign body must be excluded by flexible fiberoptic bronchoscopy.

► Treatment

In nearly all patients, conservative medical therapy is indicated and generally is sufficient. This includes broad-spectrum antibiotics, bronchodilators, humidification, expectorants, mucolytics, and effective routine postural drainage. In patients with continued infection, bronchoscopy with bronchoalveolar lavage should be considered to obtain more accurate culture results. Other adjunctive therapies include influenza and pneumococcal vaccines and, in some patients, chronic “prophylactic” antibiotic administration with trimethoprim-sulfamethoxazole, erythromycin, or ciprofloxacin. A recent advance in controlling underlying bacterial (especially *pseudomonas*) infection and symptoms associated with bronchiectasis has been the use of inhaled antibiotics. In the cystic fibrosis and chronic bronchiectasis population, nebulized tobramycin or gentamicin has proven effective in controlling infection, sputum production, and symptoms in a significant proportion of patients.

Patients who fail intensive medical therapy may be candidates for surgical resection if the following criteria are met: (1) the disease must be localized and completely resectable; (2) pulmonary reserve must be adequate; (3) the process must be irreversible (ie, not pseudobronchiectasis, bronchial stricture, foreign body, etc); and (4) significant symptoms must persist. Preoperative assessment requires a high-resolution chest CT scan, although some surgeons still prefer a bronchogram as a “road map.” Pulmonary function studies generally are not necessary, since the involved segments do not function.

The goals of surgery are to remove all active disease and to preserve as much functioning lung parenchyma as possible. The surgical approach includes complete segmental resection of the involved areas. Partial resection

almost always ends in recurrence. Resection most commonly involves all basal segments (unilaterally or bilaterally) along with the middle lobe or lingula. With tuberculosis, however, removal of the upper lobe or lobes with or without the superior segment of the lower lobes is more likely. During operation, meticulous maintenance of a clear airway devoid of mucopurulent secretions and blood is essential. Careful dissection of the bronchovascular structures is difficult in patients with chronic inflammation and scarring but is essential to avoid complications.

► Prognosis

Although most patients are successfully treated with medical therapy, some require operation. The results of pulmonary resection depend on the cause and type of parenchymal involvement. Success with elimination of symptoms occurs in up to 80% of patients with limited localized disease but only 36% of those with diffuse disease. Prognostic factors include: (1) unilateral disease restricted to the basal segments; (2) young age; (3) absence of sinusitis and rhinitis; (4) history of pneumonia; and (5) no major airway obstruction. Overall morbidity and mortality rates are surprisingly low at 3%-5% and less than 1%, respectively.

3. Middle Lobe Syndrome

Middle lobe syndrome (MLS) is characterized by recurrent or chronic collapse of the middle lobe of the right lung but can also involve the lingula of the left lung. There are two forms of MLS: obstructive and nonobstructive. Obstructive MLS occurs as a result of an endobronchial lesion or extrinsic compression of the middle lobe bronchus from hilar lymphadenopathy or tumor causing postobstructive atelectasis and pneumonitis. The most common cause of extrinsic compression of the right-middle lobe bronchus is enlargement of peribronchial lymph nodes due to fungal infections such as histoplasmosis or atypical mycobacterial infections. Adenopathy due to sarcoidosis or lymph node metastases has also been described in obstructive MLS. Less common causes include aspirated foreign objects, broncholiths, inspissated mucus (associated with cystic fibrosis), and endoluminal granulomas associated with sarcoidosis.

Nonobstructive MLS is characterized by the absence of a mechanical obstruction of the middle lobe bronchus on bronchoscopy and/or CT of the chest. Though poorly understood the narrow diameter and long length of the middle lobe bronchus, combined with an acute angle at its origin, create poor conditions for adequate drainage. This form of MLS is the most common cause and commonly occurs in adults and children with recurrent pneumonia. It is often related to asthma, bronchitis, and cystic fibrosis.

The diagnosis of MLS should be entertained in a patient with repeated episodes of right-sided pneumonia, only after other causes of obstruction (bronchogenic cancer, foreign

body, etc), have been ruled out. Evaluation includes chest radiography, bronchoscopy and CT of the chest. Most patients respond to intensive medical therapy including bronchodilators, mucolytics, and broad spectrum antibiotics in addition to therapeutic bronchoscopy. Those who do not respond should be offered resection of the right-middle lobe and/or debulking lymphadenopathy, which is associated with a low mortality rate and favorable outcome. Other indications for surgery include bronchiectasis, fibrosis (bronchial stenosis), abscess, unresolved or intractable recurrent pneumonia, hemoptysis, and suspicion of neoplasm.

Gudbjartsson T et al: Middle lobe syndrome: a review of clinicopathological features, diagnosis and treatment. *Respiration* 2012;84:80.

4. Broncholithiasis

Broncholithiasis is defined as the presence of calculi (bronchololiths) within the tracheobronchial tree. In most cases, a bronchololith is formed by erosion and extrusion of a calcified adjacent lymph node into the bronchial lumen and is usually associated with long-standing foci of necrotizing granulomatous lymphadenitis. Calcified lymph nodes can remain attached to the bronchial wall, lodge in a bronchus, or be expectorated (lithoptysis). The most common cause of broncholithiasis in the United States is histoplasmosis. Tuberculosis is another frequent cause in some parts of the world.

Patients with broncholithiasis often complain of hemoptysis, lithoptysis (30%), cough, sputum production, fever, chills, and pleuritic chest pain. The hemoptysis is characteristically sudden and self-limited, though rarely it may be massive. Symptoms of pneumonia may indicate bronchial obstruction from an impacted bronchololith. Signs suggesting broncholithiasis include localized wheezing on physical examination, evidence of hilar calcifications or segmental atelectasis and pneumonia on chest x-ray, and bronchoscopic evidence of peribronchial disease. The diagnosis is confirmed by documentation of lithoptysis or the presence of an endobronchial "lung stone."

The complications of broncholithiasis include hemoptysis, which on occasion can be massive and life threatening; suppurative lung diseases (eg, pneumonia and bronchiectasis); midesophageal traction diverticula; and, rarely, tracheo-bronchoesophageal fistula.

In addition to instituting appropriate therapy for underlying pulmonary diseases, treatment is primarily directed at removal of endobronchial stones. This can be accomplished at the time of bronchoscopy if the bronchololith is freely floating within the tracheobronchial tree or if it extends well into the bronchial lumen and can be removed without excessive force or traction (20% of cases). The main danger of trans-bronchoscopic removal of bronchololiths is the risk for massive hemorrhage. This results during inappropriate removal

of broncholiths that remain substantially attached to the parabronchial tissues. Because of intense peribronchial fibrosis in this situation, the broncholith not infrequently becomes adherent to vascular structures such as the pulmonary artery, which may be torn with vigorous attempts at broncholith removal.

Nearly 80% of patients with broncholiths that remain *in situ* require surgical removal. The goal of surgery in this disease is preservation of lung function. The broncholith may be removed safely with bronchotomy; however, most patients require segmentectomy or lobectomy, particularly if destruction of lung parenchyma has occurred from postobstruction suppurative lung disease. Fistulas between the airway and the esophagus should be repaired with interposition of normal tissue (intercostal muscle flap, etc) between the two structures to prevent recurrence. Following surgery, the prognosis is excellent.

Cerfolio R et al: Rigid bronchoscopy and surgical resection for broncholithiasis and calcified mediastinal lymph nodes. *J Thorac Cardiovasc Surg* 2008;136:186.

5. Cystic Fibrosis and Mucoïd Impaction of the Bronchi

Cystic fibrosis is an autosomal recessive multisystem congenital disorder that is characterized by chronic airway obstruction and infection and by exocrine pancreatic insufficiency and gastrointestinal tract dysfunction with consequent effects on nutrition, growth, and maturation. The disorder is the result of several characterized mutations in the cystic fibrosis transmembrane regulator (CFTR) gene, most commonly the $\Delta F508$ mutation. Such mutations cause abnormalities of chloride and likely sodium transport leading to abnormal regulation and reduction of airway surface liquid volume. The result is a viscous and tenacious mucus that adheres to the airway surface epithelium resulting in airflow obstruction and bacterial infection (*S. aureus*, *P. aeruginosa*, and *Burkholderia cepacia*). Once established, infection of the CF lung is rarely eradicated. Pulmonary manifestations of the disorder include mucoïd impaction, bronchitis, bronchiectasis, pulmonary fibrosis, emphysema, and lung abscess. Mucoïd plugs are rubbery, semisolid, gray to greenish-yellow in color, and round, oval, or elongated in shape. There is often a history of recurrent upper respiratory infection, fever, and chest pain. Expectoration of hard mucus plugs or hemoptysis may occur.

The earliest manifestation of CF lung disease is a cough that progressively worsens to becoming a daily event and productive. It often becomes paroxysmal and associated with gagging and emesis. Sputum is usually tenacious, purulent, and often green, reflecting bacterial infection. Hyperinflation of the lungs due to airway obstruction is noted early in the progression of lung disease. Asthmatic or bronchiolitic-type

wheezing is common. CF patients typically have mild bronchitis symptoms for long periods of time punctuated by increasingly frequent acute exacerbations of symptoms that include increased intensity of cough, tachypnea, shortness of breath, decreased activity and appetite, and weight loss. Intense antibiotic therapy and assistance with clearance of mucus are usually required to reduce lung symptoms and improve lung function. End-stage lung disease is characterized by substantial hypoxemia, pulmonary hypertension, cor pulmonale, and death.

The primary objectives of CF treatment are to control infection, promote mucus clearance, and improve nutrition. Therapy includes postural drainage with chest percussion, expectorants, detergents, bronchodilators, antibiotics, and aerosol inhalation. More novel therapies include inhaled hypertonic saline which osmotically draws water onto the airway surface thereby “rehydrating” the airway mucus allowing for easier expectoration, aerosolized rhDNase which lyses the viscous DNA contained within airway mucus and ibuprofen which has been shown to slow the decline in lung function. Surgery including partial lung resection is indicated for apparently localized disease (lung abscess and bronchiectasis) and recurrent severe exacerbations. Lobectomy is occasionally indicated for massive hemoptysis that is refractory to bronchial artery embolization.

Double lung transplantation has become an accepted therapy for respiratory failure secondary to CF. Patients should be referred when their prognosis is about equal to the waiting time for donor lungs, currently about 2 years after acceptance as a lung transplant candidate. Relative contraindications to transplant include severe malnutrition (ideal body weight < 70%), chronic steroid use greater than 20 mg of prednisone daily and mechanical ventilation (center dependent). Multiresistant *P. aeruginosa* infection is not a contraindication for transplantation although pan-resistant *P. aeruginosa* is considered, at some centers, to be a contraindication. *Burkholderia cepacia* is viewed by some to be a contraindication to lung transplantation. The transplanted lungs remain free of CF, but are subject to secondary infection, acute rejection, and chronic rejection (bronchiolitis obliterans syndrome). The 5-year survival following lung transplantation is 48%. The median survival in all CF patients now exceeds 31 years.

O’Sullivan BP et al: Cystic fibrosis. *Lancet* 2009;373:1891.

6. Tuberculosis

Tuberculosis markedly declined as a cause of death between 1953 and 1984, but since 1985, this disease has experienced resurgence due to increased immigration of infected individuals and HIV infection. A reservoir of about 5000-8000 clinical cases exists, and an additional 25,000 new cases occur annually. Multidrug-resistant tuberculosis (MDR-TB)

and, most recently, extensively drug-resistant tuberculosis (XDR-TB) have emerged over the last 20 years. MDR-TB is defined as those strains resistant to at least isoniazid and rifampicin. XDR-TB strains are defined as those resistant to rifampicin, isoniazid, fluoroquinolones, and any of capreomycin, kanamycin, or amikacin. Resistance to these antitubercular drugs is the result of spontaneous mutations in the genome and is due to a myriad of factors most commonly inadequate treatment of active pulmonary tuberculosis. Less than 20% of the United States population is tuberculin-positive, but tuberculosis remains a common infectious cause of death worldwide. It is estimated that there are 440,000 new MDR-TB cases identified each year worldwide, many of these arising in previously treated patients. Nearly 50% of cases occur in India and China. The prognosis of treatment of MDR-TB or XDR-TB is significantly worse than for drug-susceptible disease.

Several species of the genus mycobacterium may cause lung disease, but 95% of cases of lung disease are due to *Mycobacterium tuberculosis*. Several “atypical” species of *Mycobacterium*, such as *Mycobacterium bovis* and *Mycobacterium avium*, that are chiefly soil-dwellers, have become clinically more important in recent years because they are less responsive to preventive and therapeutic measures. Mycobacteria are nonmotile, nonsporulating, weakly gram-positive rods classified in the order Actinomycetales. Dormant organisms remain alive for the life of the host.

The initial infection often involves pulmonary parenchyma in the midzone of the lungs. When hypersensitivity develops after several weeks, the typical caseation appears. Regional hilar lymph nodes become enlarged. Most cases arrest spontaneously at this stage. Should the infection progress, caseation necrosis develops and giant cells produce a typical tubercle. A cause of latent disease in the elderly or debilitated patient is dormant reactivation tubercles. Sites in the apical and posterior segments of the upper lobes and superior segments of the lower lobes are the usual areas of infection.

► Clinical Findings

A. Symptoms and Signs

Patients may present with minimal symptoms, including fever, cough, anorexia, weight loss, night sweats, excessive perspiration, chest pain, lethargy, and dyspnea. Extrapulmonary disease may be associated with more severe symptoms, such as involvement of the pericardium, bones, joints, urinary tract, meninges, lymph nodes, or pleural space. Erythema nodosum is seen occasionally in patients with active disease.

B. Laboratory Findings

False-negative tests with intermediate-strength PPD are usually due to anergy, improper testing, or outdated tuberculin. Anergy is sometimes associated with disseminated tuberculosis, measles, sarcoidosis, lymphomas, or recent vac-

ination with live viruses (eg, poliomyelitis, measles, rubella, mumps, influenza, or yellow fever). Immunosuppressive drugs (eg, corticosteroids, azathioprine) and disease states (eg, AIDS, organ transplantation) may also cause false-negative responses. Mumps skin tests are negative in patients taking immunosuppressive drugs. Culture of sputum, gastric aspirates, and tracheal washings as well as pleural fluid and pleural and lung biopsies may establish the diagnosis.

C. Imaging Studies

Radiographic findings include involvement of the apical and posterior segments of the upper lobes (85%) or the superior segments of the lower lobes (10%). Seldom is the anterior segment of the upper lobe solely involved, as in other granulomatous diseases such as histoplasmosis. Involvement of the basal segments of the lower lobes is uncommon except in women, blacks, and diabetics, but endobronchial disease usually involves the lower lobes, producing atelectasis or consolidation. Differing x-ray patterns correspond to the pathologic variations of the disease: the local exudative lesion, the local productive lesion, cavitation, acute tuberculous pneumonia, miliary tuberculosis, Rasmussen aneurysm, bronchiectasis, bronchostenosis, and tuberculoma.

► Differential Diagnosis

It is critical to distinguish the x-ray findings from bronchogenic carcinoma, particularly when there is tuberculoma without calcification.

► Treatment

A. Medical Treatment

Active disease should be treated with one of the chemotherapeutic regimens that have recently been shown to shorten the period of treatment while maintaining their potency. Such drugs include isoniazid, streptomycin, rifampin, and ethambutol.

Treatment of MDR-TB and XDR-TB is less well defined. The World Health Organization (WHO) recently updated and put forth recommendations for treating MDR-TB. This includes:

- Rapid drug-susceptibility testing of isoniazid and rifampicin should be performed at the initial diagnosis of tuberculosis.
- The use of sputum microscopy and culture should be used instead of microscopy alone.
- Later generation fluoroquinolones, as well as ethionamide, should be used in patients with MDR-TB.
- The treatment of MDR-TB should include at least pyrazinamide, a fluoroquinolone, a parenteral agent (kanamycin, amikacin, or capreomycin), ethionamide, and either cycloserine or p-aminosalicylic acid.

- An intensive treatment of at least 8-months duration is recommended.

The success of MDR-TB therapy ranges from 36% to 79% with a mortality rate of 11%. It is estimated that less than 10% of people with MDR-TB are receiving appropriate treatment according to international guidelines.

B. Surgical Treatment

The role of surgery in treatment of tuberculosis has diminished dramatically since chemotherapy became available. It is now confined to the following indications: (1) failure of chemotherapy; (2) performance of diagnostic procedures; (3) destroyed lung; (4) postsurgical complications; (5) persistent bronchopleural fistula; and (6) intractable hemorrhage. The most common parenchymal resections include lobectomy, followed by pneumonectomy. Muscle flap coverage is strongly recommended. The infectious process often involves the pleural space and it is useful to perform an extrapleural dissection to minimize contamination or bacterial superinfection of the resection cavity.

Pulmonary resection is adjunctive to chemotherapy. The rationale for lung resection of parenchyma affected by MDR-TB is to remove a large focal burden of organisms present in destroyed nonviable lung tissue. The destroyed lung parenchyma and associated cavities are an ideal environment for the bacillus to grow due to its isolation from the circulation and therefore the host's defenses. Surgery is recommended in MDR-TB patients with extensive drug resistance—those with localized disease amenable to resection and those with high drug activity. Pretreatment with chemotherapeutic regimens for at least 2 months is required before operation to reduce the bacterial burden, followed by 12–24 months of treatment after surgery.

Diagnostic lung resection may be necessary to rule out other diseases, such as cancer, or to obtain material for cultures. Patients with destroyed lobes or cavitary tuberculosis of the right-upper lobe containing large infected foci may sometimes be candidates for resection.

The disease can become reactivated in some patients who have had thoracoplasty, plombage, or resection, and a few will require reoperation. The most common indications for surgery after plombage therapy are pleural infection (pyogenic or tuberculous) and migration of the plombage material, causing pain or compression of other organs. Following pulmonary resection, tuberculous empyema may develop in the postpneumonectomy space, sometimes associated with a bronchopleural fistula or bony sequestration. Persistent bronchopleural fistula after chemotherapy and closed tube drainage may require direct operative closure. Use of muscle flaps (intercostal, etc) is highly recommended to cover any bronchial stumps, especially in the setting of pneumonectomy.

Tuberculous empyema poses unique problems of management. Treatment depends on whether the empyema is:

(1) associated with parenchymal disease; (2) mixed tuberculous and pyogenic or purely tuberculous; and (3) associated with bronchopleural fistula. The ultimate objective is complete expansion of the lung and obliteration of the empyema space. Pulmonary decortication or resection may be used for tuberculosis, but open or closed drainage is necessary when the process is complicated by pyogenic infection or bronchopleural fistula.

► Prognosis

The prognosis is excellent in most cases treated medically; the death rate decreased from 25% in 1945 to less than 10% currently. Perioperative mortality for pulmonary resections for tuberculosis ranges from 10% for pneumonectomy to 3% for lobectomy and 1% for segmentectomy and subsegmental resections.

The morbidity of surgical resection ranges from 12% to 39% with the most common complications being bleeding, empyema, wound complications, and bronchopleural fistula. The rate of sputum sterilization ranges from 78% to 96% in MDR-TB patients. Factors leading to poorer outcomes include retreatment cases, XDR-TB, bilateral disease, and low body mass index.

FUNGAL INFECTIONS OF THE LUNG

Pulmonary fungal infections are increasing due to the widespread use of broad-spectrum antibiotics, the use of corticosteroids and other immunosuppressive drugs, and the spread of HIV infection. However, infection can occur in immunocompetent hosts. Fungal infections frequently involve the respiratory tract and include histoplasmosis, coccidioidomycosis, blastomycosis, cryptococcosis, aspergillosis, mucormycosis, and candidiasis. Fungal infections, though ubiquitous, are notable for several characteristic endemic areas. Candidiasis rarely if ever requires operative treatment and thus will not be discussed here.

1. Histoplasmosis

Histoplasma capsulatum is a dimorphic soil fungus found in soil enriched by the nitrogen contained in bird and bat guano. Abandoned buildings, attics, lofts, and areas under trees that serve as bird and bat roosts and caves are especially

likely to contain high concentrations. In endemic areas, exposure is common, and most infections are sporadic. Outbreaks have been traced to spelunking, demolition of buildings, and activities that disrupt contaminated soil. This organism is found primarily in the Ohio and Mississippi River valleys and in Central America. Mammals, including humans, inhale the organism and macrophages engulf the fungus. It then transforms into the budding yeast form, causing activation of inflammatory cytokines. Over several months the ongoing inflammation causes granuloma formation in lymph nodes with resulting caseation, necrosis, fibrosis, and calcification. The diagnosis of histoplasmosis is made definitively by growth of the organism from either sputum, BAL fluid, lung tissue, or mediastinal lymph nodes—though incubation periods of 4-6 weeks are required. Serology also plays an important role in the diagnosis. Both complement fixation and immunodiffusion tests should be ordered. Serology is not useful in immunosuppressed patients who are unable to mount an antibody response. The *Histoplasma* EIA has been under development as a diagnostic aid and detects the galactomannan component of the cell wall of *H capsulatum*. The original assay was marked by poor sensitivity; however, with modifications its sensitivity has increased to 65% in patients with acute pulmonary histoplasmosis.

Most infections in immunocompetent individuals are asymptomatic. Infections are classified as acute, chronic, or disseminated. Acute infections are manifested: (1) as a flu-like syndrome with fever, chills, dry cough, headache, retrosternal discomfort, arthralgias, and a rash suggesting erythema nodosum; (2) with symptoms similar to a flu-like syndrome but limited to the lungs and occasionally accompanied by a productive cough; or (3) as an acute diffuse nodular disease with mild symptoms. Radiographic findings in these three acute syndromes typically demonstrate ill-defined upper lobe nonsegmental opacities; nonsegmental areas of consolidation that tend to change; and diffuse, discrete 3- to 4-mm nodules, respectively. Hilar adenopathy on chest x-ray is common. Physical examination can be normal or may reveal signs of pneumonia.

In contrast, chronic infections include: (1) an asymptomatic solitary, discrete nodule less than 3 cm in diameter known as a histoplasmoma (most common), often with central and concentric calcifications (“target lesion”) and frequently located in the lower lobes; (2) chronic cavitory histoplasmosis, which typically occurs in patients with underlying obstructive disease, characteristically mild symptoms, fibronodular upper lobe infiltrates, and centrilobular emphysematous spaces; (3) mediastinal granulomas that may result in broncholithiasis, esophageal traction diverticula, superior vena cava compression, and tracheobronchoesophageal fistulas; and (4) fibrosing mediastinitis, which can produce compression of the superior vena cava, tracheobronchial tree, or esophagus.

Disseminated disease includes an acute, subacute, and chronic form. These infections occur in children (acute and subacute) as well as adults (subacute and chronic). Fever and abdominal pain are common. Other findings include hepatosplenomegaly, pancytopenia, meningitis, endocarditis, adrenocortical insufficiency, and oropharyngeal ulceration (chronic form).

Radiographic imaging in disseminated disease may demonstrate diffuse interstitial pneumonitis (25%) or minimal findings. The symptoms and roentgenographic findings of histoplasmosis resemble those of tuberculosis, although the disease appears to progress more slowly. There may be cough, malaise, hemoptysis, low-grade fever, and weight loss. As many as 30% of cases coexist with tuberculosis. Pulmonary fibrosis, bulla formation, and pulmonary insufficiency occur in advanced cases of histoplasmosis. Mediastinal involvement is quite frequent and may take the form of granuloma formation, or dysphagia. Furthermore, mediastinal fibrosis is among the most common benign causes of superior vena caval syndrome (discussed earlier in the chapter). Erosion of inflammatory lymph nodes into bronchi may cause expectoration of broncholiths, hemoptysis, wheezing, or bronchiectasis. Traction diverticula of the esophagus may lead to development of tracheoesophageal fistula. Pericardial involvement may lead to constrictive pericarditis.

In lesions that present as solitary pulmonary nodules, histoplasmosis is diagnosed in about 15%-20% of cases. Radiologically, early infections appear as diffuse mottled parenchymal infiltrations surrounding the hila, with enlargement of hilar lymph nodes. Cavitation indicates advanced infection and is the complication about which the surgeon is most often consulted. The diagnosis rests on finding a positive skin test or complement fixation test and culturing the fungus from sputum or a bronchial aspirate.

Medical therapy of histoplasmosis is indicated only in cavitory and severe disease and for most infections in immunocompromised hosts. Azoles are recommended as first-line treatment for patients who have mild to moderate pulmonary histoplasmosis. Itraconazole (200-400 mg/d for 6 months) is the drug of choice for cavitory disease, while amphotericin B (1-2 g total dose) is reserved for patients with more serious infections and infections in immunocompromised patients. Reflecting increasing use of corticosteroids for ARDS in the last decade, the current American Thoracic Society Guidelines recommend the use of intravenous methylprednisilone as adjunctive therapy for severe acute pulmonary histoplasmosis. Operative intervention is reserved for treatment of complications and to rule out neoplastic disease in the case of suspicious pulmonary nodules. Broncholithectomy via rigid bronchoscopy with or without pulmonary resection, repair of tracheobronchoesophageal fistulas, decompression of mediastinal granulomas, and spiral saphenous vein bypass of severe symptomatic superior

vena cava obstruction are typical examples. The Infectious Diseases Society of America recommends pericardiectomy for recurrent pericardial effusions. In cases of vascular fibrosis of the superior vena cava and pulmonary vessels percutaneous intravascular dilation and stenting is recommended as first-line treatment.

2. Coccidioidomycosis

Coccidioides immitis is a dimorphic soil fungus endemic to the Sonoran life zone (Utah, Arizona, California, Nevada, and New Mexico) and is associated with creosote brush. Dry heat with brief intense rain is essential for this fungus, which is spread by strong winds. Infection occurs through inhalation of as few as 1-10 arthrospores, which then germinate as parasitic spherules. Spherules have a double refractile cell wall and produce endospores that cause the spherule to rupture, spreading the infection to the surrounding tissues. Caseation, suppuration, abscess formation, and fibrosis follow. The diagnosis of coccidioidomycosis relies on the detection of acutely elevated titers of immunoglobulin M (IgM) antibodies (by latex agglutination and confirmed by immunodiffusion tube precipitin tests) or rising serum immunoglobulin G (IgG) antibody complement fixation titers (seroconversion or fourfold rise) in the appropriate clinical context. The coccidioidin and Spherulin skin tests, which become positive 3-21 days following infection, are generally useful only for epidemiologic studies and not for the diagnosis of acute disease. *C immitis* grows well in culture, but it is extremely hazardous to handle and requires a laminar flow hood due to the highly infectious nature of the arthrospores. Identification of the spherules in tissue, lavage samples, and fine-needle aspirates is helpful in making the diagnosis in some patients. Although many stains can be used, including routine fungal (potassium hydroxide, KOH) preparations, Pap staining is most sensitive. Gram stains, however, fail to demonstrate spherules.

Primary infection is asymptomatic in 60% of patients, while most others develop desert fever, with fever, productive cough, pleuritic chest pain, pneumonitis, and a rash typical of erythema nodosum or erythema multiforme. Disease that includes arthralgias is known as desert rheumatism. Radiographic findings demonstrate segmental or nonsegmental, homogeneous or mottled infiltrates with a predilection for the lower lobes. Physical examination is often unrevealing, but rales and rhonchi may be present. Other findings include eosinophilia (66%), hilar adenopathy (20%), and small exudative pleural effusions (2%-20%). Symptomatic persistent infection associated with chest x-ray findings 6-8 weeks after primary infection is classified as one of five types: persistent pneumonia, chronic progressive pneumonia, miliary coccidioidomycosis, coccidioidal nodules, or pulmonary cavities. Persistent pneumonia manifests with symptoms of fever, productive cough, and pleuritic

chest pain in association with protracted infiltrates and consolidation on chest x-ray generally resolving within 8 months. Patients with chronic progressive pneumonia complain of fever, cough, dyspnea, hemoptysis, and weight loss, with bilateral apical nodular densities and multiple cavities lasting years. This presentation closely resembles tuberculosis and chronic histoplasmosis. Miliary coccidioidomycosis occurs early and rapidly, associated with bilateral diffuse infiltrates. This form of disease implies the presence of impaired immunity and has an associated mortality rate of 50%. Nearly half of patients with coccidioidal nodules are asymptomatic. These nodular densities (coccidiomas) appear in the middle and upper lung fields, often within 5 cm of the hilum; range from 1 to 4 cm in size; and do not calcify, making it hard to distinguish them from malignancy. In endemic areas, 30%-50% of all nodules are coccidiomas. Patients develop pulmonary cavities in 10%-15% of cases of coccidioidomycosis. Typically, these are solitary (90%), thin-walled, located in the upper lobes (70%), less than 6 cm in size (90%), and close spontaneously within 2 years (50%). Some cavities, however, cross fissures; cause hemoptysis (25%-50%), usually mild; rupture, producing a pyopneumothorax with a bronchopleural fistula; or become infected with *Aspergillus*. Uncommonly, dissemination can occur, particularly in immunocompromised individuals, in pregnancy (third trimester), and in non-Caucasian individuals. Although pulmonary symptoms in disseminated disease are mild, meningeal involvement is common and the mortality rate is high (50%).

Medical therapy is not indicated in asymptomatic, immunocompetent individuals. Patients with persistent or chronic pneumonia, miliary disease, and those at risk for dissemination should be treated with antifungal therapy. Amphotericin B (0.5-2.5 g intravenously as total dose) is the standard treatment, though the newer azole compounds (fluconazole, ketoconazole, and itraconazole) may be used for long-term maintenance therapy, since the relapse rate may be as high as 25%-50%. Surgery is reserved for patients with coccidiomas when cancer is a concern and in patients with cavities that have an associated radiographic abnormality suggesting carcinoma (ie, thick wall) or that develop a complication (eg, hemoptysis and pyopneumothorax from rupture). Resection should include all diseased tissue and most often requires lobectomy.

3. Blastomycosis

Blastomyces dermatitidis is a dimorphic soil fungus found in warm, wet, nitrogen-rich soil in an endemic area that extends east of a line from the Texas Gulf coast to the border between Minnesota and North Dakota (except Florida and New England). Infection occurs characteristically in males (male-to-female ratio 6:1-15:1) from 30-60 years of age through inhalation of conidia (asexual spores). At 37°C, the

conidia germinate as yeasts, producing caseation in a manner similar to tuberculosis. Rarely, infection may develop through direct skin inoculation. Risk factors include poor hygiene, exposure to dust and wood, manual labor, and poor housing conditions. Since no accurate skin or serologic tests exist, the diagnosis depends on culture or histologic identification of the yeast form. Culture of the mycelial form can be hazardous. *B dermatitidis* grows as white to tan colonies of septate hyphae at room temperature but changes to budding yeast at 37°C. This temperature-dependent change reflects the uncoupling of oxidative phosphorylation. The yeast form can be found in sputum (33%), bronchoalveolar lavage specimens (38%), lung biopsies (21%), and fine-needle aspirates (7%) and can be demonstrated with standard KOH preparations or many other histologic stains (but not Gram stain). The yeast, however, does not have a large capsule (distinguishes it from *Cryptococcus neoformans*) and does not grow intracellularly (differentiates it from *H capsulatum*).

Manifestations of blastomycosis can occur in many organ systems, including the lungs, skin, bone, genitourinary tract (prostatitis and epididymo-orchitis), and central nervous system. Pulmonary infection can be asymptomatic or may present with flu-like symptoms, evidence of pneumonia, or pleurisy. Cough (36%), weight loss (20%), pleuritic pain (26%), fever (23%), hemoptysis (21%), erythema nodosum, and ulcerative bronchitis are common. Radiographic findings include homogeneous or patchy consolidation in a non-segmental distribution with pleural effusions or thickening or cavitation (15%-35%). In some patients, the appearance of pulmonary masses may mimic carcinoma. A predilection for the upper lobes has been noted; however, unlike histoplasmosis and coccidioidomycosis, in blastomycosis, hilar and mediastinal adenopathy is unusual.

Limited disease in asymptomatic immunocompetent patients requires no specific therapy. Itraconazole, 100-200 mg/d orally for at least 2-3 months, is now the therapy of choice for nonmeningeal disease, with a response rate of over 80%. Amphotericin B (0.5-2 g), however, is indicated in patients with meningeal disease or failed therapy. Surgical resection is rarely necessary except when the possibility of malignancy cannot be excluded.

4. Cryptococcosis

Cryptococcus neoformans is an encapsulated yeast-like budding fungus. It is a saprophyte existing on the skin, nasopharynx, gastrointestinal tract, and vagina of humans as well as in pigeon excreta, grasses, trees, plants, fruits, bees, wasps, insects (cockroaches), birds, milk products, pickle brine, and soil. Cryptococcal infection generally indicates the presence of an underlying debilitating disease in an immunocompromised host. Infection occurs from inhalation of the yeast form. The diagnosis can be established by the detection of serum antigen (via complement fixation tests) in patients

with appropriate clinical and radiographic findings. More commonly, however, histologic identification with India ink stains is used; routine cultures are not performed because they are extremely time-consuming and require multiple biochemical tests for differentiation of cryptococcus from other fungi. No accurate skin test exists for cryptococcosis.

The most common sites of infection are the lungs and central nervous system. Pulmonary infection may remain asymptomatic, or patients may complain of cough, pleuritic chest pain, and fever. Radiographically, cryptococcus can appear as a localized, well-defined 3-10-cm pleural-based mass without smooth borders; as single or multiple areas of consolidation, usually within one lobe but in nonsegmental distribution; or as a disseminated miliary nodular infiltrate. A predilection for the lower lobes has been noted. Central nervous system infection usually follows an asymptomatic pulmonary infection. Central nervous system symptoms are highly variable, since many patients are severely immunocompromised and do not manifest the usual signs and symptoms of meningitis or cerebritis.

Medical therapy is indicated in most cases of pulmonary infection except for rare cases of limited localized disease. Amphotericin B (0.5-2 g) remains the treatment of choice and is often combined with flucytosine (150/mg/kg/d) for synergy. New azole compounds (eg, fluconazole, itraconazole, and voriconazole) have been used with increasing frequency as first-line therapy both as single agents and in combination. Surgery is rarely indicated and is useful only to exclude the possibility of malignancy or to determine the etiology of an undiagnosed diffuse pulmonary infiltrate by open lung biopsy.

5. Aspergillosis

Aspergillus species are ubiquitous dimorphic soil fungi found in soil and decaying organic matter. The most common pathogenic species include *Aspergillus fumigatus* (most common), *Aspergillus niger*, *Aspergillus flavus*, and *Aspergillus glaucus*. In culture, these fungi resemble an aspergillum, which is a brush used to sprinkle holy water. Aspergillosis represents the second-most common (after candidiasis) opportunistic fungal infection in immunocompromised hosts and the third-most common systemic fungal infection requiring hospital care. Infection occurs almost exclusively through inhalation of conidia into areas of lung with impaired mucociliary function (eg, tuberculous cavities). Although the diagnosis is supported by demonstrating immediate and delayed-type hypersensitivity skin reactions, by culturing uniform septate hyphae with dichotomous branching at 45 degrees, and by detecting specific IgG and IgE antibodies, a definitive diagnosis requires demonstration of hyphal tissue invasion or documentation of hyphae on methenamine silver stain in a suspected aspergilloma. Galactomannan enzyme-linked immunosorbent assays have

recently become available and serve as a sensitive serum measure of invasive infection.

Infection with *Aspergillus* species usually takes one of three forms: allergic bronchopulmonary aspergillosis, invasive aspergillosis, and aspergilloma. Allergic bronchopulmonary aspergillosis occurs in patients who are atopic (asthmatics) and in patients with cystic fibrosis. Endobronchial fungal growth leads to dilated airways filled with mucus and fungus. Continuous exposure to fungal antigens results in precipitating antibodies, increased IgE levels (which correlate with disease activity), and both immediate and delayed-type hypersensitivity. Patients complain of cough, fever, wheezing, dyspnea, pleuritic pain, and hemoptysis. Chest x-ray shows homogeneous densities in a “gloved-finger,” inverted Y, or “cluster of grapes” pattern. Five stages have been defined depending on disease activity and steroid dependency: Stage 1 includes acute infection with characteristic x-ray and laboratory evidence of disease; stage 2 occurs with steroid-induced remission; stage 3 is characterized by asymptomatic exacerbations of laboratory and x-ray findings; steroid-dependent asthma with worsening laboratory tests (total IgE, precipitins, etc) is indicative of stage 4 disease; and end-stage fibrosis, bronchiectasis, and obstruction define stage 5.

Invasive aspergillosis is found exclusively in immunocompromised patients, particularly in patients with leukemia (50%-70% of cases). Dissemination occurs frequently, and three types of pulmonary disease have been described: tracheobronchitis (uncommon), necrotizing bronchopneumonia, and hemorrhagic infarction (most common). In tracheobronchitis, disease is usually limited to the larger airways (bronchus more so than trachea) with little parenchymal involvement. Focal or diffuse mucosal ulceration, pseudomembranes, and intraluminal fungal plugs are common. Patients often present with cough, dyspnea, wheezing, and hemoptysis. Occasionally, patchy areas of atelectasis secondary to bronchial obstruction can be seen on chest x-ray. Necrotizing bronchopneumonia should be suspected in patients with unremitting fever, dyspnea, tachypnea, radiologic evidence of bronchopneumonia, and a poor response to standard antibiotic therapy. Finally, hemorrhagic infarction due to vascular permeation with nonthrombotic occlusion of small- to medium-sized arteries and necrosis typically results in either a well-defined nodule or a wedge-shaped, pleura-based density. Symptoms are nonspecific and include fever, dyspnea, dry cough, pleuritic chest pain, and hemoptysis. Cavitation is common, and radiologic examination may reveal “round” pneumonia or “air crescents” of a mycotic lung sequestrum.

Aspergillomas (“fungus balls” or mycetomas) are divided into two types: simple, thin-walled cysts lined with ciliated epithelium and surrounded by normal parenchyma; and complex cavities associated with markedly abnormal surrounding lung tissue. Aspergillomas most often occur in the

upper lobes and in the superior segments of the lower lobes. Although they may be multiple (22%), calcification and air-fluid levels are rare. Most aspergillomas—particularly complex ones—are associated with cavitary lung disease, that is, tuberculosis (most common), histoplasmosis, sarcoidosis, bronchiectasis, and others. Hemoptysis occurs in 50%-80% and can present with frequent minor episodes (30% subsequently have massive bleeding), repeated moderate episodes, or a single episode of massive hemoptysis. Chest x-ray may reveal a 3- to 6-cm round, mobile density with a crescent of air.

Corticosteroids are indicated in patients with allergic bronchopulmonary aspergillosis in addition to measures to relieve bronchospasm (inhaled β -agonists or anticholinergics). In invasive aspergillosis, amphotericin B (0.5-2 g intravenously as total dose) has been standard therapy despite a mortality of 90%. In addition, some patients with complex aspergillomas and severe pulmonary disease are not candidates for surgical resection, and intracavitary amphotericin has been used with modest success. Surgery is indicated for complications of *Aspergillus* infection. Hemoptysis due to aspergillomas is usually best treated by surgical resection. Furthermore, hemoptysis associated with localized invasive aspergillosis (particularly once cavitation has occurred) can be treated by resection and amphotericin B. Generally, wide excision (lobectomy) is required; however, in some high-risk patients with aspergillomas, cavernostomy, and muscle flap closure is an alternative.

6. Mucormycosis

Infection with *Rhizopus arrhizus*, *Absidia* species, and *Rhizomucor* species of the class *Zygomycetes* and the order *Mucorales* occurs in certain distinct immunosuppressed patient populations: people with poorly controlled diabetes and leukemia patients. These fungi are ubiquitous organisms that are found in decaying fruit, vegetable matter, soil, and manure. Infection occurs following inhalation of sporangiospores, which germinate in a hyphal form. The diagnosis is made by demonstrating the organism in symptomatic patients. No accurate skin or serologic tests exist. Although the fungi do grow in culture as broad, irregular nonseptate hyphae that branch at angles up to 90 degrees (occasionally being confused with *Aspergillus* species), most commonly the diagnosis is made on histologic examination. The sine qua non for mucormycosis is hyphal vascular invasion between the internal elastic membrane and the media of blood vessels, causing thrombosis, infarction, and necrosis.

In addition to pulmonary infections, mucormycosis manifests as distinct clinical syndromes such as rhinocerebral infection (direct extension into the central nervous system from paranasal sinus infection), cutaneous infection (burn patients), gastrointestinal infection (children with

protein-calorie malnutrition), and disseminated infection (uremic patients receiving deferoxamine therapy). Patients with pulmonary infection complain of fever, cough, pleuritic chest pain, and hemoptysis. Frequently, this type of infection occurs in immunocompromised hosts and follows a fulminant course. Three patterns of infection are noted on chest x-ray: limited disease with involvement of a single lobe or segment, diffuse or disseminated disease with involvement of both lungs and the mediastinum, and endobronchial disease with bronchial obstruction and secondary bacterial infection. Characteristic CT findings include a halo sign (area of low attenuation around a dense infiltrate), ring enhancement, and an air-crescent sign (area of contrast between normal lung and a radiodense cavitating lesion). Amphotericin B is the standard treatment. In nonneutropenic patients, the newer azole compounds may be useful; however, infection with these fungi remains highly lethal, with a mortality of 90%. The cause of death in these patients is often fungal sepsis, progressive pulmonary dysfunction, and hemoptysis. In the small group of patients with limited disease, aggressive surgical resection in combination with amphotericin B has lowered the mortality to only 50%. In contrast, the endobronchial form can be effectively treated with transbronchoscopic resection (using the Nd:YAG laser) in a large proportion of patients.

7. Pneumocystosis

Pneumocystis carinii is a fungal organism that has been found in the lungs of a variety of domesticated and wild mammals and is distributed worldwide in humans. Pulmonary involvement leads to progressive pneumonia and respiratory insufficiency. Disease has been seen with increasing frequency in recipients of organ transplants who are undergoing immunosuppressive therapy. Diagnosis is made by open lung biopsy. Without treatment with trimethoprim-sulfamethoxazole, pentamidine, or inhaled antimicrobial therapy, the course is one of relentless progression. With improved antiviral therapy for HIV infections, the incidence of pneumocystosis has been declining.

SARCOIDOSIS (BOECK SARCOID, BENIGN LYMPHOGRANULOMATOSIS)

Sarcoidosis is a noncaseating granulomatous disease of unknown cause involving the lungs, liver, spleen, lymph nodes, skin, and bones. The highest incidence is reported in Scandinavia, England, and the United States. The incidence in blacks is 10-17 times that in whites. Half of patients are

between ages 20 and 40 years, with women more frequently affected than men.

Clinical Findings

A. Symptoms and Signs

Sarcoidosis may present with symptoms of pulmonary infection, but usually these are insidious and nonspecific. Erythema nodosum may herald the onset, and weight loss, fatigue, weakness, and malaise may appear later. Fever occurs in approximately 15% of cases. Pulmonary symptoms occur in 20%-30% and include dry cough and dyspnea. Hemoptysis is rare. One-fifth of patients with sarcoidosis have myocardial involvement, and heart block or failure may occur. Peripheral lymph nodes are enlarged in 75%, scalene lymph nodes are microscopically involved in 80% and mediastinal nodes in 90%, and cutaneous involvement is present in 30%. Hepatic and splenic involvement can be shown by biopsy in 70% of cases. There may be migratory or persistent polyarthritis, and central nervous involvement occurs in a few patients.

B. Imaging Studies

The x-ray findings in sarcoidosis are classified into five descriptive categories or stages (Table 18-5). Pulmonary disease can manifest as a reticulonodular infiltrate, an acinar pattern of opacities, or large nodules with or without mediastinal adenopathy. Mediastinal lymph node involvement characteristically includes bilateral symmetric hilar and paratracheal lymphadenopathy. Anterior or posterior mediastinal adenopathy or asymmetric hilar involvement should prompt a suspicion of other diseases, particularly Hodgkin disease and non-Hodgkin lymphomas. Pleural effusions and cavitation are rare and, if present, necessitate an evaluation for tuberculosis, congestive heart failure, and coincidental pneumonia.

C. Diagnosis

Although no single test exists to confirm absolutely the diagnosis of sarcoidosis (the diagnosis remains one of exclusion), it may be suggested by the characteristic radiographic appearance of bilateral hilar and mediastinal lymphadenopathy, by

Table 18-5. Radiographic stages of sarcoidosis.

Stage 0: No x-ray abnormality
Stage 1: Hilar and mediastinal lymph node enlargement without pulmonary abnormalities
Stage 2: Hilar and mediastinal lymph node enlargement with pulmonary abnormalities
Stage 3: Diffuse pulmonary disease without adenopathy
Stage 4: Pulmonary fibrosis

gallium 67 scanning, and by elevated serum and bronchoalveolar fluid levels of angiotensin-converting enzyme and lysozyme. Pathologic documentation of noncaseating granulomas should normally be obtained either via transbronchial biopsy or mediastinoscopy (more reliable, with > 95% success rate). Culture for mycobacteria, fungi, and other atypical infections must also be negative.

D. Treatment

Asymptomatic patients and those with minimal clinical disease may require no therapy. Corticosteroids have been used in patients with pulmonary impairment and symptomatic disease with good success. Despite the indolent nature of the disease and steroid therapy, long-term mortality is reported as high as 10%. Lung transplantation has been utilized with success in patients refractory to medical management.

NEOPLASMS OF THE LUNG

PRIMARY LUNG CANCER

Lung cancer is the most common cause of cancer-related death in both men and women in the United States. In 2013, it is estimated that 228,190 new cases and 159,480 deaths will occur due to pulmonary malignancies. This represents 14% of all new cancer cases and 27% of all cancer-related deaths. Tobacco smoking accounts for 85% of all lung cancer cases. The effect is greatest for cigarettes and least for pipe smoking and is directly related to the amount of tobacco smoked. Following 5–6 years of smoking cessation, the risk exponentially declines, and after 15 years approaches, but never reaches, that of nonsmokers. “Passive” exposure to cigarette smoke, on the other hand, increases the risk in nonsmokers by two to three times. Exposure to all forms of asbestos (amosite, chrysotile, and crocidolite) has been implicated in as many as 23% of lung cancers, accounting for the high incidence among shipyard workers, insulators, cement makers, truck drivers, and plumbers. The effect is particularly pronounced in smokers and is most commonly associated with squamous cell and small cell carcinoma. Exposure to radon and its alpha-emitting daughter isotopes have been implicated in the increased incidence of lung cancer in both uranium miners and populations living in geographic areas naturally contaminated with high levels of radon gas. Although it has been known for some time that people with high activity of 4-debrisoquine hydroxylase, the so-called debrisoquine metabolic phenotype, have a 10-fold increased risk of lung cancer, only recently has the role of genetic factors been appreciated.

Chromosome deletions (particularly 11p, 13q, 17p, and 3p), tumor suppressor gene mutations (p53, Hap-1, ErbA, etc), and constitutive, high-level expression of both growth factor genes (insulin-like and transferrin-like growth factors), epidermal growth factor receptors (HER2/*neu*, *EGFR1*,

etc), and protooncogenes (*c-*, *N-*, and *L-myc*; *H-*, *N-*, and *K-ras*; and *c-myb*) have all been implicated in the pathogenesis of lung cancer. Other factors such as vitamin A deficiency, air pollution; exposure to arsenic, cadmium, chromium, ether, and formaldehyde; and employment as bakers, cooks, construction workers, cosmetologists, leather workers, pitchblende miners, printers, rubber workers, and pottery workers have also been incriminated. Finally, certain diseases (eg, progressive systemic sclerosis [scleroderma]) have a defined predisposition for the development of lung cancer. Silencing of genes by aberrant promoter hypermethylation is viewed as a crucial component in lung cancer pathobiology. High throughput genomic analysis has identified scores of genes and metabolic pathways that appear to be associated with the progression of lung cancer.

▶ Pathology

Lung cancer occurs more commonly in the right lung than the left, and the upper lobes are involved more commonly than the lower lobes or the right-middle lobe. Synchronous primary lung cancers occur in up to 7% of patients, and 10% of patients will develop a metachronous new tumor (2% per year risk postresection of early stage disease). Furthermore, patients with lung cancer are at higher risk of developing cancers of the upper respiratory tract, oral cavity, esophagus, bladder, and kidney presumably related to the “field effect” of smoking. Lung cancers typically spread by local extension to involve the visceral and parietal pleura, chest wall, great vessels, pericardium, diaphragm, esophagus, and vertebral column. Common sites of metastatic involvement include the ipsilateral pulmonary and hilar lymph nodes, the mediastinal lymph nodes, the lung, liver, bone, brain, adrenal glands, pancreas, kidney, soft tissues, and myocardium. The exact pathologic classification of lung cancer has not been uniform despite attempts at standardization by the World Health Organization. Functionally, however, squamous cell carcinoma, large cell carcinoma, and adenocarcinoma are grouped together under the designation of non-small cell carcinomas and constitute 80% of all lung tumors. Small cell carcinoma represents 15%–20%, while bronchial gland adenomas, including carcinoids, comprise the remaining 5%. The differential locations of some of these neoplasms are summarized in Table 18–6.

A. Squamous Cell Carcinoma

The major pathologic features of squamous cell carcinoma are keratinization, cellular stratification, and intercellular bridges. Squamous cell carcinomas account for about 20% of all cases of lung cancer and 70% of non–small cell tumors. Two-thirds are located centrally near the hilum and one-third peripherally. The growth rate and the rate of metastasis tend to be slower than those of other lung tumors.

Table 18–6. Location of lung cancer by histologic type.

Histology	Central (%)	Peripheral (%)
Squamous cell carcinoma	64–81	19–36
Adenocarcinoma	5–29	71–95
Large cell carcinoma	42–49	51–58
Small cell carcinoma	74–83	17–26
Overall	63	37

Reproduced, with permission, from Cameron RB: Malignancies of the lung. In Cameron RB, ed: *Practical Oncology*. New York, NY: McGraw-Hill; 1994.

B. Adenocarcinoma

Adenocarcinomas, which constitute 30% of lung cancers and 60% of non-small cell tumors, are characterized as acinar, papillary, lepidic (formerly nonmucinous bronchioloalveolar [BAC] with > 5 mm invasion), micropapillary and solid, as well as preinvasive lesions including atypical adenomatous hyperplasia and adenocarcinoma *in situ* (\leq 3 cm formerly BAC) and minimally-invasive (\leq 3 cm lepidic predominant tumor with a 5 mm invasion). Acinar adenocarcinoma is composed of glands lined by columnar cells that secrete mucin. Lepidic carcinoma is characterized by intraluminal papillary fragments that appear in alveoli or small bronchioles. The incidence of adenocarcinoma of the lung is increasing relative to squamous cell carcinoma, perhaps as a consequence of the rise in lung cancer among women, although the exact cause remains unclear.

C. Small Cell Carcinoma

Small cell (oat cell) carcinomas have small, round nuclei with nuclear chromatin and cytoplasm. They are biologically and clinically distinct from all other cell types such that the term non-small cell lung cancer (NSCLC) often is applied to all other cell types. Small cell carcinomas comprise 15%–20% of all lung cancers. They occur centrally, metastasize early but also can exhibit significant partial response to combined-modality treatment, albeit with limited 5-year survival.

D. Large Cell Carcinoma

Large cell carcinomas are composed of large polygonal spindle or oval cells arranged in sheets, nests, or clusters. Multinucleated giant cells, intracellular hyalin droplets, glycogen, and acidophilic nuclear inclusions may be present. These tumors are seen peripherally and are less common.

E. Adenosquamous Tumors

Adenosquamous tumors show both cellular features and are more biologically aggressive than other NSCLC. Survival percentages of patients with adenosquamous tumors are significantly lower than what is reported for adenocarcinoma or squamous cell cancer.

F. Bronchial Gland Adenomas

Bronchial gland adenoma is a misnomer, since the vast majority of these tumors are malignant. Included in this group are carcinoid tumors, adenoid cystic carcinomas, mucoepidermoid carcinoma, mixed tumors of the salivary gland type, and mucous gland adenoma. Carcinoid tumors are derived from Kulchitsky cells, have a vascular stroma, and tend to be located centrally in proximal airways. Although they are slow-growing, they can metastasize widely. Carcinoid syndrome is rarely associated with bronchial carcinoids, as opposed to intestinal carcinoids that metastasize to the liver. Adenoid cystic carcinomas—also referred to as cylindromas—feature groups of epithelial cells that form duct-like structures interspersed with cystic spaces. These neoplasms are locally aggressive and often extend beyond apparent gross pathologic margins. Metastases from adenoid cystic carcinomas often involve the lung, are slow growing, and are amenable to surgical excision. Mucoepidermoid carcinomas are rare tumors characterized by the presence of squamous cells, mucus-secreting cells, and an intermediate cell type. The cells are bland and less aggressive than those of adenosquamous carcinomas. Mixed tumors of the salivary type are extremely rare infiltrating tumors that are curable with wide local excision. Finally, mucus gland adenomas (papillary or bronchial cyst adenomas) are the only true benign “adenomas” of this group with no metastatic potential. These neoplasms are rare tumors of the major bronchi and consist of numerous mucus-filled cysts lined by a well-differentiated epithelium. Generally, bronchoscopic removal can be accomplished and results in long-term cure.

► Clinical Presentation

Nearly 94% of patients present with symptoms from the effects of the primary tumor, regional spread, or metastatic disease. Local effects of the primary tumor account for 27% of presenting symptoms and vary depending on the location of the tumor. Central tumors are associated with cough, hemoptysis, respiratory difficulty (wheezing, stridor, or dyspnea), pain, and pneumonia. Peripheral tumors can cause cough, chest wall pain, pleural effusions, pulmonary abscess, Horner syndrome (ipsilateral miosis, ptosis, and anhidrosis), and Pancoast syndrome (ipsilateral shoulder and arm pain in the C8–T1 nerve root distribution, Horner syndrome, and a superior sulcus—usually squamous—lung cancer). Symptoms due

to the effect of regional spread include hoarseness from recurrent nerve paralysis, dyspnea due to phrenic nerve paralysis, dysphagia from compression of the esophagus, superior vena cava syndrome from compression or invasion of the superior vena cava, and pericardial tamponade from invasion of the pericardium. Metastatic disease may present with symptoms of systemic illness (anorexia, weight loss, weakness, and malaise), local manifestations of distant metastases (jaundice, abdominal mass, bony pain or fracture, neurologic deficits, mental status changes, seizures, and soft tissue masses). A number of paraneoplastic syndromes associated with lung cancer have been identified (Table 18–7).

► Diagnosis & Evaluation

Lung cancer is usually suspected from abnormal findings on a chest x-ray obtained in the course of a routine physical examination or, more commonly, after a complaint of pul-

monary symptoms (see previous discussion). Findings vary from a small peripheral nodule to an unresolving infiltrate or even total lung atelectasis. Occasionally, the location of the abnormality may suggest certain cell types (see Table 18–7). Once the diagnosis of lung cancer is suspected, a definitive diagnosis can be obtained in over 90% of patients with either bronchoscopy for proximal lesions or fine-needle aspiration cytology for peripheral lesions.

CT scanning is an integral part of the assessment of patients with lung cancer. Chest CT scans should also include the upper abdomen to assess two of the most common sites of metastases (liver and adrenal glands). Injection of intravenous contrast while the scan is obtained facilitates evaluation of the mediastinum. Additional radiographic evaluation includes tests to evaluate other common sites of metastases, such as bone and brain. A serum alkaline phosphatase is essential, and a bone scan and brain CT scan (or preferably MRI) should be obtained if indicated by elevated alkaline phosphatase levels, neurologic symptoms, or bone pain or if advanced-stage disease (stage III or beyond) is present. Fluorodeoxyglucose (FDG) PET has evolved into a critical staging test. It is most effective as a tool for assessing for distant occult disease. It can be helpful for predicting mediastinal node involvement, but it is not definitive. False-positive rates as high as 15%-20% have been reported. Furthermore, nodules less than 1 cm in diameter generally are not imaged reliably by PET scanning. Combination high-resolution CT scan and PET scan assessment permits improved correlation of abnormal CT findings with FDG uptake suggestive of tumor.

Thoracentesis or thoracoscopy (or both) should be performed in any patient with evidence of a pleural effusion to exclude diffuse involvement of the pleura (M1 or stage IV disease) which indicates metastatic disease. Despite increasing reliance on PET scan to stage the mediastinum, patients with NSCLC but without metastatic disease should be evaluated with endobronchial ultrasound guided FNA, cervical mediastinoscopy or parasternal mediastinotomy (Chamberlain) if necessary to document the status of the mediastinal nodes in equivocal cases. PET scanning is informative but tissue confirmation typically is necessary. For small cell lung cancer staging should be directed at assessing the presence of extrathoracic disease, to confirm limited-stage tumor extent. The use of CT scans alone is inaccurate in 40%-60% of patients with enlarged lymph nodes over 1 cm (false positive) and 15% of patients without “significant” lymphadenopathy (false negative).

Once all the information from these staging procedures is in hand, the patient with NSCLC can be classified into one of three categories: (1) early lung cancer without mediastinal involvement, that is, stage I/II (see next section); (2) locally advanced lung cancer, that is stage IIIA/B; and (3) metastatic lung cancer, or stage IV. Therapy is determined by disease stage. Patients with small cell lung cancer usually

Table 18–7. Paraneoplastic syndromes associated with lung cancer.

Cardiovascular

- Thrombophlebitis
- Nonbacterial thrombotic endocarditis
- Neuromuscular
- Subacute cerebellar degeneration
- Dementia
- Limbic encephalitis
- Optic neuritis, retinopathy
- Subacute necrotic myelopathy
- Autonomic neuropathy (small cell)
- Myasthenic (Eaton-Lambert) syndrome (small cell)
- Polymyositis

Gastrointestinal

- Carcinoid syndrome (carcinoid and small cell)
- Anorexia, cachexia

Hematologic

- Erythrocytosis
- Leukocytosis

Metabolic

- Inappropriate adrenocorticotropic hormone (ACTH) (small cell)
- Inappropriate antidiuretic hormone (ADH) (small cell)
- Hypercalcemia (squamous cell carcinoma)
- Inappropriate gonadotropins

Dermatologic

- Acanthosis nigricans (adenocarcinoma)
- Dermatomyositis
- Erythema gyratum
- Ichthyosis

Other

- Hypertrophic pulmonary osteoarthropathy (squamous cell, large cell, and adenocarcinoma)
- Nephrotic syndrome
- Fever

are grouped into two categories: disease limited to the ipsilateral hemithorax, including supraclavicular nodes (limited disease), or disease extending beyond the thorax (extensive disease, eg, below the diaphragm or brain metastases).

Several recent analyses indicate that lung cancer screening by either regular routine chest radiography or sputum cytology is not recommended. Low-dose screening chest CT can be considered, but only among select individuals in the context of multidisciplinary comprehensive care that includes not only screening but also image interpretation, evaluation, management and appropriate treatment of findings.

► **Staging**

By 1987, the American Joint Committee on Cancer (AJCC) and the Union Internationale Contre le Cancer (UICC) had developed a joint staging system for lung carcinoma based on data gathered primarily by Clifford Mountain of the MD Anderson Cancer Center. The most recent iteration (7th edition) of the lung cancer staging system, published in 2007, is based on the tumor (T), the status of regional lymph nodes (N), and the presence or absence of distant metastases (M), as outlined in Table 18–8.

► **Treatment**

Treatment for small cell carcinoma consists primarily of chemotherapy and radiation, although recent data indicate that for early disease (T1-T2 lesions without hilar adenopathy) resection may improve local control and result in increased long-term survival (as high as 50%), particularly when combined with postoperative chemotherapy.

Treatment for NSCLC varies with stage. Early-stage disease (stage I/II) has historically been treated with surgery alone. Notably, several randomized prospective trials have demonstrated a statistically significant improvement in lung cancer survival among patients treated with adjuvant chemotherapy for early stage (stages II and III) NSCLC. Combined-modality therapy utilizing induction chemotherapy or chemoradiotherapy appears to confer a survival advantage for patients with potentially resectable stage IIIA disease, although overall survival was not improved compared with patients receiving chemotherapy with definitive-dose radiation therapy. Locally advanced and surgically unresectable disease (stage IIIB) is best managed with concurrent platinum-based chemotherapy and fractionated radiation therapy. Among patients with metastatic disease (stage IV), chemotherapy is best for palliation of symptoms. Radiotherapy in this case also is reserved primarily for symptomatic lesions. Combined-agent chemotherapy offers 2-3 months (20%) survival extension to advanced-stage patients. It has been shown to be cost-effective and improve quality of life and is generally well tolerated by patients with reasonable performance status. New biologic agents—so-called targeted therapies—are showing activity in clinical trials and

Table 18–8. TNM stage groupings.

Primary tumor	
TX	Primary tumor cannot be assessed, or cytologic evidence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor ≤ 3 cm in greatest diameter, completely surrounded by lung or visceral pleura, and without bronchoscopic evidence of involvement of more proximal than a lobar bronchus
T2	Tumor > 3 cm in greatest diameter, invading the visceral pleura, involving the main stem bronchus but > 2 cm distal to the carina, or tumor associated with atelectasis or obstructive pneumonitis extending to the hilum but not involving the entire lung
T3	Tumor of any size invading the chest wall, diaphragm, mediastinal pleura, parietal pericardium; tumor involving the main stem bronchus within 2 cm of but not involving the carina; or tumor associated with atelectasis or obstructive pneumonitis of the entire lung
T4	Tumor of any size invading the mediastinum, heart, great vessels, trachea, esophagus, vertebral body, or carina or tumor associated with a malignant pleural effusion
Regional lymph nodes (N stage)	
NX	Regional lymph nodes cannot be assessed
N0	No evidence of regional lymph node metastases
N1	Metastases in ipsilateral peribronchial or hilar lymph nodes, including by direct extension
N2	Metastases in ipsilateral mediastinal or subcarinal lymph nodes
N3	Metastases in contralateral mediastinal or hilar lymph nodes or ipsilateral or contralateral scalene or supraclavicular nodes
Distant metastases (M stage)	
MX	Presence of distant metastases cannot be assessed
M0	No evidence of distant metastases
M1	Distant metastases are present
Stage grouping	
Occult disease	TX, N0, M0
Stage 0	Tis, N0, M0
Stage IA	T1, N0, M0
Stage IB	T2 N0 M0
Stage IIA	T1 N1 M0
Stage IIB	T2 N1 M0 T3 N0 M0
Stage IIIA	T1–2, N2, M0, or T3, N0–2, M0
Stage IIIB	T4, any N, M0, or any T, N3, M0
Stage IV	Any T, Any N, M1

should improve overall survival statistics. It is hoped that with advances in targeted and conventional therapies, the current overall survival (< 15% at 5 years) of patients with lung cancer can be improved.

► Induction Chemotherapy

Recently completed clinical trials and several ongoing studies suggest survival benefit of treatment with platinum-based chemotherapy prior to resection. Induction chemotherapy has been standard for locally advanced surgically resectable disease, but evidence is accumulating to support induction therapy in early stage NSCLC.

A. Surgical Treatment

1. Surgical Staging—As noted earlier, almost all patients with NSCLC limited to the thorax should undergo cervical mediastinoscopy or EBUS-FNA to exclude involvement of N2 mediastinal lymph nodes (N2 or N3 disease). A possible exception is a small peripheral (T1) nodule, especially of squamous cell histology without any evidence for mediastinal adenopathy on chest CT scan. PET scan is used with increasing frequency to stage the mediastinum. Surgical staging with cervical mediastinoscopy remains the most accurate staging maneuver. Adenocarcinomas with negative mediastinal nodes by CT have an 18%-25% false-negative rate. For left-sided lesions, left parasternal mediastinotomy (Chamberlain) may be required to assess the status of the aorticopulmonary lymph nodes. Without pathologic confirmation of the status of mediastinal lymph nodes, CT scans have been associated with high false-positive and false-negative rates. A surgical assessment of the proximal airways is also required even if this means repeating this invasive procedure, often previously performed by the pulmonologist. Because treatment decisions are based on accurate staging, and treatment of early-stage disease (stage I/II) differs significantly from locally advanced disease (stage IIIA/B); this approach is essential. The importance of accurate staging for patients with NSCLC cannot be overstated.

2. Indications and Preoperative Assessment—Pulmonary resection is indicated for early-stage lung cancer (stage I/II) and in combination with chemotherapy and radiation in locally advanced resectable disease (stage IIIA or resectable T4, IIIB). In addition, resection may be indicated for patients with a single site of metastatic disease, such as a solitary brain or adrenal gland metastasis. Both relative and absolute contraindications to surgical resection are listed in Table 18–9.

Preoperative assessment is directed toward evaluating both cardiopulmonary reserve and overall patient fitness. The patient's general performance status or functional classification is probably the most accurate factor

Table 18–9. Medical and surgical contraindications to pulmonary resection.

Absolute	Relative
Myocardial infarction within previous 3 months	Myocardial infarction within previous 6 months
SVC syndrome (due to metastatic tumor)	SVC syndrome (due to primary tumor)
Bilateral endobronchial tumor	Recurrent laryngeal nerve paralysis (due to primary tumor in aortico-pulmonary window)
Contralateral lymph node metastases (N3)	Horner syndrome
Malignant pleural effusion	Small cell histology
Distant metastases (except solitary brain and adrenal metastases)	Metastases higher than the midtracheal lymph nodes
	Pericardial involvement
	FEV ₁ < 0.8 L (< 50%)
	FEV ₁ 0.9–2.4 and insufficient pulmonary reserve for planned resection
	Main pulmonary artery involvement

in predicting a successful outcome following operation. Advanced age alone is not a contraindication to resection. A thorough cardiac evaluation is also necessary since lung cancer and cardiovascular disease share common risk factors (eg, smoking). Patients with cardiac symptoms, an abnormal EKG, or other findings suggestive of ischemic heart disease should be screened by a stress test (eg, exercise treadmill, dipyridamole- or adenosine-thallium study, dobutamine echocardiogram). Significant coronary artery disease should be treated with coronary artery bypass or catheter-based intervention as indicated, prior to any contemplated pulmonary resection. Furthermore, significant pulmonary hypertension and myocardial infarction within 3 months has been associated with up to 20% perioperative mortality and constitute absolute contraindications to standard resection. Other high-risk findings include myocardial infarction within 6 months, ventricular arrhythmias and heart block, particularly left posterior fascicular hemiblock. Finally, the patient's pulmonary function and predicted ability to tolerate the required pulmonary resection should be assessed. This is accomplished with pulmonary function tests (spirometry, diffusing capacity, exercise oximetry) and with differential (quantitative)

ventilation-perfusion scanning when appropriate. In a 70-kg patient, the following preoperative studies suggest high risk for perioperative morbidity and are relative contraindications to resection: forced expiratory volume in 1 second (FEV_1) below 0.8 L, a predicted postoperative FEV_1 below 0.8, a predicted maximum voluntary ventilation under 50%, a $Paco_2$ higher than 45 mm Hg, and a Pao_2 less than 50 mm Hg. A diffusion limitation capacity of carbon monoxide (DLCO) less than 60% predicted is correlated with an increase in perioperative mortality. Generally, for patients whose predicted postoperative values for FVC, FEV_1 , or DLCO are projected to be less than 40% predicted, further assessment of functional status and operability are recommended.

3. Pulmonary Resection

A. EARLY AND LOCALLY ADVANCED NON-SMALL CELL LUNG CANCER—The extent of pulmonary resection is dictated by the location of the primary tumor and the presence or absence of involved hilar (interlobar) lymph nodes. Limited segmental resection for stage I/II NSCLC has been evaluated by the Lung Cancer Study Group and found to result in an increased local recurrence rate (15% vs 3%) and lower overall survival, although more recent cohort studies suggest that sublobar resection, particularly segmentectomy rather than non-anatomic wedge excision, may be considered for smaller lung nodules without evidence for local (N1) lymph node involvement. Lobectomy remains the standard of care for resection of early stage NSCLC. Recent case series have suggested that sublobar resection actually might be adequate in terms of local recurrence and disease-free survival particularly for stage I carcinoma; this is the focus of an ongoing multicenter clinical trial. Samples of interlobar (hilar) lymph nodes are submitted for immediate pathologic examination to exclude involvement that would require pneumonectomy. A “sleeve” resection of main stem bronchus can also be included in the resection, particularly with the right-upper lobe. Pneumonectomy may be necessary for proximal lesions involving the main stem bronchus or the interlobar (hilar) lymph nodes, although bronchial and/or vascular sleeve resections should be considered. In addition, techniques are available for more extensive resection such as intrapericardial pneumonectomy and tracheal sleeve pneumonectomy.

The overall mortality rates following segmental resection, lobectomy, and pneumonectomy are 1.4%, 2.9%, and 6.2%, respectively, in centers with large experience. Complications following pulmonary resection include cardiac arrhythmias, hemorrhage, infection (empyema), bronchopleural fistula, respiratory insufficiency, and pulmonary embolism.

B. ADVANCED (METASTATIC) NON-SMALL CELL LUNG CANCER—Patients with solitary brain and adrenal metastases, especially if metachronous, are still candidates for

resection and have benefited by prolonged survival in a few small retrospective studies in comparison with historical controls. Systemic preoperative (induction) chemotherapy and radiotherapy, however, should be administered initially. In addition, transbronchial Nd:YAG laser resection of tumors obstructing the proximal airways can provide satisfactory palliation for selected patients. Improvements in the design and deployment techniques of expansile stents have been a significant advance for palliation of proximal airway obstruction. Finally, photodynamic laser therapy with photosensitizers can alleviate airway obstruction from tumors, albeit not as quickly as Nd:YAG laser ablation.

C. SMALL CELL LUNG CANCER—Resection for small peripheral tumors followed by aggressive postoperative chemotherapy may increase the local control rate and potentially the overall survival rate in the early small cell lung cancer. Survival rates as high as 50% with this approach have been reported.

B. Radiation Therapy

1. Non-Small Cell Lung Cancer—Radiation therapy can be administered with curative intent in stage I/II disease in patients who refuse or are not medically suitable candidates for surgery. The 5-year survival rate with this approach, however, is only 22%-33%. With locally advanced disease (stage IIIA/B), radiation therapy (5500-6000 cGy) until recently has been the treatment of choice. Although local or nodal recurrence rates are less than 30%, long-term survival is less than 10% in these patients, and the type of fractionation scheme has not altered the outcome. Stereotactic radiation techniques appear to have early efficacy in terms of tumor control and overall survival, particularly for medically inoperable patients.

Adjuvant radiation therapy following resection has been extensively studied by the Lung Cancer Study Group and has been found to decrease local or nodal recurrence but not to prolong overall survival. A much-disputed meta-analysis (the PORT study) showed a decrease in survival for stage II patients treated with postoperative radiation. Differences in radiotherapy techniques within the analysis may account for the worse outcomes. Preoperative radiation has been used with T3 lesions, particularly Pancoast tumors, with improved survival; however, there is no objective evidence that radiation must be given preoperatively. A multicenter intergroup trial (SWOG) has shown a significant survival advantage for combined chemoradiotherapy (etoposide, platinum, and 4500 cGy) prior to resection for Pancoast (superior sulcus) tumors that were N1 or less. Complete resection rates were improved, 20%-25% complete pathologic responses were achieved, and survival was significantly improved (45%-50% at 3 years) over surgery alone or preoperative radiotherapy and surgery. Intraoperative radiation has been investigated

but to date has been associated with unacceptably high morbidity. Among patients with metastatic disease, therapeutic radiation is indicated in patients with symptoms of pain, neurologic symptoms, and symptoms of superior vena cava compression.

2. Small Cell Lung Cancer—Multiple randomized trials comparing the combination of radiation and chemotherapy to chemotherapy alone in limited-stage small cell lung cancer have been conducted. The majority show improved local control and modest (3-4 months) prolonged survival with the combination. This was at the cost of increased morbidity, however. In extensive disease, no benefit has been demonstrated for radiation therapy other than for palliative radiation of symptomatic metastases. Prophylactic cranial irradiation may be beneficial but can cause significant cognitive deficits.

C. Chemotherapy

1. Non-Small Cell Lung Cancer—Although chemotherapy alone has not generally been used in the treatment of early or locally advanced NSCLC, combinations of chemotherapy and radiotherapy have been evaluated in locally advanced unresectable disease. In some instances, no benefit to the combination was demonstrated, particularly when only single agents were used; however, improved results with both radiation and combined-agent chemotherapy have recently been documented. In the presence of metastatic disease, multiple trials of combination chemotherapy have demonstrated a modest improvement in overall survival (14 weeks or 25% improved survival) but not without some toxicity. Even so, quality of life assessments and cost analyses support the use of outpatient combined-agent chemotherapy over palliative care alone.

A. POSTOPERATIVE ADJUVANT THERAPY—A progressive trend in lung cancer therapy has evolved in favor of far more widespread use of adjuvant chemotherapy. Three large multicenter randomized trials in Europe and North

America have served as a basis for the increased application of postoperative platinum-based chemotherapy (Italian Stage IB, the International Adjuvant Lung Cancer Trial [IALT], Cancer and Leukemia Group B [CALGB] 9633, and National Cancer Institute of Canada [NCIC] BR10). The benefit of chemotherapy appears to vary based on patient selection but is estimated to be an increase of 5%-15% survival measured at 5 years from diagnosis (Table 18-10).

2. Small Cell Lung Cancer—Combination chemotherapy currently produces 85%-95% and 75%-85% response rates in limited-stage and extensive-stage disease, respectively. Furthermore, median survival is 12-16 months and 7-11 months in each group. Regimens of doublet therapy consisting of cisplatin and etoposide, irinotecan, or paclitaxel have had good efficacy with less toxicity than prior alkylator-based treatment regimens. The optimal duration of therapy has not been defined, but the majority of the effect appears to occur within the first four cycles.

D. Immunotherapy

Immunotherapy using bacillus Calmette-Guérin (BCG), levamisole, IL-2, TNF- α , lymphokine-activated killer (LAK) cells, and tumor-infiltrating lymphocytes has not proved beneficial in any clinical studies to date.

E. Targeted Therapies

Molecular-based therapies targeting overexpressed growth receptors (*EGFR1*, *HER-2/neu*) by monoclonal antibody or small molecules have demonstrated clinical effectiveness among select patient populations. Additional agents targeting signal transduction pathways (eg, farnesyl transferase inhibitors) for the *ras* pathway as well as antisense oligonucleotide and gene therapies are all in advanced clinical testing stages and in combination with standard cytotoxic chemotherapy appear to enhance response rates. Prospective randomized trials evaluating the efficacy of

²4-year survival statistics.

EGFR tyrosine kinase inhibitor therapy have not been able to validate the findings of earlier non-randomized (phase I/II) trials.

► **Prognosis**

A. Non-Small Cell Lung Cancer

The survival of patients with NSCLC is highly dependent on the pathologic stage. Overall, the 5-year survival of patients with stages I, II, IIIA, IIIB, and IV is 43%-64%, 20%-40%, 15%-25%, 5%-7%, and less than 2%, respectively. A breakdown of survival by TNM classification is set forth in Table 18-11. Improved survival will likely depend on earlier diagnosis and further coordinated efforts among surgeons, medical oncologists, and radiation oncologists.

B. Small Cell Lung Cancer

Patients with limited-stage disease achieve a median survival of 12-16 months with 5%-25% 2-year survival, while those

with extensive-stage disease have a median survival of only 7-11 months, with only 1%-3% surviving 2 years.

UNUSUAL PULMONARY NEOPLASMS

► **Malignant Neoplasms**

Bronchial adenomas are a group of low-grade malignancies arising from the bronchial tree. Carcinoid tumors constitute 85%-90% of these neoplasms, with adenoid cystic carcinoma (10%) and mucoepidermoid carcinoma (< 5%) accounting for most of the remainder. Carcinoid tumors are classified as either typical or atypical, with markedly different histologic characteristics (Table 18-12). Adenoid cystic carcinomas occur in the lower trachea; infiltrate locally along submucosal and perineural tissue planes, often far beyond the boundaries of gross tumor; and metastasize late. Mucoepidermoid carcinomas resemble salivary tumors, with varying numbers of three distinct cell types: mucous, squamous, and intermediate. Patients with bronchial adenomas complain of cough, recurrent pulmonary infections, hemoptysis, pain, and wheezing. Only 15% of patients are completely asymptomatic. Carcinoid syndrome is rare with pulmonary carcinoid tumors. Most bronchial adenomas are diagnosed with a combination of plain chest radiography, CT, and bronchoscopy. Biopsy at the time of bronchoscopy

Table 18–12. Characteristics of typical and atypical carcinoid tumors.

	Typical %	Atypical %
Incidence	90	10
Central location	80	50
Peripheral location	20	50
Metastases	10–15	50–70

can be associated with significant bleeding, and measures to control this must be readily available.

Lung resection is indicated for these tumors, with lobectomy being the most common procedure. Sleeve and bronchoplastic resections are particularly useful to preserve pulmonary function in these patients and make standard pneumonectomy rare. Removal of adenoid cystic carcinomas requires generous margins and frozen section examination of the margins at the time of surgery. Up to 8 cm of trachea can be removed with primary anastomosis. In addition, postoperative radiation may be indicated for close margins. With the possible exception of atypical carcinoid, chemotherapy is generally not indicated in the treatment of these neoplasms.

The long-term outlook is good for patients with metastatic disease. Even patients with adenoid cystic carcinoma and distant metastases may do well for extended periods due to the slow-growing nature of this malignancy; however, lymph node and distant metastases in patients with carcinoid tumors generally carry a poor prognosis.

► Benign Neoplasms

Benign neoplasms of the lung are uncommon, accounting for less than 1% of all pulmonary tumors. Most are hamartomas, but fibromas, leiomyomas, neurofibromas, myoblastomas, and benign metastasizing leiomyomas also occur. Most lesions are peripheral and asymptomatic; however, central lesions can produce symptoms of cough, wheezing, hemoptysis, and recurrent pneumonia. Typically, the lesions are discovered on routine chest radiographs and appear as a 1- to 2-cm well-circumscribed, bosselated lower lung nodule with calcifications in 10%-30%. Central lesions may require bronchoscopy for diagnosis, but a pathologic diagnosis is most often obtained by fine-needle aspiration biopsy or surgery. Surgical resection should be conservative and limited to wedge excision unless the lesion occupies the proximal bronchial airway and is associated with recurrent distal infections or bronchiectasis. In such cases, lobectomy is indicated. Following resection, the prognosis is excellent.

SPECIAL PROBLEM: THE SOLITARY PULMONARY NODULE

With the frequent use of chest radiography, solitary pulmonary nodules (“coin lesions”) are frequently found in patients without pulmonary symptoms. These lesions pose a diagnostic problem for clinicians because they may represent something as benign as a nipple shadow or as malignant as lung cancer. The overall incidence of cancer in coin lesions is as low as 10%. Other diagnostic possibilities include: (1) infections due to mycobacteria (tuberculosis), fungi (histoplasmosis, coccidioidomycosis), and helminths (echinococcosis); (2) inflammatory nodules from rheumatoid arthritis, focal pneumonitis, and Wegener granulomatosis; (3) congenital anomalies, such as bronchogenic cysts and arteriovenous malformations; (4) benign neoplasms such as hamartomas, hemangiomas, papillary tumors, fibrous tumors of the pleura; (5) malignant neoplasms of the lung; and (6) miscellaneous processes such as hematomas, pulmonary infarcts, pleural plaques, loculated effusions, chest wall masses, and mucoid impaction. Although certain radiographic findings may suggest malignancy or benignity, solid pathologic proof that the nodule does not represent a malignancy rests with the clinician. In general, malignant neoplasms are larger and grow rapidly, appear spiculated, often with surface umbilication or notching and eccentric excavation. In addition, cancers often occur in smokers (or former smokers) over the age of 40 with negative skin tests for tuberculosis, histoplasmosis, or coccidioidomycosis (although positive tests do not exclude cancer), and in nodules that lack calcium (CT Hounsfield units < 175). In contrast, benign lesions are small (< 1 cm), stable (> 2 years), and calcified (“target” or “popcorn” distribution; CT Hounsfield units > 175) and are associated with positive skin tests in 70%-90% of patients.

Evaluation of these patients usually includes chest CT scan, but sputum cytology, cultures, bronchoscopy, and mediastinoscopy are sometimes helpful. FDG-PET scanning plays an important role in the evaluation of tumors that are suspicious for malignancy. PET scan can often differentiate among lesions suspicious for malignancy.

With the advent of spiral CT scanning, the incidence of asymptomatic pulmonary nodules can vary from 25% to 70%. The vast majority of these lesions now identified are less than 1 cm and often as small as 2-3 mm. In one series, the incidence of lung cancer in the asymptomatic 10 pack-year smoking history population over the age of 50 years was 27% of all lesions identified, followed, and treated. Ongoing trials are assessing the efficacy and cost-effectiveness of CT screening for lung cancer. In the properly selected high-risk patient population (eg, over 60 years of age, moderate COPD, FEV₁ < 70%), and an over 20 pack-year smoking history), spiral CT may prove to be cost-effective and will save lives.

Ultimately, a pathologic diagnosis must be made. In some instances, fine-needle aspiration cytology may be helpful, particularly if a tissue diagnosis of hamartoma can be made or if cultures demonstrating infectious organisms are obtained. The vast majority of solitary pulmonary nodules require excisional biopsy to exclude the possibility of malignancy. Currently, this is accomplished with video-assisted techniques in most patients, particularly if the lesion is in the periphery of the lung. If a benign lesion is encountered, nothing further is warranted, but if a lung cancer is diagnosed, immediate lobectomy is indicated. The prognosis following resection of a coin lesion that turns out to be a bronchogenic carcinoma is good, with a 5-year survival of as high as 80%-90% for lesions smaller than 1 cm.

SECONDARY LUNG CANCER

Autopsy studies have demonstrated that 30% of all patients with malignancies develop pulmonary metastases, and 12% have been shown to have isolated lung disease that is totally resectable. In addition, 10% of these latter patients (1.2% of all patients) have solitary lung metastases. Most pulmonary metastases occur through hematogenous spread from the primary site—lymphatic or transbronchial spread is extremely rare. Secondary metastatic spread to the pulmonary and mediastinal lymph nodes, however, can also occur.

In patients with known extrathoracic primary cancers, multiple pulmonary lesions almost always represent metastatic disease. Solitary lesions, however, may be due to benign disease (18%) or new primary lung cancer (18%) as well as metastatic disease (64%). Most patients with pulmonary metastases are asymptomatic even with extensive disease. If symptoms do develop, cough, hemoptysis, fever, dyspnea, and pain are common. The diagnosis is generally initially suggested by routine chest radiography, and CT of the chest should always be ordered to assess the lungs for other nodules. Although CT scans are more sensitive, detecting nodules as small as 3 mm, they are also less specific (false-positive rate of 55%) than plain x-rays. Pathologic confirmation of the diagnosis is essential and usually is obtained at the time of resection. For patients who are not surgical candidates, fine-needle aspiration cytology is useful for peripheral lesions, while central lesions may require bronchoscopy for tissue diagnosis.

Medically fit patients with resectable disease are surgical candidates as long as the following criteria are fulfilled: (1) the primary tumor must be controlled or imminently controllable; (2) no other sites of disease may exist; (3) no other therapy can offer comparable results; and (4) the operative risk must be low. Since adenocarcinomas (especially breast cancer) commonly involve multiple organs, it is imperative that with this histology a full evaluation be performed, including bone scan

and head CT or MRI. Solitary squamous cell nodules, even in the presence of a previous squamous cell carcinoma (eg, head and neck tumors), should be addressed as a new primary (lung) cancer.

Pulmonary resection can be accomplished through a standard posterolateral thoracotomy, median sternotomy, or bilateral anterior thoracotomies. The latter approach is particularly beneficial for bilateral disease involving the lower lobes. Video-assisted thoracoscopy is increasingly applied to metastatic disease in an attempt to reduce the morbidity of multiple resections. On occasion, during open operations for metastatic disease, several unsuspected nodules are found by direct palpation that might be missed with thoracoscopy. Wedge resection is the treatment of choice unless the lesion is a solitary squamous cell carcinoma or adenocarcinoma. These latter lesions cannot be distinguished from primary lung cancer on frozen section pathologic examination, and they must therefore be treated as primary lung cancers with lobectomy and mediastinal lymph node dissection. Occasionally, other malignant tumors identified by histologic examination may require lobectomy or, rarely, even pneumonectomy because of involvement of the proximal pulmonary artery or bronchus.

The success rate with surgical removal of pulmonary metastases has been greatest with testicular (51% 5-year survival) and head-neck cancers (47% 5-year survival). Other types of tumors, such as osteogenic and soft tissue sarcomas, renal cell carcinoma, and colon carcinoma, are all associated with prolonged survival in 20%-35% of patients. Results of resection for melanoma are less favorable (10%-15% survival benefit). Isolated, resectable pulmonary metastases from rectal cancer can have as high as a 55% 5-year survival with metastasectomy alone.

Furthermore, multiple thoracotomies over periods in excess of 10 years are not unusual with the sarcomas. Numerous studies have been conducted in attempts to identify prognostic factors that could aid in the selection of patients for resection. Adverse prognostic factors have included: (1) multiple or bilateral lesions; (2) more than four lesions seen on CT scan; (3) tumor doubling time less than 40 days; (4) a short disease-free interval; and (5) advanced age.

Although no consensus has developed regarding the selection of candidates for surgical exploration, it is generally agreed that no single criterion should be used to exclude patients from surgical resection. In all series, long-term benefit and survival hinges on complete resection. If a complete resection is not deemed possible, resection should not be offered.

MULTIPLE CHOICE QUESTIONS

- Chest wall masses
 - Are nearly always benign
 - Are common in postmenopausal women
 - Mostly arise from bone or cartilage
 - Most commonly arise from muscle, nerve, or fascia
 - Are rarely resectable
- Risk factors for lung cancer include all of the following except
 - Exposure to asbestos
 - Tobacco smoking
 - Vitamin A deficiency
 - Iodine deficiency
 - Exposure to arsenic
- Pleural effusion, the presence of fluid within the pleural space, can collect through all of the following mechanisms except
 - Increase in the pulmonary vascular hydrostatic pressure (congestive heart failure and mitral stenosis)
 - Ureteral obstruction with transdiaphragmatic urine leak
 - Decrease in the vascular colloid oncotic pressure (hypoproteinemia)
 - Increase in the capillary permeability due to inflammation (pneumonia, pancreatitis, and sepsis)
 - Pancreatic pseudocyst rupture with transdiaphragmatic movement of abdominal fluid
- The four sources of mediastinal infection include the following, except
 - Spontaneous bacterial mediastinitis of sarcoidosis
 - Direct contamination
 - Hematogenous or lymphatic spread
 - Extension of infection from the neck or retroperitoneum
 - Extension from the lung or pleura
- Cystic fibrosis is all of the following except
 - An autosomal recessive multisystem congenital disorder
 - Characterized by chronic airway obstruction and infection
 - The result of mutation in the cystic fibrosis transmembrane regulator gene
 - Effectively cured by double lung transplantation with a 10-year graft survival exceeding 85%
 - A predisposing factor for chronic lung infection

The Heart: I. Surgical Treatment of Acquired Cardiac Disease

Jonathan W. Haft, MD

19

CORONARY ARTERY DISEASE

► Pathophysiology

The heart has the highest metabolic demands when compared to other organs. The vast majority of the energy substrate utilization is expended during unrelenting periodic contraction of the myocardium. Blood flow is delivered at a rate of 1 mL/g of cardiac tissue per minute at rest. Increases in myocardial oxygen consumption, via adenosine diphosphate and adenosine mediated arteriolar vasodilation, can result in a reciprocal increase in blood flow, up to five times normal. This increased blood flow is accommodated by recruitment of an extensive capillary bed within the myocardium, with nearly 1 capillary per myocyte. Between 70% and 80% of available oxygen is extracted from coronary blood flow at rest. Thus, the metabolic needs of the heart are tightly coupled to the availability of coronary blood flow, since additional extraction is limited. In addition, blood flow through the left ventricular epicardial arteries is phasic. During myocardial contraction, extravascular compression of intramyocardial capillaries prevents forward flow during systole, limiting flow to the diastolic phase of the cardiac cycle. This is even more pronounced in the subendocardial region where myocardial oxygen demands are greatest as a result of increased wall tension and greater sarcomere shortening. Because of the elevated and insistent myocardial oxygen consumption, the restriction of blood flow to diastole, and the high basal level of oxygen consumption, the heart is particularly susceptible to ischemic injury related to stenosis of the epicardial coronary arteries.

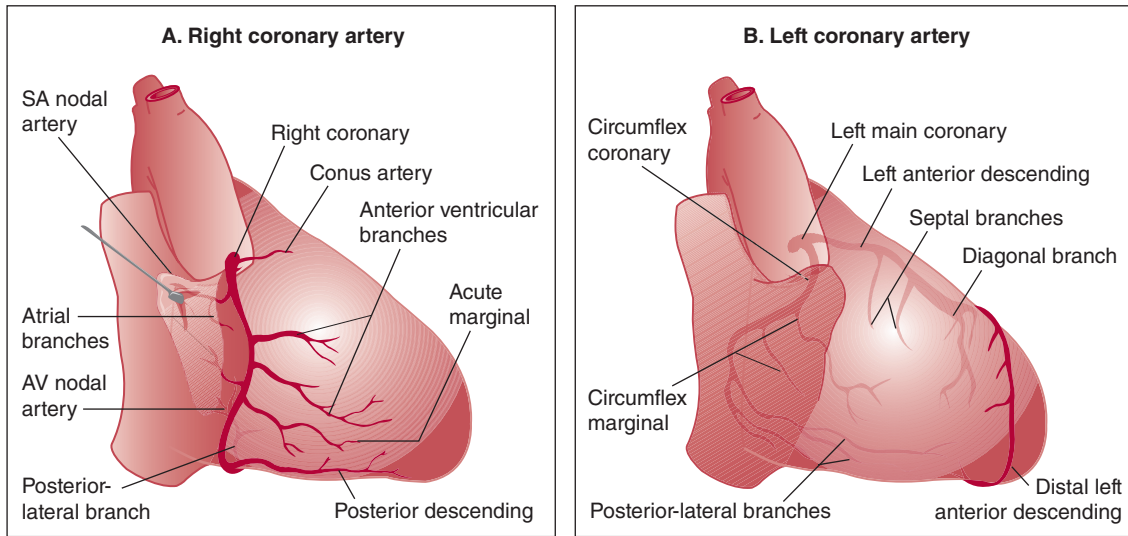

The heart receives its blood supply from the left and right coronary arteries (Figure 19-1). These epicardial vessels originate as the first branches off of the aortic root, in their respective sinuses of Valsalva. The coronary circulation is traditionally divided into three territories or regions: the left anterior descending (LAD), the circumflex (arising

from the left coronary artery), and the right (from the right coronary artery). The dominance of the heart refers to which major artery terminates as the posterior descending branch. Ninety percent of individuals are right dominant, as the right coronary artery supplies the posterior descending artery. The remaining 10% are left dominant, as the terminal branch of the circumflex artery supplies the posterior descending artery.

The left coronary artery is referred to as the left main coronary artery. After its origin in the left sinus of Valsalva, it courses between the left atrial appendage and the pulmonary artery. The left main coronary artery varies in length but is typically less than 2 cm long. It terminates in two branches: the LAD and the circumflex coronary arteries. In less than 1% of patients, the left main artery is absent, with the LAD and circumflex originating as separate ostia from the left sinus of Valsalva.

The LAD, or anterior interventricular artery, courses anteriorly and inferiorly in the interventricular groove toward the apex of the heart. Several branches of the LAD travel along the anterolateral surface of the left ventricle and are known as diagonal arteries. Their number and size are highly variable. Branches to the interventricular septum take off perpendicularly, the first of which is often sizable. The LAD is the most prominent of the three coronary territories and carries approximately 50% of myocardial blood flow.

After arising from the left main, the circumflex coronary artery dives posteriorly along the atrioventricular groove. Several obtuse marginal branches supply the lateral wall of the left ventricle; these branches vary in both size and number. In 10% of patients, the circumflex continues posteriorly and gives rise in its terminal branch to the posterior descending coronary artery, running from the posterior atrioventricular groove toward the posterior apex in the interventricular groove. Some patients have a third branch of the left main referred to as the ramus intermedius. If present, this branch is often large and supplies the anterolateral wall of the left ventricle.

▲ **Figure 19-1.** Anatomy of the coronary circulation.

The right coronary artery originates from the right sinus of Valsalva in the aortic root. It courses anteriorly and rightward until reaching the right atrioventricular groove. The vessel then descends around the acute margin of the heart, giving rise to one or more branches supplying the right ventricle. In 90% of patients, the right coronary artery continues posteriorly, terminating as the posterior descending coronary artery and the posterolateral artery.

Atherosclerosis, a progressive multifocal disease of medium and large muscular arteries of the systemic circulation, tends to occur predominantly at vessel bifurcations, sharp curvatures, and other regions creating pressure wave reflections and recirculation. Because of these flow-related considerations, atherosclerotic stenotic lesions are generally restricted to the proximal regions of the large epicardial coronary arteries. In particular, stenosis found in the LAD and circumflex vessels are frequently isolated, short, and in the proximal segments. The right coronary artery, however, develops diffuse obstructions, although rarely extending into the posterior descending or intramural branches.

The pathologic mechanism of coronary atheroma formation is identical to the lesions found elsewhere in the vascular tree. Endothelial injury from cigarette smoke, hypercholesterolemia, hyperglycemia, hypertension, or other causes of inflammation initiate a cascade of events. These include endothelial dysfunction with reduced nitric oxide production, monocyte adhesion and migration, lipid accumulation, and smooth muscle cell proliferation. The end result is an enlarging plaque encroaching on the arterial lumen, separated from the blood stream by a collagen-rich fibrous plaque. The lesion can cause flow limitations, particularly

when the luminal cross-sectional area is reduced by at least 75%. With this degree of obstruction, the vasodilatory reserve required during increased myocardial demand is restricted, resulting in transient myocardial ischemia until demand returns to baseline. The atherosclerotic plaque also causes coronary ischemia when the lesion becomes unstable. The fibrous plaque can fracture, causing rupture of the plaque contents and complete epicardial thrombosis, the presumed mechanism of ST-segment elevation myocardial infarction (STEMI). Additionally, subtotal plaque disruption can cause vasoconstriction, platelet activation, and embolization, resulting in ischemia without total occlusion of the epicardial vessel. This is the presumed mechanism of unstable angina and non-ST-segment elevation myocardial infarction (NSTEMI).

► Patient Presentation

Patients with coronary atherosclerosis can present with a variety of symptoms depending on the severity and nature of their occlusive lesions as well as on their other medical comorbidities. Chronic stable angina is the most frequent complaint of the patient with coronary artery disease. At rest, coronary blood flow is adequate to meet myocardial demand, and patients are without symptoms. However, during exercise or stress, as myocardial oxygen demand increases, autoregulatory mechanisms vasodilate to increase myocardial blood flow fivefold to sixfold. Stable coronary obstructions become flow limiting, resulting in an imbalance of oxygen demand and supply. Chest pain develops rapidly and is typically described as tightness, squeezing,

constricting, or aching. It is usually midsternal and radiates to the left shoulder, arm, or neck. The classically described Levine sign with a clenched fist over the sternum is a common finding. Some patients, however, describe symptoms that are collectively referred to as “anginal equivalents.” These include dyspnea, diaphoresis, nausea, heartburn, and dizziness or presyncope. Although the clinical manifestations of angina are variable, the pathognomonic feature of chronic stable angina is that the symptoms occur predictably with exertion and are always relieved with rest.

Acute coronary syndrome (ACS) encompasses a spectrum of conditions related to coronary occlusive disease, including unstable angina, NSTEMI, and STEMI. Patients with unstable angina experience chest pain or an anginal equivalent that is new, occurs at rest, or occurs with increasing severity from their baseline chronic stable symptoms, also called crescendo angina. Patients who develop NSTEMI have evidence of myocardial injury with elevated blood levels of myocardial enzymes (troponin and the myoglobin [Mb] fraction of creatine kinase). Unstable angina and NSTEMI are important prognostic indicators, as 10% of patients will die of cardiovascular causes within 6 months.

STEMI represents the consequences of large epicardial vessel occlusion typically associated with plaque rupture. Patients usually describe severe retrosternal chest pain that persists for more than 30 minutes. Patients with previous chronic stable angina will report that the current pain does not resolve with rest or nitroglycerine and is more intense in quality. Patients often describe additional symptoms such as diaphoresis, nausea, and dizziness. Although improvements in health systems have drastically increased survival from myocardial infarction, mortality for STEMI remains near 10%.

► Diagnostic Evaluation

Patients with suspected coronary artery disease should undergo a resting electrocardiogram. Although most patients with chronic stable angina have a normal electrocardiogram pattern, evidence of previous myocardial infarctions may be identified with the presence of either Q waves or conduction abnormalities. The most widely used diagnostic test to evaluate for coronary artery disease is exercise electrocardiography. Using standardized protocols, patients are exercised on a treadmill or bicycle ergometer while a 12-lead electrocardiogram is continuously recorded. The test is continued until the patient’s symptoms are noted or until the development of significant ST segment shifts suggesting myocardial ischemia. The diagnostic accuracy of exercise stress electrocardiogram testing can be enhanced with myocardial perfusion imaging. Several radioactive tracers are used clinically, the most frequent of which is thallium-201. Because of its similarities to potassium ions, it is taken up preferentially by the viable cardiac myocytes. Its distribution within the

myocardium is proportional to the rate of perfusion. In some cases, patients are unable to exercise because of additional physical or psychological limitations. Pharmacologic agents can substitute for exercise by increasing myocardial oxygen demand (dobutamine) or by directly vasodilating coronary arteries (adenosine), thus demonstrating regions with fixed restrictions in myocardial blood flow. Echocardiography can be used as an alternative to nuclear perfusion imaging to increase the accuracy of exercise electrocardiogram testing. Echocardiography demonstrates regional changes in wall motion that can be observed during myocardial ischemia. It can also identify valvular abnormalities or other conditions that may influence treatment choices.

Coronary angiography, also known as cardiac catheterization, is indicated in symptomatic patients with suspected coronary occlusive lesions. After percutaneous access is obtained in the arterial system, preformed catheters of varying sizes are advanced fluoroscopically to selectively engage the ostia of the left and right coronary arteries. Radiopaque contrast is injected with imaging of the opacified coronary artery. Standardized views are obtained of both the right and left coronary systems to provide different projections to clearly define the vascular anatomy and to quantify the severity of occlusive lesions (Figure 19–2). Additionally, catheters can be inserted across the aortic valve into the left ventricular cavity. Contrast injection for ventriculography can provide information about ventricular systolic function, cavity size, and the presence of left-sided valvular abnormalities. During cardiac catheterization, stenotic lesions in the epicardial vessels can be treated using percutaneous techniques, described in the section on Percutaneous Intervention. Newer imaging techniques using high-resolution multislice CT scanning with 3D reconstruction and magnetic resonance imaging (MRI) are increasingly utilized. These noninvasive approaches have the potential to improve the safety and convenience of coronary imaging; however, resolution remains inferior to standard coronary angiography.

► Medical Treatment

Medical therapy of coronary artery disease begins with controlling risk factors that contribute to formation and destabilization of the atherosclerotic plaque. The most important intervention is cessation of cigarette smoking. Other interventions include control of hypertension, diabetes, and hypercholesterolemia. Dietary modifications and exercise can improve all of these conditions, but pharmacologic treatment is often necessary.

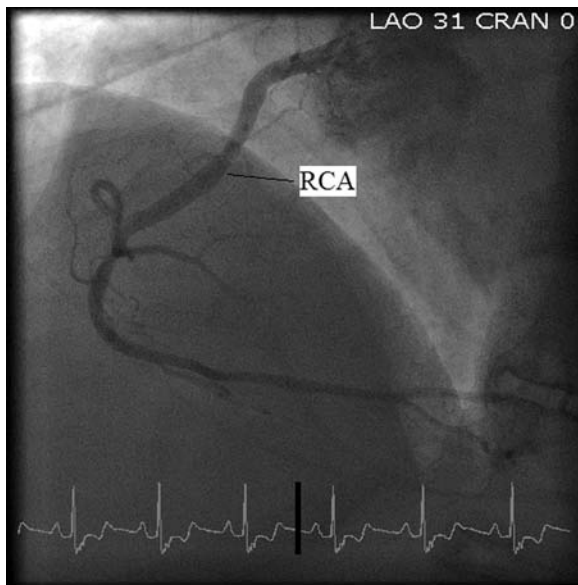

Statins can improve cholesterol levels and improve the ratio of low-density to high-density lipoproteins, and they have been demonstrated to reduce rates of myocardial infarction and death. Angiotensin-converting inhibitors have been shown to reduce mortality and myocardial

infarction in patients with coronary artery disease coupled with hypertension, diabetes, or left ventricular dysfunction. Aspirin, by inhibiting platelet activity, reduces death and myocardial infarctions in patients with coronary artery disease and should be prescribed to all patients unless significant contraindications exist. Beta-blocking agents reduce myocardial oxygen consumption by reducing heart

rate and wall tension, and they increase oxygen delivery by increasing the diastolic phase and thus subendocardial perfusion. Despite these perceived benefits, beta-blockers have not been shown to reduce cardiovascular mortality or morbidity in patients without left ventricular dysfunction or hypertension. Nitrates also decrease myocardial oxygen consumption via venodilation, reducing cardiac preload

and waltension, and vasodilation, reducing afterload. Some epicardial vasodilation will occur, improving coronary blood flow. Nitrates can control symptoms, either immediately when given sublingually or prophylactically when used as an oral long-acting agent. Headaches are notable side effects, and the vasodilatory properties of nitrates can be exaggerated by phosphodiesterase inhibitors frequently used for the treatment of erectile dysfunction. Medical treatment alone is appropriate for patients with coronary artery disease affecting one or two epicardial vessel territories and satisfactory symptom control.

► Percutaneous Intervention

In 1977, Dr. Andreas Gruentzig performed the first percutaneous intervention with balloon angioplasty on a stenotic lesion in the LAD. This pioneer laid the foundation for a revolution in the treatment of coronary artery disease worldwide. Percutaneous coronary intervention is among the most frequently performed medical procedures in the world, and its use continues to expand. These interventions include balloon angioplasty, intracoronary stent implantation, as well as rotational and laser atherectomies. Using the same techniques described for cardiac catheterization, small, highly flexible and steerable guidewires can be advanced percutaneously down the lumen of stenotic epicardial coronary arteries. Over this guidewire, balloon tipped-catheters can be advanced across the stenosis and inflated to supra-atmospheric pressures. This stretches and dilates the affected vessel, restoring the lumen to its predisease dimensions. Restenosis with balloon angioplasty was common, occurring in nearly 40% of patients. The use of nitinol scaffolding stents has greatly reduced restenosis rates to nearly 15% and they are now used in nearly 90% of percutaneous procedures in the United States. The latest addition in the armamentarium of percutaneous coronary interventions is the drug-eluting stent. The drugs impregnated into the walls of the stent are antiproliferative, similar to agents used to prevent replication of immune cells in transplant recipients. The sirolimus eluting and paclitaxel eluting stents have further reduced the rate of target vessel restenosis and the need for repeat interventions. However, reports of late stent thrombosis have raised concerns, and indefinite use of antiplatelet regimens has been recommended.

► Surgical Treatment

Although alternative surgical approaches to myocardial ischemia had been attempted previously, René Favaloro is credited with creation of the coronary bypass procedure from his work at the Cleveland Clinic. Since its inception in 1967, coronary artery bypass grafting (CABG) has increased in volume until the last decade, with minimal growth, presumably from improved percutaneous and medical treatments (Figure 19-3). Despite the recent trends, CABG

▲ **Figure 19-3.** Trend in reduction of coronary bypass graft procedures in the United States.

continues to be among the most frequent, successful, and well-studied procedures performed in medicine.

A. Indications

Three large prospective multicenter randomized clinical trials evaluating CABG versus medical therapy are widely quoted and should be understood when considering the indications for coronary bypass grafting. Despite the historical nature of these studies and the evolution in both surgical technique and medical treatment, these trials continue to provide important information about the benefits of surgical revascularization in patients with advanced coronary atherosclerosis.

The Veterans Administration Cooperative Study enrolled 1000 patients between 1970 and 1974. Patients had chronic anginal complaints and were free of myocardial infarction within 6 months. Medical treatment consisted largely of nitrates and aspirin, and surgical mortality was extremely high when compared to contemporary results. A statistically significant survival advantage was seen in the surgical group versus the medical group at 7 years (77% vs 72%), despite 38% of medical patients crossing over to surgical treatment. Subgroup analysis demonstrated more pronounced survival advantages for patients with three-vessel disease, patients with left ventricular dysfunction, and patients with significant stenosis of the left main coronary artery.

The European Coronary Surgery Study recruited 767 men with chronic angina from 1973 to 1976. Only patients with preserved left ventricular function were included. A

survival advantage for the surgical group was seen in the overall cohort, but particularly in patients with three-vessel disease and those with proximal LAD stenosis. There were also advantages demonstrated in reduction of angina and exercise capacity.

The Coronary Artery Surgery Study enrolled patients from a nonrandomized registry of patients who underwent coronary angiography from 1974 to 1979 at 15 centers. Patients with mild angina were randomized to medical treatment and CABG. There was no survival advantage in the 790 randomized patients; however, the cohort with left ventricular dysfunction had better survival with surgery, particularly those with left ventricular dysfunction and three-vessel disease. Evaluation of the nonrandomized patients in the registry also found survival advantages for surgically treated patients with left main stenosis or left main equivalent stenosis.

Although these three landmark studies are nearly 30 years old, some important principles continue to apply: patients with more advanced coronary atherosclerosis, particularly those with left ventricular dysfunction, stand to achieve the most benefit from surgical revascularization.

Numerous clinical trials have more recently compared CABG with percutaneous interventions. The Randomized Intervention Treatment of Angina (RITA) trial compared balloon angioplasty with CABG for patients with single and multivessel disease. There was no difference in survival, but repeat intervention was required five times more frequently in the angioplasty group. The Bypass Angioplasty Revascularization Investigation (BARI) enrolled 1829 patients with chronic or unstable angina from 1988 to 1991. There was no survival advantage at 5 years; however, 31% of the patients in the percutaneous group crossed over for CABG. The need for repeat revascularization was again five times higher in the percutaneous group, and the subgroup of patients with diabetes had improved survival at 5 years (81% vs 66%).

A recent comparison between patients with multivessel coronary disease treated with PCI versus CABG was performed using Medicare claims data as well as the Society of Thoracic Surgeons Database and the American College of Cardiology Foundation PCI Data Registry. Adjusted and unadjusted survival rates were superior for those undergoing CABG at 4 years. As technology and pharmacology continue to evolve, additional studies will be required. However, CABG offers survival and quality-of-life advantages in selected patients with coronary artery disease. The most recent recommendations from the American Heart Association and the American College of Cardiology regarding the indications for coronary bypass surgery are presented in Table 19-1.

B. Techniques

The principles of coronary bypass surgery are to restore normal myocardial perfusion by creating alternative routes

Table 19-1. American heart association guidelines for coronary bypass graft surgery*

Asymptomatic	
•	Left main coronary artery disease or left main equivalent (proximal LAD, proximal circumflex) (class I)
•	Three-vessel coronary artery disease (class I)
•	Proximal LAD disease and one- or two-vessel disease (class IIa, particularly if there is decreased LV function or extensive ischemia on noninvasive study)
Symptomatic	
Stable angina	
•	Left main coronary artery disease or left main equivalent (class I)
•	Three-vessel coronary artery disease (class I)
•	Two-vessel coronary artery disease and proximal LAD with decreased LV function or significant ischemia on noninvasive study (class I)
•	One- or two-vessel disease not involving the proximal LAD but with high-risk findings on noninvasive study (class I)
•	One-vessel disease involving the proximal LAD (class IIa)
Unstable angina/NSTEMI	
•	Left main coronary artery disease or left main equivalent (class I)
•	Three-vessel coronary artery disease (class I)
•	One- or two-vessel disease with ongoing ischemia; vessels are not amenable to percutaneous therapy (class I)
•	One- or two-vessel disease not involving the proximal LAD (class IIa)
STEMI	
•	Ongoing chest pain or hemodynamic instability with lesions not amenable to percutaneous treatment (class I)
•	Surgical complications of myocardial infarction, such as ruptured papillary muscle or postinfarct ventricular septal defect (class I)
•	Cardiogenic shock (class I)
•	Recurrent malignant arrhythmias (class I)
Decreased LV function	
•	Left main, left main equivalent, or three-vessel coronary artery disease (class I)
•	Two-vessel coronary artery disease (class I)
•	Proximal LAD disease (class IIa)
Failed PTCA	
•	Ongoing ischemia with adequate distal target (class I)
•	Hemodynamic instability (class I)

*Evidence class I: Evidence of or general agreement that the treatment is effective. Class IIa: Conflicting evidence or diverging opinion, but evidence favors treatment. Class IIb: Conflicting evidence or diverging opinion, but efficacy is less well established. Class III: Evidence suggests the treatment is *not* helpful. LAD, left anterior descending; LV, left ventricular; NSTEMI, non-ST-segment elevation myocardial infarction; STEMI, ST-segment elevation myocardial infarction.

for blood to reach the jeopardized territories. This strategy has several advantages, including the large-caliber conduits, their extramyocardial location in avoiding the compressive forces during systole, and their attachment at strategic locations to maximize return of normal blood flow. The most important aspect of the procedure is

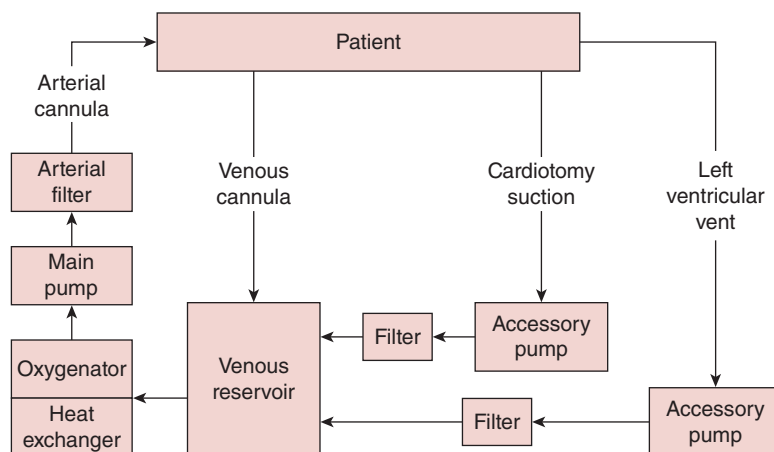

construction of a technically sound and strategically well-created bypass graft.

A variety of conduits may be chosen; the most traditional and still most frequently utilized is the saphenous vein. The vessel is easily harvested with minimal morbidity, and it is technically easy to create the precise anastomosis. Minimally invasive approaches using endoscopic techniques now reduce the impact on the patient. Limitations of the saphenous vein are primarily based on its tendency to develop accelerated atherosclerotic lesions. The vein graft plaque is more frequently circumferential and diffuse, with a weaker fibrous cap and a higher predilection for distal embolization. Patency of saphenous vein grafts is approximately 50% at 10 years. In addition, suitable vein conduit may not be available, either harvested for previous coronary or peripheral bypass procedures or unusable from varicosities or sclerosis.

The left internal mammary artery can be mobilized from its pedicle on the left subclavian artery and anastomosed to the anterior or lateral epicardial vessels of the heart, most frequently to the LAD. This strategy has several well-described advantages owing to the improved patency rate of the internal mammary graft when compared to saphenous vein grafts. The right internal mammary artery can also serve as a bypass conduit; however, harvesting of both internal mammary vessels increases the risk of sternal ischemia and surgical wound-healing complications. Because of the improved patency of arterial grafts as compared to saphenous vein grafts, the radial and gastroepiploic artery have been explored as alternatives to vein grafts. However, improved long-term patency has not been reliably established, and morbidity from harvesting has slowed widespread adoption of this approach.

The standard approach for coronary bypass grafting is via the median sternotomy, where the sternum is divided longitudinally, exposing the heart and great vessels. The left thoracotomy could be alternatively used, particularly after previous heart surgery where sternal reentry could hazard injury to adhered cardiac structures or patent grafts. Preparation is then made to institute cardiopulmonary bypass (CPB). Anticoagulation with 300 IU heparin per kilogram is infused to achieve an activated clotting time of greater than 400 seconds. Typically, the ascending aorta is used for arterial inflow, and venous return is accomplished via a cannula in the right atrial appendage (Figure 19-4). CPB is commenced, evacuating venous blood into the cardiomy reservoir. Mechanical ventilation can be discontinued. Using a heat exchanger, the blood is actively cooled to 28-32°C to reduce tissue oxygen requirements and organ injury. Shed mediastinal blood can be scavenged and returned to the CPB system, reducing blood loss during the anticoagulation period. Cardioplegic arrest is then initiated by cross-clamping the ascending aorta and infusing cold blood cardioplegia solution into the aortic root. The makeup of cardioplegia solutions differs among centers and even among surgeons; however, most centers combine autologous blood obtained from the CPB system with crystalloid solution cooled to 12°C containing citrate to bind ionic calcium, dextrose, pH buffers, and potassium (~ 30 mM/L) to arrest all cardiac activity. Cardioplegia is administered intermittently to maintain myocardial temperature and diastolic arrest during the cross-clamp period.

With the arrested heart, a dry and motionless surgical field is created, allowing creation of precise surgical anastomoses on even the smallest of epicardial coronary

▲ **Figure 19-4.** Schematic of cardiopulmonary bypass (CPB). (From Morgan GE, Mikhail MS, Murray MJ: *Clinical Anesthesiology*, 4th ed. McGraw-Hill, 2006.)

arteries. The targets are identified on the epicardial surface, and the sites for anastomotic reconstruction are determined on the basis of information from the preoperative cardiac catheterization and suitability of the native vessel. An arteriotomy is created on the exposed vessel, and it is extended for approximately 5 mm. The conduit is fashioned with an appropriately sized bevel or spatulation, and the anastomosis is created, typically in running fashion with fine polypropylene suture. The conduits are tested for patency and hemostasis, and they are cut to the appropriate size, avoiding tension or kinking. Saphenous vein or free arterial conduits are typically connected to the ascending aorta. A 4-5 mm punch device is used to create a circular aortotomy. The anastomoses are constructed in running fashion with polypropylene suture. If conduit length is limited, the proximal anastomoses can be created as Y grafts off of other vein grafts or off of the pedicled internal mammary artery graft.

After completion of all anastomoses, weaning from CPB is prepared. The patient is warmed to normothermia. As the heart begins to warm, ventricular fibrillation often occurs, requiring electrical defibrillation. Temporary conduction abnormalities may require epicardial pacing, but it is often transient. Mechanical ventilation is resumed, and the patient is gradually weaned from CPB. Pharmacologic inotropic support may be required but is often unnecessary if ventricular function was preserved preoperatively. An appropriate dose of protamine is infused to reverse the effects of heparin, and cannulae for bypass are removed. Once hemostasis is adequate, chest closure is performed with stainless steel wires. The pericardium is typically left open to avoid constriction of the atria or kinking of the bypass grafts. The pedicled left internal mammary artery graft is positioned posterior to the anterior surface of the left lung to protect it from injury should sternal reentry be required in the future.

Recently, attempts to reduce the invasive nature of coronary bypass grafting and the potential complications of CPB have been introduced. Techniques to perform bypass grafting without CPB have improved and are promoted by its advocates. Off-pump coronary bypass grafting (OPCAB) have potential advantages in reducing neurologic complications associated with air and atheroemboli, as well as reducing blood transfusion requirements and cost. The procedure involves manipulation and stabilization of the beating heart to expose the epicardial targets. Particularly for vessels on the posterior and posterolateral surfaces, hemodynamic instability can result while the heart is elevated and rotated for optimal exposure. The anesthesiologist must be capable of responding to these rapid changes, and the surgeon must have the judgment and ability to immediately abandon off-pump attempts and institute CPB before significant organ injury occurs. The anastomoses are more challenging, with blood in the moving operative field. Although several single-center reports have demonstrated satisfactory short-term results and mid-term graft patency rates, multi-

center randomized and observation studies have suggested that OPCAB techniques may offer some benefits but at the expense of reduced graft patency rates and increased incomplete revascularization. As a result, OPCAB penetrance has not markedly increased over the last several years.

C. Results

Since the creation of the Society of Thoracic Surgeons voluntary reporting database in 1989, short-term outcomes of coronary bypass grafting are widely available to the public, providing information for patients, referring physicians, and practicing surgeons to compare their results to national averages. The Society also provides a validated risk assessment scoring system, creating mortality estimates based on an individual patient's clinical data. Overall, risk of perioperative death is 1%-3%. Multivariate predictors of death include advanced age, recent myocardial infarction, decreased ventricular function, renal insufficiency, and female gender. Conduit patency is determined from clinical trials that included angiographic assessments at varying time intervals in the absence of symptoms. Data are largely historical and are subject to biases of patient selection but are largely considered to be reliable. Saphenous vein grafts occlude 20%-30% by 1 year. Early graft loss is felt to be attributable to anastomotic imperfections or graft kinking, endothelial injury during harvest, limited native coronary runoff, or progression of native occlusive disease. Late failures appear to occur at a rate of 5% per year, with 10-year patency approximately 40%-50%. Late failures are primarily attributed to accelerated atherosclerosis of the vein conduit. The pedicled internal mammary artery has far superior patency, particularly when anastomosed to the LAD. With adequate target vessel runoff, 10-year patency rates of 90%-95% have been reported in multiple independent studies. Radial arteries and free mammary artery conduits appear to have patency rates intermediate to saphenous vein and pedicled mammary arteries and are more frequently utilized in younger patients.

VALVULAR HEART DISEASE

MITRAL REGURGITATION

► Pathophysiology

A. Anatomy

The mitral valve separates the left atrium from the left ventricle. It should be considered as the sum of its three components: the leaflets, the annulus to which the leaflets attach, and the subvalvar apparatus, consisting of the cords and papillary muscles. The mitral valve has two leaflets, anterior and posterior (Figure 19–5). The anterior leaflet is larger in surface area, but its attachment to the annulus represents only one-third of the circumference. The anterior portion of the mitral valve annulus is in direct continuity with the annulus of the left and noncoronary cusps of the aortic valve, also known as the aortomitral continuity. The posterior leaflet is shorter, but its annular attachments cover two-thirds of the circumference. The posterior leaflet often can be separated into three distinct scallops, although the prominence of these separations varies among individuals. The anterior

▲ **Figure 19–5.** Anatomy of the mitral and tricuspid valves (MAL, mitral anterior leaflet; MPL, mitral posterior leaflet; TAL, tricuspid anterior leaflet; TSL, tricuspid septal leaflet; TPL, tricuspid posterior leaflet).

and posterior leaflets are separated from each other by the anterolateral and posteromedial commissures, which mark the location of the right and left fibrous trigones respectively. The trigones are dense collagenous structures within the annulus representing a portion of the fibrous skeleton of the heart. The mitral annulus is elliptical in shape, and its dimensions change dynamically during cardiac contraction, reducing its cross-sectional area by as much as 40%. The anterolateral and posteromedial papillary muscles are vertically oriented bundles of cardiac myocytes. Chordae tendinae originate from the heads of the papillary muscles and span the distance to both the anterior and posterior mitral valve leaflets. Chords are designated as primary if they attach to the leading edge of the leaflet, secondary if they attach to the ventricular surface of the leaflets, or tertiary if they attach to the ventricular surface of the mitral annulus. The chords play an important role in preventing leaflet prolapse. The posteromedial papillary muscle is prone to ischemic injury, since it relies on a single right coronary artery for circulation. In contrast, the anterolateral papillary muscle gains its blood supply from the LAD and circumflex branches and tends to be more resistant to ischemic injury.

B. Classification of Mitral Regurgitation

Regurgitation through the mitral valve can result from a variety of pathologic conditions. Alain Carpentier developed a simplified classification scheme based on leaflet motion (Table 19–2) to organize the different disease processes that can cause mitral regurgitation. In Carpentier type I mitral regurgitation, the leaflet motion is normal. The regurgitation is a result of either dilation of the annulus, as can be seen in cardiomyopathy with progressive ventricular enlargement, or of leaflet perforation, as can be seen with destructive endocarditis. Type II is associated with excessive leaflet motion. Patients with type II mitral regurgitation have ruptured chordae or papillary muscles from ischemia or endocarditis, or they have with pathologically redundant mitral leaflet tissue. Redundant, prolapsing, or myxomatous mitral leaflets can be either acquired from fibroelastic deficiency or hereditary from weak connective tissue. In either case, the

Table 19–2. Carpentier classification of mitral regurgitation.

I	Normal leaflet motion <i>Annular dilation, leaflet perforation</i>
II	Excessive leaflet motion <i>Prolapsed or myxomatous leaflet, ruptured chord</i>
III	Restricted leaflet motion <i>Rheumatic disease, ischemic mitral regurgitation</i>

excessive leaflet motion prevents proper coaptation of the anterior and posterior leaflets. Patients with type III have restricted leaflet motion. Type III is often associated with rheumatic heart disease, where leaflets can become calcified, and the chords are thickened and foreshortened. The leaflets do not adequately rise in systole, and coaptation is impaired. Alternatively, some patients develop severe mitral regurgitation owing to ischemic injury. Typically, a previous myocardial infarction has resulted in ventricular remodeling, resulting in dilation and retraction of the papillary muscles. As a result, the leaflets are tethered into the ventricle, limiting mobility and preventing proper coaptation.

Mitral regurgitation is always pathologic but can be tolerated surprisingly well when the onset is gradual, allowing for a series of physiologic adaptations. On the other hand, acute mitral regurgitation, as can be associated with infective endocarditis or ischemic papillary muscle rupture, results in immediate pulmonary congestion because the unprepared left atrium is incapable of handling the additional volume load. Several compensatory mechanisms occur as mitral regurgitation develops and progressively worsens. The left atrium and pulmonary venous system gradually dilates, thus increasing compliance to better accommodate the excess volume. The backwards flow of mitral regurgitation reduces ventricular afterload, reducing myocardial wall tension. The reduction in forward flow is accounted for by increased diastolic filling, increasing preload. This maintains cardiac output and can delay onset of symptoms for significant time. Gradually, left ventricular end diastolic volume continues to rise, resulting in pathologic remodeling, creating a dilated and more spherical ventricular cavity. Systolic function is progressively and inexorably impaired as a result of both mechanical considerations owing to the altered shape and molecular mechanisms both intracellular and extracellular. A vicious cycle ensues, with deteriorating systolic function and rising end diastolic volume promoting further ventricular remodeling and dilation and worsening mitral regurgitation. Longstanding mitral regurgitation will result in sustained elevation in left atrial pressure and volume, resulting in pulmonary vascular changes, pulmonary hypertension, and eventually, right ventricular dysfunction.

C. Symptoms

Acute mitral regurgitation is poorly tolerated and is typically associated with pulmonary congestion and low cardiac output. Patients describe dyspnea, poor exercise tolerance, and fatigue. Often, the etiology of the mitral regurgitation is more dominant in the clinical presentation. Patients with acute endocarditis may have fever, shaking chills, and manifestations of septic embolization such as stroke and intestinal or extremity ischemia. Patients suffering from acute myocardial infarction with a ruptured papillary muscle complain of chest pain and diaphoresis.

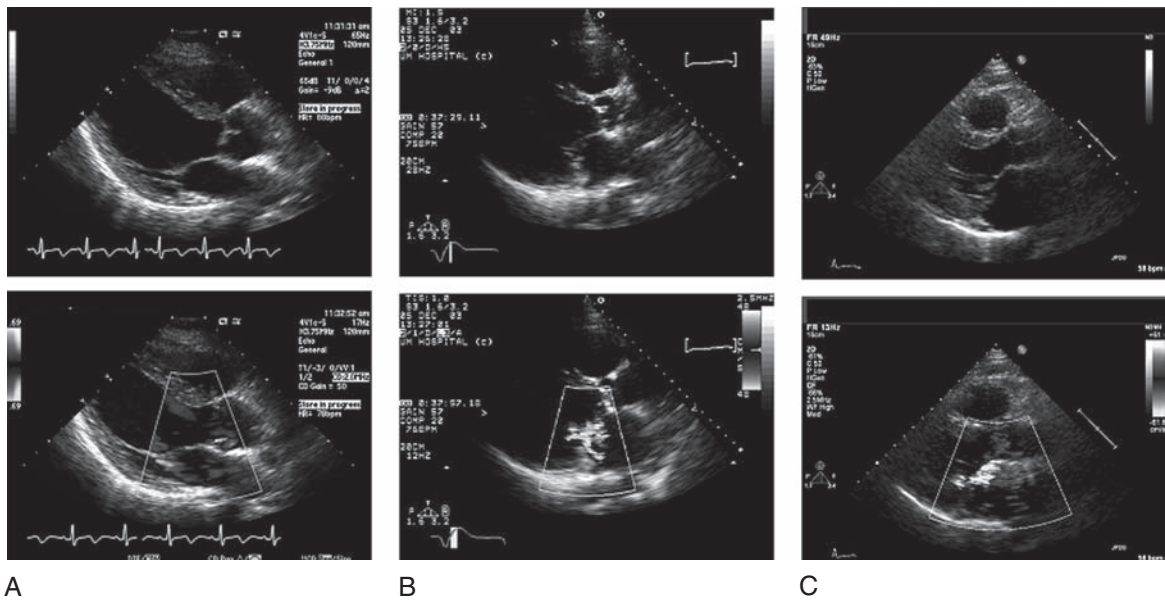

Chronic mitral regurgitation can be asymptomatic for many years as a result of progressive atrial and ventricular adaptation. Eventually, patients develop symptoms of heart failure, including dyspnea, fatigue, and lower extremity edema. When left atrial dilation results in atrial fibrillation, patients may describe heart palpitations. Often, the onset of atrial fibrillation is the initial presentation of symptoms, as rapid ventricular response decreases diastolic filling time and creates a sudden reduction in cardiac output. As ventricular function deteriorates and pulmonary vascular changes occur, signs of right-sided heart failure develop, such as lower extremity edema and ascites.

► Diagnostic Testing

The physical findings of mitral regurgitation vary depending on the duration and the degree of compensation. For patients with longstanding mitral regurgitation, ventricular dilation displaces the point of maximal impulse (PMI) laterally. On auscultation, an S3 gallop is often heard, resulting from increased diastolic flow. The systolic murmur is characteristically described as blowing, best heard over the cardiac apex and radiating to the axilla. In acute mitral regurgitation, the murmur tends to be limited to early in systole. With more chronicity, the murmur is progressively holosystolic.

The chest radiograph often demonstrates cardiomegaly from ventricular dilation. With severe uncompensated heart failure, pulmonary edema may be evident; however, this is more commonly seen with acute mitral regurgitation. The electrocardiogram is often nonspecific but may demonstrate evidence of previous myocardial infarction and will confirm the presence of atrial fibrillation.

Echocardiography is the mainstay in the diagnosis of mitral regurgitation; it provides information about the mechanism of the disease, which is essential in planning surgical intervention. Images of the leaflets can determine if the leaflet motion is normal, restricted, or excessive. Information about annular size and mobility can be obtained. Using color Doppler, the size and direction of the regurgitant jet can quantify the severity and give clues as to the mechanism (Figure 19–6). The severity of the regurgitation is determined by the width and length of the regurgitant jet or the presence of reversed flow within the pulmonary veins. Echocardiography also provides information about the chronicity of the disease and can document progressive adaptation such as left atrial and ventricular dilation. This information is often used in determining timing of surgical intervention, particularly in asymptomatic patients. Echocardiography is usually performed transthoracic. However, in some patients, the views are obscured by body habitus or emphysema, limiting the image quality. Transesophageal echocardiography (TEE) can improve the resolution of images and better clarify the severity and mechanism of the mitral valve pathology.

▲ **Figure 19-6.** Echocardiographic view of the mitral valve. **A:** Normal valve. **B:** Dilated annulus with central regurgitation. **C:** Prolapsing posterior leaflet with eccentric regurgitation.

Cardiac catheterization is an important adjunctive tool, helping to identify additional cardiac pathology, and can determine the adequacy of preoperative medical optimization. Coronary angiography is performed preoperatively to identify coronary arterial occlusive lesions that may require bypass grafting at the time of mitral valve repair or replacement. Although contrast ventriculography can demonstrate the regurgitant jet, it is no longer necessarily used to quantify the regurgitant volume, since echocardiography has become the standard technique. Right heart catheterization will demonstrate intravascular volume overload and low cardiac output. It may also be helpful in diagnosing pulmonary vascular changes in patients who deny symptoms.

► Surgical Treatment

A. Indications

The indications for operation on the mitral valve depend on the specific pathology as well as clinical symptoms. In addition, the indications have evolved in recent years owing to improved outcomes related to better surgical techniques, anesthetic considerations, myocardial protection, and post-operative care. Furthermore, intervention on the mitral valve may be performed for less severe disease if operation is indicated for coronary artery disease or aortic valve pathology.

Certainly, among patients who represent reasonable operative risks, those with severe mitral regurgitation and

heart failure symptoms should be offered an operation. In addition, those with severe mitral regurgitation and signs of left ventricular dysfunction should undergo operation because myocardial decompensation can progress rapidly without corrective action. There is insufficient evidence that operative intervention for asymptomatic severe mitral regurgitation and normal ventricular function improves survival. Historically, these patients were observed with close clinical follow-up and serial echocardiography. Signs of left ventricular dilation, dysfunction, or new-onset symptoms prompted surgical referral. Some have argued that the presence of pulmonary hypertension or atrial fibrillation represent maladaptive changes and suggest surgical correction.

Surgical techniques of addressing the mitral valve have changed dramatically in recent years. Increasingly, operations have focused on repair rather than prosthetic replacement of the mitral valve. Valve preservation has several advantages. The interaction of the mitral valve and the left ventricle goes beyond just competence and the handling of blood volume. A complex interdependence exists between ventricle and valve, and long-term ventricular function depends on its relationship with the mitral annulus, papillary muscles, and chordae tendineae. Surgical techniques to correct mitral regurgitation that preserve these relationships are more likely to maintain normal ventricular function. In addition to the effects on ventricular function, prosthetic mitral valves carry limitations. Bioprosthetic

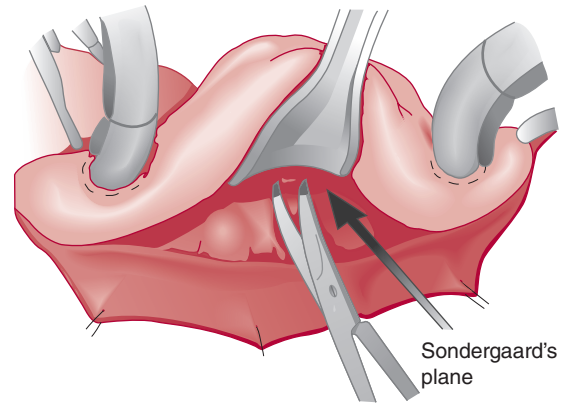

devices (porcine or bovine) have limited durability because of structural valvular degeneration. The rate of bioprosthetic valve failure is proportional to age, with faster deterioration in younger patients. Mechanical valves are more durable but require lifelong systemic anticoagulation with warfarin. Because of the limitations imposed by prosthetic valves (durability and anticoagulation), surgical referral for mitral regurgitation is often delayed if there is a high likelihood of valve replacement. If valve repair is expected because of mitral pathology and surgeon experience, earlier operation for mitral regurgitation is often considered, particularly in the absence of symptoms or ventricular dilation.

Surgical indications for operation in endocarditis of the mitral valve are different than for other pathologies. Certainly, valvular destruction with severe mitral regurgitation, heart failure, and ventricular dilation requires operative intervention. However, there are other specific indications for valve replacement. A history of systemic embolization or the presence of large, highly mobile vegetations at risk of embolization necessitates urgent surgical intervention. In addition, ongoing bacteremia despite appropriate antibiotic treatment coverage mandates early operation. The presence of certain organisms, such as highly resistant bacteria or fungal endocarditis warrants surgical treatment. Surgery is required for the presence of mitral annular abscess with incipient cardiac conduction abnormalities or creation of an intracardiac fistula. Prior to surgery, attempts at controlling the original source of infection should be made, including dental extractions and drainage of abscesses.

B. Techniques

Approach to the mitral valve is best accomplished via a median sternotomy. Although the mitral valve can be exposed via a right or left thoracotomy, the median sternotomy offers the best access for initiation of CPB as well as the ability to perform other cardiac procedures if necessary, such as coronary bypass grafting or aortic valve replacement. CPB is initiated, typically draining the superior and inferior vena cavae separately, and infusing into the ascending aorta. The heart is arrested using cold cardioplegia delivered into the aortic root. The left ventricle is vented, typically using the right superior pulmonary vein.

A variety of incisions can be used to expose the mitral valve, and the quality of exposure is essential in obtaining a good surgical result. The most frequent approach is by an incision directly into the left atrium. The interatrial groove of Sondergaard can be developed using sharp technique, lifting the right atrium anteriorly off of the left atrium (Figure 19-7). A vertical incision is made in the left atrium, just medial to the confluence of the right-sided pulmonary veins. Self-retaining retractors are available to elevate the atriotomy and provide visualization. Often, rotation of the table to the left away from the surgeon improves the

▲ **Figure 19-7.** Exposure of the mitral valve via the interatrial groove. (From Cohn LH: *Cardiac Surgery in the Adult*, 3rd ed. McGraw-Hill, 2007.)

exposure. Alternatively, an approach across the interatrial septum can be chosen. The superior and inferior vena cavae are controlled with snares, and the right atrium is opened. The fossa ovalis is identified and incised vertically. This incision is extended superiorly toward the superior vena cava through the muscular portion of the interatrial septum. The septal incision can also be extended medially along the dome of the left atrium, the so-called superior septal approach. While exposure of the mitral valve is excellent, there is a risk of injury to the sinus node, requiring implantation of a permanent pacemaker.

Once the valve has been exposed, assessment of the mitral valve is performed to determine the mechanism of mitral regurgitation and the technique for repair or replacement. Injection of cold saline into the left ventricle will identify the location of regurgitation and the presence of flail or significantly prolapsed leaflets. The leaflets are inspected for their mobility and the presence of calcifications or perforations. The annulus is inspected for dilation and calcium. Once the mechanism of regurgitation is clear, a plan is made for repair or replacement. The strategy used depends on the pathologic mechanism (Figure 19-8).

When the mitral regurgitation is purely a result of annular dilation or posterior leaflet restriction from a previous myocardial infarction, mitral annuloplasty alone often adequately alleviates the leak. Horizontal sutures are placed along the mitral annulus, including the fibrous trigones. Care must be taken to avoid injury to underlying structures, such as the circumflex coronary artery, the coronary sinus, and the atrioventricular node. Annuloplasty is typically performed with the assistance of prosthetic rings or bands of varying degrees of rigidity. Some of the rings completely encircle the entire annulus, and some are incomplete,

▲ **Figure 19-8.** Panels A–E represent atrial views of posterior leaflet reconstruction for isolated posterior leaflet prolapse and insertion of an annuloplasty ring.

designed to extend posteriorly from trigone to trigone (Figure 19-9). The annular mattress sutures are brought up through the sewing cuff of the ring and tied down. The

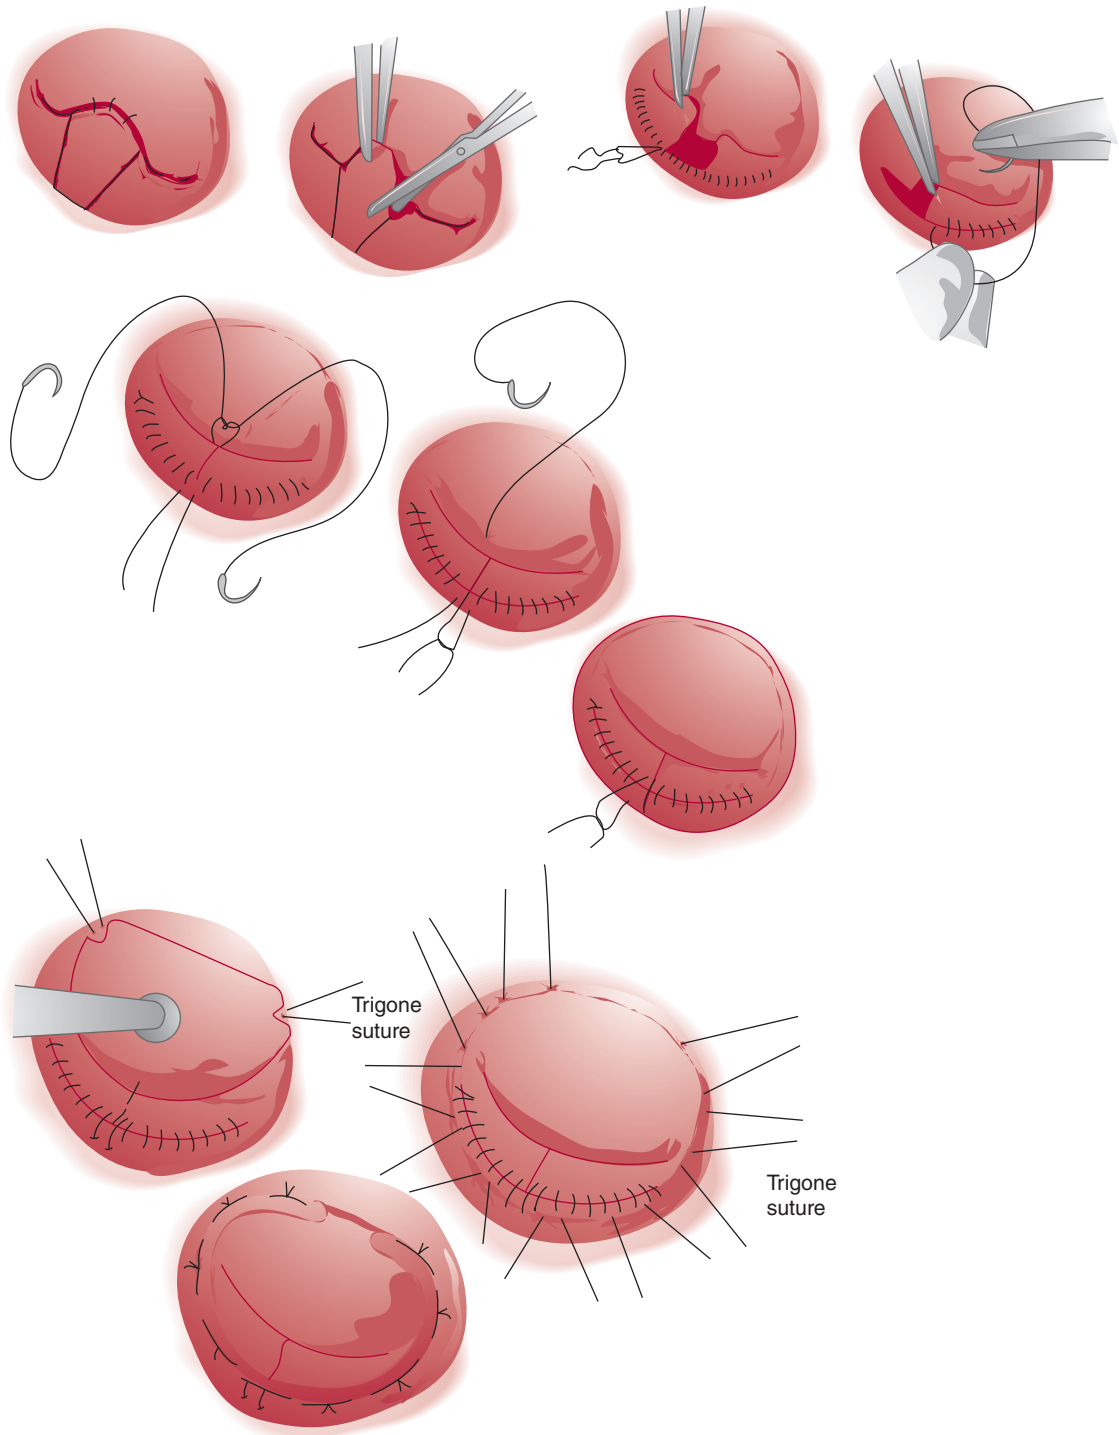

▲ **Figure 19-9.** Operative photograph of a mitral ring annuloplasty for ischemic mitral regurgitation. The ring plicates the posterior annulus to restore leaflet coaptation.

size of the ring is selected to match the area of the anterior leaflet and the distance between the trigones. Competence is tested with saline injection, and the cardiac chambers are closed. After weaning from CPB, the valve is inspected using transesophageal echocardiography. An adequate repair must demonstrate both competence and low resistance, as evidenced by low pressure gradients across the valve.

Myxomatous degeneration of the mitral valve typically involves the posterior leaflet, particularly the P2 scallop. This lesion can be reproducibly repaired using techniques with the potential for indefinite durability. After exposure of the mitral valve, the point of prolapse is identified. A quadrangular portion of the prolapsing section is excised to the annulus. The gap is bridged by undercutting the annular attachments of the adjacent portion of the posterior leaflet. The mobilized edge of the posterior leaflet is sewn back to the annulus with running suture (Figure 19-10), reducing its effective height. An annuloplasty can be performed to address any annular dilation as well as to provide reinforcement to the posterior annular reconstruction.

When prolapse or chordal rupture involve the anterior leaflet, repair is more difficult. A variety of approaches have been described, but the likelihood of durable repair is far

▲ **Figure 19–10.** Quadrangular resection and sliding annuloplasty for prolapse of the posterior mitral valve leaflet. (From Cohn LH: *Cardiac Surgery in the Adult*, 3rd ed. McGraw-Hill, 2007.)

less when compared to the more common posterior leaflet prolapse. One approach involves the creation of artificial chords. Typically, polytetrafluoroethylene is used to create neochords from the papillary muscle to the edge of the leaflet. The challenge is to create the precise length to allow coaptation without prolapse. Alternatively, the flail anterior segment can be removed and is replaced with a resected portion of the posterior leaflet, including its attached chords. A simpler approach is the edge-to-edge technique, in which the opposing edges of the anterior and posterior leaflets are sewn together with a single suture, creating a double-orifice mitral valve. Popularized by Alfieri and colleagues, this approach has been applied using catheter-based techniques, obviating the need for open surgery.

Often, the regurgitant mitral valve cannot be repaired, such as when there is severe valvular destruction from infective endocarditis or extensive calcifications as can be seen with rheumatic mitral valve disease. The mitral valve is exposed, and the leaflets are excised. Attempts are made to preserve chordal attachments to the annulus, and portions of the posterior leaflet can be plicated to the annulus to preserve secondary chords. This is typically not possible with rheumatic disease because the calcified annulus will require extensive debridement. Annular mattress sutures with felt or Teflon pledgets are placed circumferentially. For mechanical prostheses, the pledgets are oriented on the atrial side to avoid interference with the actuation of the disk. For bioprosthetic implants, the pledgets can be placed on the ventricular side, which allows for a slightly larger prosthetic (Figure 19–11). After sutures are placed, the annulus is sized and an appropriate prosthetic is chosen. The sutures are driven through the sewing ring of the valve and tied down. After weaning from CPB, the valve is carefully inspected using transesophageal echocardiography for signs of para-valvular leak, normal motion of the leaflets or disks, and a low pressure gradient across the valve.

C. Results

Repair or replacement of the mitral valve for regurgitation preserves ventricular function and allows some remodeling by eliminating the volume overload and its associated incipient changes. However, loss of myocardial contractility, as a result of longstanding mitral regurgitation or otherwise, typically does not recover. Only its progressive decline can be halted. This reinforces the need to intervene before severe ventricular dilation has occurred, even in asymptomatic patients.

Mitral regurgitation associated with prolapsing myxomatous leaflets carries low perioperative mortality, and the freedom from degeneration of a repaired valve is greater than 90% at 10 years. Some of the low periprocedural mortality is related to the young age and low incidence of comorbidities in this patient population. Mitral valve repair associated with

▲ **Figure 19–11.** Percutaneous device for mitral valve repair, currently in clinical trials. (Reproduced with permission from Abbott Laboratories, Abbott Park, Illinois.)

coronary bypass grafting carries a perioperative mortality of approximately 5%, with ejection fraction, renal function, and age being independent predictors of death. Although mortality after coronary bypass grafting is associated with the severity of preoperative mitral regurgitation, there is no evidence that mitral repair reduces this mortality. Repairing the mitral valve, however, is associated with improved long-term survival, as compared to replacing the valve.

MITRAL VALVE STENOSIS

► Pathophysiology

Rheumatic heart disease is the most common cause of mitral valve stenosis. Although nearly 20 million people are affected with rheumatic fever in underdeveloped countries, the incidence in the United States and Western Europe has declined markedly, largely a result of advanced medical care and use of antibiotics to treat infections caused by group A streptococci. Untreated infection results in an immunologic response to bacterial antigens that resemble cardiac tissue. The degree of the immunologic response and the severity of ongoing valvular destruction appear to be related to genetic factors. Although the damage can affect the entire

A

B

endocardium and even the pericardium, the mitral valve is the most commonly involved, with 40% of patients having only mitral valve disease. Mitral and aortic valve disease is also frequently seen, and rarely patients will have isolated aortic valve involvement. It remains unclear why right-sided valves are rarely affected.

The characteristic features of rheumatic mitral valve disease include leaflet and chordal thickening and retraction (Figure 19–12). Commissural fusion is also apparent, and a late feature is dense calcification of the annulus and leaflets. Turbulence created by impaired leaflet mobility exacerbates the valve destruction, accelerating further fibrosis and calcification.

Mitral valve stenosis can also be caused by mitral annular calcification, which can become quite bulky, protruding into the valve orifice. The posterior leaflet can become contracted and fixed, while the anterior leaflet thickens and becomes less mobile. Structural valvular degeneration of bioprosthetic mitral valves can cause mitral valve stenosis as well as thrombosis or pannus formation in mechanical prostheses. Advanced endocarditis can result in effective mitral valve stenosis, as bulky vegetations obstruct the inflow path. Congenital abnormalities, such as the parachute mitral valve with a single papillary muscle, can become stenotic, requiring intervention.

The stenotic mitral valve results in a pressure gradient between the left atrium and ventricle. This fixed resistance increases the left atrial pressure even further during exercise, as cardiac output increases, but resistance across the valve is unchanged. Severe mitral valve stenosis is associated with a mean transvalvular gradient of 10–15 mm Hg at rest. Cardiac

output is dependent on ventricular filling, and left ventricular end diastolic pressure and volume are typically low. Exercise-induced tachycardia decreases diastolic filling time, producing a paradoxical reduction in cardiac output. Left ventricular function is typically normal or hyperdynamic, but some patients have combined mitral valve stenosis and mitral regurgitation, as well as significant aortic valve insufficiency, and will develop chronic left ventricular volume overload and dysfunction. Thus, the hemodynamic consequences of mitral valve stenosis depend to a certain degree on the presence of mitral regurgitation and other associated valvular pathology.

As the mitral transvalvular gradient worsens, the left atrial wall hypertrophies. The a-wave on the atrial pressure tracing is accentuated during atrial contraction. Progressively, the left atrium dilates, creating disorganized electrical conduction pathways. Reentry pathways lead to frequent premature atrial contractions and eventually to atrial fibrillation. The onset of atrial fibrillation often is the inciting clinical event, with the reduced diastolic filling time from rapid ventricular response and the loss of atrial contraction both resulting in reduced left ventricular filling and a drop in cardiac output. The sustained elevation in left atrial pressure results in pulmonary vascular changes producing pulmonary hypertension. These changes can lead to right ventricular pressure overload with tricuspid valve insufficiency and to right ventricular volume overload.

Symptoms of mitral valve stenosis often do not develop until the disease is advanced, owing to ventricular and atrial adaptive responses. Patients describe dyspnea from pulmonary congestion or reduced cardiac output, initially limited to exertion. Onset of atrial fibrillation often prompts urgent

evaluation, as the loss of atrial contraction and tachycardia cause a precipitous drop in cardiac output and pulmonary congestion. Late findings include signs of right-sided heart failure such as ascites and lower extremity edema. Cerebrovascular events or other thromboembolic complications from an intracardiac thrombus are not uncommon with longstanding mitral valve stenosis, as the dilated left atrium and left atrial appendage have regions of stagnation and thrombus formation, particularly in the setting of atrial fibrillation. Since two-thirds of the patients with mitral valve stenosis are women, symptoms often present during later stages of pregnancy as the increased cardiac output results in higher left atrial pressures and pulmonary congestion.

► Diagnostic Evaluation

Because presentation tends to be late, many patients present with signs of longstanding heart failure, including cachexia, ascites, and lower extremity edema. On auscultation, the low diastolic rumble is best heard over the cardiac apex. An opening snap can be heard in the early stages of the disease, and the systolic murmur of tricuspid regurgitation is a late finding, as is a parasternal heave from right ventricular hypertrophy.

The electrocardiogram will diagnose atrial fibrillation, and right axis deviation may be present, suggesting advanced pulmonary hypertension. The chest radiograph is often normal but may demonstrate straightening of the left heart border caused by dilation of the pulmonary arteries. Pulmonary edema may be present on initial evaluation when atrial fibrillation is the inciting event. Cardiac catheterization is important in identifying associated coronary arterial pathology and can confirm the severity of the mitral stenosis using simultaneous left and right heart catheterization with pressure measurements. The degree of pulmonary hypertension and its reversibility with provocative agents may be assistive in determining surgical candidacy in advanced cases.

Echocardiography is the mainstay in diagnosis of mitral valve stenosis. Surface or transthoracic echocardiography is preferred because it is noninvasive, and can usually provide images demonstrating the characteristic thickening and restricted mobility of the mitral leaflets. If images are obscured by patient body habitus or obstructive lung disease, a transesophageal echocardiogram can be performed. The proximity of the esophagus with the left atrium provides excellent visualization and can easily demonstrate the thickened mitral subvalvar apparatus typical of rheumatic disease. Color Doppler can be used to show turbulent flow across the valve orifice, and the pressure gradients can be estimated by measuring the peak and mean velocity of blood through the valve.

► Treatment

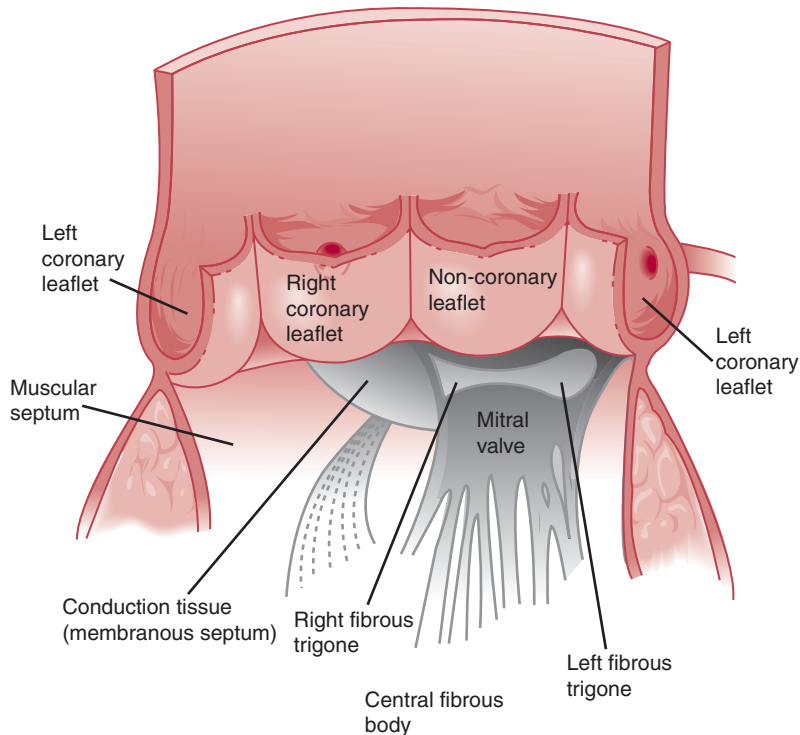

Medical treatment is limited to control of symptoms. Recurrent episodes of infection must be prevented, as accel-

erated progression of the disease can be seen. Prompt initiation of antibiotics for suspected infections is prudent. Complications of mitral valve stenosis should be addressed and controlled. Rapid ventricular response to atrial fibrillation can be treated with a number of pharmacologic agents, and attempts at cardioversion should be made once the presence of intracardiac thrombus has been excluded. It is often difficult to maintain sinus rhythm in the mitral valve stenosis patient with a significantly dilated left atrium in whom rate control alone may be acceptable. Systemic anticoagulation with warfarin should be initiated if there has been a history of atrial fibrillation. Once the patient describes symptoms of heart failure, intervention on the mitral valve should be considered. For symptomatic patients not candidates for catheter-based or surgical intervention, diuretics and oral sodium restriction to control heart failure symptoms is all that is available.

Catheter-based balloon mitral valvotomy can reduce the obstructing pressure gradient and improve symptoms in selected patients. Patients with severe mitral valve stenosis and symptoms and asymptomatic patients with severe mitral valve stenosis and pulmonary hypertension are eligible if there is no mitral regurgitation, no left atrial thrombus, and favorable valve morphology, such as absence of extensive subvalvular fibrosis and calcification. The procedure is performed by femoral venous puncture and transeptal access to the mitral valve across the interatrial septum. A 25-mm hourglass Inoue balloon is advanced across the valve orifice and inflated. Significant improvement in hemodynamics is seen immediately, with reduction in transvalvular pressure gradients by as much as 15 mm Hg. The incidence of restenosis in selected patients is approximately 25% at 4 years.

Indications for surgical treatment are the same as for balloon valvuloplasty, including symptomatic patients with moderate or severe mitral valve stenosis and asymptomatic patients with pulmonary hypertension. Valve repair can be performed in carefully selected patients with reasonable long-term results. CPB is initiated in the same manner as for mitral repair for mitral regurgitation. After cardioplegic arrest, the mitral valve is exposed. Any thrombus within the atrium or atrial appendage is removed. The left atrial appendage can be transected and oversewn at its base to remove its future embolic potential. The areas of commissural fusion are cut, and the leaflets are decalcified. Occasionally, fused chords are divided to increase leaflet mobility. In carefully selected patients, recurrent mitral valve stenosis is less than 20% in up to 15 years.

In most cases, however, severe leaflet and subvalvular calcification has made the valve unreconstructable, requiring valve replacement. Overaggressive debridement of the posterior mitral annulus can result in perforation and atrioventricular separation and should be avoided. The selection of valve prosthetic depends on the unique clinical circumstances. Bioprosthetic valves are minimally thrombogenic

▲ **Figure 19–13.** Anatomic relationships of the aortic root. (From Cohn LH: *Cardiac Surgery in the Adult*, 3rd ed. McGraw-Hill, 2007.)

and do not require lifelong anticoagulation with warfarin. However, they are prone to structural valvular degeneration resulting in recurrent mitral valve stenosis or mitral regurgitation. Valve prosthetics are improving, and freedom from structural valvular degeneration is as high as 85% at 10 years. Mechanical valves are thrombogenic and require lifelong anticoagulation, such as warfarin, which is associated with a 1%-2% annual incidence of major bleeding complications. They are more durable and reduce the need for reoperation. In general, patients younger than 60 years of age or those already requiring warfarin for atrial fibrillation should be considered for a mechanical valve.

AORTIC VALVE DISEASE

The aortic valve separates the outflow tract of the left ventricle with the ascending aorta. It is a trileaflet structure, with three semilunar cusps named for the coronary arteries that arise within the underlying sinuses. The left and right coronary arteries originate within these respective sinuses, with no coronary artery arising within the *noncoronary* sinus. The free edges of the cusps are thickened at regions called the nodules of Arantius. The valve leaflets attach to

the wall of the aorta at the annulus, and the locations where two adjacent cusps meet are the commissures. Important structures can be identified under these triangular-shaped zones (Figure 19–13). The commissure between the right and noncoronary cusp serves as the superior border to the membranous interventricular septum and the atrioventricular conduction center. The non-left commissure guards the aortomitral curtain and the center of the anterior leaflet of the mitral valve. The left-right commissure overlies the muscular interventricular septum and the medial border of the right ventricular outflow tract. These intimate intracardiac relationships are no more apparent than within the left ventricular outflow tract.

The thin-walled aortic valve leaflets easily open and close during the cardiac cycle, purely following the pressure changes and blood flow path. Under normal circumstances, opening offers very little resistance to flow. The aortic sinuses have an important role during valve closure, as the volume of blood within the space between the opened valve cusp and the aortic wall develop vortices as blood velocity falls. These vortices exert central pressure and initiates valve closure. The sudden reversal of flow from deceleration completes the diastolic closure.

AORTIC STENOSIS

► Pathophysiology

The most common cause of aortic stenosis is senile calcific aortic stenosis. It is believed to represent degenerative changes at the cellular level, including lipid accumulation and inflammatory infiltrates, similar to atherosclerotic changes seen in the medium-sized arterial tree. Not surprisingly, it is associated with elevated cholesterol, hypertension, cigarette smoking, diabetes, and other risk factors for atherosclerosis. It is most common in the seventh and eighth decades of life and occurs in patients whose valves previously appeared normal. The cusps become progressively immobilized and calcified, starting at the flexion points and extending both along the leaflets and into the wall of the aortic root.

Congenital bicuspid aortic valve represents the most common congenital cardiac lesion, occurring in 2% of the general population. Turbulent flow across the valve causes trauma, leading to fibrosis and calcium deposition, further increasing turbulence, and accelerating the process. Significant stenosis typically occurs in the fifth and sixth decades of life, although they can present earlier. Patients with congenital bicuspid aortic valves often have dilation or aneurysmal degeneration of the ascending aorta. Some evidence suggests a genetic etiology, with the presence of abnormal microfibrils causing premature cystic medial necrosis.

Rheumatic heart disease can affect the aortic valve, although it is unusual for the disease to be limited to the aorta, with mitral involvement far more common. As with rheumatic mitral stenosis, fusion of the commissures tends to be the initial feature, followed by progressive thickening and retraction of the leaflets. The reduced leaflet mobility results in a clinical picture of combined aortic valve stenosis and insufficiency.

Aortic stenosis develops gradually, allowing adaptive changes to maintain cardiac output. The left ventricle gradually hypertrophies in response to the severity of the outflow tract obstruction, often resulting in pressure gradients exceeding 100 mm Hg. As a result, patients can remain asymptomatic until severely advanced disease is present. While concentric left ventricular hypertrophy maintains systolic function in the face of severe outflow obstruction, diastolic function of the thickened and noncompliant ventricle is progressively impaired. Diastolic dysfunction can be overcome to a certain degree with atrial hypertrophy and enhanced atrial kick. In addition, as left ventricular end diastolic pressure rises, intravascular volume status and peripheral vascular resistance adjust to maintain the required preload. Certain triggers can disrupt this delicate balance, including loss of atrial contribution from atrial fibrillation or reduced diastolic filling time from increased heart rate, as might be seen during exercise. These triggers can create sudden clinical decompensation, producing markedly reduced

cardiac output and pulmonary edema, even in a previously asymptomatic patient.

The most common clinical presentation in a patient with aortic stenosis is gradual decrease in exercise tolerance. The fixed outflow obstruction prevents an increase in stroke volume typically seen in exercise with elevated circulating catecholamines. Any change in cardiac output is limited to an increase in heart rate, decreasing diastolic filling time for the stiff and noncompliant ventricle. As a result, there is limited boost in cardiac output during exercise, producing premature exertional fatigue and dyspnea. Some patients describe angina, as myocardial oxygen demand exceeds supply. The hypertrophied heart consumes more oxygen without reciprocal increase in epicardial delivery. In addition, the outflow obstruction prolongs systole, further increasing oxygen demand. Symptoms are typically exertional, as the increased heart rate reduces diastolic coronary perfusion time. Syncope or presyncope is occasionally described in patients with aortic stenosis, presumably related to systemic vasodilation during exercise without a reciprocal increase in cardiac output. Advanced heart failure with symptoms at rest or with minimal activity suggest a decrease in systolic function, likely a result of longstanding disease with alterations within the myocardium at the cellular level.

► Diagnostic Evaluation

Physical examination of the patient reveals several findings specific for aortic stenosis. There is a characteristic systolic crescendo/decrescendo murmur heard best over the base of the heart and radiating up the carotid arteries. The murmur becomes harsher and peaks later in systole as the severity worsens. Palpation of the carotid pulses reveals *parvus et tardus*, or a late peaking and low-amplitude pulse. A palpable thrill may be felt over the right second intercostal space.

The electrocardiogram demonstrates left ventricular hypertrophy in the majority of patients. Conduction or rhythm abnormalities are identified in some patients. The chest radiograph typically is normal but may demonstrate dilation of the ascending aorta in patients with congenital bicuspid valve. Cardiac catheterization provides important information about associated cardiac pathology, particularly coronary occlusive disease. In addition, hemodynamic assessment can confirm the severity of the aortic valve stenosis and quantify the degree of pulmonary hypertension.

The standard evaluation of patients with suspected aortic stenosis is echocardiography. Images of the valve reveal the severity of the stiffness and calcifications. Images also differentiate bicuspid from tricuspid anatomy and identify associated dilation of the ascending aorta. Ventricular function and additional valvular pathology, particularly in patients with rheumatic heart disease, is essential. Doppler echocardiography can measure the velocity of the aortic jet,

allowing reliable estimates of the pressure gradients using the modified Bernoulli equation.

► Treatment

A. Medical Therapy

Because aortic stenosis can progress over 10-15 years, patients with mild to moderate disease and without symptoms can be followed without intervention. Serial echocardiography should be performed annually or every other year to assess for disease progression. The most important aspect of medical therapy is education of the patient about potential symptoms. Since symptoms can develop gradually, many patients will unconsciously alter their lifestyles and activity levels without recognizing the presence of limitations. Although there is some suggestion that cholesterol reduction with statins can reduce the calcifications, there is little evidence that medications can adequately palliate the symptomatic patient or can alter the timing of surgical intervention in asymptomatic patients.

B. Indications for Surgery

The indications for surgery on the stenotic aortic valve have been largely determined by the presence of symptoms. Numerous studies have demonstrated reasonably good prognosis in asymptomatic patients managed without surgery. However, symptoms may be equivocal, particularly in the elderly population. Exercise stress testing under the observation of a physician can help elucidate significant limitations that may not be apparent by merely questioning the patient. Surgery is also indicated for patients with moderate to severe aortic stenosis who are undergoing cardiac surgery for other indications, such as coronary bypass grafting or mitral valve replacement.

Handling of the asymptomatic patient with severe aortic stenosis is under some controversy. The severity of aortic stenosis can be quantified using Doppler echocardiography to estimate the pressure gradient across the aortic valve using the velocity of the outflow jet and the modified Bernoulli equation. Severe aortic stenosis is present when the mean gradient exceeds 40 mm Hg in the normal ventricle. Although some have described an increase in the rate of sudden death in patients with severe aortic stenosis, there remains no evidence to justify aortic valve replacement in the absence of symptoms.

AORTIC INSUFFICIENCY

► Pathophysiology

Several conditions can cause incompetence of the aortic valve. Any of the disease processes that cause aortic stenosis can also cause some degree of aortic valve insufficiency, including senile calcific aortic stenosis, degenerated bicus-

pid aortic valve, and rheumatic aortic valve disease. Aortic valve endocarditis is another common cause of aortic valve insufficiency. The most common cause of incompetence of the aortic valve is related to pathology within the aortic root and ascending aorta. Aneurysmal dilation of the ascending aorta, either from congenital conditions such as Marfan disease, from degenerative age-related changes, or from changes associated with a bicuspid aortic valve, can cause aortic valve insufficiency. As the wall of the aorta enlarges, the aortic valve annulus dilates and the leaflets separate, causing incompetence.

As with mitral valve regurgitation, aortic valve insufficiency is best tolerated when it occurs gradually. As the volume of regurgitation worsens, the ventricle adapts by dilating to accommodate the increased preload, and it hypertrophies to maintain the same level of systolic pressure at larger volumes. Despite progressive dilation, ventricular output and systolic function are maintained for long periods of time, leaving many patients asymptomatic for years. While end diastolic volume is elevated, end systolic volume is normal. With severe degrees of chronic aortic insufficiency, the heart can require ejecting as much as two to three times the circulating cardiac output, resulting in longstanding volume overload. Eventually, systolic function declines, resulting in a rapid and progressive rise in end diastolic volume, and heart failure symptoms ensue.

Most patients with chronic aortic insufficiency do not develop symptoms of heart failure until there is severe left ventricular dilation. Some patients describe palpitations or the sensation of ventricular heave, particularly when lying down. Acute aortic valve insufficiency, as can occur with aortic valve endocarditis, can present with cardiogenic shock because the relatively noncompliant ventricle is unprepared for the excess volume during both systole and diastole. There is a combination of high intracardiac filling pressures and low cardiac output. Patients are tachycardic and hypotensive as well as acutely dyspneic at rest. The patient with endocarditis may also be febrile with signs of embolization of vegetations, causing stroke, or extremity or intestinal ischemia.

► Diagnostic Testing

Certain characteristic physical examination findings are pathognomonic for chronic aortic valve insufficiency. The water-hammer pulse can be appreciated, with accentuated systole and abrupt collapse. Patients may have a head bob with each heart beat, or a pulse may be seen in the uvula. A systolic thrill is also described over the femoral artery from the augmented forward flow. The apical impulse is displaced laterally and inferiorly from cardiomegaly, and diastolic blood pressure is low. Auscultation will reveal a high-pitched diastolic murmur heard immediately after the second heart sound. The severity of the valvular lesion usually correlates with the duration of the murmur, not the intensity. The

murmur is best heard with the patient leaning forward during a breath hold.

Echocardiography will establish the etiology of the aortic valve insufficiency, visualizing the motion of the leaflets and dilation of the aorta or the presence of vegetations or leaflet perforations. In addition, the ventricular size can be followed, as elevated end systolic volumes or reduced ejection fraction are indications for surgery. Reversal of flow seen in the descending aorta is a sign of severe aortic valve insufficiency. More sophisticated techniques can quantify the regurgitant volume, such as evaluating the regurgitant jet velocity/time integral.

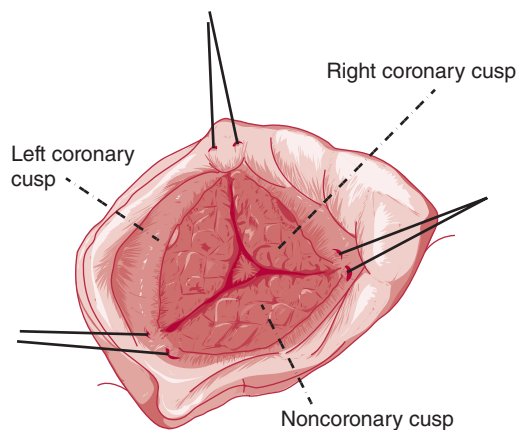

► Treatment

For asymptomatic patients with moderate aortic insufficiency and normal ventricular dimensions, no treatment is necessary. Patients with severe aortic valve insufficiency and normal ventricular size should be followed every 6 months with assessment of symptoms and echocardiography. Some advocate the use of afterload reduction agents to reduce the volume of regurgitant blood, but no evidence demonstrates reduced need for surgery. Symptomatic patients who are not candidates for surgery should be treated with afterload reduction agents, such as calcium channel blockers or inhibitors of angiotensin-converting enzyme. Diuretics and salt restrictions may help in alleviating heart failure symptoms.

For operative candidates, development of heart failure symptoms is an indication for surgery. Asymptomatic patients with decreased left ventricular systolic function or elevated left ventricular end systolic volumes should also undergo operative treatment. Because ventricular dilation is associated with irreversible changes at the cellular level, intervention is best performed before these permanent changes occur.

► Surgical Techniques

As with most other cardiac surgical procedures, median sternotomy is the standard incision utilized for access to the aortic valve. The pericardium is opened longitudinally, and the reflection is mobilized off of the great vessels. The pulmonary artery and aorta are separated as they emanate from the heart, taking care to avoid injury to the takeoff of the right pulmonary artery or the left main coronary artery. The patient is anticoagulated with 300 IU heparin, and an activated clotting time of at least 400 seconds is confirmed. Cannulation for CPB is performed, using the distal ascending aorta or the transverse aortic arch to maximize the distance between the aortic cross-clamp and the aortotomy. Venous return is via the right atrial appendage. CPB is initiated, and the left ventricle is vented via a catheter advanced from the right superior pulmonary vein. The patient is cooled systemically to 32°C. An aortic cross-clamp is applied to the distal ascending aorta just proximal to the CPB cannula. The heart is arrested with cold blood cardioplegia

▲ **Figure 19-14.** Surgeon's view of the stenotic trileaflet aortic valve. (From Cohn LH: *Cardiac Surgery in the Adult*, 3rd ed. McGraw-Hill, 2007.)

solution with dextrose, phosphate, and potassium at 8°C. The cardioplegia is delivered antegrade down the coronary arteries using a catheter in the aortic root. Cardioplegia solution is also delivered retrograde via a balloon-tipped catheter in the coronary sinus. If severe aortic valve insufficiency is present, only retrograde cardioplegia can be delivered. Once diastolic cardiac arrest is achieved, the ascending aorta is opened transversely approximately 1-2 cm above the takeoff of the right coronary artery. The aortotomy is extended two-thirds of the circumference of the aorta, providing excellent visualization of the valve, the coronary ostia, and the ventricular outflow tract (Figure 19-14).

Excision of the stenotic aortic valve can be time consuming and requires meticulous attention to detail. The extensive calcifications can extend deep into the annulus and up the wall of the aortic root or down along the anterior leaflet of the mitral valve. The calcium buildup must be debrided aggressively enough to allow proper seating of the valve prosthesis without a paravalvular leak while avoiding residual outflow tract obstruction. However, overaggressive debridement can result in perforations of the aortic wall, ventricular septal defect, or unhinging of the mitral leaflet with resultant severe mitral regurgitation. In cases of endocarditis, any granulation tissue or residual vegetations must be removed and debrided to avoid recurrent infection of the implanted prosthetic. The outflow tract and aortic root is thoroughly irrigated to ensure removal of loose deposits and debris.

Once the native valve has been removed and the annulus satisfactorily debrided, the outflow tract is sized using tools provided by each manufacturer of valve prostheses. The appropriately sized valve is selected and secured in place. Mechanical valve prosthetics are implanted using a pledgetted mattress technique, leaving the pledgets on the aortic side. This eliminates the likelihood of the bulky pledgets interfering with

the disk mechanisms on the ventricular surface. Alternatively, if a bioprosthetic valve is selected, the pledgets can be oriented on the ventricular side of the annulus. This allows supra-annular seating of the bioprosthetic and implantation of a slightly larger valve. The sutures are then placed through the sewing cuff of the prosthetic, and the valve is lowered into the surgical field. The sutures are tied, ensuring that the valve has seated properly to the annulus. The ostia of the coronary arteries should be inspected and clearly free of impingement by the prosthetic valve. The aortotomy is then closed with running polypropylene suture, occasionally reinforced with Teflon felt in the older patient with a thin aortic wall.

The patient is then gradually weaned from CPB, thoroughly deairing with gentle suction applied using the left ventricular vent and the aortic root catheter. Using the transesophageal echocardiogram, the valve is carefully inspected for competency and adequacy of the size. There should be no paravalvular leak, and the gradients across the valve should be low. Elevated pulmonary artery pressures or reduced cardiac output should alert the surgeon of the possibility of an unrecognized paravalvular leak.

Aortic valve endocarditis also poses unique surgical challenges. The infective process often results in abscess formation and occasionally intracardiac fistulas. The most important first step in addressing these problems is aggressive debridement of infected and devitalized tissue. Not only will residual infection colonize the implanted prosthetic but inadequate debridement with securing of the prosthetic to infected and devitalized tissue will lead to dehiscence with

need for early reoperation. Abscesses are common within the intervalvular fibrous body. The annular defect should be covered with a pericardial patch. Often, the entire root requires excision, requiring replacement with a valved conduit and reimplantation of the coronary ostia. Results for endocarditis are dependent on the clinical status of the patient at the time of surgery as well as the etiology of the infection. Intravenous drug users carry the worst prognosis, in large part related to recurrence of their addiction with subsequent reinfection.

TRANSCATHETER AORTIC VALVE REPLACEMENT

Recently, aortic valve replacement has been approached without sternotomy using endovascular techniques. Bioprosthetic valves of bovine or porcine pericardium are crimped and loaded onto a metallic frame (Figure 19–15). A 18–24 French delivery system can be inserted via the femoral vessels and expanded at the level of the left ventricular outflow tract either by balloon or using self-expanding titanium alloys. The native aortic valve is displaced by the prosthetic rather than removed as is done in surgical aortic valve replacement. The procedure can often be performed under local anesthesia, dramatically reducing perioperative morbidity. Current indications for this approach are patients with severe aortic stenosis and either prohibitive surgical risk or as an alternative to surgery in higher risk patients (estimated perioperative mortality of 15%). While the femoral access route is most frequently utilized, some

patients with small peripheral vessels or extensive atherosclerotic disease may not accommodate the large size delivery systems. Alternative approaches include the iliac artery, axillary artery, ascending aorta, and the left ventricular apex. The latter two require mini-thoracotomies for exposure. Paravalvular leaks are common, with moderate to severe regurgitation occurring in 10%-15% of patients. Long-term survival is diminished in patients with significant aortic insufficiency. Stroke represents a concern as the large catheters traverse the aortic arch and the calcified aortic valve is dilated, hazarding cerebral embolization. When directly compared to surgery in high risk patients, the risk of neurologic event was twice as high with transcatheter aortic valve replacement (TAVR) (5.5% vs 2.4%). This risk may be justified in the context of an overall reduction in perioperative mortality for TAVR as compared to surgical aortic valve replacement in these high risk patients (3.4% vs 6.5%). While TAVR appears to be efficacious for high risk patients with severe aortic stenosis, it remains unclear if this approach will expand to a lower risk population.

THORACIC AORTA

The ascending aorta represents a continuation of the aortic root at the sinotubular junction. The aortic arch extends from the ascending aorta, traveling posteriorly and to the left as it gives off the three “head vessels” superiorly: the innominate, left carotid, and left subclavian arteries. The thoracic aorta continues from the aortic arch into the descending thoracic aorta beyond the left subclavian artery. The descending thoracic aorta continues until the level of the diaphragm, where it becomes the abdominal aorta. The only branches originating from the descending thoracic aorta are the bronchial and esophageal arteries and multiple intercostal vessels that contribute important sources of blood flow to the spinal cord.

Some common variants are seen in the branch pattern of the thoracic aorta. The most common is the “bovine arch” in which the left carotid originates from the innominate artery. An aberrant right subclavian artery originates from the distal aortic arch on the lesser curvature and travels posterior to the esophagus from left to right. It has been associated with unusual causes of dysphagia from mechanical compression of the esophagus. Other abnormal variants of the aortic arch include a right-sided arch and double ligamentum arteriosum, which can cause tracheal or esophageal compression early in life and are discussed in the second part of this chapter, Congenital Heart Disease.

THORACIC AORTIC ANEURYSMS

► Pathophysiology

During systole, kinetic energy imparted by ventricular ejection is absorbed in the compliance of the aorta, resulting in transient expansion and recoil. The amount of energy absorption is proportional to the proximity to the left ventricle. As such, the ascending, descending, and abdominal aorta have different cellular features to accommodate their unique fluid-mechanical environments. Elastin fiber content is typically higher in the ascending aorta. These fibers are synthesized and degraded continuously by the smooth muscle cells, and a progressive fragmentation of these fibers is associated with aging, which is the reason for gradual dilation of the ascending aorta in the elderly. However, certain acquired conditions can accelerate the process, producing the pathologically enlarged aorta resulting in aneurysms. Aortic atherosclerosis is associated with aneurysm formation, predominantly in the descending thoracic aorta. The inflammatory process extends from the intima to the media, causing elastin fiber breakdown. Cystic medial degeneration is the end result of any of the acquired degenerative processes, resulting in elastin fiber fragmentation and loss of smooth muscle cells. The weakened aortic media progressively dilates and can become prone to rupture or dissection. Infection, inflammatory conditions, and trauma can also cause localized medial degeneration and aneurysm formation.

Certain heritable conditions are also associated with aneurysmal disease of the thoracic aorta. Most notable is Marfan syndrome, an autosomal dominant abnormality of fibrillin, an important component in elastin. Patients with Marfan syndrome present with aneurysmal degeneration of the thoracic aorta at any level, most notably in the ascending aorta, in the second and third decades of life. Patients with bicuspid aortic valves are prone to develop aneurysms of the ascending aorta, likely related to abnormalities of their aortic smooth muscle.

The natural history of unresected thoracic aortic aneurysms is dependent on the size and the etiology. The larger the aneurysm, the greater the wall tension and thus the risk of rupture or dissection. Beyond 5.5 cm in maximal diameter, there is a significant increase in the risk of rupture, dissection, or death. Although it varies with age and etiology, there is a reasonably predictable growth rate, estimated at approximately 0.1-0.2 cm per year. Marfan syndrome and other genetic causes of thoracic aortic pathology tend to have a higher likelihood of rupture at smaller aneurysm sizes, and the growth rate is faster than in acquired thoracic aneurysms.

Most patients with thoracic aortic aneurysms are asymptomatic. The diagnosis is often established on screening chest radiograph, CT, or echocardiography performed for other indications. Occasionally, patients with unrup-

▲ **Figure 19–16.** CT scan of a dilated ascending aorta.

tured aneurysms describe chest pain presumably related to rapid enlargement or encroachment on adjacent structures. Unfortunately, many patients are not diagnosed with a thoracic aortic aneurysm until the time of rupture or dissection. Rupture of ascending aneurysms typically presents with crushing chest pain, whereas descending aneurysms cause tearing back or flank pain.

► Diagnostic Testing

In a patient presenting with a thoracic aneurysm without rupture, the physical examination is typically unremarkable. Chest radiograph may demonstrate a widened mediastinum. The electrocardiogram is helpful only for associated cardiac pathology. An echocardiogram demonstrates enlargement of the ascending aorta or descending aorta. The aortic arch is typically obscured from view by the trachea and the lungs.

Contrast-enhanced CT scanning is the most widely used test for aneurysms of the thoracic aorta (Figure 19–16). The CT scan can diagnose the aneurysm and accurately describe its size and extent, can be used for direct comparison for patients managed expectantly, and can differentiate isolated aneurysmal disease from an aortic dissection. Three-dimensional reconstruction is helpful in accurately assessing size and location of branch vessels. The limitation of CT scanning is the need for intravenous iodinated contrast, with its inherent nephrotoxic properties.

MRI provides quality resolution similar to CT scanning but can provide dynamic imaging for cardiac assessment and does not require iodinated contrast material. MRI, however,

is more time consuming and less available in many centers. Cardiac catheterization and aortography are performed only in planning operative intervention to exclude coronary artery disease or pulmonary hypertension.

► Surgical Therapy

The most frequent indication for operation on the aneurysmal ascending aorta is incidental to other cardiac pathology. It is generally agreed that an asymptomatic ascending aorta greater than 4.5–5 cm in size should be replaced at the time of aortic valve replacement or coronary bypass surgery, assuming the risk of the procedure would not be significantly altered. Any patient with a symptomatic ascending aneurysm should receive urgent surgery, although it is unusual for patients with ruptured ascending aortas to survive long enough to be given this opportunity. For asymptomatic patients without associated cardiac pathology, the indication for surgery is when the maximal diameter of the ascending aorta is greater than 5.5 cm. For patients with Marfan syndrome, surgery is indicated for lesser degrees of dilation. Additionally, for patients followed with serial CT scans, interval enlargement of the ascending aorta by a least 1 cm warrants consideration for surgical resection.

Sudden rupture or dissection is less frequent in the descending aorta, and thus the indications for operation are less stringent. In general, operation should be considered when the aneurysm reaches 6 cm in maximal diameter or if there is interval enlargement by at least 1 cm over 1 year. Patients with Marfan syndrome require surgery at smaller aortic sizes to prevent catastrophic complications. Increasingly, the descending thoracic aorta is treated using endovascular techniques. Balloon or self expanding stents are covered with vascular grafts and inserted via peripheral vessels and deployed creating a seal at the proximal and distal extent of the descending thoracic aneurysm, the so called “landing zones.” Although the aneurysm is not removed, pressurized blood is excluded from the sac, eliminating the risk of rupture (Figure 19–17). Because the procedure does not require thoracotomy and aortic clamping, morbidity is substantially lower. However, endoleaks are frequent, in which there is failure to completely exclude blood flow into the aneurysm sac. These endoleaks may result in late aneurysm related complications. Endovascular treatment of descending thoracic aneurysm continues to evolve with experience and refinement of technology.

Medical treatment of small ascending or descending aneurysms involves aggressive blood pressure control using beta-blocking agents to reduce the forceful contraction against the weakened aortic wall, activity restriction to avoid straining, cessation of cigarette smoking, and weight loss. Patients followed with ascending or descending aortic aneurysms should receive repeat imaging for signs of interval growth prompting surgical intervention.

AORTIC DISSECTION

► Pathophysiology

Dissection of the thoracic aorta is among the most feared entities in all of medicine because of the exceedingly high mortality and the speed with which its injuries become irreversible. An intimal tear of the aorta allows blood flow to exit the lumen and travel a variable distance within the media. Depending on the location of the intimal tear and the direction in which blood travels, aortic dissections can be categorized using two prominent classification schemes. The DeBakey classification describes the location and the extent, whereas the more simplified Stanford classification looks at location alone. A Stanford type A dissection involves the ascending aorta; a Stanford type B involves the arch or descending aorta (Figure 19-18).

The precise etiology of aortic dissections is unclear, but there is an unambiguous association with a variety of conditions, including aortic aneurysms, hypertension, smoking, pregnancy, and recent intravascular trauma. Once blood enters the medial plane, the intima “floats” within the aortic lumen and has a characteristic appearance on CT scans (Figure 19-19). The blood within the false lumen reenters the true lumen through any number of naturally created fenestrations or holes, either from disruption of the side branches or from reentry at the termination of the false lumen. Blood flow to any of the side branches off of the aorta can be com-

promised by the intimal flap, causing ischemia, a condition referred to as malperfusion. Malperfusion can involve the coronary arteries, branches of the aortic arch to the brain, the renal arteries, the mesenteric arteries, or branches to the

▲ **Figure 19-18.** DeBakey and Stanford Classifications of aortic dissection. DeBakey types I and II represent Stanford type A, whereas DeBakey type III is the same as a Stanford type B.

▲ **Figure 19–19.** CT scan of an acute aortic dissection. This Stanford type A dissection involves both the ascending and descending aortae. The large false lumen is nearly obstructing the true lumen.

lower extremities or the spinal cord. Blood can also exit the false lumen pathway into the adventitial space, causing free rupture. Rupture is more likely in Stanford type A dissections because of the intrapericardial location of the ascending aorta and the increased mechanical forces related to the proximity to the left ventricular outflow tract. Type B dissections in the descending aorta do not experience the same mechanical forces, because the more proximal aorta absorbs a significant amount of the kinetic energy. In addition, the extrapleural tissue helps reinforce the weakened adventitia, containing potential ruptures.

In addition to the free intrapericardial rupture of type A dissections, there are two other modes of early death responsible for the nearly 50% mortality associated with type A dissections. Malperfusion of the coronary ostia, typically the right coronary artery, causes acute myocardial infarction resulting in ventricular arrhythmias and myocardial dysfunction with shock. In addition, proximal migration of the dissection flap can disrupt the attachments of the aortic valve to the wall of the aortic root. The unsupported valve tissue prolapses into the ventricle during diastole, producing massive aortic valve insufficiency.

Patients with aortic dissections complain of tearing back pain or crushing chest pain. They are often hypertensive and tachycardic. The diagnosis can often be confused with acute myocardial infarction, ureterolithiasis, cholelithiasis, or pancreatitis. Patients with malperfusion can present with flank

or abdominal pain from renal or mesenteric ischemia, lower extremity pain or paresthesias from iliac occlusion, stroke from carotid occlusion, or acute paralysis from occlusion of the multiple branches to the spinal cord. These symptoms of malperfusion can often overwhelm the chest or back pain from the dissection, clouding the diagnostic evaluation. Delay in diagnosis is exceedingly common in acute aortic dissection.

► Diagnostic Testing

On physical examination, patients appear acutely ill and are tachycardic and hypertensive. Hypotension should warrant suspicion of pericardial tamponade, myocardial infarction, aortic valve insufficiency, or free rupture. Blood pressure should be assessed in all four extremities to document perfusion abnormalities from the dissection flap. Abdominal pain should prompt evaluation of possible mesenteric or renal malperfusion. Neurologic deficits suggest either cerebral embolization or spinal ischemia.

Chest radiographs are often performed as the initial diagnostic test. They may reveal widening of the mediastinum, a left pleural effusion, or cardiomegaly if pericardial tamponade is present. CT is the standard imaging modality used to diagnose aortic dissection and should be obtained promptly in a patient with new-onset tearing back or chest pain. The CT scan diagnoses the dissection and identifies associated aneurysmal disease as well as organs at risk for malperfusion. Transesophageal echocardiography has a critical role in patients with aortic dissection. TEE excludes involvement of the ascending aorta in cases that are equivocal on CT scan. In addition, TEE identifies cardiac dysfunction and, most importantly, aortic valve insufficiency from extension of the dissection into the aortic root.

► Treatment

A. Medical Therapy

Initial management of the patient with an acute aortic dissection is immediate control of elevated blood pressure. Narcotic agents can be given initially to control pain and reduce the catecholamine surge. Beta-blocking agents are particularly critical not only to reduce blood pressure but also to lower the force of contraction and the sheer stress directly impacting the weakened aortic tissue. Esmolol is a short-acting agent that can be administered as a continuous infusion to obtain fine control of blood pressure, avoiding excessive bradycardia or hypotension. If high blood pressure persists, an arterial vasodilator can be given, such as nitroprusside, with a goal of maintaining systolic blood pressure of 100–120 mm Hg.

Patients with type B aortic dissections are frequently treated with medical therapy only, consisting of pain and blood pressure control, as well as observation for signs of malperfusion or rupture. Most patients with type B dissections can be safely discharged from the hospital once blood

pressure control is adequate and the pain has resolved. They are carefully followed for good antihypertensive control as well as surveillance CT scanning to assess for interval growth in the size of the descending aorta. The indications for operative intervention in an acute type B aortic dissection is ongoing chest pain despite adequate blood pressure control, aneurysmal enlargement of the descending aorta greater than 6 cm, or evidence of impending rupture on CT scanning.

B. Surgical Therapy

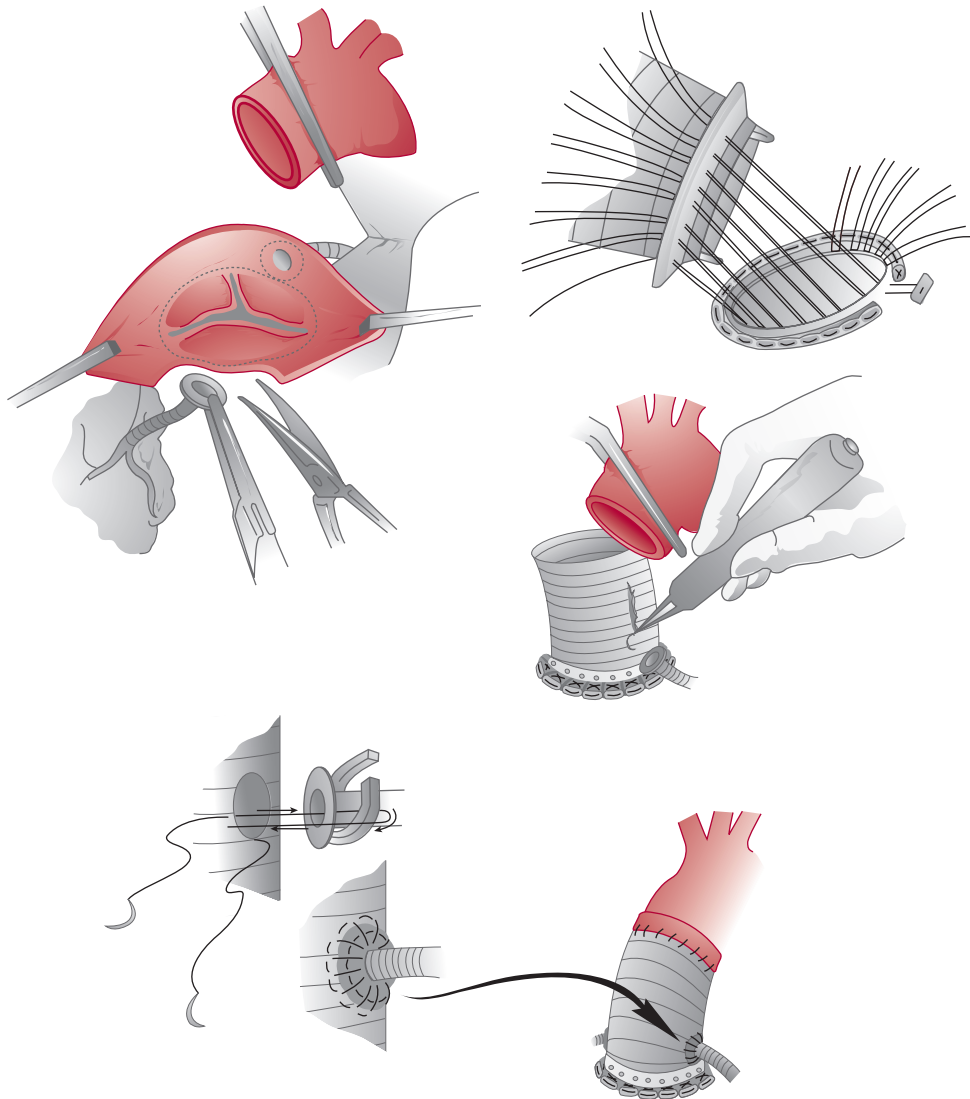

1. Indications—Patients with type A aortic dissections should undergo emergency surgery to avoid one of the three fatal complications associated with 95% of patients with untreated dissections. These complications include intrapericardial rupture with tamponade, aortic valve insufficiency, or acute myocardial infarction. Once the diagnosis of a type A dissection has been established, either by CT scan or TEE, the patient should be taken emergently to the operating room in preparation for emergency surgery. The only exception to immediate emergency surgery is when signs of malperfusion of the abdominal viscera exist. Although this strategy remains controversial, some advocate angiographic investigation for signs of malperfusion. Using a combination of contrast fluoroscopy, intravascular ultrasound, and selective cannulation of all branches from the aorta with pressure measurements, the extent of the dissection can be evaluated and areas of definite malperfusion can be identified. If the intimal flap is obstructing blood flow to any of the aortic branches, fenestration using balloon catheters can restore flow from the false to the true lumen, reperfusing ischemic organs. While patients with severe visceral malperfusion can have mortality rates of nearly 80%, more recent series adopting a strategy of initial catheter-based fenestration followed by surgical repair show estimated mortality rates in selected patients of less than 20%. Since catheter-based techniques are becoming more universally available, this strategy of delayed surgical repair may become more widespread.

2. Techniques—Once a patient with a type A dissection has been diagnosed, emergency surgery is usually indicated. The femoral or axillary artery is exposed for arterial cannulation for CPB. A median sternotomy is performed, exposing the dilated and dissected ascending aorta. After administration of 300 IU/kg of heparin, the patient is cannulated for CPB, using the right atrium for venous drainage. The patient is cooled aggressively to 18°C in preparation for hypothermic circulatory arrest. A catheter is placed in the coronary sinus to deliver retrograde cardioplegia for myocardial protection. A left ventricular vent is placed in the right superior pulmonary vein. Once the core body temperature has reached 18°C, CPB is discontinued, and the ascending aorta can be opened. The dissected aorta is

removed, typically extending along the lesser curvature of the aortic arch. The remaining arch is carefully inspected for additional intimal tears. An appropriately sized and spatulated Dacron graft is anastomosed to the aortic arch using running polypropylene suture buttressed with Teflon felt. CPB can be reinstated, flushing air and debris out of the open anastomosis. The aortic cross-clamp can then be applied to the graft material. The proximal ascending aorta is resected to the sinotubular junction, and the Dacron graft is trimmed to size. The proximal anastomosis is performed in a similar fashion using running polypropylene suture buttressed with felt. A deairing needle is placed in the graft, and the aortic cross-clamp is removed. The patient is rewarmed and weaned from CPB.

Occasionally, the pathology extends proximally into the aortic root, requiring reconstruction or resection. If the root is not significantly enlarged, the dissection flap can be obliterated by inserting Teflon felt into the false lumen and reapproximating the intima to the adventitia using polypropylene suture. The aortic valve commissures can be resuspended to the aortic wall with pledgeted sutures from intima to adventitia. If the aortic root is dilated, the sinuses and valve tissue can be excised and replaced with a mechanical valve conduit, reattaching the coronary ostia using the Bentall technique (Figure 19–20). Under certain scenarios, the entire aortic arch must be removed and replaced with Dacron graft material. When the aortic arch is significantly aneurysmal, if the intimal tear is within the aortic arch, or in a patient with Marfan syndrome, the entire arch should be replaced. Each branch of the arch can be individually reimplemented to the graft, the three vessels can be attached as an island, or a multibranch graft of Dacron with side branches preattached can be anastomosed to the individual arch branches. When the arch is reconstructed, a longer duration of hypothermic circulatory arrest will be required. Cerebral perfusion can be initiated using balloon-tipped catheters inserted directly into the innominate and left carotid arteries. Blood flow at a rate of 600 cc/min at 18°C is generally considered adequate to prevent neurologic compromise.

3. Results—As previously described, the mortality of acute aortic dissection may be as high as 50%, since many patients will rupture before arrival at a qualified hospital. Operative mortality is in the range of 10%-20%, which includes consideration of the selection bias of choosing operative candidates. Cause of death is primarily related to malperfusion syndrome, resulting in neurologic, intestinal, or extremity ischemia. Cerebral injury related to hypothermic circulatory arrest is limited and should result in clinically significant stroke in less than 5% of patients. Long-term survival following repair of acute aortic dissection is good, approximately 50%-60% at 10 years.

SURGICAL TREATMENT OF HEART FAILURE

HEART TRANSPLANTATION

► Indications

The incidence of congestive heart failure (CHF) is steadily rising, owing to the increase in the aging population and the reduced mortality of myocardial infarction. Nearly 5 million

Americans live with heart failure, and 500,000 new cases are diagnosed annually. Causes are multifactorial, but by far the most frequent etiology is related to coronary occlusive disease, with repeated ischemic insults and loss of viable myocardial contractility. Chronic ventricular volume overload from conditions such as undiagnosed valvular pathology or intracardiac septal defects can result in cardiomyopathy and advanced heart failure. Other causes of heart failure include viral myocarditis, peripartum cardiomyopathy, and idiopathic dilated cardiomyopathy.

All of these processes lead to the same result: loss of myocardial contractility with decreased cardiac output, elevated diastolic cardiac filling pressures, and pathologic neurohormonal adaptive responses. This leads to increased sympathetic tone, elevated peripheral vascular resistance, and salt and water retention, creating a vicious cycle with further reduction in cardiac output, edema, and pulmonary congestion.

Medical therapy includes reduction in salt intake and modest exercise to reduce sympathetic activation. Diuretics and aldosterone inhibitors counteract the inappropriately activated renin-angiotensin system. Angiotensin-converting enzyme inhibitors decrease peripheral vascular resistance and alter the myocardial intercellular matrix, allowing opportunities for reverse cardiac remodeling. The inotropic properties of digitalis glycosides have been demonstrated to reduce hospital admission for heart failure exacerbations, although at higher levels can increase mortality because of its proarrhythmic properties. Beta-blocking agents reduce sympathetic tone, allow upregulation of beta-receptors, and significantly reduce mortality in advanced heart failure patients. As the left ventricle dilates, electrical reentry pathways are generated, predisposing to malignant ventricular arrhythmias and sudden cardiac death. Strong evidence now demonstrates that implantation of automated internal cardiac defibrillators reduces mortality, and their use has become standard practice in heart failure management. In addition, selected patients with conduction system disturbances may benefit from cardiac resynchronization therapy by insertion of biventricular pacemakers that stimulate both the left and right ventricles simultaneously.

The effectiveness of medical therapy is often described by the New York Heart Association (NYHA) classification (Table 19-3). As a patient's NYHA functional class deteriorates despite adequate medical therapy, consideration for transplantation should be made. Because heart transplantation remains a scarce resource, selection of patients is crucial to maximize outcomes. Exclusion criteria have been established on the basis of solid evidence of increased perioperative or reduced long-term survival; criteria are listed in Table 19-4. The most frequently applied exclusion criteria include advanced age, end-organ injury from diabetes mellitus, chronic renal insufficiency (serum creatinine > 2.5), poor medical compliance or psychosocial instability, and morbid obesity (body mass index > 35).

Table 19-3. New York Heart Association classification of heart failure symptoms.

I	No limitations
II	Dyspnea with ordinary activity
III	Dyspnea with less than ordinary activity
IV	Dyspnea

Creation of concrete inclusion criteria has been more elusive because it is often difficult to predict mortality in this population. Historically, patient selection has relied on exercise stress evaluation and determination of maximal oxygen consumption (VO_2 max). Patients with a VO_2 max of less than 10 mL/kg/min have a definite survival advantage with transplantation, and those with a peak VO_2 of less than 14 mL/kg/min with NYHA class III or IV limitations appear to have a survival advantage. Recently, several scoring models have allowed more accurate risk stratification of mortality for ambulatory patients with advanced heart failure. These models have proven helpful for those patients in whom exercise testing appears intermediate in risk assessment, such as those with peak VO_2 between 10 and 14 mL/kg/min. The Heart Failure Survival Score (HFSS) uses seven independent predictors of mortality and creates high-, medium-, and low-risk groups for 1-year mortality. These variables include peak VO_2 , QRS interval, ejection fraction, serum sodium, resting heart rate, ischemic versus nonischemic etiology, and mean blood pressure. Patients with intermediate peak VO_2 scores should be considered for transplantation if scoring models such as the HFSS predict high or medium risk for mortality.

Heart transplants are allocated according to a protocol prioritizing based on need and geographic distribution. Patients are assigned within a classification system as listed in Table 19-5. Status 1A patients receive the highest priority, as they require mechanical circulatory support with a device that will not allow discharge from the hospital, are supported by a device that is failing, or require infusion of inotropic agents at high doses and require pulmonary artery

Medication noncompliance

catheters to continuously monitor intracardiac filling pressures. Patients are assigned status 1B if they are supported with implantable circulatory support devices that allow ambulatory support or if they require continuous inotropic infusions at modest doses and do not require pulmonary artery catheters. Patients are considered status 2 if they do not require inotropes or mechanical circulatory support. Patients are designated status 7 if they are temporarily unsuited for a transplant. Organs are allocated with a complex algorithm that considers patient status, size, blood type compatibility, and geography.

► Technique

Patients are briefly evaluated to ensure that there have been no interval changes in their health status since their transplant evaluation. In particular, anticoagulation status is assessed and reversed if necessary, renal function should be reasonably stable, and a pulmonary artery catheter should be inserted to ensure that pulmonary vascular resistance has not changed appreciably since the most recent evaluation. Potential concerns should be discussed between the transplant surgeon and heart failure cardiologist.

Upon confirmation by the procuring team that the donor heart is visibly suitable, the recipient is anesthetized and prepared. A median sternotomy is performed. In the current era, the majority of recipients have undergone previous cardiac surgery, often including insertion of ventricular assist devices. As such, significant time may be required for dissection and identification of cardiac structures, and appropriate time should be allowed. The patient is heparinized to achieve an activated clotting time of at least 450 seconds. Arterial cannulation is preferred high on the lesser curvature of the aortic arch to allow for significant aortic removal, particu-

larly if the recipient has a ventricular assist device. Venous cannulation is in the superior and inferior vena cavae, and CPB is initiated. The cavae are controlled with snares, and an aortic cross-clamp is applied when the donor heart is within 20-30 minutes of arrival. Recipient cardiectomy is performed initially along the right atrioventricular groove and extending down into the coronary sinus. The aorta is transected just above the coronary arteries, avoiding entry into the dome of the left atrium or injury to the right pulmonary artery. The pulmonary artery is transected at the level of the pulmonary valve. The interatrial septum is opened, and the left atrium is divided along the mitral valve annulus. Once the recipient heart is removed, the left atrium is trimmed, removing the appendage and a portion of the interatrial septum.

The donor heart is carefully inspected for abnormalities, including a patent foramen ovale. The atrial cuff is trimmed to size-match the recipient. The left atrial anastomosis is performed with polypropylene in running fashion, everting the edges to minimize incorporation of epicardial tissue within the atria. Before completion of the anastomosis, the left ventricular vent is inserted via the right superior pulmonary vein through the mitral valve. This facilitates deairing and prevents premature rewarming from pulmonary effluent. The donor and recipient ascending aortas are trimmed appropriately, and the anastomosis is performed with running polypropylene suture. At the completion of this suture line, the aortic cross-clamp can be removed, thus terminating the period of cold ischemia. The ascending aorta and left ventricle are vented of residual air. Spontaneous resumption of cardiac activity typically occurs. The inferior vena cava anastomosis is completed with running polypropylene suture. A flexible cardiectomy suction catheter is placed through the donor superior vena cava and advanced into the coronary sinus to improve visualization. The superior vena cava is anastomosed with running polypropylene suture, and the caval snares can be removed. The pulmonary artery anastomosis is performed with running polypropylene, typically imbricating the posterior wall for greater strength. Care must be taken to avoid excess length and potential kinking of the pulmonary artery. The technique just described is for a *bicaval* implant. With a *biatrial* technique, the recipient cardiectomy preserves the superior and inferior vena caval attachments, instead creating an atriotomy along the lateral wall of the right atrium. The donor superior vena cava is ligated, and an incision in the inferior vena cava is extended several centimeters along the posterolateral atrial wall. This older approach is technically easier but is associated with more tricuspid valve regurgitation and atrial arrhythmias, and thus less desirable.

The patient is rewarmed, ventilated, and then weaned off of CPB. If sinus rhythm is less than 100-110 beats/min, atrial pacing is initiated. Inotropic support is typically required in light of the cold ischemic time, even for young and vigorous donor hearts. Right ventricular dysfunction is the most

Table 19-5. United network for organ sharing listing status for heart transplantation.

Listing Status	Clinical Criteria
1A	Dependent on extracorporeal membrane oxygenation, intra-aortic balloon pump, total artificial heart, mechanical ventilation, or ventricular assist device with evidence of device malfunction or device-related complications Dependent on 2 inotropic infusions or 1 high-dose inotrope (7.5 mcg/kg/min dobutamine, dopamine, or 0.5 mcg/kg/min milrinone) with pulmonary artery catheter in place
1B	Dependent on ventricular assist device or inotropic infusion
2	Eligible for transplant but not dependent on inotropes or mechanical circulatory support
7	Hold; temporarily medically unsuitable for transplant

frequently seen complication, attributed to recipient pulmonary hypertension in the “untrained” heart and the inherent sensitivity of the right ventricle to preservation injury. This can be exacerbated by postoperative bleeding necessitating blood product transfusions with volume overload and worsening of pulmonary vascular resistance. Judicious volume administration, rapid pacing, and catecholamine infusions can overcome right ventricular dysfunction. Inhaled nitric oxide or prostacycline can selectively reduce pulmonary vascular resistance and improve hemodynamic stability.

Immunosuppression after heart transplantation is similar to that for other solid organs and includes antimetabolite agents such as mycophenolate, calcineurin inhibitors such as cyclosporine or tacrolimus, and corticosteroids. Because of their nephrotoxicity, initiation of calcineurin inhibitors is often delayed during the immediate postoperative period. As an alternative, induction therapy with either monoclonal or polyclonal antibodies against specific immune cells can be administered. Although routine use of induction therapy has not been demonstrated to improve outcomes, selected use for patients with perioperative renal insufficiency may be beneficial.

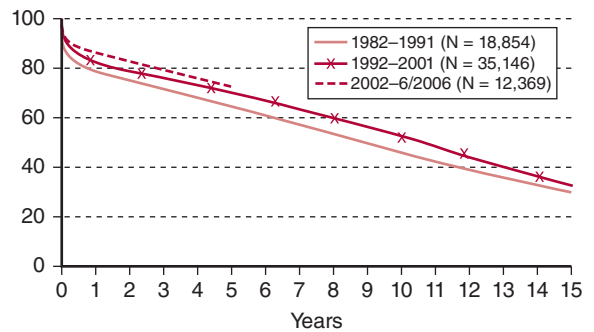

► Outcomes

Despite the absence of any prospective randomized evidence, heart transplantation offers long-term survival advantages over medical therapy for appropriately selected patients with advanced heart failure. Survival rates have improved since the introduction of the procedure in 1967, with 1-year survival now approximately 85%. Most early deaths are attributable to perioperative complications or severe rejection. After this early period of attrition, there continues to be a linear decrement in survival, at a rate of approximately 3%-4% per year, and this rate has not decreased over the last 20 years. Causes of late mortality include transplant vasculopathy, opportunistic infections, immunosuppressive related malignancies, and rejection. Transplant vasculopathy is an accelerated coronary artery disease unique to the heart transplant recipient and is a result of repetitive vascular injury and sustained inflammatory response. Statins and vitamin supplements appear to slow the progression of vasculopathy, but the diffuse nature makes the disease less amenable to percutaneous or surgical revascularization. Median survival after heart transplant is estimated to be between 10 and 11 years (Figure 19–21).

MECHANICAL CIRCULATORY SUPPORT

► Indications

Although heart transplantation has long been considered the gold standard treatment for advanced heart failure, the limited availability of suitable donors affords support for only a small percentage of those in need. Mechanical circulatory support to assist or replace the failing heart has made enormous progress over the last 40 years. Since the introduction

▲ **Figure 19–21.** Kaplan-Meier survival for adult heart transplants performed between January 1982 and June 2006 by era. All comparisons are significant at $p < 0.0001$. (Reproduced with permission from Taylor DO et al: Registry of the International Society for Heart and Lung Transplantation: twenty-fifth official adult heart transplant report—2008. *J Heart Lung Transplant* 2008;27:943.)

of CPB by Gibbon in 1953, the engineering of mechanical blood pumps has become more sophisticated, allowing treatment of an increasing population of patients on an ambulatory basis with reduced size, better blood biocompatibility and improved pump durability. As this rapid evolution continues, the indications, techniques, and expected results will change dramatically. More than any other aspect of cardiac surgery, the treatment of today will likely be remarkably different only a few years in the future.

The indications for implantable circulatory support are severe cardiac dysfunction despite maximal medical therapy. However, there are three distinct goals of support that represent vastly different patient populations and clinical scenarios: bridge to recovery, bridge to transplant, and destination therapy. Cardiogenic shock may have reversible causes, such as viral or peripartum cardiomyopathy, acute myocardial infarction, and postcardiotomy shock. Initiation of mechanical circulatory support can restore hemodynamics, unload the ventricle, and allow time for myocardial recovery. Chronic heart failure patients felt to be suitable candidates for heart transplantation can rapidly deteriorate, causing end-organ dysfunction and closing their window of opportunity. Implantable circulatory support can reverse acute organ injury and allow functional rehabilitation, improving their candidacy for and potentially their outcomes after heart transplantation. Patients with advanced heart failure and contraindications for transplantation, such as older age, chronic renal insufficiency, obesity, or fixed pulmonary hypertension, may benefit from implantable circulatory support as destination therapy.

► Pumps

A variety of devices are available for mechanical circulatory support to satisfy each of the goals, and many more are cur-

rently in clinical trials or preclinical testing. Device selection depends on the clinical circumstances, with considerations including ease of implantation, adequacy and flexibility of support, patient quality of life, durability, and cost. The available devices are discussed in the context of their most frequently used application.

A. Short-term Devices

Intra-aortic balloon pumps provide counterpulsation during diastole, increasing coronary perfusion and reducing afterload and myocardial oxygen consumption. They are typically inserted percutaneously via the femoral artery and advanced into the descending thoracic aorta. Balloon timing automatically coincides with the electrocardiogram tracing or the arterial pressure waveform. They can be easily removed and have few complications. Intra-aortic balloon pump support is limited, improving cardiac output only by as much as 20%. The Abiomed BVS 5000 and AB 5000 are pneumatically driven extracorporeal blood pumps capable of up to 6 L/min of blood flow (Figure 19–22). The devices can be connected to any of the cardiac chambers to provide support for the failing left or right ventricle in a variety of configurations. A pneumatic compressor physically actuates a diaphragm within the pump, producing pulsatile flow. The rate of actuation varies with the pump chamber filling, thus automatically adjusting output according to the patient's volume status. The Thoratec CentriMag is a centrifugal blood pump with a magnetically levitated rotor to improve

▲ **Figure 19–22.** Abiomed AB 5000 ventricular assist device. (Reproduced with permission from Abiomed, Inc., Danvers, MA.)

biocompatibility. There are no valve sinuses or other zones of stagnation, improving thrombogenicity. It produces continuous flow and requires manual pump speed adjustment under conditions of changing preload. The TandemHeart percutaneous ventricular assist device (VAD) uses a venous drainage cannula inserted from the femoral vein and advanced across the inter-atrial septum. Blood is drained from the left atrium using a centrifugal pump and infused into a cannula inserted into the femoral artery (Figure 19–23). Because of its femoral access, it requires a supine and immobilized patient. The Impella catheters are microaxial blood pumps placed across the aortic valve, draining blood from the left ventricular

▲ **Figure 19-24.** Impella percutaneous microaxial blood pump. (Reproduced with permission from Abiomed, Inc, Danvers, MA.)

cavity and infusing into the aortic root (Figure 19-24). The catheters can be inserted peripherally, such as via the femoral artery, or directly into the ascending aorta. The largest of the Impella catheters can produce up to 5 L/min of flow.

B. Long-term Devices

Implantable mechanical circulatory support, such as left ventricular assist devices (LVADs) are increasingly used for patients with end stage irreversible heart failure, either as bridge to heart transplantation or for lifelong support (destination therapy). There have been substantial technologic advances in this field and the use of implantable circulatory support pumps is increasing at rapid pace.

Early LVADs were large, pulsatile pumps which used either electric or pneumatic force to actuate a diaphragm producing pulsatile ejection. These devices were limited by their large size and the tendency for the motor bearings to fail after prolonged support.

The current generation of circulatory support devices are valveless continuous-flow pumps which use continuously spinning impellers to generate blood flow. Since there is no displacement chamber to generate the flow pulse, the devices are smaller and silent, allowing support to smaller patients and improved patient satisfaction. In addition, the continuous nature of the mechanical load on a single bearing has the important advantage of improved durability.

The first of these pumps to gain Food and Drug Administration (FDA) approval is the HeartMate II

▲ **Figure 19-25.** HeartMate II left ventricular assist device. (Reproduced with permission from Thoratec, Inc., Pleasanton, CA.)

(Figure 19-25). After median sternotomy and creation of a small preperitoneal pocket, the diaphragm is divided allowing access to the left ventricular apex. On CPB, the inlet cannula of the HeartMate II is inserted into the left ventricular apex. The outflow graft is sutured to the ascending aorta. A percutaneous lead exits the right upper quadrant and is connected to a controller allowing interface with the pump. The controller is connected to a power source, either a power base unit plugged into standard wall outlets, or connected to wearable batteries which can provide untethered support for up to 10 hours. Early experience demonstrates improved success when compared to predicate devices. While median survival of VAD patients continues to improve, complications continue to limit the potential success of VAD therapy. Gastrointestinal bleeding occurs in approximately 30% of patients with continuous flow VADs, likely related to the combination of the required warfarin anticoagulation and acquired platelet dysfunction from device shear forces. The incidence of stroke is approximately 8%-10% per year from both primary intracerebral hemorrhage and embolic events. Infections at the driveline insertion site can require debridement, prolonged intravenous antibiotics, and when severe, require complete pump exchange.

The next generation of LVADs is continuous-flow pumps with centrifugal design, utilizing magnetically levitated rotors. These LVADs eliminate entirely the need for contacting bearings, creating the potential for indefinite support without mechanical failure. In addition, these devices

▲ **Figure 19–26.** HeartWare® Ventricular Assist System featuring the HVAD® Pump. The HeartWare® Ventricular Assist System is currently in clinical trial. (Reproduced with permission from HeartWare International, Inc., Framingham, MA.)

may have improved blood handling characteristics and could reduce some of the complications seen in prolonged mechanical assistance. The HeartWare Ventricular Assist System is currently in US clinical trials. Its miniature design allows implantation within the pericardial space, obviating the need for a preperitoneal pocket or incision of the diaphragm. Approval by the FDA is imminently expected at the time of this (Figure 19–26). The significant technological progress in mechanical circulatory support will likely have an enormous impact on the nature of surgical treatment of heart failure in the near future.

MULTIPLE CHOICE QUESTIONS

- Which of the following does NOT contribute to the susceptibility of coronary ischemia?
 - High baseline oxygen extraction
 - Coronary flow limited largely during diastole
 - Atherosclerosis tends to occur diffusely in small coronary vessels
 - Increased myocardial oxygen demand requires proportional increase in coronary blood flow
- Which of the following is true about aortic stenosis?
 - Senile calcific aortic stenosis is associated with ascending aortic aneurysms
 - Rheumatic heart disease affects the aortic valve most commonly, followed by the mitral and tricuspid valves
 - Presence of left ventricular hypertrophy is an indication for surgery in patients with aortic stenosis
 - Typical symptoms are exertional dyspnea, angina or syncope
- For patients with mitral regurgitation, indications for mitral reconstruction do NOT include:
 - Left ventricular dilation
 - Dyspnea
 - Asymptomatic with a prolapsed anterior mitral leaflet
 - Moderate mitral regurgitation at the time of coronary bypass surgery
- Which of the following is true of the thoracic aorta?
 - Fibrosis results in contraction of the ascending aorta with age
 - The ascending aorta should only be replaced when its maximum diameter exceeds 5.5 cm in the absence of symptoms
 - Stanford type B dissections cause early death from intrapericardial rupture, aortic valve insufficiency or coronary malperfusion
 - Malperfusion of the abdominal viscera can occur with either Stanford type A or type B aortic dissections
- Which of the following is true regarding advanced heart failure?
 - Beta-blockers improve survival in heart failure in part by up-regulation of beta-receptors
 - The incidence of heart failure is decreasing because of advances in medical treatment
 - The use of mechanical circulatory support does not affect priority status for heart transplantation
 - Left ventricular dysfunction is the most frequent early complication following heart transplantation

II. Congenital Heart Disease

19

Jennifer S. Nelson, MD

Jennifer C. Hirsch-Romano, MD, MS

Richard G. Ohye, MD

Edward L. Bove, MD

DIAGNOSIS

Congenital heart disease encompasses a wide range of anomalies that result from abnormal fetal development of the heart. Defects can range from simple to complex. The age of presentation of these defects depends primarily on the physiologic impact of the anomaly. After birth, patients can present within minutes to hours with profound hypoxemia or hemodynamic collapse. Others may present weeks to months later with evidence of a new murmur or signs of congestive heart failure. Relatively asymptomatic lesions can go undetected until children are school age or adolescents. With current ultrasound imaging, many cardiac anomalies are identified on prenatal examination.

Early and accurate diagnosis of congenital heart disease requires careful identification of signs and symptoms of heart disease. The initial workup begins with a focused history and physical examination. Classification of heart murmurs can be highly suggestive of underlying cardiac anomalies. Early signs of heart disease include cyanosis, tachypnea, unequal pulses, and failure to thrive. Key symptoms of congenital heart disease in the patient's history include feeding difficulties, irritability, and frequent respiratory infections.

Standard diagnostic studies include a chest radiograph (CXR) and electrocardiography (EKG). Some cardiac defects have pathognomonic findings on CXR. Other anomalies may be suspected based on heart size, increased or decreased pulmonary markings, aortic arch sidedness, or situs abnormalities (the heart located in the mid- or right chest rather than the typical location in the left chest). EKG can identify rhythm disturbances, axis deviation, atrial enlargement, and ventricular hypertrophy. Transthoracic echocardiography is often the only diagnostic test needed to provide the anatomic detail required for surgical planning. Cardiac catheterization, cardiac magnetic resonance imaging (cMRI), and computed tomography angiography (CTA) are used as adjunct diagnostic tests when additional

information on flow, pressure, resistance, or anatomic detail is required.

PREOPERATIVE MANAGEMENT

The care of congenital heart disease patients requires a collaborative effort of a multidisciplinary team of cardiologists, surgeons, interventionalists, echocardiographers, and radiologists. For the majority of congenital heart defects, surgical correction or catheter-based intervention is necessary for definitive treatment. Careful timing and planning of operative and catheter-based interventions along with highly skilled preoperative and postoperative care are essential to a successful outcome.

Certain defects such as atrial septal defects (ASDs), ventricular septal defects (VSDs), and patent ductus arteriosus (PDA) may resolve spontaneously over the first several years of life. The remaining defects require intervention when the risk of surgery is reasonable, when symptoms can no longer be managed medically, and/or prior to the onset of irreversible complications.

Neonates presenting with ductal-dependent lesions require ductal blood flow to maintain systemic or pulmonary perfusion. Ductal patency is achieved with intravenous prostaglandin E₁ therapy. Supplemental oxygen is supplied only as necessary for cyanosis as newborns tolerate relative cyanosis (oxygen saturations > 70%) quite well. The remainder of therapy is directed toward managing congestive heart failure symptoms with diuretics, afterload reduction, and maximal caloric intake.

OPERATIVE MANAGEMENT

For most congenital heart defects, surgical correction is possible. For more complex defects, staged repair with early palliation as well as staged palliation remain options. The anticipated somatic growth of the child must be considered when determining the surgical approach. Invasive monitoring

lines are essential for monitoring patients during surgery and postoperatively. All patients have arterial and central venous catheters placed along with peripheral intravenous catheters and a Foley catheter. For neonates, the umbilical vessels are the desired venous and arterial access. Avoidance of long-standing and repeated femoral lines is important because patency of these vessels is often essential for diagnostic and interventional catheter procedures later in life. Due to variable blood flow with perfusion techniques and underlying cardiac anomalies, it is possible to have differential cooling and rewarming. Therefore, temperature probes are placed in the nasopharynx, the rectum, and on the skin to allow for accurate monitoring.

Most surgical repairs require cardiopulmonary bypass. This involves drainage of venous blood from the patient via cannulae placed in the superior and inferior vena cava (for intracardiac repairs) or a single cannula in the right atrium. Blood passes through the bypass circuit, which warms or cools the blood to the desired temperature, adds oxygen and removes carbon dioxide, and pumps the blood back into the body via an arterial cannula, usually in the ascending aorta. Hypothermia may be employed to decrease the metabolic demands of the body and heart, which provides additional protection against ischemia. The degree of hypothermia, 18-34°C, depends on the complexity and time needed to complete the procedure. The heart can be arrested with high-potassium cardioplegic solution delivered through the coronary arteries antegrade (through a cannula proximal to an aortic cross-clamp in the aorta) or retrograde (through a cannula placed in the coronary sinus). Arresting the heart allows the surgeon to operate safely with a still and bloodless field. An additional vent can be placed via the right superior pulmonary vein to capture pulmonary venous return and to assist in deairing of the heart.

Hypothermic circulatory arrest is required for complex aortic arch reconstructions. This involves cooling the patient to 18°C for a minimum of 20 minutes to ensure even cooling of the brain and body. The head is packed in ice, the patient's blood is drained into the venous reservoir, and the pump is turned off. The cannulae can then be removed from the field to aid in visualization and repair of the arch. No absolute safe duration of hypothermic circulatory arrest has been determined, but it is generally felt that it should be limited to no more than 45 minutes. Alternative techniques, such as regional cerebral perfusion and intermittent low-flow perfusion, have been employed to minimize the need for hypothermic circulatory arrest. To date, however, there is no literature to support that these techniques have additional benefit without additional risk.

POSTOPERATIVE MANAGEMENT

Patients are brought to the intensive care unit intubated and mechanically ventilated. All patients have temporary

pacing wires in place for management of bradyarrhythmias and tachyarrhythmias. Many patients have additional intracardiac lines in place for pulmonary artery and left atrial pressure monitoring. Drainage catheters are placed within the mediastinum to prevent accumulation of blood and fluid. These are usually removed 2-4 days following surgery. Prophylactic antibiotics are given preoperatively as well as postoperatively when drainage tubes are in place.

Cardiopulmonary bypass produces a significant inflammatory response due to activation of cytokines. Patients exhibit fluid retention and pulmonary dysfunction as a result, requiring aggressive use of diuretics and mechanical ventilation as needed. Bleeding is a common complication following cardiac surgery and infrequently requires surgical exploration (< 2%). Postoperative coagulopathy results from a multitude of factors, including hemodilution, platelet damage, factor consumption, immature hepatic production of clotting factors, and incomplete reversal of heparin with protamine sulfate. Approximately 30% of all patients will have some arrhythmia after surgery, ranging from simple premature ventricular contractions to malignant tachyarrhythmias. The risk for long-term arrhythmias requiring chronic medication or heart block requiring a permanent pacemaker is approximately 1%. Most patients require hemodynamic support with vasopressors along with afterload reduction as necessary for ventricular dysfunction. Dopamine, epinephrine, and vasopressin are the first-line vasopressors for pediatric patients. Milrinone is used primarily for afterload reduction. Critically ill neonates may have thyroid and adrenal hypofunction, which can further exacerbate postoperative hemodynamic instability. Profound hemodynamic compromise occasionally requires additional mechanical assistance. Extracorporeal membrane oxygenation (ECMO) is the most widely and acutely available mechanical support for the pediatric population. The survival for congenital heart disease patients requiring ECMO support is approximately 50%. For patients in low cardiac output state, it is essential to rule out residual defects or repair failures that could be readdressed surgically or in the catheterization laboratory.

The pediatric population has highly reactive pulmonary vasculature that is unique from the adult cardiac surgery population. Postoperative pulmonary hypertensive crises can occur in the newborn and infant population. Crises can be initiated with agitation such as endotracheal suctioning. Maneuvers to minimize and treat pulmonary hypertensive crises include high-dose opioid anesthesia with fentanyl, paralysis, respiratory alkalosis, high fraction of inspired oxygen, and inhaled nitric oxide. Chronic agents to treat persistent pulmonary hypertension include phosphodiesterase inhibitors (eg, sildenafil) and prostacyclin (eg, Flolan).

CYANOTIC HEART DEFECTS

Cyanotic heart defects result from shunting of deoxygenated blood from the right side of the heart to the oxygenated left side of the heart or inadequate pulmonary blood flow. The relative mixing of deoxygenated and oxygenated blood produces desaturation of the arterial blood. The majority of cyanotic heart defects are diagnosed within the first few days to months of life. Cyanotic heart defects represent approximately 25% of all congenital heart defects.

The classic 5 T's of cyanotic heart defects—(1) tetralogy of Fallot (TOF); (2) transposition of the great arteries (TGAs); (3) truncus arteriosus; (4) total anomalous pulmonary venous return; and (5) tricuspid atresia are presented in this chapter along with hypoplastic left heart syndrome (HLHS).

► Tetralogy of Fallot

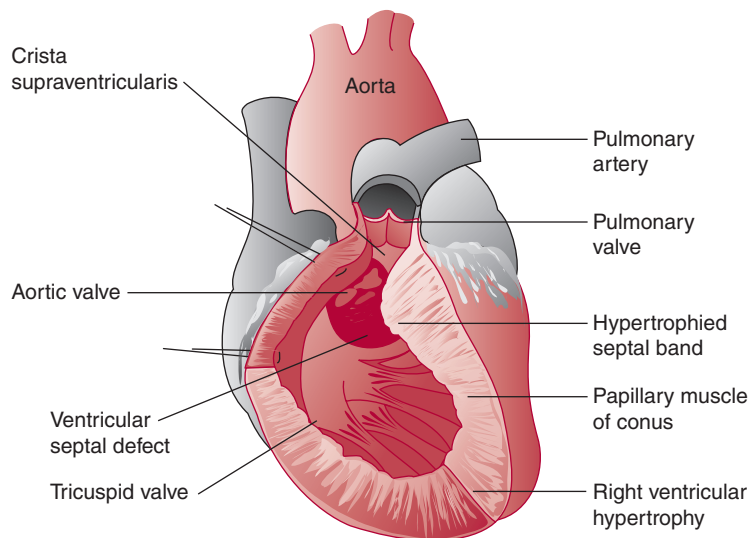

A. General Considerations

TOF is the most common cyanotic congenital heart defect. It occurs in 0.6 per 1000 live births and has a prevalence of about 4% among all patients with congenital heart disease. The pathologic anatomy is frequently described as having four components: VSD, overriding aorta, pulmonary stenosis, and right ventricular (RV) hypertrophy (Figure 19–27). Embryologically, the anatomy of TOF is thought to result from a single defect: anterior malalignment of the infundibular septum. The infundibular septum normally separates

the primitive outflow tracts and fuses with the ventricular septum. Anterior malalignment of the infundibular septum creates a VSD due to failure of fusion with the ventricular septum and also displaces the aorta over the VSD and right ventricle. Infundibular malalignment also crowds the RV outflow tract, causing pulmonary stenosis and, secondarily, RV hypertrophy. Prominent muscle bands also extend from the septal insertion of the infundibular septum to the RV free wall and contribute to the obstruction of the RV outflow tract. The pulmonary valve is usually stenotic and is bicuspid in 58% of cases. Pulmonary atresia occurs in about 7% of cases. The branch pulmonary arteries in TOF may exhibit mild diffuse hypoplasia or discrete stenosis (most frequently of the left pulmonary artery at the site of ductal insertion). Coronary artery anomalies are frequently present. The origin of the left anterior descending artery from the right coronary artery, which occurs in 5% of cases, is clinically important because the vessel crosses the RV infundibulum and is vulnerable to injury at the time of surgery. A right aortic arch is present in 25% of patients. Associated defects include ASD, complete atrioventricular septal defect (AVSD), PDA, or multiple VSDs.

B. Clinical Findings

Patients with TOF develop cyanosis due to right-to-left shunting across the VSD. The degree of cyanosis depends on the severity of obstruction of the RV outflow tract. Frequently, cyanosis is mild at birth and may remain undetected for

weeks or months. Neonates with severe infundibular obstruction or pulmonary atresia will develop symptoms shortly after birth and require a prostaglandin infusion to maintain ductal patency to ensure adequate pulmonary blood flow. In other patients, the RV outflow tract obstruction is minor, and the predominant physiology is that of a large VSD with left-to-right shunting and congestive heart failure.

The occurrence of intermittent cyanotic spells is a well-known feature of tetralogy. The etiology of “spelling” is still controversial but is clearly related to a transient imbalance between pulmonary and systemic blood flow. A spell may be triggered by hypovolemia or peripheral vasodilation (eg, after a bath or vigorous physical exertion). Spells may occur in neonates but are most frequently reported in infants between the ages of 3 and 18 months. Most spells resolve spontaneously within a few minutes, but some spells may be fatal. Older children have been observed to spontaneously squat to terminate spells. The squatting position is thought to increase systemic vascular resistance, which thereby favors pulmonary blood flow.

Cyanosis is the most frequent physical finding in TOF. Auscultation reveals a normal first heart sound and a single second heart sound. A systolic ejection murmur is present at the left upper sternal border. Older children may develop clubbing of the fingers and toes. Chest radiography typically demonstrates a boot-shaped heart due to elevation of the cardiac apex from RV hypertrophy. Pulmonary vascular markings are usually reduced. A right aortic arch may be present. An electrocardiogram shows RV hypertrophy. Echocardiography is definitive, and catheterization is not necessary in most cases.

C. Treatment

The medical management of TOF is directed toward the treatment and prevention of cyanotic spells. The immediate treatment of the spelling patient includes administration of oxygen, narcotics for sedation, and correction of acidosis. Transfusion is indicated for anemic infants. Alpha-agonists are useful for increasing systemic vascular resistance (which favors pulmonary blood flow). Some centers have used beta-blockers as a form of long-term therapy to suppress the incidence of spells. Long-term complications of untreated TOF include clubbing of the fingers and toes, severe dyspnea on exertion, brain abscesses (secondary to right-to-left shunting), paradoxical embolization, and polycythemia (which may lead to cerebral thrombosis). Long-term survival is unlikely for most patients with untreated TOF.

All patients with TOF should undergo surgical repair. Asymptomatic patients should be repaired electively between 4 and 6 months of age. Early repair is indicated for neonates with severe cyanosis and for infants who have had a documented spell or worsening cyanosis.

Classically, the repair of TOF was accomplished in two stages. During the first stage, pulmonary blood flow was augmented by creating a connection (or shunt) between a systemic artery and the pulmonary artery. At the second stage, the shunt was taken down, and a complete repair was performed. The first shunt procedure was the Blalock-Taussig shunt, in which the subclavian artery was mobilized and divided distally, and an end-to-side anastomosis was created between the inferiorly deflected subclavian and the ipsilateral pulmonary artery. The modified Blalock-Taussig shunt is the most common type of shunt used today and consists of an interposition graft (polytetrafluoroethylene) between the innominate or subclavian artery and the ipsilateral pulmonary artery. Creation of a shunt may be accomplished with or without the use of cardiopulmonary bypass.

Currently, one-stage repair of TOF is preferred by most centers. Initial palliation with a shunt is still indicated for some patients who present a high risk for complete repair, such as those with multiple congenital anomalies, significant prematurity, severe concurrent illness, or an anomalous coronary artery crossing a hypoplastic infundibulum.
